The phenotype varies depending on the proportion of XY cells and their distribution. About two-thirds of such children are reared as females. Many have ambiguous genitalia, including phallic enlargement, a urogenital sinus, and some labioscrotal fusion. In most the testis is intraabdominal; individuals with a testis in the inguinal or scrotal position are usually reared as males. A uterus, vagina, and at least one fallopian tube are almost invariably present.

The prepubertal testis appears relatively normal. The postpubertal testis contains abundant Leydig cells, but the seminiferous tubules lack germinal elements and contain only Sertoli cells. The streak gonad, a thin, pale, elongated structure located either in the broad ligament or along the pelvic wall, is composed of ovarian stroma. At puberty the testis secretes androgen, causing virilization and phallic enlargement. Feminization is rare; when it occurs, estrogen secretion from a gonadal tumor should be suspected.

Approximately a third of these individuals exhibit somatic features of 45,X gonadal dysgenesis. Approximately two-thirds have the 45,X/46,XY karyotype, and the remainder have a 46,XY karyotype or a variant mosaicism. The origin of 45,X/46,XY mosaicism is best explained by the loss of a Y chromosome during an early mitotic division of an XY zygote similar to the postulated loss of the X chromosome in the 46,XY/47,XXY mosaicism shown in Fig. 338-2.

Pathophysiology It is assumed (but has been difficult to prove) that the 46,XY cell line stimulates testicular differentiation, whereas the 45,X stem leads to the development of the contralateral streak gonad. Both masculinization and mullerian duct regression in utero are incomplete. Since Leydig cell function may be that of a normal male at puberty, inadequate virilization in utero may be due to delayed development of a testis that is ultimately capable of normal Leydig cell function.

TREATMENT

For the older child or adult in whom gender is established prior to diagnosis, the central consideration is the possibility of tumor development in the gonads, which can occur prior to puberty. The overall incidence of seminomas and gonadoblastomas may be as high as 25%. Such tumors occur most frequently in subjects with a female phenotype who lack the somatic features of 45,X gonadal dysgenesis and are more common in testes than in the streak gonad. When the diagnosis is established in phenotypic females, prophylactic gonadectomy should be performed because gonadal tumors may occur in childhood and because the testes secrete androgen at puberty and thus cause virilization. Such women, like those with gonadal dysgenesis, are then given estrogen to induce and maintain feminization.

When the diagnosis is established in phenotypic males during late childhood or in adults, the management is more complicated. Men with mixed gonadal dysgenesis are infertile (no germinal elements are present in the testes) and have a high risk of developing gonadal tumors. In deciding which testes can be safely conserved the following observations apply: (1) tumors develop in scrotal streak gonads but not in scrotal testes, (2) tumors that develop in intraabdominal testes are always associated with ipsilateral mullerian duct structures, and (3) tumors in streak gonads are always associated with tumors in the contralateral abdominal testis. Based on these observations, it is recommended that (1) all streak gonads should be removed, (2) scrotal testes should be preserved, and (3) intraabdominal testes should be excised unless they can be relocated in the scrotum and are not associated with ipsilateral mullerian duct structures. Reconstructive surgery of the phallus should be performed when appropriate.

When the diagnosis is established in early infancy and the genitalia are ambiguous, gender assignment is usually female, and resection of the phallus and gonadectomy can be performed in infancy, sometimes in one procedure. If the decision is for male gender assignment, the same criteria apply as to which testes should be removed as in older males.

TRUE HERMAPHRODITISM

Clinical Features True hermaphroditism is a condition in which both an ovary and a testis or one or more gonads with features of both (ovotestis) are present. To justify the diagnosis, both types of gonadal epithelium must be documented histologically, the presence of ovarian stroma without oocytes not being sufficient. The incidence is unknown, but more than 400 cases have been reported. Three categories are recognized: (1) one-fifth are bilateral -- testicular and ovarian tissue (ovotestes) on each side; (2) two-fifths are unilateral -- an ovotestis on one side and an ovary or a testis on the other; and (3) the remainder are lateral -- a testis on one side and an ovary on the other.

The external genitalia exhibit all gradations of the male-to-female spectrum. Two-thirds of affected individuals are sufficiently masculinized to be reared as males, but fewer than one-tenth have normal male external genitalia; most have hypospadias and incomplete labioscrotal fusion. Two-thirds of phenotypic females have an enlarged

clitoris, and most have a urogenital sinus. Differentiation of the internal ducts usually corresponds to the adjacent gonad. Although an epididymis usually develops adjacent to a testis, the vas deferens is usually incomplete. Of the patients with an ovotestis, three-fourths have an epididymis, two-thirds have a fallopian tube, one-tenth have a vas deferens, and one-tenth have both a vas deferens and a fallopian tube. The uterus may be hypoplastic or unicornuate. The ovary is usually in the normal position, but the testis or ovotestis may be found at any level along the route of testicular descent, frequently associated with an inguinal hernia. Testicular tissue is present in the scrotum or the labioscrotal fold in one-third, in the inguinal canal in one-third, and in the abdomen in one-third.

Variable feminization and virilization ensue at puberty; three-fourths develop gynecomastia, and about half menstruate. In phenotypic men, menstruation may cause cyclic hematuria. Ovulation occurs in approximately one-fourth and is more common than spermatogenesis. In men, ovulation may cause testicular pain. Fertility has been reported in women and more rarely in men. Congenital malformations of other systems are unusual.

Pathophysiology About two-thirds of individuals have a 46,XX karyotype, a tenth have a 46,XY karyotype, and the remainder are chimeras or mosaics in whom a Y cell line is present. The mechanism responsible for the abnormal gonadal development is unknown. Only 10% of 46,XX true hermaphrodites are *SRY* positive, presumably the consequence of mosaicism or translocation of a portion of the Y chromosome; the remainder are believed to result from gain-of-function mutations in downstream genes involved in *SRY* action. On occasion, multiple sibs with a 46,XX karyotype are affected, possibly the result of an autosomal or X-linked mutation.

Because corpora lutea are frequently present in the ovaries, it is presumed that the female neuroendocrine axis functions normally in such individuals. Feminization (gynecomastia and menstruation) is the result of secretion of estradiol by ovarian tissue. In masculinized patients, secretion of androgen predominates, and some produce sperm.

TREATMENT

When the diagnosis is made in early infancy, gender assignment depends on the anatomic features. In older children and adults, gonads and internal duct structures that are contradictory to the predominant phenotype (and the gender of rearing) should be removed, and the external genitalia should be modified when appropriate. Gonadal tumors are rare but have been reported in true hermaphrodites who carry Y chromosome sequences. Consequently, the possibility of future tumor development must be taken into account when the decision is made to preserve gonadal tissue.

DISORDERS OF GONADAL SEX

Disorders of gonadal sex result when chromosomal sex is normal but differentiation of the gonads is abnormal. Thus, gonadal sex does not correspond to chromosomal sex.

PURE GONADAL DYSGENESIS

Clinical Features Pure gonadal dysgenesis is a disorder in which phenotypic females with gonads and genitalia characteristic of gonadal dysgenesis (bilateral streaks, infantile uterus and fallopian tubes, and sexual infantilism) have normal height, few if any somatic anomalies, and either a normal 46,XX or 46,XY karyotype. This disorder is about one-tenth as common as gonadal dysgenesis. It is genetically distinct but cannot be distinguished clinically from those instances of gonadal dysgenesis with minimal somatic abnormalities. The height is normal or greater than normal, some individuals being >170 cm. Estrogen levels vary from profound deficiency typical of 45,X gonadal dysgenesis to some breast development and menses that terminate in an early menopause. About 40% have some feminization. Axillary and pubic hair is scanty, and the internal genitalia consist of mullerian derivatives only. In both the 46,XX and the 46,XY forms the disorder prevents differentiation of ovary or testis, respectively; the development of the female phenotype and the elevation of gonadotropin secretion are due to failure of gonadal development.

Tumors may develop in the streak gonads, particularly dysgerminoma or gonadoblastoma in the 46,XY disorder. Such tumors may be heralded by the development of virilizing signs or a pelvic mass.

Pathophysiology Although chromosomal mosaicisms have been described under this nosology, the designation here is restricted to women with uniform 46,XX or 46,XY karyotypes. (Those with mosaicism are variants of gonadal dysgenesis or mixed gonadal dysgenesis, as described above.) The rationale for this restricted definition is based on the fact that both the XX and XY varieties can result from single gene mutations that are presumed to involve gene(s) essential for gonadal development. Several sibships have been reported in which more than one individual is affected with the 46,XX disorder, frequently the result of consanguineous matings, suggesting an autosomal recessive inheritance.

The 46,XY variety may occur in families; in some the disorder appears to be inherited as an X-linked trait, and in others the pattern suggests a male-limited autosomal recessive inheritance. About 15% of 46,XY women have either a deletion or a mutation in the *SRY* coding sequence. Other instances could be due to mutations in *SRY* outside the coding sequence, in other genes that influence *SRY* expression, or in the downstream genes that are controlled by *SRY*. Indeed, mutations in several genes that are downstream of *SRY* are now known to be a cause of the dysgenetic testes syndrome (also termed *dysgenetic male pseudohermaphroditism*; see below).

TREATMENT

The management of the estrogen deficiency is identical to that in gonadal dysgenesis; namely, appropriate estrogen replacement therapy is initiated at the time of expected puberty and maintained in adult life (Chap. 336). Because of the high frequency of gonadal tumors in the 46,XY variety, the streak gonads should be removed once the diagnosis is made; development of virilizing signs is indication for immediate surgery. The natural history of the gonadal tumors is uncertain, but the prognosis after surgical removal is usually good.

DYSGENETIC TESTES

Individuals with these disorders are genetic males with disorders of testicular development that vary from streak gonads similar to those in gonadal dysgenesis to less severe defects. The disorders are frequently associated with systemic abnormalities, because many of the genes involved are also involved in the development of other tissues. The first of these genes to be identified was the Wilms' tumor gene *WT1*; mutations of this gene cause two disorders -- the Denys-Drash and Frasier syndromes. *Denys-Drash syndrome* is an autosomal dominant disorder characterized by development of Wilms' tumors in males with a spectrum of gonadal defects ranging from streak gonads to less severely affected testes; urogenital defects include diffuse mesangial sclerosis of the kidneys. The underlying mutations in the zinc finger region of WT-1 are believed to inhibit the function of the wild-type protein and hence act as dominant negative mutations. Patients with *Frasier syndrome* have gonadal dysgenesis, impaired virilization, and focal sclerosis of the kidney but do not develop Wilms' tumors. Mutations in intron 9 of the *WT1* gene that cause Frasier syndrome interfere with the synthesis of specific splice variants of *WT1*.

A second downstream gene that is essential for differentiation of the testes is *SF1* (also known as *FTZF1*), a member of the nuclear hormone receptor superfamily. SF-1 regulates the expression of many genes involved in adrenal and gonadal development and steroidogenesis, as well as the *AMH* gene. Heterozygous mutation of this autosomal gene has been associated with 46,XY gonadal dysgenesis with adrenal insufficiency.

Another downstream gene is *SOX9*, a close relative of *SRY* that maps to chromosome 17q. This gene is expressed in high levels in the testes, where it is believed to be a key regulator of male differentiation. Heterozygous mutations of this gene cause 46,XY gonadal dysgenesis and skeletal abnormalities (*campomelic dysplasia*).

46,XY gonadal dysgenesis is also associated with duplication of the short arm of the X chromosome (Xp21), a phenomenon termed *dosage-sensitive sex reversal*. Loss-of-function mutations of the *DAX1* gene in this region of the X chromosome are associated with adrenal hypoplasia congenita and hypogonadotrophic hypogonadism. The DAX-1 protein inhibits the expression of SF-1-regulated genes, providing a potential mechanism by which an excess of DAX-1 could cause gonadal dysgenesis in genetic males with Xp21 duplications.

THE ABSENT TESTES SYNDROME (ANORCHIA, TESTICULAR REGRESSION, GONADAL AGENESIS, AGONADISM)

Clinical Features A spectrum of phenotypes occurs in 46,XY males with absent or rudimentary testes but in whom unequivocal evidence exists that endocrine function of the testis (e.g., consistent mullerian duct regression and variable testosterone synthesis) was present at some time during embryonic life. In pure gonadal dysgenesis, in contrast, no evidence can be inferred for gonadal function during embryonic development. The manifestations vary from complete failure of virilization to incomplete virilization of the external genitalia to otherwise normal men with bilateral anorchia.

The purest form is represented by 46,XY females with absent testes, sexual infantilism, and absence of both mullerian duct derivatives and accessory organs of male reproduction. Such individuals differ from those with 46,XY pure gonadal dysgenesis in that no gonadal remnant can be identified, including no streak gonad and no mullerian derivatives. Testicular failure must have occurred, therefore, between the onset of AMHsynthesis and the onset of testosterone secretion (e.g., after development of Sertoli cells but before the onset of Leydig cell function).

In others, testicular failure occurred later in gestation, and these individuals may constitute problems in gender assignment. In some, failure of mullerian regression is more pronounced than failure of testosterone secretion, but none exhibit normal mullerian development. In those with more extensive virilization, the external genitalia are phenotypically male, but rudimentary oviducts and vasa deferentia may coexist internally.

At the final extreme is the syndrome of bilateral anorchia in which phenotypic men have absence of mullerian structures and gonads but male wolffian duct derivatives and external genitalia. Microphallus implies that failure of testosterone secretion occurred late in embryogenesis after anatomic development of the male urethra was complete. Gynecomastia may or may not be present.

Pathophysiology The pathogenesis is not understood. Testicular regression could be the result of mutant genes, teratogen, or trauma, and the disorder may well be heterogeneous in origin. Several instances of agonadism have occurred in the same family, some unilateral and others bilateral. Some individuals in whom no testes can be identified at laparotomy have blood testosterone values above the castrate range, presumably derived from remnant testes.

TREATMENT

The management of the two extremes is clear-cut. Sexually infantile, phenotypic females should be given adequate estrogen to ensure appropriate feminization, and any coexisting vaginal agenesis should be treated by surgical or medical means. Likewise, phenotypic males with anorchia should be given androgen replacement to allow normal male secondary sexual development. Individuals with incomplete virilization or ambiguous external genitalia demonstrate a more complex problem and require careful assessment to determine appropriate gender assignment, hormonal therapy at the time of expected puberty, and surgical correction of the external genitalia when appropriate.

DISORDERS OF PHENOTYPIC SEX

Disorders of phenotypic sex occur in 46,XX or 46,XY individuals with appropriate gonadal sex but in whom development of the urogenital tract is inappropriate for the chromosomal/gonadal sex.

FEMALE PSEUDOHERMAPHRODITISM

Female pseudohermaphroditism occurs in 46,XX women with bilateral ovaries but with variable virilization of the urogenital tract because of androgen excess during fetal life.

Congenital Adrenal Hyperplasia

Clinical Features The pathways by which glucocorticoids are synthesized in the adrenal gland and androgens are formed in the testis and adrenal are summarized inFig. 338-3. Three reactions are common to both pathways (cholesterol side chain cleavage, 3b-hydroxysteroid dehydrogenase/isomerase, and 17a-hydroxylase); impairment of any of these reactions results in deficiency of glucocorticoid and androgen synthesis and consequently causes both congenital adrenal hyperplasia (due to enhanced ACTH levels) and defective virilization of the male embryo (male pseudohermaphroditism). Two reactions are involved exclusively in androgen synthesis (17,20-lyase and 17b-hydroxysteroid dehydrogenase); deficiency in either results in pure male pseudohermaphroditism with normal glucocorticoid synthesis. Deficiency of either of the terminal two enzymes of glucocorticoid synthesis (21-hydroxylase and 11b-hydroxylase) impairs formation of hydrocortisone; the compensatory increase in ACTH secretion causes adrenal hyperplasia and a secondary increase in androgen formation that virilizes the female and induces precocious masculinization in the male.

The major features of congenital adrenal hyperplasia are listed inTable 338-4. The *adrenal insufficiency* can be equally severe and life-threatening in both sexes and is described inChap. 331. Some defects in steroidogenesis cause female pseudohermaphroditism, and some cause male pseudohermaphroditism. (3b-hydroxysteroid dehydrogenase/isomerase deficiency can cause either male or female pseudohermaphroditism, but since incomplete virilization of the male is more common, the disorder will be discussed under male pseudohermaphroditism.)

Congenital adrenal hyperplasia due to classic 21-hydroxylase deficiency is the most common cause of ambiguous genitalia in the newborn, with an incidence of between 1 in 5000 and 1 in 15,000 live births in Europe and the United States; it may or may not be associated with mineralocorticoid deficiency (salt loss) (Table 338-4). Virilization is usually apparent at birth in the female and within the first 2 to 3 years of life in the male. Manifestations in females include hypertrophy of the clitoris with ventral chordee, partial fusion of the labioscrotal folds, and variable virilization of the urethra. The uterus, fallopian tubes, and ovaries are normal, and the wolffian ducts do not virilize, probably because adrenal function begins relatively late in embryogenesis. The external appearance of an affected female newborn is similar to that of a male with bilateral cryptorchidism and hypospadias. The labioscrotal folds are bulbous and rugated and resemble a scrotum. Rarely, the virilization is so severe that development of a complete penile urethra and prostate results in errors in sex assignment at birth. Radiography following the injection of radiopaque dye into the external genital orifice is helpful in demonstrating the presence of vagina, uterus, and (sometimes) fallopian tubes. Occasionally, virilization of the female is slight or absent at birth and becomes evident in later infancy, adolescence, or adulthood (the so-called nonclassic or late-onset form of the disorder). In both sexes, rapid somatic maturation results in premature epiphyseal closure and a short adult height. The untreated female with the classic disorder grows rapidly during the first year of life and has progressive virilization. At the time of expected puberty there is a failure of normal female sexual development and absence of menstruation.

Since male phenotypic differentiation is normal, the condition is usually not recognized at birth in boys in the absence of adrenal insufficiency. However, early maturation of the external genitalia, development of secondary sex characteristics, coarsening of the voice, frequent erections, and excessive muscular development are noticeable during the first few years of life. Virilization in the male can follow two patterns. Excessive adrenal androgens can inhibit gonadotropin production so that the testes remain infantile in size despite the acceleration of masculinization. Such untreated adult men are capable of erection and ejaculation but have no spermatogenesis. Alternatively, adrenal androgen secretion can induce premature maturation of the hypothalamic-pituitary axis and initiate a true precocious puberty including early maturation of spermatogenesis (Chap. 335). The untreated male is also subject to the development of ACTH-dependent "tumors" of the adrenal rest cells of the testes.

In classic 21-hydroxylase deficiency, which accounts for about 95% of congenital adrenal hyperplasia, decreased production of hydrocortisone leads to increased release of ACTH, enlargement of the adrenal glands, and partial or complete compensation of the defect in the secretion of hydrocortisone. In about half, the enzyme defect appears to be partial, and cortisol secretion is normal. This form is termed *simple virilizing*. When deficiency of the enzyme is more complete, the so-called salt-losing form of 21-hydroxylase deficiency, production of cortisol and aldosterone is inadequate, leading to severe salt wastage with anorexia, vomiting, volume depletion, and vascular collapse within the first few weeks of life. In untreated patients, there is overproduction of the cortisol precursors prior to the 21-hydroxylase step, causing an increase in plasma progesterone and 17-hydroxyprogesterone. These steroids are weak aldosterone antagonists at the receptor level; in the compensated state aldosterone production increases to attempt to maintain normal sodium balance. Increased substrate availability is also responsible for the enhanced androgen synthesis and hence for the virilization.

Female pseudohermaphroditism also occurs in 11b-hydroxylase deficiency. In this disorder, a block in hydroxylation at the 11-carbon results in the accumulation of 11-deoxycortisol and deoxycorticosterone (DOC), a potent salt-retaining hormone that causes hypertension rather than salt loss. The clinical features that stem from glucocorticoid deficiency and androgen excess are similar to those in 21-hydroxylase deficiency.

Pathophysiology Both disorders are due to autosomal recessive mutations. The carrier frequency for CYP21A2 deficiency is about 1 in 50. Because the gene is located on the sixth chromosome close to the HLA-B locus, heterozygous carriers and homozygotes within a given family can be identified on the basis of the HLA haplotype. At the molecular level the mutations that give rise to 21-hydroxylase deficiency are highly polymorphic; indeed, partial gene deletions (10 to 30%), conversion of the gene from a functional state to a form that is not transcribed normally (10%), and point mutations (60 to 75%) have been characterized in the disorder. The classic disorder is due to mutations that severely impair enzyme activity, and less severe mutations cause the nonclassic, or late-onset, variety. 11b-hydroxylase activity is encoded by two genes on chromosome 8; mutations of the *CYP11B1* gene are responsible for this disorder. The *CYP11B2* gene encodes aldosterone synthase. A late-onset variant of 11b-hydroxylase deficiency exists but has not been characterized at the molecular level.

Urinary excretion of 17-ketosteroids and of the metabolites that accumulate proximal to the enzymatic blocks is increased. Plasma ACTH is elevated. In CYP21A2 deficiency, 17-hydroxyprogesterone accumulates in blood and is excreted predominantly as pregnanetriol. In CYP11B1 deficiency, 11-deoxycortisol accumulates in blood and is excreted predominantly as tetrahydrocortexolone.**For additional discussion of the endocrine pathology, see Chap. 331.*

TREATMENT

Gender assignment should correspond to the chromosomal and gonadal sex, and appropriate surgical correction of the external genitalia should be undertaken as early as possible. This is of importance because appropriately treated men and women are capable of fertility. However, if the correct diagnosis is made late (after 3 years of age), gender assignment should be changed only after careful consideration of the psychosexual background.

Treatment with appropriate glucocorticoids prevents the consequences of hydrocortisone deficiency, arrests the rapid virilization, and prevents premature somatic and epiphyseal maturation. The suppression of the abnormal steroid secretion corrects the hypertension in CYP11B1 deficiency and in both disorders allows normal onset of menses and development of female secondary sex characteristics. In males, glucocorticoid therapy suppresses adrenal androgens and results in normal gonadotropin secretion, testicular development, and spermatogenesis. The usual maintenance dose of hydrocortisone is 10 to 20 mg/m$_2$per day, given in three divided doses. However, the dose must be adjusted on an individual basis to optimize ACTH suppression while avoiding glucocorticoid side effects, which include growth retardation as well as Cushingoid features. Measurements of plasma 17-hydroxyprogesterone, androstenedione, ACTH, and renin levels have all been used to assess adequacy of replacement therapy. In severe CYP21A2 deficiency associated with salt loss or elevated plasma renin activity, treatment with mineralocorticoids is also indicated, and plasma renin levels should be monitored to assess the adequacy of mineralocorticoid replacement. Trials are underway to assess the potential use of antiandrogens (e.g., spironolactone, cyproterone acetate, flutamide) or aromatase inhibitors (e.g., latrazole, testolactone) as adjunctive therapy that may allow reductions in glucocorticoid dose. Treatment of affected fetuses in utero (beginning at 4 to 6 weeks) has been accomplished by administering dexamethasone (which crosses the placenta) to the mother. Though this treatment can reduce the extent of virilization in some girls, it is associated with maternal side effects, and the long-term consequences have not been established.

Other Causes of Female Pseudohermaphroditism Placental aromatase deficiency due to mutations in the gene encoding aromatase (*CYP19*) causes virilization of female embryos because of defective conversion of androgens to estrogens in the placenta and the secondary increase in testosterone levels in the fetus; in postnatal life CYP19 deficiency in women causes hirsutism and development of polycystic ovaries. Female pseudohermaphroditism can also occur in babies born to mothers with virilizing tumors of the ovary (e.g., arrhenoblastomas or luteomas of pregnancy) and, rarely, to mothers with virilizing adrenal tumors. In the past, the administration to pregnant women of progestogens with androgenic side effects (such as 17a-ethinyl-19-nor-testosterone) to

prevent abortion resulted in masculinization of female fetuses.

Developmental Disorders of Mullerian Ducts (Congenital Absence of the Vagina, Mullerian Agenesis)

Clinical Features Congenital hypoplasia or absence of the vagina in combination with abnormal or absent uterus (the Mayer-Rokitansky-Kuster-Hauser syndrome) is second to gonadal dysgenesis as a cause of primary amenorrhea. Most patients are ascertained after the time of expected puberty because of failure to menstruate. The height is normal, and the breasts, axillary and pubic hair, and habitus are feminine in character. The uterus can vary from almost normal, lacking only a conduit to the introitus, to the characteristic rudimentary bicornuate cords with or without a lumen. In some patients cyclic abdominal pain indicates that sufficient functional endometrium is present to result in retrograde menstruation and/or hematometra.

About one-third have abnormal kidneys, most commonly agenesis, ectopy, fused kidneys of the horseshoe type, or solitary ectopic kidneys in the pelvis. Skeletal abnormalities are present in one-tenth; most involve the spine, and limb and rib defects account for the rest. Specific abnormalities include wedge vertebrae, fused rudimentary or asymmetric vertebral bodies, supernumerary vertebrae, and the Klippel-Feil syndrome (congenital fusion of the cervical spine, short neck, low posterior hairline, and painless limitation of cervical movement).

Pathophysiology The karyotype is 46,XX. Familial occurrence has been described, and the pattern of inheritance in most is consistent with a sex-limited autosomal dominant mutation. Sporadic cases may represent new mutations of the type responsible for the familial disorder or be multifactorial in etiology. In the familial cases, expressivity is variable; some have skeletal or renal abnormalities only, and some have other abnormalities of mullerian derivatives such as a double uterus. Bilateral renal aplasia in stillborn infants is commonly associated with absence of the uterus and vagina. Thus, the family history should be probed for isolated skeletal and renal abnormalities and for stillbirths that might result from congenital absence of both kidneys. Ovarian function is normal, and successful pregnancies have occurred after corrective vaginal surgery in patients with a normal uterus.

TREATMENT

Vaginal agenesis can be treated by surgical or nonsurgical means. Surgical repair generally utilizes a split-thickness skin graft around a solid rubber mold to create an artificial vagina. Medical therapy involves the repeated application of pressure against the vaginal dimple with a simple dilator to force development of adequate vaginal depth. In view of complication rates of 5 to 10% in surgical series, surgery should be reserved for patients in whom a well-formed uterus is present and the possibility of fertility exists. Frequent coitus or instrumental dilatation is essential for maintaining patency of neovaginas formed by either technique.

MALE PSEUDOHERMAPHRODITISM

Defective virilization of the 46,XY embryo (male pseudohermaphroditism) can result

from defects in androgen synthesis, defects in androgen action, defects in mullerian duct regression, and uncertain causes.

Abnormalities in Androgen Synthesis

Clinical Features Enzymatic defects that result in defective testosterone synthesis (Fig. 338-3) account for only about a fifth of cases of male pseudohermaphroditism (Tables 338-4 and338-5). Each of the defects blocks a step in the conversion of cholesterol to testosterone. Three enzymatic reactions are common to the synthesis of other adrenal hormones as well: cholesterol side chain cleavage, 3b-hydroxysteroid dehydrogenase/isomerase, and 17a-hydroxylase (CYP17). Consequently, their deficiency results in congenital adrenal hyperplasia (Table 338-4) as well as male pseudohermaphroditism. Two others (17,20-lyase and 17b-hydroxysteroid dehydrogenase 3) are unique to the pathway of androgen synthesis, and their deficiency results only in male pseudohermaphroditism. Since androgens are obligatory precursors of estrogens, synthesis of estrogen is also low in all but the terminal defect (17b-hydroxysteroid dehydrogenase 3 deficiency).

Adrenal dysfunction is described in Chap. 331, and the present discussion concerns the abnormal sexual development. In genetic males with defective testosterone synthesis, absence of the uterus and fallopian tubes indicates that mullerian duct inhibition was normal during embryogenesis. Masculinization of the urogenital tract and external genitalia and virilization at puberty vary from almost normal to absent, and, therefore, the manifestations vary from men with mild hypospadias to phenotypic women who prior to puberty resemble women with complete testicular feminization. This heterogeneity is the consequence of varying severity of the enzymatic defects, varying effects of the steroids that accumulate proximal to the various metabolic blocks, and the presence of alternative enzymatic pathways in some disorders. In patients with partial defects in whom the plasma testosterone level is normal, the diagnosis can only be made by measuring the steroids that accumulate proximal to the metabolic block.

Congenital lipoid adrenal hyperplasia is an autosomal recessive disorder in which virtually no urinary steroids (either 17-ketosteroids or 17-hydroxycorticoids) can be detected. Since the defect blocks the conversion of cholesterol to pregnenolone, a step catalyzed by the cholesterol side chain cleavage enzyme (CYP11A1), it was originally assumed that the defect must involve this enzyme. However, the disorder is instead caused by mutations in the *st*eroidogenic *a*cute *r*egulatory (*StAR*) gene, which encodes the protein that transports cholesterol from the cytosol to the inner mitochondrial membrane in the adrenal and gonads. Manifestations of the disorder include salt wasting and profound adrenal insufficiency, and most affected individuals die during infancy. At autopsy, the adrenals and testes are enlarged and infiltrated with lipid. Affected males are incompletely masculinized, whereas affected female infants have normal genital development because lipid accumulation in the ovary does not occur until there is follicular development and active steroidogenesis.

3b-Hydroxysteroid dehydrogenase/isomerase 2 deficiency causes varying failure of masculinization and the development of a vagina in male infants. Female infants may be modestly virilized at birth due to the weak androgenic potency of dehydroepiandrosterone, the major steroid secreted. If the enzyme is absent in both the

adrenal and testis, no urinary steroids contain aD^4-3-keto configuration, whereas in patients in whom the defect is partial or affects only the testis, the urine may contain normal or elevated levels ofD^4-3-ketosteroids. Most patients have marked salt wasting and profound adrenal insufficiency, and long-term survival in untreated cases occurs only in states of partial deficiency. Minimally affected males may experience an otherwise normal male puberty except for profound gynecomastia. In these boys, a low-normal blood testosterone level is accompanied by elevatedD^5precursor steroids. 3b-Hydroxysteroid dehydrogenase activity is catalyzed by more than one isoenzyme. The type 2 isoenzyme is expressed in adrenals and gonads; the disorder described above is due to any of several mutations in this enzyme. The coding sequence of this gene is said to be normal in several individuals with the late-onset variant of the disease, the pathophysiology of which is unclear.

17a-Hydroxylase-17,20-lyase(CYP17) deficiency impairs the introduction of the 17-hydroxyl and the scission of the C-17,20 carbon bond that convert pregnenolone and progesterone to dehydroepiandrosterone and androstenedione, respectively. These reactions are mediated by a single enzyme CYP17, which is encoded on chromosome 10; it remains unclear why both reactions occur in the ovary and testis, whereas in the adrenal 17-hydroxyprogesterone is largely converted to glucocorticoids and mineralocorticoids rather than the 19-carbon steroids. Of note, some patients appear to have selective impairment of either 17a-hydroxylase or 17,20-lyase activity. These mutations have identified enzyme domains proposed to undergo posttranslational modification and selective interactions with cofactors that switch enzymatic activity. Whatever the mechanism, the consequences of 17a-hydroxylase and 17,20-lyase deficiencies are different.

17a-Hydroxylase deficiency is characterized by hypogonadism, absence of secondary sex characteristics, hypokalemic alkalosis, hypertension, and virtually undetectable hydrocortisone secretion in phenotypic women. Formation of both corticosterone and DOCby the adrenal is elevated, and urinary 17-ketosteroids are low. Aldosterone secretion is low due to high plasma DOC and depressed angiotensin levels and returns to normal after suppressive doses of glucocorticoids. In 46,XX individuals, amenorrhea, absent sexual hair, and hypertension are common, but the phenotype is that of a normal prepubertal woman. In males, the deficiency results in defective virilization that varies from complete male pseudohermaphroditism to ambiguous genitalia with perineoscrotal hypospadias and, in some, gynecomastia. Adrenal insufficiency does not develop, since the secretion of both corticosterone (a weak glucocorticoid) and DOC (a mineralocorticoid) is elevated. Hypertension and hypokalemia are prominent (even in the neonatal period) and remit after suppression of the DOC secretion by glucocorticoid replacement. A variety of point mutations, deletions, and insertions in the *CYP17* gene have been characterized in affected individuals.

17,20-Lyase deficiency in males is associated with normal function of the adrenal cortex and a variable pattern of male pseudohermaphroditism. In the majority there is genital ambiguity at birth, with some virilization at the time of expected puberty. Rare 46,XY patients have had a female phenotype and no virilization at the time of expected puberty. The disorder has been recognized in one 46,XX woman with sexual infantilism. Mutations of *CYP17* that cause this disorder involve an area of the gene that is known to encode a binding site for the redox-partner of the enzyme.

17b-Hydroxysteroid dehydrogenase 3 (17b-HSD-3) deficiency involves the final step in testosterone biosynthesis, reduction of the 17-keto group of androstenedione. This is the most common enzymatic defect in testosterone synthesis. Affected 46,XY males usually have a female phenotype with a blind-ending vagina and absence of mullerian derivatives, but inguinal or abdominal testes and virilized wolffian duct structures are present. At the time of expected puberty, both virilization (with phallic enlargement and development of facial and body hair) and a variable degree of feminization take place. In some untreated patients, reversal of gender behavior from female to male occurs at puberty. Plasma testosterone level may be in the low-normal range, making it essential to document elevation in plasma androstenedione to make the diagnosis. Isoenzymes encoded by several different genes possess 17b-hydroxysteroid dehydrogenase activity, but the isoenzyme 3 is expressed in the testes. A variety of mutations have been characterized in the 17b-HSD-3 gene in affected individuals.

Pathophysiology These various disorders are inherited as autosomal recessive traits. The pattern of steroid secretion and excretion depends on the site of the various metabolic blocks (Fig. 338-3). In general, gonadotropin secretion is high, and many individuals with incomplete defects are able to compensate so that the steady-state levels of testosterone may be normal or almost normal.

In rare cases of male pseudohermaphroditism, testosterone formation is deficient for reasons other than a single enzyme defect in androgen synthesis. These include disorders in which Leydig cell agenesis is due to autosomal recessive loss-of-function mutations of theLHreceptor or to the secretion of a biologically inactive LH molecule. In addition, as described above, several disorders, including familial 46,XY pure gonadal dysgenesis, sporadic dysgenetic testes, and the absent testis syndrome, are characterized by deficient testosterone production due to abnormal gonadal development.

TREATMENT

Therapy with glucocorticoids and in some instances mineralocorticoids is indicated in those disorders causing adrenal hyperplasia. The management of the genital abnormalities depends on the individual case. Fertility has not been reported, and its consideration does not enter into sex assignment. In genetic females there is no problem (except in diagnosis), in that affected individuals are raised appropriately as females and estrogen therapy is begun at the time of expected puberty to promote development of female secondary sex characteristics. Whether newborn males with ambiguous genitalia should be raised as males or females depends on the anatomic defect; in general, the more severely affected should be raised as females, and corrective surgery of the genitalia and removal of the testes should be undertaken as early as possible. In such women estrogen therapy is begun at the appropriate age to allow development of normal female secondary sex characteristics. In individuals raised as males, corrective surgery is indicated for any coexisting hypospadias, and plasma androgens should be monitored at the time of expected puberty to determine whether testosterone therapy is appropriate.

Abnormalities in Androgen Action Several disorders of male phenotypic development

result from abnormalities of androgen action. The spectrum of phenotypes is described in Tables 338-4 and338-5. In these disorders, testosterone formation and mullerian regression are normal, but male development is impaired because of resistance to androgen action in target tissues.

Steroid 5a-Reductase 2 Deficiency This autosomal recessive disorder is characterized by (1) severe perineoscrotal hypospadias; (2) a blind vaginal pouch of variable size opening either into the urogenital sinus or into the urethra; (3) testes with normal epididymides, vasa deferentia, and seminal vesicles, and termination of the ejaculatory ducts in the blind-ending vagina; (4) a female habitus with normal axillary and pubic hair but without female breast development; (5) the absence of uterus and fallopian tubes; (6) normal male plasma testosterone; and (7) masculinization to a variable degree at the time of puberty.

The realization that virilization during embryogenesis is defective only in the urogenital sinus and the external genitalia provided insight into the fundamental abnormality. Testosterone, the androgen secreted by the fetal testis, is responsible for conversion of the wolffian duct into the epididymis, vas deferens, and seminal vesicle, whereas dihydrotestosterone mediates virilization of the urogenital sinus and the external genitalia. Consequently, impairment of dihydrotestosterone formation in a male embryo would be expected to cause the phenotype in this disorder -- normal male wolffian duct derivatives with defective masculinization of the external genitalia and urogenital sinus. Since testosterone itself regulatesLHsecretion (Chap. 335), plasma LH level is normal or minimally elevated. As a result, testosterone and estrogen production rates are those of normal men, and gynecomastia does not develop.

The fact that 5a-reductase 2 enzyme is deficient in this disorder was established by assay of biopsied tissues and cultured fibroblasts from affected individuals. Deletions or point mutations in the gene encoding steroid 5a-reductase 2 have been identified in most families studied. Approximately 40% are compound heterozygotes.

Receptor Disorders The androgen receptor is a member of the steroid/thyroid family of receptors with steroid-binding, DNA-binding, and functional domains and is encoded by a gene on the long arm of the X chromosome. Mutations of this gene impair receptor function and hence impair male phenotypic differentiation and/or virilization.

CLINICAL FEATURES Complete testicular feminization (also called *complete androgen insensitivity*) is a common form of male pseudohermaphroditism; estimates of frequency vary from 1 in 20,000 to 1 in 64,000 male births. It is the third most common cause of primary amenorrhea after gonadal dysgenesis and congenital absence of the vagina. The features are characteristic. Namely, a woman is ascertained either because of inguinal hernia (prepubertal) or primary amenorrhea (postpubertal). The development of the breasts, the habitus, and the distribution of body fat are female in character so that most have a truly feminine appearance. Axillary and pubic hair is absent or scanty, but some vulval hair is usually present. Scalp hair is that of a normal woman, and facial hair is absent. The external genitalia are unambiguously female, and the clitoris is normal. The vagina is short and blind-ending and may be absent or rudimentary. All internal genitalia are absent except for testes that contain normal Leydig cells and seminiferous tubules without spermatogenesis. The testes may be located in the abdomen, along the

course of the inguinal canal, or in the labia majora. Occasionally, remnants of mullerian or wolffian duct origin are present in the paratesticular fascia or in fibrous bands extending from the testis. Patients tend to be rather tall, and bone age is normal. Psychosexual development is unmistakably female with regard to behavior, outlook, and maternal instincts.

The major complication of undescended testes in this disorder, as in all forms of cryptorchidism, is the development of tumors (Chap. 96). Since affected individuals undergo normal pubertal growth and feminize at the time of expected puberty and since testicular tumors rarely develop until after puberty, it is usual to delay gonadectomy until after the time of expected puberty. Prepubertal gonadectomy is indicated if the testes are present in the inguinal region or labia majora and result in discomfort or hernia formation. (If hernia repair is indicated prepubertally, most physicians prefer to remove the testes at the same time to limit the number of operative procedures.) If the testes are removed prepubertally, estrogen therapy is required at the appropriate age to ensure normal growth and breast development. Postpubertal gonadectomy causes menopausal symptoms and other evidence of estrogen withdrawal, and suitable estrogen replacement is indicated (Chap. 336).

Incomplete testicular feminization is about one-tenth as frequent as the complete form. In this disorder there is minor virilization of the external genitalia (partial fusion of the labioscrotal folds and/or some degree of clitoromegaly), normal pubic hair, and mixed virilization and feminization at the time of expected puberty. The vagina is short and blind-ending, but in contrast to the complete form, the wolffian duct derivatives are often partially developed. Since women with the incomplete disorder virilize at the time of expected puberty, gonadectomy should be performed before the expected time of puberty in all prepubertal patients with clitoromegaly or posterior labial fusion.

Reifenstein syndrome (also called *partial androgen insensitivity*) is the term applied to forms of incomplete male pseudohermaphroditism initially described by a number of eponyms (Reifenstein syndrome, Gilbert-Dreyfus syndrome, Lubs syndrome). These syndromes are mutations that partially impair the function of the androgen receptor. The most common phenotype is a man with perineoscrotal hypospadias and gynecomastia, but the spectrum of defective virilization in affected families ranges from men with azoospermia to phenotypic women with pseudovaginas. Axillary and pubic hair is normal, but chest and facial hair is scanty. Cryptorchidism is common, the testes are small, and azoospermia is present. Some have defects in wolffian duct derivatives such as absence or hypoplasia of the vas deferens. Since the psychological development in most is unequivocally male, the hypospadias and cryptorchidism should be corrected surgically. The treatment of the gynecomastia is surgical removal.

A disorder of the androgen receptor that is not actually a form of male pseudohermaphroditism is manifested as *infertility and/or undervirilization in phenotypic men*. Some such individuals are minimally affected members of families with Reifenstein syndrome in whom azoospermia is the only manifestation of the receptor defect. The *undervirilized fertile male* is an even more subtle manifestation of androgen receptor defect. In these families, affected men have gynecomastia and undervirilization, and some are fertile. More commonly, however, individuals with negative family histories present with male infertility with or without undervirilization.

PATHOPHYSIOLOGY The karyotype is 46,XY, and the mutation is X-linked. The frequency of a positive family history varies from about two-thirds of patients with testicular feminization and Reifenstein syndrome to only occasional patients with the infertile male syndrome. The disorder in subjects with a negative family history is believed to be the result of new mutations.

Hormone dynamics are similar in all disorders of the androgen receptor. Plasma testosterone levels and rates of testosterone production by the testes are normal or high. Elevated testosterone production is caused by the high mean plasma level ofLH, which, in turn, is due to defective feedback regulation caused by resistance to the action of androgen at the hypothalamic-pituitary level. Elevated LH concentration is responsible also for the increased estrogen production by the testes (Chap. 337). (In normal men, most estrogen is derived from peripheral formation from circulating androgens, but when the plasma LH level is elevated, the testes secrete increased amounts of estrogen into the circulation.) Thus resistance to the feedback regulation of LH secretion by circulating androgen results in elevated plasma LH levels, and this, in turn, results in the enhanced secretion of both testosterone and estradiol by the testes. Gonadotropin levels rise even higher (and menopausal symptoms may develop) when the testes are removed, indicating that gonadotropin secretion is under partial feedback control. Presumably, in the steady state and in the absence of an androgen effect, estrogen alone regulates LH secretion, a control purchased at the expense of an elevated plasma estrogen concentration for a male. The hormonal changes in the infertile male syndrome are similar to those in the other receptor disorders but less marked. Some men with this syndrome do not have an elevation of plasma LH or plasma testosterone level.

Feminization in these disorders is the result of two interlocking phenomena. First, androgens and estrogens have antagonistic effects, and in the absence of androgen action, the cellular effect of estrogen is unopposed. Second, the testicular production of estradiol is greater than that of the normal male (although less than that of the normal female). Variable degrees of androgen resistance and enhanced estradiol production result in different degrees of defective virilization and enhanced feminization in the four clinical syndromes.

Each of these syndromes is the result of defects in the androgen receptor. In most families, the fundamental defect is due to point mutations in the coding sequence leading to premature termination codons or to amino acid substitutions in the hormone-binding domain. Such mutations impair receptor function to variable degrees. Some families with clinical syndromes typical of an androgen receptor disorder have normal androgen binding in fibroblasts; in most, point mutations in the DNA-binding domain of the androgen receptor are responsible for the androgen resistance.

TREATMENT

Individuals with 5a-reductase deficiency who are raised as females but elect at the time of expected puberty to change social sex to male or who are raised from the first as males should be monitored carefully and given supplemental androgens, preferably those such as nandrolone decanoate that do not require 5a-reduction for activation,

when virilization is incomplete. Fertility has been reported in such an individual. Individuals with 5a-reductase deficiency who continue to function as females should be gonadectomized, given feminizing doses of estrogens indefinitely, and receive surgical correction of the introitus when appropriate. The management of subjects with androgen receptor defects depends on the phenotypic manifestations. Women with testicular feminization should be castrated (preferably after the completion of the pubertal growth spurt and the feminization of the breasts) to prevent tumor development in the testes and receive estrogen replacement to maintain feminization, prevent hot flashes, and protect the bones; shallow vaginal depth can usually be treated medically with the Frank technique. Men with the Reifenstein phenotype should have surgical correction of the hypospadias and may require surgery for gynecomastia; supplemental androgen therapy in these men rarely improves the incomplete virilization.

Persistent Mullerian Duct Syndrome Men with this uncommon disorder have testes and male phenotypic development and in addition have fallopian tubes and a uterus. In some, one or both testes are descended and the uterus and ipsilateral fallopian tube are in the inguinal canal or scrotum; both testes and fallopian tubes may be present in the hernia sac or can be drawn into it. In others, the testes are located high in the abdomen and hernias are not present. In both types, the vasa deferentia are embedded in the wall of the uterus, a feature that complicates surgical procedures designed to preserve potential fertility. Most individuals have uninformative family histories, but in some the condition is inherited as an autosomal recessive trait. Because the external genitalia are well developed and the subjects masculinize normally at puberty, it is assumed that during the critical stage of embryonic differentiation the fetal testes produce a normal amount of androgen. However, mullerian regression does not occur. Two types of mutations have been described in this disorder. In one the gene that encodesAMH is defective, and blood levels of AMH are usually low or undetectable; in the other the AMH receptor is defective, and blood levels of AMH are elevated. To minimize the chance of tumor development and to maintain virilization, orchiopexy should be performed. Malignancy in the uterus or vagina has not been described, and because the vasa deferentia are closely associated with the broad ligaments, the uterus and vagina should be left in place to avoid disruption of the vasa deferentia during removal and consequently to preserve possible fertility.

Developmental Defects of the Male Genitalia

Hypospadias Hypospadias is a congenital anomaly in which the urethra terminates in an abnormal position along the ventral midline of the penis at some site between the normal urethral meatus and the perineum. This malformation occurs in 0.5 to 0.8% of male births in the United States and is often associated with ventral contraction and bowing of the penis (chordee). It is common to categorize hypospadias as glandular (involving the glans penis), penile, or perineoscrotal. Since androgens control penile development, hypospadias is generally assumed to result from some unidentified defect in androgen formation or action during embryogenesis. Indeed, hypospadias occurs in most disorders of male sexual differentiation, and a rare cause of hypospadias is maternal ingestion of progestational agents early in pregnancy. However, the known causes (single-gene defects, chromosomal abnormalities, and maternal drug ingestion) account for only about one-fourth of cases, and the etiology of most is unknown. The management is surgical.

Cryptorchidism The control of testicular descent is poorly understood, both in regard to the nature of the forces that cause the movement and to the hormonal factors that regulate the process. In anatomic terms, testicular descent can be divided into three phases: (1) transabdominal movement of the testis from its site of origin above the kidney to the inguinal ring, (2) formation of the opening in the inguinal canal (processus vaginalis) through which the testis exits the abdominal cavity, and (3) actual movement of the testis through the inguinal canal to its permanent site in the scrotum. This process occurs over a 6- to 7-month period during gestation, beginning at about the sixth week, and is not completed in some until after birth. Impairment at any stage in this process can impair descent of one or both testes. About 3% of full-term and 30% of premature male infants have at least one cryptorchid testis at birth, but descent is usually completed within the first few weeks of life, so that the incidence of failure of descent by 6 to 9 months of age is only 0.6 to 0.7%. It is this latter category of maldescent that requires intervention.

Permanent cryptorchidism can be classified as intraabdominal (10%), canalicular (in the inguinal canal) (20%), high scrotal (40%), or obstructed (30%), in which maldescent is due to a physical barrier between the inguinal pouch and the inlet of the scrotum. These disorders must be distinguished from the temporarily retracted normal testis.

The cryptorchid testis functions poorly after puberty, but the extent to which maldescent is the result of an abnormality of the testis or the cause of abnormal function is unknown. Two general theories have been advanced as to the etiology -- inadequate intraabdominal pressure and deficient endocrine function of the testis either because of deficient testosterone synthesis or inadequate formation ofAMH. Indeed, defects that result in inadequate development of intraabdominal pressure or inadequate development of the testes can cause cryptorchidism. As in hypospadias, however, the known causes of cryptorchidism constitute only a small fraction of the cases, and the etiology in most remains to be identified. Two complications of cryptorchidism are important; spermatogenesis cannot occur at the temperature of the abdominal cavity, and it is necessary to correct the process as early as possible to allow possible fertility. The fact that infertility is common in men who have been treated for unilateral as well as bilateral cryptorchidism suggests that maldescent is usually the consequence rather than the cause of the testicular malfunction. There is also a greater frequency of malignancy in undescended testes, which should be surgically corrected for this reason (Chap. 96).

339. DISORDERS AFFECTING MULTIPLE ENDOCRINE SYSTEMS- *Steven I. Sherman, Robert F. Gagel*

NEOPLASTIC DISORDERS AFFECTING MULTIPLE ENDOCRINE ORGANS

Several distinct genetic disorders predispose to endocrine gland neoplasia and cause hormone excess syndromes (Table 339-1). DNA-based genetic testing is now available for these disorders, but effective management requires an understanding of endocrine neoplasia and the range of clinical features that may be manifest in an individual patient.

MULTIPLE ENDOCRINE NEOPLASIA (MEN) TYPE 1

Clinical Manifestations MEN 1, or Wermer's syndrome, is characterized by neoplasia of parathyroid, pituitary, and pancreatic islet cells (Table 339-1). The syndrome is inherited as an autosomal dominant trait, so that each child of an affected parent has a 50% chance of inheriting the predisposing gene.

Several features of the pathogenesis ofMEN 1 have important implications for its management. Though each tumor is derived from a single cell (clonal in origin), any endocrine cell within the affected organs can become transformed. Hyperplasia is the initiating lesion, followed later by adenomatous or carcinomatous changes. Consequently, the disease process within a single organ is multicentric. Neoplasia in one organ may affect the progression of disease in another organ. For example, the ectopic production of hypothalamic releasing hormones by a pancreatic tumor may stimulate the growth of a pituitary tumor. Because MEN 1 generally evolves over a 30- to 40-year period, the manifestations depend in part on when the disorder is identified.

Hyperparathyroidism is the most common manifestation ofMEN 1. Hypercalcemia may be present during the teenage years, and most individuals are affected by age 40 (Fig. 339-1). Screening for hyperparathyroidism involves measurement of either an albumin-adjusted or ionized serum calcium level. The diagnosis is established by demonstrating elevated levels of serum calcium and intact parathyroid hormone. Manifestations of hyperparathyroidism in MEN 1 do not differ substantially from those in sporadic hyperparathyroidism and include calcium-containing kidney stones, bone abnormalities, and gastrointestinal and musculoskeletal complaints (Chap. 341).

Other familial disorders associated with hypercalcemia include familial parathyroid hyperplasia, familial adenomatous hyperparathyroidism, and familial hypocalciuric hypercalcemia (FHH). Calcium excretion is usually elevated in the patient withMEN 1 or other forms of primary hyperparathyroidism and low in FHH. Another distinguishing feature is that the serum calcium level is rarely elevated at birth in patients with MEN 1 but is frequently elevated in newborns with FHH. Differentiation of hyperparathyroidism of MEN 1 from other forms of familial primary hyperparathyroidism is usually based on family history, histologic features of resected parathyroid tissue, and, sometimes, long-term observation to determine whether other manifestations of MEN 1 develop. FHH is due to inactivating mutations of the calcium sensor, a transmembrane G protein-coupled receptor found in parathyroid tissue and kidney (Chap. 341).

Parathyroid hyperplasia is the common cause of hyperparathyroidism inMEN 1,

although single and multiple adenomas have been described. Hyperplasia of one or more parathyroid glands is common in younger patients; adenomas are usually found in older patients or those with long-standing disease.

Neoplasia of the pancreatic islets is the second most common manifestation ofMEN 1 and tends to occur in parallel with hyperparathyroidism (Fig. 339-1). Increased pancreatic islet cell hormones include pancreatic polypeptide (75 to 85%), gastrin [60%; Zollinger-Ellison syndrome (ZES)], insulin (25 to 35%), vasoactive intestinal peptide (VIP) (3 to 5%; Verner-Morrison or watery diarrhea syndrome), glucagon (5 to 10%), and somatostatin (1 to 5%). The tumors rarely produce adrenocorticotropin (ACTH), corticotropin-releasing hormone (CRH), growth hormone-releasing hormone (GHRH), calcitonin gene products, neurotensin, gastric inhibitory peptide, and others. Many of the tumors produce more than one peptide. The pancreatic neoplasms differ from the other components of MEN 1 in that approximately one-third of the tumors display malignant features, including hepatic metastases (Chap. 93).

Pancreatic islet cell tumors are diagnosed by identification of a characteristic clinical syndrome, hormonal assays with or without provocative stimuli, or radiographic techniques. One approach involves annual screening of people at risk with measurement of basal and meal-stimulated levels of pancreatic polypeptide to identify the tumors as early as possible; the rationale of this screening strategy is the concept that surgical removal of islet cell tumors at an early stage will be curative. Other approaches to screening include measurement of serum gastrin and pancreatic polypeptide levels every 2 to 3 years, with the rationale that pancreatic neoplasms will be detected at a later stage but can be managed medically, if possible, or by surgery. High-resolution, early-phase computed tomography (CT) scanning provides the best noninvasive technique for identification of these tumors, but intraoperative ultrasonography is the most sensitive method for detection of small tumors.

ZESis caused by excessive gastrin production and occurs in more than half ofMEN 1 patients with pancreatic islet cell tumors (Fig. 339-1) (Chap. 93). Clinical features include increased gastric acid production, recurrent peptic ulcers, diarrhea, and esophagitis. The ulcer diathesis is refractory to conservative therapy such as antacids. The diagnosis is made by finding increased gastric acid secretion, elevated basal gastrin levels in serum [generally >115 pmol/L (200 pg/mL)], and an exaggerated response of serum gastrin to either secretin or calcium. Other causes of elevated serum gastrin levels, such as achlorhydria, treatment with H_2receptor antagonists or omeprazole, retained gastric antrum, small-bowel resection, gastric outlet obstruction, and hypercalcemia, should be excluded. Gastrin-producing carcinoid-like tumors are frequently present in the duodenal wall.

Insulinoma causes hypoglycemia in about one-third ofMEN 1 patients with pancreatic islet cell tumors (Fig. 339-1). The tumors may be benign or malignant (25%). The diagnosis can be established by documenting hypoglycemia during a short fast with simultaneous inappropriate elevation of serum insulin and C-peptide levels. More commonly, it is necessary to subject the patient to a supervised 72-h fast to provoke hypoglycemia (Chap. 334). Large insulinomas may be identified byCTscanning; small tumors not detected by radiographic techniques may be localized by selective arteriographic injection of calcium into each of the arteries that supply the pancreas and

sampling the hepatic vein for insulin to determine the anatomic region containing the tumor. Intraoperative ultrasonography can also be used to localize these tumors, but preoperative calcium injection data are helpful in guiding the subtotal pancreatectomy if multiple or no abnormalities are detected by intraoperative ultrasonography.

Glucagonoma in occasionalMEN 1 patients causes a syndrome of hyperglycemia, skin rash (necrolytic migratory erythema), anorexia, glossitis, anemia, depression, diarrhea, and venous thrombosis. In about half of these patients the plasma glucagon level is high, leading to its designation as the *glucagonoma syndrome*, although elevation of plasma glucagon level in MEN 1 patients is not necessarily associated with these symptoms. The glucagonoma syndrome may represent a complex interaction between glucagon overproduction and the nutritional status of the patient.

The *Verner-Morrison* or *watery diarrhea syndrome* consists of watery diarrhea, hypokalemia, hypochlorhydria, and metabolic acidosis. The diarrhea can be voluminous and is almost always found in association with an islet cell tumor, prompting use of the term *pancreatic cholera*. However, the syndrome is not restricted to pancreatic islet tumors and has been observed with carcinoids or other tumors. This syndrome is believed to be due to overproduction ofVIP, although plasma VIP levels may not be elevated. Hypercalcemia may be induced by the effects of VIP on bone as well as by hyperparathyroidism.

Pituitary tumors occur in more than half of patients withMEN 1 and tend to be multicentric, making them difficult to resect (Chap. 328). Prolactinomas are most common (Fig. 339-1) and are diagnosed by finding serum prolactin levels >200 ug/L, with or without a pituitary mass evident by magnetic resonance imaging (MRI). Values<200 ug/L may be due to a prolactin-secreting neoplasm or to compression of the pituitary stalk by a different type of pituitary tumor. Acromegaly due to excessive growth hormone (GH) production is the second most common syndrome caused by pituitary tumors in MEN 1 (Chap. 328) but can rarely be due to production ofGHRH by an islet cell tumor. Cushing's disease can be caused byACTH-producing pituitary tumors or by ectopic production of ACTH orCRH by other tumors in the MEN 1 syndrome. Diagnosis of pituitary Cushing's disease is generally best accomplished by a high-dose dexamethasone suppression test or by petrosal venous sinus sampling for ACTH after intravenous injection of CRH (Chap. 328). Differentiation of a primary pituitary tumor from an ectopic CRH-producing tumor may be difficult because the pituitary is the source of ACTH in both disorders; documentation of CRH production by a pancreatic islet or carcinoid tumor may be the only method of proving ectopic CRH production. Adrenal cortical tumors are found in almost one-half of gene carriers but are rarely functional; malignancy in the cortical adenomas is uncommon.

Unusual manifestations of MEN 1 The rare carcinoid tumors in MEN 1 are of the foregut type and are derived from thymus, lung, stomach, or duodenum; they may metastasize or be locally invasive. These tumors usually produce serotonin, calcitonin, orCRH; the typical carcinoid syndrome with flushing, diarrhea, and bronchospasm is rare (Chap. 93). Subcutaneous or visceral lipomas and cutaneous leiomyomas may also be present but rarely undergo malignant transformation. Skin angiofibromas or collagenomas are seen in most patients with MEN 1 when carefully sought.

GENETIC CONSIDERATIONS

MEN1 is transmitted as an autosomal dominant trait, reflecting the fact that the *MEN1* gene, located on chromosome 11q13, encodes a tumor suppressor protein termed *menin* (Fig. 339-2). Affected individuals typically harbor a germline mutation in *MEN1* and acquire a "second hit" in the normal gene as a result of another mutation or, more commonly, loss of the portion of chromosome 11 that contains the *MEN1* locus (Chap. 81). Though the function of menin is not well understood, it is a nuclear protein that interacts with a transcriptional factor, Jun D, suggesting a role in cell growth control. Several missense mutations in menin prevent its interaction with Jun D.

MEN1 gene mutations are found in>90% of families with the syndrome (Fig. 339-2). Genetic testing can be performed in individuals at risk for the development ofMEN 1, particularly when the specific mutation is known. The value of genetic testing for this disorder, in contrast to MEN 2 (see below), is debated because predisposed individuals must still be screened repeatedly using endocrine tests. A negative genetic analysis will, however, exclude disease with near 100% certainty in kindreds with a known mutation; for this reason, genetic testing is likely to gain favor as it becomes more widely available. A significant percentage of sporadic parathyroid, islet cell, and carcinoid tumors also have loss or mutation of *MEN1*. It is presumed that these mutations are somatic and occur in a single cell, leading to subsequent transformation.

TREATMENT

Almost everyone who inherits a mutant *MEN1* gene develops at least one clinical manifestation of the syndrome. Most develop hyperparathyroidism, 80% develop pancreatic islet cell tumors, and more than half develop pituitary tumors. For most of these tumors, initial surgery is not curative and patients frequently require multiple surgical procedures and surgery on two or more endocrine glands during a lifetime. For this reason, it is essential to establish clear goals for management of these patients rather than to recommend surgery casually each time a tumor is discovered. Ranges for acceptable management are discussed below.

Hyperparathyroidism Individuals with serum calcium levels >3.0 mmol/L (12 mg/dL), evidence of calcium nephrolithiasis or renal dysfunction, neuropathic or muscular symptoms, or bone involvement (including osteopenia) should undergo parathyroid exploration. InMEN 1 an additional criterion for parathyroid surgery is hypercalcemia associated with elevated gastrin levels, because elevated serum calcium may stimulate gastrin production andZES, a condition that may be improved by return of calcium levels to normal. There is less agreement regarding the necessity for parathyroid exploration in individuals who do not meet these criteria, and observation may be appropriate in the MEN 1 patient with asymptomatic hyperparathyroidism.

When parathyroid surgery is indicated inMEN 1, all parathyroid tissue should be identified and removed at the time of primary operation, and parathyroid tissue should be implanted in the nondominant forearm. Thymectomy should also be performed because of the potential for later development of malignant carcinoid tumors. If reoperation is necessary, transplanted tissue can be resected under local anesthesia with titration of tissue removal to return the serum calcium level to normal. A less

desirable approach is to remove 3 to 3$_{1/2}$ parathyroid glands from the neck, carefully marking the location of residual tissue so that the remaining tissue can be located easily during subsequent surgery.

Pancreatic Islet Tumors (See Chap. 93 for discussion of pancreatic islet tumors not associated with MEN 1.) Two features of pancreatic islet cell tumors in MEN 1 complicate the management. First, the pancreatic islet cell tumors are multicentric, malignant about a third of the time, and cause death in 10 to 20% of patients. Second, removal of all pancreatic islets to prevent malignancy causes diabetes mellitus, a disease with severe long-term complications. These features make it difficult to formulate clear-cut guidelines, but some general concepts appear to be valid. First, islet cell tumors producing insulin, glucagon, VIP, GHRH, or CRH should be resected because medical therapy is generally ineffective. Second, gastrin-producing islet cell tumors that cause ZES are frequently multicentric. Recent experience suggests that a high percentage of ZES in MEN 1 is caused by duodenal wall tumors and that resection of these tumors improves the cure rate. Treatment with H_2 receptor antagonists (cimetidine or ranitidine) and the H^+,K^+-ATPase inhibitors (omeprazole or lansoprazole) provides an alternative to surgery for control of ulcer disease in patients with multicentric tumors or with hepatic metastases. Third, in families in which there is a high incidence of malignant islet cell tumors that cause death, total pancreatectomy at an early age may be justified to prevent malignancy.

Management of metastatic islet cell carcinoma is unsatisfactory. Hormonal abnormalities can sometimes be controlled. For example, ZES can be treated with H_2 receptor antagonists or H^+,K^+-ATPase inhibitors; the somatostatin analogue, octreotide, is useful in the management of carcinoid and the watery diarrhea syndrome. Bilateral adrenalectomy may be required for ectopic ACTH syndrome if medical therapy is ineffective (Chap. 331). Islet cell carcinomas frequently metastasize to the liver but may grow slowly. Hepatic artery embolization or chemotherapy (5-fluorouracil, streptozocin, chlorozotocin, doxorubicin, or dacarbazine) may reduce tumor mass, control symptoms of hormone excess, and prolong life; however, these treatments are never curative.

Pituitary Tumors Treatment of prolactinomas with dopamine agonists (bromocriptine, cabergoline, or quinagolide) usually returns the serum prolactin level to normal and prevents further tumor growth (Chap. 328). Surgical resection of a prolactinoma is rarely curative but may relieve mass effects. Transsphenoidal resection is appropriate for neoplasms that secrete ACTH, GH, or the a-subunit of the pituitary glycoprotein hormones. Octreotide reduces tumor mass in one-third of GH-secreting tumors and reduces GH and insulin-like growth factor I levels in >75% of patients. Radiation therapy may be useful for large or recurrent tumors.

Improvements in the management of MEN 1, particularly islet cell and pituitary tumors, have improved outcome in these patients substantially. As a result, other neoplastic manifestations, such as carcinoid syndrome, are now seen with increased frequency.

MULTIPLE ENDOCRINE NEOPLASIA TYPE 2

Clinical Manifestations Medullary thyroid carcinoma (MTC) and pheochromocytoma

are associated in two major syndromes:MEN type 2A and MEN type 2B (Table 339-1). MEN 2A is the combination of MTC, hyperparathyroidism, and pheochromocytoma. Three subvariants of MEN 2A are familial medullary thyroid carcinoma (FMTC), MEN 2A with cutaneous lichen amyloidosis, and MEN 2A with Hirschsprung disease. MEN type 2B is the combination of MTC, pheochromocytoma, mucosal neuromas, intestinal ganglioneuromatosis, and marfanoid features.

Multiple Endocrine Neoplasia Type 2A MTC is the most common manifestation. This tumor usually develops in childhood, beginning as hyperplasia of the calcitonin-producing cells (C cells) of the thyroid. MTC is typically located at the junction of the upper one-third and lower two-thirds of each lobe of the thyroid, reflecting the high density of C cells in this location; tumors >1 cm in size are frequently associated with local or distant metastases. Measurement of the serum calcitonin level after calcium or pentagastrin injection makes it possible to diagnose this disorder when the likelihood of metastasis is low (see below).

Pheochromocytoma occurs in approximately 50% of patients withMEN 2A and causes palpitations, nervousness, headaches, and sometimes sweating (Chap. 332). About half the tumors are bilateral, and>50% of patients who have had unilateral adrenalectomy develop a pheochromocytoma in the contralateral gland within a decade. A second feature of these tumors is a disproportionate increase in the secretion of epinephrine relative to norepinephrine. Capsular invasion is common, but malignant behavior is uncommon.

Hyperparathyroidism occurs in 15 to 20% of patients, with the peak incidence in the third or fourth decade. The manifestations of hyperparathyroidism do not differ from those in other forms of primary hyperparathyroidism (Chap. 341), with nephrolithiasis being common. Diagnosis is established by finding hypercalcemia, hypophosphatemia, hypercalciuria, and an inappropriately high serum level of intact parathyroid hormone. Multiglandular parathyroid hyperplasia is the most common histologic finding, although with long-standing disease adenomatous changes may be superimposed on hyperplasia.

Multiple Endocrine Neoplasia Type 2B The association ofMTC, pheochromocytoma, mucosal neuromas, and a marfanoid habitus is designatedMEN 2B. MTC in MEN 2B develops earlier and is more aggressive than in MEN 2A. Metastatic disease has been described prior to 1 year of age, and death commonly occurs in the second or third decade of life. However, the prognosis is not invariably bad even in patients with metastatic disease, as evidenced by a number of multigenerational families with this disease.

Pheochromocytoma occurs in more than half ofMEN 2B patients and does not differ from that in MEN 2A. Hypercalcemia is rare in MEN 2B, and there are no well-documented examples of hyperparathyroidism.

The mucosal neuromas and marfanoid body habitus are the most distinctive features and are recognizable in childhood. Neuromas are present on the tip of the tongue, under the eyelids, and throughout the gastrointestinal tract and are true neuromas, distinct from neurofibromas. Children may present with gastrointestinal symptoms,

including increased gas, intermittent obstruction, and diarrhea caused by neuromas.

GENETIC CONSIDERATIONS

Mutations of the *RET* proto-oncogene have been identified in 93 to 95% of patients withMEN 2 (Fig. 339-3). *RET* encodes a tyrosine kinase receptor that is normally activated by glial cell line-derived neurotropic factor. *RET* mutations induce constitutive activity of the receptor, explaining the autosomal dominant transmission of the disorder.

Naturally occurring mutations localize to two regions of the RET tyrosine kinase receptor. The first is a cysteine-rich extracellular domain; point mutations in the coding sequence for one of five cysteines (codons 609, 611, 618, 620, or 634) cause amino acid substitutions that induce receptor dimerization and activation in the absence of its ligand. Codon 634 mutations occur in 80% ofMEN 2A kindreds and are most commonly associated with classic MEN 2A features (Figs. 339-3 and339-2); an arginine substitution at this codon accounts for half of all MEN 2A mutations. All reported families with MEN 2A and cutaneous lichen amyloidosis are consistently associated with a codon 634 mutation. Mutations of codons 609, 611, 618, or 620 occur in 10 to 15% of MEN 2A kindreds and are more commonly associated withFMTC(Fig. 339-3). Mutations in codons 609, 618, and 620 have also been identified in MEN 2A and in the Hirschsprung variant (Fig. 339-3).

The second region of the RET tyrosine kinase that is mutated inMEN 2 is in the substrate recognition pocket at codon 918 (Fig. 339-3). This activating mutation is present in approximately 95% of patients with MEN 2B and accounts for 10 to 15% of all *RET* proto-oncogene mutations in MEN 2. Mutations of codon 883 and 22 have also been identified in a few patients with MEN 2B.

From 3 to 5% of kindreds withFMTChave no identifiable mutation of either of these regions. In a few such kindreds mutations of codons 768, 790, 791, 804, and 891 have been identified (Fig. 339-3).

Somatic mutations (found only in the tumor and not transmitted in the germline) of the *RET* proto-oncogene have been identified in sporadicMTC; 25 to 35% of sporadic tumors have codon 918 mutations, and somatic mutations in codons 630, 768, and 804 have also been identified (Fig. 339-3). Germline mutations of the *RET* proto-oncogene are present in about 6% of patients with apparent sporadic MTC, indicating that other family members may be at risk for the disease.

TREATMENT

Screening for Multiple Endocrine Neoplasia Type 2 Death fromMTC can be prevented by early thyroidectomy. The identification of *RET* proto-oncogene mutations and the application of DNA-based molecular diagnostic techniques to identify these mutations has simplified the screening process. During the initial evaluation of a kindred, a *RET* proto-oncogene analysis should be performed on an individual with provenMEN 2A. Establishment of the specific mutation in a kindred facilitates the subsequent analysis of other family members. Each family member at risk should be tested twice for the presence of the specific mutation; the second analysis should be

performed on a new DNA sample and, ideally, in a second laboratory to exclude sample mix-up or technical error (see *endrcr06.mda.uth.tmc.edu* for a list of laboratory testing sites). Individuals in a kindred with a known mutation who have two normal analyses can be excluded from further screening.

There is general consensus that children with codon 883, 918, and 922 mutations, or those associated withMEN 2B, should have a total thyroidectomy and central lymph node dissection (level VI) performed during the first months of life or soon after identification of the syndrome. If local metastasis is discovered, a more extensive lymph node dissection (levels II to V) is generally indicated. In children with codon 611, 618, 620, 630, 634, and 891 mutations, thyroidectomy should be performed before the age of 6 years because of reports of local metastatic disease in children this age. Finally, there are kindreds with codon 609, 768, 790, 791, and 804 mutations where the phenotype ofMTCappears to be less aggressive. In these kindreds, and in those with rare mutations, two management approaches have been suggested in association with genetic counseling: (1) perform a total thyroidectomy with or without central node dissection at some arbitrary age (perhaps 6 to 12 years of age), or (2) continue annual or biannual provocative testing for calcitonin release with performance of total thyroidectomy with or without central neck dissection when the test becomes abnormal. The pentagastrin test involves measurement of serum calcitonin basally and 2, 5, 10, and 15 min after a bolus injection of 5 ug pentagastrin per kilogram body weight. Patients should be warned before injection of epigastric tightness, nausea, warmth, and tingling of extremities and reassured that the symptoms will last approximately 2 min. The recent unavailability of pentagastrin in the United States has led to use of a short calcium infusion, performed by obtaining a baseline serum calcitonin and then infusing 150 mg calcium salt intravenously over 10 min with measurement of serum calcitonin at 5, 10, 15, 30 min after initiation of the infusion.

The *RET* proto-oncogene analysis should be performed in patients with suspectedMEN 2B to detect codon 883, 918, and 922 mutations, especially in newborn children where the diagnosis is suspected but the clinical phenotype is not fully developed. Other family members at risk for MEN 2B should also be tested because the mucosal neuromas can be subtle and not always identified. In the rare families with proven germline transmission of MTC but no identifiable *RET* proto-oncogene mutation, annual pentagastrin or calcium-pentagastrin testing should be performed on members at risk.

Annual screening for pheochromocytoma in subjects with germline *RET* mutations should be performed by measuring basal plasma or 24-h urine catecholamines and metanephrines. The goal is to identify a pheochromocytoma before it causes significant symptoms or is likely to cause sudden death, an event most commonly associated with large tumors. Although there are kindreds withFMTC and specific *RET* mutations in which no pheochromocytomas have been identified (Fig. 339-3), it is not clear that a large enough experience has been gained to exclude pheochromocytoma screening in these individuals. Radiographic studies, such asMRI orCTscans, are generally reserved for individuals with abnormal screening tests or with symptoms suggestive of pheochromocytoma (Chap. 332). Women should be tested during pregnancy because undetected pheochromocytoma can cause maternal death during childbirth.

Measurement of serum calcium and parathyroid hormone levels every 2 to 3 years

provides an adequate screen for hyperparathyroidism, except in those families in which hyperparathyroidism is a prominent component, where measurements should be made annually.

Treatment of Medullary Thyroid Carcinoma MTC is a multicentric disorder. Total thyroidectomy with a central lymph node dissection should be performed in children who carry the mutant genes. Incomplete thyroidectomy leaves the possibility of later transformation of residual long-term C cells. The goal of early therapy is cure, and a strategy that does not accomplish this goal is short-sighted. Long-term follow-up studies indicate an excellent outcome with approximately 90% of children free of disease 15 to 20 years after surgery. In contrast, 15 to 25% of patients in whom the diagnosis is made on the basis of a palpable thyroid nodule die from the disease within 15 to 20 years.

In adults withMTC>1 cm in size, metastases to regional lymph nodes are common. Total thyroidectomy with central lymph node dissection and selective dissection of other regional chains provide the best chance for cure. In patients with extensive local metastatic disease in the neck, external radiation may prevent local recurrence or reduce tumor mass but is not curative. Chemotherapy with combinations of adriamycin, vincristine, cyclophosphamide, and dacarbazine may provide palliation.

Treatment of Pheochromocytoma The long-term goal for management of pheochromocytoma is to prevent death and cardiovascular complications. Improvements in radiographic imaging of the adrenals make direct examination of the apparently normal contralateral gland during surgery less important, and the rapid evolution of laparoscopic surgery has simplified management of early pheochromocytoma. The major question is whether to remove both adrenal glands or to remove only the affected adrenal at the time of primary surgery. Issues to be considered in making this decision include the possibility of malignancy (<15 reported cases), the likelihood of developing pheochromocytoma in the apparently unaffected gland over an 8- to 10-year period, and the risks of adrenal insufficiency caused by removal of both glands (at least two deaths related to adrenal insufficiency inMEN 2 patients). Most clinicians recommend removing only the affected gland. If both adrenals are removed, glucocorticoid and mineralocorticoid replacement is mandatory. An alternative approach is to remove the pheochromocytoma and adrenal medulla, leaving the adrenal cortex behind. This approach is usually successful and eliminates the necessity for steroid hormone replacement, although the pheochromocytoma recurs in some.

Treatment of Hyperparathyroidism Hyperparathyroidism has been managed by one of two approaches. Removal of $3\frac{1}{2}$glands with maintenance of the remaining half gland in the neck is the usual procedure. In families in whom hyperparathyroidism is a prominent manifestation (almost always associated with a codon 634 *RET* mutation) and recurrence is common, total parathyroidectomy with transplantation of parathyroid tissue into the nondominant forearm is preferred. This approach is discussed above in the context of hyperparathyroidism associated withMEN1.

OTHER GENETIC TUMOR SYNDROMES

A number of mixed syndromes exist in which the neoplastic associations differ from those inMEN 1 or 2 (Table 339-1).

The cause of von Hippel-Lindau (VHL) syndrome, the association of central nervous system tumors, renal cell carcinoma, pheochromocytoma, and islet cell neoplasms, is mutations in the *VHL* tumor-suppressor gene. Germline-inactivating mutations of the *VHL* gene cause tumor formation when there is additional loss or somatic mutation of the normal *VHL* allele in brain, kidney, pancreatic islet, or adrenal medullary cells. A specific subset of mutations is more common in families with pheochromocytomas.

The molecular defect in type 1 neurofibromatosis inactivates neurofibromin, a cell membrane-associated protein that normally activates a GTPase. Inactivation of this protein impairs GTPase and causes continuous activation of p21 Ras and its downstream tyrosine kinase pathway. Endocrine tumors also form in less common neoplastic genetic syndromes. These include Cowden's disease, Carney complex, familial acromegaly, and familial carcinoid syndrome.

IMMUNOLOGIC SYNDROMES AFFECTING MULTIPLE ENDOCRINE ORGANS

When immune dysfunction affects two or more endocrine glands and other nonendocrine immune disorders are present, the *polyglandular autoimmune* (PGA) *syndromes* should be considered. The PGA syndromes are classified as two main types: the type I syndrome starts in childhood and is characterized by mucocutaneous candidiasis, hypoparathyroidism, and adrenal insufficiency; the type II, or *Schmidt syndrome*, is more likely to present in adults and most commonly comprises adrenal insufficiency, thyroiditis, and type 1 diabetes mellitus. However, the type II syndrome is heterogeneous and may consist of autoimmune thyroid disease along with a variety of other autoimmune endocrine disorders (Table 339-2).

POLYGLANDULAR AUTOIMMUNE SYNDROME TYPE I

PGAtype I is usually recognized in the first decade of life and requires two of three components for diagnosis: mucocutaneous candidiasis, hypoparathyroidism, and adrenal insufficiency. Mineralocorticoids and glucocorticoids may be lost simultaneously or sequentially. This disorder is also called *autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy* (APECED). Other endocrine defects can include gonadal failure, hypothyroidism, anterior hypophysitis, and, less commonly, destruction of the bcells of the pancreatic islets and development of insulin-dependent (type 1) diabetes mellitus. Additional features include hypoplasia of the dental enamel, ungual dystrophy, tympanic membrane sclerosis, vitiligo, keratopathy, and gastric parietal cell dysfunction resulting in pernicious anemia. Some patients develop autoimmune hepatitis, malabsorption (variably attributed to intestinal lymphangiectasia, IgA deficiency, bacterial overgrowth, or hypoparathyroidism), asplenism, achalasia, and cholelithiasis (Table 339-2). At the outset, only one organ may be involved, but the number increases with time so that patients eventually manifest two to five components of the syndrome.

Most patients initially present with oral candidiasis in childhood; it is poorly responsive to treatment and relapses frequently. Chronic hypoparathyroidism usually occurs before adrenal insufficiency develops. More than 60% of postpubertal women develop premature hypogonadism. The endocrine components, including adrenal insufficiency

and hypoparathyroidism, may not develop until the fourth decade, making continued surveillance necessary.

Type IPGAsyndrome allows no HLA associations and is inherited as an autosomal recessive trait. The responsible gene, designated as either *APECED* or *AIRE*, encodes a transcription factor that is expressed in thymus and lymph nodes; a variety of different mutations have been reported.

POLYGLANDULAR AUTOIMMUNE SYNDROME TYPE II

PGAtype II is characterized by two or more of the endocrinopathies listed inTable 339-2. Most often these include primary adrenal insufficiency, Graves' disease or autoimmune hypothyroidism, type 1 diabetes mellitus, and primary hypogonadism. Because adrenal insufficiency is relatively rare, it is frequently used to define the presence of the syndrome. Among patients with adrenal insufficiency, type 1 diabetes mellitus coexists in 52% and autoimmune thyroid disease occurs in 69%. However, many patients with antimicrosomal and antithyroglobulin antibodies never develop abnormalities of thyroid function. Thus, increased antibody titers alone are poor predictors of future disease. Other associated conditions include hypophysitis, celiac disease, atrophic gastritis, and pernicious anemia. Vitiligo, caused by antibodies against the melanocyte (seePlate IIA-11), and alopecia are less common than in the type I syndrome. Mucocutaneous candidiasis does not occur. A few patients develop a late-onset, usually transient hypoparathyroidism caused by antibodies that compete with parathyroid hormone for binding to the parathyroid hormone receptor. Up to 25% of patients with myasthenia gravis, and an even higher percentage who have myasthenia and a thymoma, have PGA type II (Chap. 380).

The type II syndrome is familial in nature but does not exhibit a characteristic Mendelian pattern of transmission. Like many of the individual autoimmune endocrinopathies, certain HL-DR3 and HLA-DR4 alleles increase disease susceptibility; several different genes probably contribute to the expression of this syndrome.

A variety of autoantibodies are seen inPGA type II, including antibodies directed against: (1) thyroid antigens such as thyroid peroxidase, thyroglobulin, or the thyroid stimulating hormone (TSH) receptor; (2) adrenal side chain cleavage enzyme, steroid 21-hydroxylase, orACTHreceptor; and (3) pancreatic islet glutamic acid decarboxylase or the insulin receptor, among others. The roles of cytokines such as interferon and cell-mediated immunity are unclear.

DIAGNOSIS

The clinical manifestations of adrenal insufficiency often develop slowly, may be difficult to detect, and can be fatal if not diagnosed and treated appropriately. Thus, prospective screening should be performed routinely in all patients and family members at risk forPGAtypes I and II. The most effective screening test for adrenal disease is a cosyntropin stimulation test (Chap. 331). A fasting blood glucose level can be obtained to screen for hyperglycemia. Additional screening tests should include measurements ofTSH, luteinizing hormone, follicle-stimulating hormone, and, in men, testosterone levels. In families with suspected type I PGA syndrome, calcium and phosphorus levels

should be measured. These screening studies should be performed every 1 to 2 years up to about age 50 in families with PGA type II syndrome and until about age 40 in patients with type I syndrome. Screening measurements of autoantibodies against potentially affected endocrine organs are of uncertain prognostic value. The differential diagnosis of PGA syndrome should include the DiGeorge syndrome (hypoparathyroidism due to glandular agenesis and mucocutaneous candidiasis), Kearns-Sayre syndrome (hypoparathyroidism, primary hypogonadism, type 1 diabetes mellitus, and panhypopituitarism), Wolfram's syndrome (congenital diabetes insipidus and diabetes mellitus), and congenital rubella (type 1 diabetes mellitus and hypothyroidism).

TREATMENT

With the exception of Graves' disease, the management of each of the endocrine components of the disease involves hormone replacement and is covered in detail in the chapters on adrenal, thyroid, gonadal, and parathyroid disease (Chaps. 330,331,335,336, and341). One aspect of therapy deserves special emphasis. Namely, primary hypothyroidism can mask adrenal insufficiency by prolonging the half-life of cortisol; consequently, administration of thyroid hormone to a patient with unsuspected adrenal insufficiency can precipitate adrenal crisis. Thus, all patients with hypothyroidism in the context ofPGAsyndrome should be screened for adrenal disease and, if it is present, be treated with glucocorticoids prior to or concurrently with thyroid hormone therapy.

OTHER AUTOIMMUNE ENDOCRINE SYNDROMES

Insulin Receptor Antibodies Rare insulin-resistance syndromes occur in patients who develop antibodies that block the interaction of insulin with its receptor. Conversely, other classes of anti-insulin receptor antibodies can activate the receptor and can cause hypoglycemia; this disorder should be considered in the differential diagnosis of fasting hypoglycemia (Chap. 334).

Patients with insulin receptor antibodies and acanthosis nigricans are often middle-aged women who acquire insulin resistance in association with other autoimmune disorders such as systemic lupus erythematosus or Sjogren's syndrome. Vitiligo, alopecia, Raynaud's phenomenon, and arthritis may also be seen. Other autoimmune endocrine disorders, including thyrotoxicosis, hypothyroidism, and hypogonadism, occur rarely. Acanthosis nigricans, a velvety, hyperpigmented, thickened skin lesion, is prominent on the dorsum of the neck and other skin fold areas in the axillae or groin and often heralds the diagnosis in these patients. However, acanthosis nigricans also occurs in patients with obesity or polycystic ovarian syndrome, in which insulin resistance appears to be due to a postreceptor defect; thus acanthosis nigricans itself is not diagnostic of the immunologic form of insulin resistance.

Some patients with acanthosis nigricans have mild glucose intolerance, with a compensatory increase in insulin secretion that is only detected when insulin levels are measured. Others have severe diabetes mellitus requiring massive doses of insulin (several thousand units per day) to lower the blood glucose levels. The nature of the antibodies determines the manifestations; though insulin resistance is more common,

fasting hypoglycemia can result from insulinomimetic antibodies.

Ataxia telangiectasia is an autosomal recessive disorder caused by mutations in *ATM*, a gene involved in cellular responses to ionizing radiation and oxidative damage (Chap. 364). This disorder is characterized by ataxia, telangiectasia, immune abnormalities, and an increased incidence of malignancies. Insulin-resistant diabetes mellitus occurs and is associated with anti-insulin antibodies.

Autoimmune Insulin Syndrome with Hypoglycemia This disorder typically occurs in patients with other autoimmune disorders and is caused by polyclonal insulin-binding autoantibodies that bind to endogenously synthesized insulin. If the insulin dissociates from the antibodies several hours or more after a meal, hypoglycemia can result. Most cases of the syndrome have been described from Japan, and there may be a genetic component. In plasma cell dyscrasias such as multiple myeloma, the plasma cells may produce monoclonal antibodies against insulin and cause hypoglycemia by a similar mechanism.

Antithyroxine Antibodies and Hypothyroidism Circulating autoantibodies against thyroid hormones in patients with both immune thyroid disease and plasma cell dyscrasias such as Waldenstrom's macroglobulinemia can bind thyroid hormones, decrease their biologic activity, and result in primary hypothyroidism. In other patients the antibodies simply interfere with thyroid hormone immunoassays and cause false elevations or decreases in measured hormone levels.

Crow-Fukase Syndrome The features of this syndrome are highlighted by an acronym that emphasizes its important features: *p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, *M*-proteins, and *s*kin changes (POEMS). The most important feature is a severe, progressive sensorimotor polyneuropathy associated with a plasma cell dyscrasia. Localized collections of plasma cells (plasmacytomas) can cause sclerotic bone lesions and produce monoclonal IgG or IgA proteins. Endocrine manifestations include amenorrhea in women and impotence and gynecomastia in men, hypogonadism, hyperprolactinemia, type 2 diabetes mellitus, primary hypothyroidism, and adrenal insufficiency. Skin changes include hyperpigmentation, thickening of the dermis, hirsutism, and hyperhidrosis. Hepatomegaly and lymphadenopathy occur in about two-thirds of patients, and splenomegaly is seen in about one-third. Other manifestations include increased cerebrospinal fluid pressure with papilledema, peripheral edema, ascites, pleural effusions, glomerulonephritis, and fever. Five-year survival is about 60%.

The systemic nature of the disorder may cause confusion with other connective tissue diseases. The endocrine manifestations suggest an autoimmune basis of the disorder, but circulating antibodies against endocrine cells have not been demonstrated. Increased serum and tissue levels of interleukin 6, interleukin 1b, vascular endothelial growth factor, and tumor necrosis factor a are present, but the pathophysiologic basis for thePOEMSsyndrome is uncertain. Therapy directed against the plasma cell dyscrasia such as local radiation of bony lesions, chemotherapy, plasmapheresis, and treatment with all-*trans* retinoic acid may result in endocrine improvement.

MISCELLANEOUS DISORDERS WITH ENDOCRINE MANIFESTATIONS

A variety of other clinical and genetic disorders are associated with multiple endocrine manifestations are summarized inTable 339-3.

SECTION 2 -DISORDERS OF BONE AND MINERAL METABOLISM

340. INTRODUCTION TO BONE AND MINERAL METABOLISM - *Michael F. Holick*, *Stephen M. Krane*

BONE STRUCTURE AND METABOLIM (See also Chap. 343)

Bone is a dynamic tissue that is remodeled constantly throughout life. The arrangement of compact and cancellous bone provides a strength and density suitable for mobility. In addition, bone provides a reservoir for calcium, magnesium, phosphorus, sodium, and other ions necessary for homeostatic functions. The skeleton is highly vascular and receives about 10% of the cardiac output.

The extracellular components of bone consist of a solid mineral phase in close association with an organic matrix, of which 90 to 95% is type I collagen (Chap. 351). The noncollagenous portion of the organic matrix contains proteins derived from serum (albumin anda_2-HS glycoproteins), proteins containing a-carboxyglutamic acid (GLA) [*bone* GLA protein (BGP), *osteocalcin*, and a matrix GLA protein], the glycoprotein *osteonectin*, the phosphoprotein *osteopontin*, sialoproteins, *thrombospondin*, and other less well characterized proteins. Some of these proteins may function in initiating mineralization and in binding of the mineral phase to the matrix. The mineral phase is made up of calcium and phosphate and is best characterized as a poorly crystalline hydroxyapatite. The mineral phase of bone is deposited initially in intimate relation to the collagen fibrils and is found in specific locations in the "holes" between the collagen fibrils. This architectural arrangement of mineral and matrix results in a two-phase material well suited to withstand mechanical stresses.

Osteoblasts synthesize and secrete the organic matrix. Mineralization of the matrix, both in trabecular bone and in osteones of compact cortical bone (haversian systems), begins soon after the matrix is secreted (primary mineralization) but is not completed until after several weeks (secondary mineralization). Osteoblasts are derived from cells of mesenchymal origin (Fig. 340-1*A*). Although relatively little is known about the controls of osteoblast development, two genes have been shown to be important: core-binding factor A1 (*CBFA1*) and Indian hedgehog (*Ihh*). CBFA1 is a transcription factor and a homologue of the Drosophila factor, runt, and is expressed specifically in osteoblast progenitors and regulates the expression of several osteoblast-specific genes including osteopontin, bone sialoprotein, type I collagen, osteocalcin, and receptor-activator of NFkB (RANK) ligand. CBFA1 expression is regulated, in part, by bone morphogenic proteins (BMPs). *Cbfa1*-deficient mice are devoid of osteoblasts. Mice with a functional deletion of *Cbfa1* (*Cbfa1-/-*) have a cartilaginous skeleton but no osteoblasts and no bone, whereas mice with a deletion of only one allele (*Cbfa1+/-*) do have an osseous skeleton but have a delay in intramembranous bone formation of some cranial bones and the clavicles. The latter abnormalities are similar to those in the human disorder cleidocranial dysplasia, which maps to the locus that corresponds to *Cbfa1*.

The growth factorIhh also plays a critical role in osteoblast development, as evidenced by the fact that Ihh-deficient mice lack osteoblasts in bone formed by endochondral ossification. Numerous other growth-regulatory factors affect osteoblast function,

including transforming growth factor (TGF) b types I and II, acidic fibroblast growth factor (aFGF) and basic fibroblast growth factor (bFGF), platelet-derived growth factor (PDGF), and insulin-like growth factors (IGFs) I and II. Active osteoblasts are characterized by their location and morphology; the presence of a specific skeletal form of alkaline phosphatase; the presence of receptors for parathyroid hormone (PTH) and 1,25-dihydroxyvitamin D [1,25$(OH)_2$D]; and the ability to synthesize specific matrix proteins, such as type I collagen, osteocalcin, and osteopontin. As an osteoblast secretes matrix, which is then mineralized, the cell becomes an *osteocyte*, still connected with its blood supply through a series of canaliculi. Osteocytes are thought to be the mechanosensors in bone that communicate signals to surface osteoblasts and their progenitors through the canalicular network.

Resorption of bone is carried out mainly by *osteoclasts*, multinucleated cells that are formed by fusion of cells derived from hematopoietic stem cells related to the mononuclear phagocyte series. Multiple factors regulating osteoclast development have been identified (Fig. 340-1*B*). Macrophage colony stimulating factor (M-CSF) plays a critical role at several steps in the pathway that ultimately leads to fusion of osteoclast progenitor cells to form multinucleated, active osteoclasts. Discovery of theRANKsignaling pathway provides new insight into the pathway that links osteoblast and osteoclast development (Fig. 343-2). RANK ligand is expressed on the surface of osteoblast progenitors and stromal fibroblasts. In a process involving cell-cell interactions, it binds to the RANK receptor on osteoclast progenitors, stimulating a signal transduction cascade that leads to osteoclast differentiation and activation. Alternatively, a soluble decoy receptor, referred to as *osteoprotegerin* (OPG), can bind RANK ligand and inhibit osteoclast differentiation. Several growth factors and cytokines, including interleukins (IL) 1, 6, and 11, tumor necrosis factor (TNF), interferong, and M-CSF, modulate the osteoclast differentiation and function. Osteoclasts are also regulated indirectly by osteoblasts and adjacent stromal fibroblasts in the marrow. For example,PTHreceptors are not found on mature osteoclasts, and PTH increases osteoclastic bone resorption by first acting on osteoblasts or stromal fibroblasts. 1,25$(OH)_2$D receptors are found in precursor cells that can differentiate into monocytes or osteoclasts, and 1,25$(OH)_2$D also promotes differentiation along the osteoclast pathway.

In the embryo and in the growing child, bone develops by remodeling and replacing previously calcified cartilage (endochondral bone formation) or is formed without a cartilage matrix (intramembranous bone formation). ThePTH/PTHrP receptor plays a central role in the control of chondrocyte differentiation at growth plates (Chap. 341).Ihhproduction by growth plate chondrocytes stimulates the production of PTH-related peptide (PTHrP), which slows the differentiation of chondrocytes. This pathway creates a local feedback system as Ihh is suppressed by the actions of PTHrP. Consistent with this mechanism, mice with null mutations of the PTH/PTHrP receptor or PTHrP exhibit growth plate chondrodysplasia that reflects accelerated differentiation of proliferating chondrocytes. In humans, homozygous inactivating mutations of the PTH/PTHrP receptor cause Blomstrand's chondrodysplasia.

New bone, whether formed in infants or in adults during repair, has a relatively high ratio of cells to matrix and is characterized by coarse fiber bundles of collagen that are interlaced and randomly dispersed (woven bone). In adults, the more mature bone is

organized with fiber bundles regularly arranged in parallel or concentric sheets (lamellar bone). In long bones, deposition of lamellar bone in a concentric arrangement around blood vessels forms the haversian systems. Growth in length of bones is dependent on proliferation of cartilage cells and on the endochondral sequence at the growth plate. Growth in width and thickness is accomplished by formation of bone at the periosteal surface and by resorption at the endosteal surface, with the rate of formation exceeding that of resorption. In adults, after the epiphyses close, growth in length and endochondral bone formation cease, except for some activity in the cartilage cells beneath the articular surface. Even in adults, however, remodeling of bone (remodeling of haversian systems as well as trabecular bone) continues throughout life. In adults, ~4% of the surface of trabecular bone (such as iliac crest) is involved in active resorption, whereas 10 to 15% of trabecular surfaces is covered with osteoid. Radioisotope studies indicate that as much as 18% of the total skeletal calcium is deposited and removed each year. Thus, bone is an active metabolizing tissue that requires an intact blood supply.

The response of bone to fractures, infection, and interruption of blood supply and to expanding lesions is relatively limited. Dead bone must be resorbed, and new bone must be formed, a process carried out in association with growth of new blood vessels into the involved area. In injuries that disrupt the organization of the tissue, such as a fracture in which apposition of fragments is poor or when motion exists at the fracture site, the progenitor stromal cells differentiate into cells with functional capacities different from those of osteoblasts, and varying amounts of fibrous tissue and cartilage are formed. When there is good apposition with fixation and little motion at the fracture site, repair occurs predominantly by formation of new bone without other scar tissue.

Remodeling of bone occurs along lines of force modulated by the mechanical stresses to which it is subjected. The signals from these mechanical stresses are sensed by osteocytes, which then transmit other signals to osteoclasts (or their precursors) or osteoblasts (or their precursors). A bowing deformity increases new bone formation at the concave surface and resorption at the convex surface, seemingly designed to produce the strongest mechanical structure. Expanding lesions in bone, such as tumors, induce resorption at the surface in contact with the tumor. Even in a disorder as architecturally disruptive as Paget's disease, remodeling is dictated by mechanical forces. Thus, the plasticity of bone is due to the interaction of cells with each other and with the environment.

The cycle of bone resorption and formation is a highly orchestrated process carried out by the basic multicellular unit (BMU), composed of a group of osteoclasts and osteoblasts (Fig. 340-2). Osteoclast-mediated resorption of bone takes place in scalloped spaces (*Howship's lacunae*) where the osteoclasts are attached through a specificav,b3 integrin to components of the bone matrix such as osteopontin. This clear zone contains contractile proteins. The resorbing end of the cell forms a specialized ruffled border, which is in contact with the bone. Proteins, including a specialized proton-pump ATPase, are found in the ruffled border membrane and contribute to the acid environment, which solubilizes the mineral phase. In addition to the proton pump, carbonic anhydrase (type II isoenzyme) is required to maintain the acid pH. Other features of active osteoclasts include expression of the proto-oncogene c-*src*, tartrate-resistant acid phosphatase, cell-surface receptors for calcitonin, sodium pumps

of the kidney type, a bicarbonate/chloride exchanger of the band 3 family, and an ability to resorb mineralized bone. The bone matrix is resorbed in the acid environment adjacent to the ruffled border by proteinases that act at low pH, such as cathepsin K, following solubilization of the mineral phase.

Bone formation involves deposition of an organic matrix by osteoblasts followed by mineralization. The mineral phase is composed of calcium and phosphorus, and the concentration of these ions in the plasma and extracellular fluid (ECF) influences the rate at which mineral is formed. In vitro, mineralization can proceed and crystals of hydroxyapatite can grow at concentrations of calcium and phosphorus similar to those in an ultrafiltrate of plasma. The calcium phosphate solid phase at the inception of mineralization is brushite ($CaHPO_4 \times 2H_2O$). As mineralization progresses, the solid phase is a poorly crystalline hydroxyapatite with a relatively low (~1.2) calcium/phosphate molar ratio. With age and maturation, the perfection of the crystals and the calcium/phosphate ratio increase. Fluoride ions, when incorporated into the mineral phase, decrease the proportion of amorphous calcium phosphate and enhance the crystal structure.

There is a limit for the concentration of calcium and phosphorus ions in the ECF below which mineralization does not occur. A "solubility product" for bone mineral is difficult to calculate because (1) the mineral phase itself is of variable composition, and (2) the various components in ECF that regulate this solubility product are not known. Nevertheless, when the concentrations of calcium and phosphorus in ECF are excessive, a mineral phase may form in areas (e.g., soft tissues) that are not normally mineralized.

Collagens from a variety of sources can catalyze the nucleation of a mineral phase of calcium and phosphorus from solutions of these ions. The organization of collagen probably influences the amount and type of mineral phase formed in bone. The primary structures of type I collagen in skin and bone tissues are similar. There are differences, however, in posttranslational modifications of type I collagen, such as hydroxylations; glycosylations; and the type, number, and distribution of intermolecular cross-links (Chap. 351). In addition, the holes in the packing structure of the collagen are larger in mineralized collagen of bone and dentin than in unmineralized collagens such as tendon. Single amino-acid substitutions in the helical portion of either the a1 ora2 chain of type I collagen due to mutations in the *COL*1A1 or *COL*1A2 genes in osteogenesis imperfecta disrupt the organization of bone, and this indicates the importance of the fibrillar matrix in the structure of bone. At the time of their discovery, it was thought that some of the non-collagenous bone proteins -- e.g., osteocalcin (bone-GLA protein), osteonectin, and osteopontin -- played a role in mineralization, although such a role has not been established. Osteocalcin, a product exclusively of osteoblasts, is measurable by immunoassays in normal human serum, and its levels correlate with other measurements of bone formation. Matrix-GLA protein (MGP), a component of bone as well as non-osseous tissues, acts to inhibit mineralization in the non-osseous tissues. Thus, functional deletion of the MGP gene in mice results in massive soft tissue calcification, particularly in arterial walls.

Alkaline phosphatase is a marker for osteoblasts, and cellular levels of this enzyme correlate with rates of bone formation. Although mineralization defects occur in

individuals with mutations that decrease alkaline phosphatase activity (hypophosphatasia), the function of alkaline phosphatase in mineralization is not completely understood. Other circulating markers of bone formation include osteocalcin and type I procollagen C-terminal peptides. Urinary markers for bone resorption are hydroxyproline, hydroxylysine and its glycosides, and the bone-specific hydroxypyridinium collagen cross-links (Chap. 342). Inorganic pyrophosphate is a potent inhibitor of mineralization at levels below those necessary to bind calcium ions.

CALCIUM METABOLISM

A total of 1 to 2 kg of calcium is present in the average adult,>98% of it in the skeleton. The calcium of the mineral phase at the surface of the crystals is in equilibrium with that in theECF, but only a minor fraction of the total pool (~0.5%) is exchangeable. In normal adults plasma levels range from 2.2 to 2.6 mmol/L (8.8 to 10.4 mg/dL). The calcium in plasma is present as three forms: free ions, ions bound to plasma proteins, and, to a small extent, diffusible complexes. The concentration of free calcium ions, averaging 1.2 mmol/L (4.8 mg/dL), influences many cellular functions and is subjected to tight hormonal control, especially throughPTH(Chap. 341). The concentration of serum proteins is an important determinant of calcium ion concentration; most calcium ion is bound to albumin. Ionized calcium can be measured directly with the use of calcium-specific electrodes. If ionized calcium cannot be measured, certain approximations can be used to estimate the protein-bound and ionized fractions. One formula that approximates the amount of calcium bound to protein is

A simplified correction is sometimes used to assess whether the total serum calcium concentration is abnormal when serum proteins are low. The correction is to add 1 mg/dL to the serum calcium level for every 1 g/dL by which the serum albumin level is below 4.0 g/dL. If the serum calcium level, for example, is 7.8 mg/dL (a subnormal value) and the serum albumin level is only 3.0 g/dL, then the stated serum calcium level is corrected by adding 1 mg/dL; the corrected value of 8.8 mg/dL is within the normal range.

The concentration of calcium ions in theECF is kept constant by processes that constantly add and remove calcium. Calcium enters the plasma via absorption from the intestinal tract and resorption of ions from the bone mineral. Calcium leaves the ECF via secretion into the gastrointestinal tract (~100 to 200 mg/d), urinary excretion (~50 to 300 mg/d), deposition in bone mineral, and losses in sweat (up to 100 mg/d). Bone resorption and formation are tightly coupled, with approximately 12 mmol (500 mg) calcium entering and leaving the skeleton daily (Fig. 340-3). Calcium ions inside the cell mediate a variety of cellular functions. The level of free calcium in the cell is very low, approximately 0.1 umol/L; thus, the gradient between plasma and intracellular free calcium is about 10,000 to 1. This gradient is tightly regulated by various channels and ion pumps.

The average dietary calcium intake for most adults in the United States is approximately 15 to 20 mmol/d (0.6 to 0.8 g/d). However, with heightened awareness of the role of adequate calcium intake for the prevention of osteoporosis, many adults on

supplements have an intake of 20 to 37 mmol/d (0.8 to 1.5 g/d). Less than half of dietary calcium is absorbed in adults. Calcium absorption increases during periods of rapid growth in children, in pregnancy, and in lactation and decreases with advancing age. Most of the calcium is absorbed in the proximal small intestine, and the efficiency of absorption decreases in the more distal intestinal segments. Both active transport and diffusion-limited absorption are involved; the former is more important in the upper intestine and the latter in the lower intestine. Both processes are influenced by vitamin D (see below). All forms of calcium in the diet are not equally absorbed; calcium as the chloride is probably absorbed more efficiently than that in other preparations. Secretion of calcium into the intestinal lumen is constant and independent of absorption. If calcium availability in the diet is low [<12 mmol/d (500 mg/d)], a positive calcium balance requires an efficiency of absorption>30 to 40%.

The urinary calcium excretion of normal adults having an average calcium intake ranges between 2.5 and 10 mmol/d (100 and 400 mg/d). When the dietary calcium level is<5 mmol/d (200 mg/d), urinary calcium excretion is usually <5 mmol/d (200 mg/d). However, in most normal individuals, wide variations in dietary intake have little effect on urinary calcium. Hence, when the diet is low in calcium, the relative inefficiency of renal calcium conservation leads to a negative calcium balance unless calcium absorption is maximal (Fig. 340-3).

The amount of calcium in the urine is small compared with that filtered by the glomerulus [~150 to 250 mmol/d (6 to 10 g/d)] because the rates of reabsorption of the filtered calcium are high. Reabsorption takes place predominantly in the proximal tubule (~60%) and in Henle's loop (~25%) and to a small extent in the distal tubule. The calcium-sensing receptor also plays a role in renal calcium excretion, though the mechanisms that regulate its function have not been fully defined (Chap. 341). The excretion of other electrolytes affects the urinary excretion of calcium. For example, urinary calcium is usually proportional to urinary sodium; sulfate also increases calcium excretion.

A deficiency ofPTH or vitamin D, intestinal disease, or severe dietary calcium deprivation may provide challenges to calcium homeostasis that cannot be compensated adequately by renal calcium conservation, resulting in a negative calcium balance. Increased bone resorption may protect againstECFcalcium depletion even in states of chronic negative calcium balance but only at the expense of progressive bone loss.

PATHOPHYSIOLOGY

A decrease in the concentration of free calcium ions in plasma results in increased neuromuscular irritability and tetany. This syndrome is characterized by peripheral and perioral paresthesia, carpal spasm, pedal spasm, anxiety, seizures, bronchospasm, laryngospasm, Chvostek's sign, Trousseau's sign, and Erb's sign, and lengthening of the QT interval of the electrocardiogram. In infants tetany may be manifested only by irritability and lethargy. The level of calcium ions that determines which features of tetany will be manifested varies among individuals. Tetany is also influenced by other components of theECF; e.g., hypomagnesemia and alkalosis lower whereas hypokalemia and acidosis raise the threshold for tetany.

Increases in total serum calcium concentration are usually accompanied by increases in free calcium levels and may be associated with anorexia, nausea, vomiting, constipation, hypotonia, depression, and occasionally lethargy and coma. Persistent hypercalcemia, especially when accompanied by normal or elevated levels of serum phosphate, may cause ectopic deposition of a solid phase of calcium and phosphate in walls of blood vessels, connective tissue about the joints, gastric mucosa, cornea, and renal parenchyma. Hypercalcemia per se alters renal function in addition to the pathologic effects of calcium phosphate deposition.

PHOSPHORUS METABOLISM

Phosphorus is a major component of bone and of all other tissues and in some form is involved in almost all metabolic processes, including energy storage, membrane transport, membrane composition, and signal transduction. About 600 g of phosphorus is present in the normal adult, of which 85% is present in the crystalline structure of the skeleton.

In plasma from fasting subjects, most of the phosphorus is present as inorganic orthophosphate in concentrations of approximately 0.75 to 1.45 mmol/L (2.5 to 4.5 mg/dL). In contrast to calcium, of which ~50% is bound, only ~12% of the phosphorus in plasma is bound to proteins. Free HPO_4^{2-} and $NaHPO_4^-$ normally account for ~75% of the total phosphorus, and free $H_2PO_4^-$ accounts for ~10%. Since so many species are present, depending on pH and other factors, concentrations are usually expressed in terms of elemental phosphorus, in units of mmol/L or mg/dL. The serum phosphorus, however, can vary based on age; young children have almost twice the serum phosphorus as adults due to the need for rapid skeletal mineralization. Postmenopausal women also have higher circulating phosphorus levels. After ingesting a meal containing carbohydrate, there is a decrease in serum phosphorus levels [by 0.3 to 0.5 mmol/dL (1.0 to 1.5 mg/dL)] in response to the increase in insulin secretion, which enhances cellular phosphorus uptake and utilization. An increase in serum pH will decrease serum phosphorus, whereas a decrease in pH increases phosphorus concentration. There is a circadian variation in phosphorus concentration even during a 24-h fast: the nadir occurs between 9:00 A.M. and noon followed by an increase to a plateau in the afternoon and another small peak after midnight.

Phosphorus is plentiful in the diet. Common sources include dairy products, meats, eggs, and carbonated beverages that contain phosphoric acid. Approximately 60 to 70%of phosphorus is passively absorbed in the small intestine (Fig. 340-4). $1,25(OH)_2D$ enhances phosphorus absorption along the entire small intestine, with the highest efficiency in the jejunum and ileum. Chronic low phosphorus intake (<2 mg/kg of body weight per day) decreases serum phosphorus levels. Low serum phosphorus stimulates the renal production of $1,25(OH)_2D$, which, in turn, increases the efficiency intestinal absorption up to 80 to 90%. $1,25(OH)_2D$ also decreasesPTHsecretion and, thereby reduces renal tubular loss of phosphorus.

The major control of phosphorus balance is exerted by the kidney. Approximately 90% of phosphorus in the circulation is filtered through the glomerulus and is largely absorbed by the proximal tubule such that only 10 to 15% of the filtered load is normally

excreted. Urinary phosphorus excretion is reflective of dietary intake. Phosphorus absorption in the proximal tubule is coupled with sodium absorption. The primary regulation of phosphorus metabolism occurs in the distal convoluted tubule, and this mechanism is independent of sodium reabsorption. Volume expansion and decreased sodium reabsorption increase phosphorus clearance.

HYPOPHOSPHATEMIA

Causes Although there are many potential causes for hypophosphatemia (Table 340-1), the most common etiologies include: (1) decreased intestinal phosphorus absorption, either due to vitamin D deficiency or the presence of a phosphorus-binding antacid; (2) urinary losses that are PTH- or alcohol-mediated; and (3) a shift of phosphorus from extracellular to intracellular compartments due to exogenous administration of insulin or consumption of nutrients that stimulate insulin release (e.g., carbohydrates). Increased renal clearance of phosphorus occurs in primary hyperparathyroidism, vitamin D deficiency, vitamin D-resistant and D-dependent rickets, hyperglycemic states, and oncogenic osteomalacia. In vitamin D deficiency, serum phosphorus is low because of decreased intestinal absorption as well as secondary hyperparathyroidism, which increases phosphorus losses in the urine. In X-linked hypophosphatemic rickets, there is a genetic defect in the *PHEX* gene, which encodes a neutral endopeptidase presumed to degrade the phosphaturia hormone known as *phosphatonin*. The disorder is associated with a severe renal leak of phosphorus into the urine. In addition, there is a defect in hypophosphatemia-mediated stimulation of 25(OH)D-1a-hydroxylase, resulting in decreased intestinal phosphorus absorption. Acidosis and hyperglycemic states associated with polyuria also cause excessive phosphorus loss in the urine. Ketoacidosis enhances intracellular and organic phosphorus degradation, thereby releasing large amounts of inorganic phosphorus into the circulation that is cleared into the urine. In ketosis, the serum phosphorus is often normal because of the continuous shift of phosphorus from intracellular to extracellular pools. However, when the ketosis is corrected, hypophosphatemia is apparent because of the return of phosphorus into the intracellular compartment (Chap. 333). A severe, acquired form of hypophosphatemia, *oncogenic osteomalacia*, is associated with vascular, mesenchymal tumors such as hemangiopericytomas but occasionally also with small cell lung cancer, prostate cancer, and other malignant tumors. It is likely that these tumors secrete a substance similar or identical to phosphatonin. The phosphorus levels in these patients are usually extremely low [0.4 to 0.5 mmol/L (1.2 to 1.5 mg/dL)], and the $1,25(OH)_2D$ levels are low or undetectable. The disorder is associated with severe fatigue, muscle weakness, and unrelenting bone discomfort.

Alcohol abuse is the most common cause of severe hypophosphatemia, which is caused by poor dietary intake of phosphorus, ethanol-enhanced urinary excretion of inorganic phosphorus, the use of calcium- or aluminum-containing antacids, and vomiting. Hypophosphatemia may transiently worsen with refeeding. Alcoholics may also have associated calcium and vitamin D deficiency and secondary hyperparathyroidism, which enhances phosphorus-wasting in the urine. Alcoholic ketoacidosis induces marked phosphaturia. Intense hyperventilation for prolonged periods may depress serum phosphorus levels due to associated alkalosis. Rapid correction of chronic respiratory acidosis has also been associated with hypophosphatemia and can lead to diaphragm weakness and an exacerbation of

respiratory failure. Advanced leukemia with blast crisis (leukocyte counts usually>100,000) may cause severe hypophosphatemia; the likely cause is a rapid uptake of phosphorus into the rapidly dividing cells.

Laboratory and Clinical Findings Serum phosphorus levels should be determined in a fasting state. Mild hypophosphatemia is not usually associated with clinical symptoms. In severe hypophosphatemia [£0.3 mmol/L (£1.0 mg/dL)], multiple organ systems are affected. Patients become irritable, apprehensive, and hyperventilate, resulting in complaints of muscle weakness, numbness, and paresthesia. In the most severe form, they are confused or obtunded and suffer from seizures and coma, which can ultimately lead to death. This metabolic encephalopathy is often associated with slowing of the electroencephalogram.

Phosphorus is essential for muscle function because of the need for large amounts of ATP and creatine phosphate. Patients with severe hypophosphatemia often complain of fatigue, muscle weakness, myalgia, and myopathy. Hypophosphatemia can cause rhabdomyolysis, which is particularly common in chronic alcoholics or during alcohol withdrawal. Rhabdomyolysis can be precipitated during treatment for diabetic ketoacidosis or by hyperalimentation or refeeding in a malnourished patient. Cardiomyopathy can also occur, resulting in reduced cardiac output, impaired pressor responsiveness to catecholamines, hypotension, and ventricular arrhythmias. Restoration of phosphorus deficits can result in prompt reversal. Severe muscle weakness can lead to respiratory insufficiency.

Erythrocytes and leukocytes are highly dependent on phosphorus for their function. Chronic hypophosphatemia decreases 2,3-bisphosphoglycerate and ATP, enhancing oxygen dissociation from hemoglobin and leading to tissue hypoxia. Hypophosphatemia causes impaired phagocytosis and opsonization and, therefore, increases susceptibility to bacterial and fungal infections.

Chronic hypophosphatemia causes a mineralization defect of the skeleton. In children, this causes rickets. In adults, chronic hypophosphatemia (often due to vitamin D deficiency) causes osteomalacia (see below). Patients with severe renal phosphorus-wasting and severe chronic hypophosphatemia may have marked fatigue, muscle weakness, and severe bone pain, especially of their long bones and ribcage.

TREATMENT

Mild hypophosphatemia usually resolves spontaneously when the underlying cause is corrected. Oral phosphorus replacement is sufficient if serum phosphorus is>0.3 mmol/L (1 mg/dL) and the patient is asymptomatic. Milk is an excellent source of phosphorus as it contains 1 g of inorganic phosphorus per liter. Carbonated beverages that contain phosphoric acid provide another source of phosphorus, especially for patients with lactase deficiency. Pharmaceutical preparations of phosphorus, such as Neutraphos or KPhos, contain sodium and potassium salts of phosphate. Depending on the degree of hypophosphatemia, up to 3 g/d can be given in four to six divided doses per 24 h. These doses usually do not cause diarrhea; >5 g/d will induce diarrhea.

For severe hypophosphatemia, with serum phosphorus levels <0.2 to 0.3 mmol/L (<0.5

to 1.0 mg/dL),[3]3 g/d of phosphorus may be required over several days to replete body stores. In patients with severe symptomatic hypophosphatemia who are unable to eat, intravenous phosphorus can be given, up to 1 g in 1 L of fluid over 8 to 12 h. Some caution is necessary when giving phosphorus intravenously because of the potential for precipitating soft tissue calcification. A serum calcium ´ serum phosphorus product >70 markedly increases the risk of soft tissue calcification and nephrocalcinosis. Patients with chronic hypophosphatemia caused by inherited or acquired renal phosphorus leak require vigilance when receiving high doses of oral phosphorus. Transiently elevated serum phosphorus levels can decrease ionized calcium levels, resulting in chronic stimulation of the parathyroid gland and leading to autonomous, persistent hyperplasia of the parathyroid glands. Thus, it is best to give frequent divided doses of phosphorus (four to six times a day), equaling a total of 2 to 3 g/d.

Phosphorus should not be given intramuscularly or subcutaneously because it can cause soft tissue necrosis and severe discomfort. Intravenous sodium or potassium phosphate, 15 mmol (0.465 g) of elemental phosphorus given in 100 mL of 0.9% saline over 60 min, elevates serum phosphorus levels by an average of 0.6 to 1.2 mmol/L (1.75 to 3.8 mg/dL).

HYPERPHOSPHATEMIA

In adults, hyperphosphatemia is defined as a serum phosphorus level>1.6 mmol/L (5 mg/dL). In children, this level is much higher. The most common causes of hyperphosphatemia are acute and chronic renal failure (Table 340-2). In renal failure, the loss of tubular function impairs phosphorus excretion. This results in a cascade of events that can also affect calcium and phosphorus metabolism. The increase in serum phosphorus levels reduces serum calcium levels and the production of $1,25(OH)_2D$, leading to decreased intestinal calcium absorption and secondary hyperparathyroidism. Patients with pseudohypoparathyroidism and tumoral calcinosis also have decreased renal phosphorus clearance that results in hyperphosphatemia. Hypothyroidism reduces renal phosphorus excretion and may increase circulating concentrations of phosphorus. Vitamin D intoxication, due to excessive ingestion of either vitamin D or one of its analogues, can cause hyperphosphatemia along with hypercalcemia. Severe hypothermia, crush injuries, nontrauma rhabdomyolysis, tumoral calcinosis, and cytotoxic therapy of hematologic malignancies such as acute lymphoblastic leukemia can be associated with hyperphosphatemia. The serum phosphorus level can be artifactually elevated due to hemolysis of the blood sample. Thrombocytosis and multiple myeloma can cause spuriously elevated serum phosphorus levels due to thrombocytolysis.

Laboratory and Clinical Findings A rapid elevation of serum phosphorus can cause hypocalcemia and symptoms of neuromuscular irritability and tetany. Chronic hyperphosphatemia in association with normocalcemia can result in nephrocalcinosis and soft tissue calcification.

TREATMENT

In addition to treating the underlying disorder, dietary phosphorus intake should be limited by restricting carbonated beverages containing phosphoric acid and decreasing

milk and dairy product consumption. The dietary intake of phosphorus should be between 600 and 1000 mg a day with modest protein restriction. For control of chronic hyperphosphatemia, usually in patients with chronic renal failure, oral aluminum hydroxide or aluminum carbonate gels are indicated. Prolonged use of aluminum-containing compounds is not recommended because of aluminum toxicity causing adynamic bone disease, proximal myopathy, encephalopathy, and anemia. When hyperphosphatemia is due to vitamin D intoxication, calcium salts are contraindicated because the high efficiency of calcium absorption can lead to severe hypercalcemia, soft tissue calcification, and nephrocalcinosis.

MAGNESIUM METABOLISM

Magnesium is the most abundant intracellular divalent cation. It is an essential cofactor for a multitude of enzymatic reactions that are important for the generation of energy from ATP. Approximately 30% of magnesium in the serum is protein-bound, 55% is ionized, and the remaining 15% is complexed. Like calcium, magnesium is bound to albumin, and it is the ionized fraction that is important for physiologic processes including neuromuscular function and maintenance of cardiovascular tone.

The serum concentration of magnesium is tightly regulated within a narrow range of approximately 0.7 to 1.1 mmol/L (1.4 to 2.2 meq/L)(1.7 to 2.6 mg/dl) as a result of the efficient absorption of dietary magnesium by the small intestine and conservation of magnesium in the kidney. About 30% of dietary magnesium is absorbed in the small intestine, but this fraction increases markedly when intake is substantially reduced. Approximately 96% of filtered magnesium is reabsorbed along the nephron, and only 4%is excreted into the urine. Because there is no regulation of magnesium absorption in the distal tubule and because magnesium reabsorption is very efficient, an increase in distal delivery increases magnesium loss in the urine.

HYPOMAGNESEMIA

Although magnesium deficiency is a common clinical problem, serum magnesium levels are often overlooked or not measured in patients at risk for the disorder. Approximately 10% of patients admitted to city hospitals are hypomagnesemic, and up to 65% of patients in intensive care units may be magnesium-deficient. Hypomagnesemia is caused primarily by renal or gastrointestinal losses or decreased efficiency of intestinal magnesium absorption (Table 340-3). Reduced renal reabsorption due to loop diuretics and alcohol use is a common cause of hypomagnesemia. Because magnesium excretion is tightly coupled to sodium and calcium excretion, intravenous fluid therapy and volume-expanded states, such as primary hyperaldosteronism, may result in hypomagnesemia. Hypercalcemia and hypercalciuria decrease tubular reabsorption of magnesium. Osmotic diuresis in diabetes mellitus is one of the more common causes of hypomagnesemia.

Vomiting and nasogastric suctioning can cause severe magnesium depletion because intestinal tract fluids contain ~0.5 mmol/L (1.2 mg/dL)(1 meq/L). Fluid loss from diarrhea can contain as much as 7.4 mmol/L (18 mg/dL)(15 meq/L). Consequently, ulcerative colitis, Crohn's disease, and intestinal or biliary fistulas can result in magnesium depletion. Hypomagnesemia is prevalent in alcoholics. Ethanol causes a transient loss

of magnesium in the urine. In most alcoholics, however, the magnesium deficit is modest. A more profound fall in serum magnesium levels may occur during alcohol withdrawal, where the decrease is associated with falls in levels of serum phosphate and potassium, probably due to shifts of these ions into intracellular compartments. The use of loop diuretics, as well as aminoglycosides, cisplatin, cyclosporine, and amphotericin B can increase renal loss of magnesium.

The clinical manifestations of hypomagnesemia are similar to those of severe hypocalcemia. The signs and symptoms of hypomagnesemia include muscle weakness, prolonged PR and QT intervals, and cardiac arrhythmias. Positive Chvostek's and Trousseau's signs indicative of hypocalcemia are often positive in hypomagnesemic patients as well; carpopedal spasm can also occur with hypomagnesemia. Magnesium is important for effectivePTHsecretion as well as the renal and skeletal responsiveness to PTH; thus, hypomagnesemia is often associated with hypocalcemia due to impaired PTH secretion and function (Chap. 341).

Low serum magnesium levels <0.7 mmol/L (1.8 mg/dL)(1.5 meq/L) are indicative of magnesium deficiency. For mild deficiency, oral magnesium replacement is effective. The major side effect is diarrhea. Symptoms often occur when the serum magnesium is <0.5 mmol/L (1.2 mg/dL)(1.0 meq/L). This level is indicative of significantly depleted total-body magnesium stores. Because most magnesium resides in the intracellular space, the total-body magnesium deficit is often ~200 mmol (4800 mg) by the time serum levels fall to <0.5 mmol/L (1.2 mg/dL)(1.0 meq/L). Parenteral magnesium administration is usually needed under these circumstances. Two grams of magnesium sulfate [8.0 mmol (192 mg)(16.2 meq) of magnesium] can be given intravenously, with a cumulative dose up to 24 mmol (576 mg)(48 meq) over 24 h. Alternatively, a 50% solution of 2 g of magnesium sulfate can be given every 8 h intramuscularly although these injections can be painful. Patients with severe hypomagnesemia and associated seizures or acute arrhythymias can be given 4 to 8 mmol (96 to 192 mg)(8 to 16 meq) of magnesium as an intravenous injection over 5 to 10 min, followed by 24 mmol/d (576 mg/d)(48 meq/d).

A normal serum magnesium concentration attained after acute magnesium repletion is not necessarily indicative of repletion of the total-body magnesium stores. Restoration of urinary magnesium excretion is a better indicator of magnesium repletion. Once urinary magnesium excretion increases, the body stores are usually replenished. Patients who have chronic magnesium loss from intestinal or renal sources may require continued oral magnesium supplementation on a daily basis of up to 12.5 mmol/d (300 mg/d) in divided doses. Patients with renal failure need to be monitored carefully to prevent hypermagnesemia.

HYPERMAGNESEMIA

Hypermagnesemia is rare but can be seen in renal failure when patients are taking magnesium-containing antacids, laxatives, enemas, or infusions (Table 340-4). It can also be seen in acute rhabdomyolysis.

The most readily detected clinical sign of hypermagnesemia is the disappearance of deep tendon reflexes. Neuromuscular symptoms include depressed respiration and

apnea due to paralysis of the voluntary muscles, prolonged PR intervals, and increased QRS duration and QT interval; complete heart block and cardiac arrest can occur. Hypocalcemia may occur because hypermagnesemia depressesPTHsecretion and induces an end-organ resistance to PTH similar to the effect seen in hypomagnesemia.

Treatment includes stopping the antacid or other preparations that contain large amounts of magnesium. The excess magnesium is quickly excreted by the kidney. Renal failure patients may require dialysis against a low magnesium bath. For severe hypermagnesemia with associated life-threatening complications, intravenous calcium in doses of 100 to 200 mg (elemental) over 5 to 10 min will antagonize the toxic effects of magnesium.

VITAMIN D

Vitamin D is a hormone rather than a classic vitamin, since with adequate exposure to sunlight, no dietary supplements are needed. Vitamin D exerts its physiologic effects on bone, intestine, kidney, and the parathyroid glands to modulate calcium and phosphorus metabolism. The active principle of vitamin D is synthesized under metabolic control via successive hydroxylations in the liver and kidney and is transported through the blood to its main target tissues (the small intestine and bone), where it regulates calcium homeostasis.

PHOTOBIOGENESIS

Vitamin D_3 is a derivative of 7-dehydrocholesterol (provitamin D_3), the immediate precursor of cholesterol. When skin is exposed to sunlight or certain artificial light sources, the ultraviolet radiation enters the epidermis and causes transformation of 7-dehydrocholesterol to vitamin D_3. Wavelengths between 290 and 315 nm are absorbed by the conjugated double bonds at $C_5$and $C_7$of 7-dehydrocholesterol to produce previtamin D_3(Fig. 340-5). Vitamin D_3 is made in the skin from the previtamin for many hours after a single sun exposure (Fig. 340-5). Once vitamin D_3 is synthesized, it is translocated from the epidermis into the circulation by the vitamin D-binding protein. Melanin in the skin competes with 7-dehydrocholesterol for ultraviolet photons and thus can limit the synthesis of previtamin D_3. The photochemical isomerization of previtamin D_3 and vitamin D_3 to biologically inert products appears to be more important in preventing excessive production of previtamin D_3 and vitamin D_3during prolonged exposure to the sun.

Aging decreases the capacity of the skin to produce vitamin D_3; this capacity is reduced more than fourfold after age 70. Topical sunscreens can reduce or prevent cutaneous production of vitamin D_3 by absorbing the solar radiation responsible for previtamin D_3synthesis in the skin. Other factors that affect the cutaneous synthesis of vitamin D_3include altitude, geographic location, time of day, and area exposed. Latitude has profound effects on the cutaneous synthesis of vitamin D_3. As the zenith angle of the sun increases with approaching winter, more of the high-energy ultraviolet photons responsible for formation of the previtamin are absorbed by the ozone layer. In an area such as Boston (42°N), the absorption of these photons is so complete that essentially no vitamin D_3 is made in the skin between the months of November through February.

When the entire body is exposed to sufficient sunlight to cause mild erythema, the increase in the blood vitamin D is approximately equivalent to consuming oral doses of 10,000 to 25,000 international units (1 IU = 0.025 ug) of vitamin D. Only when skin irradiation is insufficient to produce the required quantities of vitamin D_3 is dietary supplementation needed to prevent skeletal mineralization defects. The fortification of milk and some cereals with either crystalline vitamin D_2(Fig. 340-5) or vitamin D_3should prevent rickets and osteomalacia. A survey of the vitamin D content in milk from the United States and western Canada revealed, however, that 71% did not contain 80 to 120% of the amount of vitamin D on the label and that ~15% of skim milk did not contain detectable vitamin D.

In 1997, the Food and Nutrition Board for the Institute of the Medicine recommended 200 IU/d as the adequate intake of vitamin D for neonates, children, and adults up to 50 years. For adults 51 to 70 and >71 years, the committee recommended 400 and 600 IU/d, respectively. In the absence of adequate sunlight exposure, all children and adults require at least 400 to 600 IU/d.

METABOLISM

In the liver, vitamin D is metabolized to 25-hydroxyvitamin D [25(OH)D] by hepatic mitochondrial and/or microsomal enzyme(s) (Fig. 340-5). 25(OH)D is one of the major circulating metabolites, and its half-life is about 21 days. The concentrations of 25(OH)D and some of its metabolites in the serum are measured using competitive binding assays. The normal serum 25(OH)D concentration varies among different laboratories from 20 to 200 nmol/L (8 to 80 ng/mL). Individuals exposed to excessive sunlight may have concentrations of 25(OH)D up to 250 nmol/L (100 ng/mL) without adverse effects on calcium metabolism. The serum 25(OH)D levels usually reflect both 25-hydroxyvitamin D_2[$25(OH)D_2$] and 25-hydroxyvitamin D_3[$25(OH)D_3$]. The ratio of these two 25-hydroxylated derivatives depends on the relative amounts of vitamins D_2 or D_3present in the diet and the amount of previtamin D_3produced by exposure to sunlight.

The hepatic 25-hydroxylation of vitamin D is regulated by a product feedback mechanism. This regulation, however, is not tight; an increase in dietary intake or endogenous production of vitamin D_3increases 25(OH)D levels in the serum. The levels can rise to>1200 nmol/L (500 ng/mL) when the intake of vitamin D is excessive. Serum 25(OH)D levels are reduced in severe chronic liver disease (Table 340-5). 25(OH)D is probably not biologically active at physiologic levels in vivo but is active in vitro at high concentrations.

After formation in the liver, 25(OH)D is bound by the vitamin D-binding protein and transported to the kidney for an additional stereospecific hydroxylation on either C_1 or C_{24}(Fig. 340-5). The kidney plays a pivotal role in the metabolism of 25(OH)D to the biologically active metabolite. The renal mitochondrial 25(OH)D-1-hydroxylase activity is enhanced by hypocalcemia to increase the rate of conversion of 25(OH)D to $1,25(OH)_2D$. Hypocalcemia may not control this hydroxylation directly, however. Any decrease in the serum concentration of calcium below normal is a stimulus for increased secretion ofPTH, which increases the synthesis of $1,25(OH)_2D$ in the renal proximal convoluted tubule. The renal production of $1,25(OH)_2D$ enhances the effects of PTH in

lowering circulating concentrations (and presumably renal intracellular concentrations) of phosphate (Fig. 340-6). 1,25(OH)$_2$D also influences the renal metabolism of 25(OH)D by diminishing 25(OH)D-1a-hydroxylase activity and enhancing the metabolism of 25(OH)D to 24*R*,25-dihydroxyvitamin D [24,25(OH)$_2$D].

24,25(OH)$_2$D is normally present in serum at a concentration of 1 to 10 nmol/L (0.5 to 5.0 ng/mL). 24,25(OH)$_2$D is also a substrate for renal 25(OH)D-1a-hydroxylase and is converted to 1a,24*R*,25-trihydroxyvitamin D [1,24,25(OH)$_3$D], which, in turn, is metabolized to the biologically inactive substance calcitroic acid (Fig. 340-5). Cultured cells that possess nuclear receptors for 1,25(OH)$_2$D, such as chondrocytes, skin keratinocytes and fibroblasts, and intestinal and melanoma cells, also metabolize 25(OH)D to 24,25(OH)$_2$D. Studies of the vitamin D-24-hydroxylase null mice indicate that the major role of 24-hydroxylation is in the regulation of levels of 1,25(OH)$_2$D.

PHYSIOLOGY

1,25(OH)$_2$D, produced by the kidney and the placenta, is the only known important metabolite of vitamin D; the potential roles of other metabolites have not been clarified. 1,25(OH)$_2$D bound to a vitamin D-binding protein is delivered to various target organs, where the free form is taken up by cells and transported to a specific nuclear receptor protein. The vitamin D receptor (VDR) belongs to the nuclear receptor superfamily of steroid-retinoid-thyroid hormone-vitamin D transcription regulatory factors (Chap. 327). The VDR interacts with the retinoic acid X receptor (RXR) to form a heterodimeric (RXR-VDR) complex that binds to specific DNA sequences, termed the *vitamin D response elements* (VDREs). After 1,25(OH)$_2$D binds to the receptor, it induces conformational changes that result in the recruitment of a multitude of transcriptional coactivators that stimulate the transcription of target genes. In the intestine, the activated VDR stimulates calcium-binding protein synthesis; in bone, it stimulates production of osteocalcin, osteopontin, and alkaline phosphatase. 1,25(OH)$_2$D also may have nonnuclear effects on its target tissues; 1,25(OH)$_2$D increases the transport of calcium from the extracellular to intracellular space, and it can mobilize calcium from intracellular calcium pools and enhance phosphatidylinositol metabolism. In the intestine, the net effect of 1,25(OH)$_2$D is to stimulate calcium and phosphate transport from the lumen of the small intestine into the circulation (Fig. 340-6). The effect of 1,25(OH)$_2$D on the enhancement of bone resorption is synergistic with that ofPTH. Mature osteoclasts do not possess receptors for either PTH or 1,25(OH)$_2$D. Both PTH and 1,25(OH)$_2$D interact with their specific receptors on osteoblasts or stromal fibroblasts to induce the production ofRANKligand on the osteoblast's cell surface. As described above, the RANK ligand interacts with the RANK receptor on immature osteoclasts, stimulating immature osteoclastic precursors to differentiate into mature osteoclasts. The role of 1,25(OH)$_2$D in the renal handling of calcium and phosphorus remains uncertain. Whatever the role of extraintestinal VDRs may be, the compelling evidence is that the phenotype of VDR null mice is corrected in the setting of normal mineral ion homeostasis. Thus the skeletal consequences of VDR ablation are the result of impaired intestinal calcium absorption and/or the accompanying secondary hyperparathyroidism and hypophosphatemia.

Receptors for 1,25(OH)$_2$D are also present in cells not classically considered target organs for this hormone, including skin, breast, pituitary, parathyroids, pancreatic beta

cells, gonads, brain, skeletal muscle, circulating monocytes, and activated B and T lymphocytes. Although its physiologic role in these cells remains to be determined, $1,25(OH)_2D$ inhibits proliferation of keratinocytes and fibroblasts, stimulates terminal differentiation of keratinocytes, induces monocytes to produce interleukin (IL)1 and to differentiate into macrophages and osteoclast-like cells, inhibits the production ofPTH, and inhibits the production of IL-2 and immunoglobulin by activated T and B lymphocytes, respectively.

In addition, a variety of tumor cell lines, including lines derived from breast carcinomas, melanomas, and promyeloblasts, possess receptors for $1,25(OH)_2D$. Tumor cell lines that have $1,25(OH)_2D$ receptors respond to the hormone by decreasing the rate of proliferation and enhancing differentiation. For example, when malignant receptor-positive human promyelocytic cells (HL-60) are exposed to $1,25(OH)_2D$, the cells mature into functioning macrophages within 1 week. Although calcitriol [$1,25(OH)_2D$] is not useful for the treatment of leukemia, the antiproliferative effects of calcitriol and its analogue calcipotriene provide the rationale for their use in the treatment of psoriasis.

$1,25(OH)_2D$ regulatesPTHsynthesis by negative feedback (Fig. 340-6). This effect is the rationale for giving $1,25(OH)_2D_3$, and its less calcemic-inducing analogue 19-nor-1,25-dihydroxyvitamin D_3(Fig. 340-7), to lower circulating levels of PTH in patients with chronic renal failure (Chap. 341).

The principal physiologic mechanism regulating the production of $1,25(OH)_2D$ appears to involve changes in serum extracellular calcium concentrations that result in reciprocal changes in secretion ofPTH, the latter controlling, possibly through actions on serum or tissue phosphorus levels, the rate of $1,25(OH)_2D$ production. Other factors that enhance $1,25(OH)_2D$ production include estrogen, prolactin, and growth hormone. Humans adapt to increased calcium requirements during growth, pregnancy, and lactation by increasing the efficiency of intestinal calcium absorption, possibly by enhancing 25(OH)D-1a-hydroxylase activity. During the first two trimesters of pregnancy, the levels of $1,25(OH)_2D$ increase in proportion to the concentration of the vitamin D-binding protein; levels of free $1,25(OH)_2D$ do not change. During the last trimester, the need for calcium for mineralization of the fetal skeleton is met by an increase in the concentrations of free $1,25(OH)_2D$ and enhanced maternal intestinal calcium absorption.

Most measurements of circulating $1,25(OH)_2D$ in various physiologic or pathologic states utilize a receptor/competitive binding assay. Serum levels of vitamin D and 25(OH)D vary with the season and with vitamin D intake, whereas levels of $1,25(OH)_2D$ appear to be unaltered by seasonal variation, by increases in dietary vitamin D, or by exposure to sunlight (Table 340-6); as long as vitamin D supplies and circulating concentrations of 25(OH)D are sufficient, metabolic influences control the renal 25(OH)D-1a-hydroxylase to ensure a closely regulated circulating concentration of $1,25(OH)_2D$. The serum concentration of $1,25(OH)_2D$ ranges from 40 to 160 pmol/L (16 to 65 pg/mL), and its serum half-life is from 3 to 6 h.

PHARMACOLOGY

Casual exposure to sunlight provides most people with adequate vitamin D. In elderly

individuals, exposure of hands, face, and arms to a suberythemal dose of sunlight two to three times a week is usually adequate. A variety of over-the-counter vitamin preparations contain 400 IU of either vitamin D_2(ergocalciferol) or vitamin D_3(cholecalciferol). More potent preparations of vitamin D (calciferol) are available in capsule and tablet form (50,000 IU), as oil (500,000 IU/mL), and in oral solution (8000 IU/mL). A single oral dose of 50,000 IU of vitamin D_2increases the circulating concentration of vitamin D from<25 nmol/L (10 ng/mL) to 130 to 260 nmol/L (50 to 100 ng/mL) within 12 to 24 h; the plasma half-life is about 2 days. Serum concentrations of 25(OH)D and 1,25$(OH)_2$D are not changed by these doses of vitamin D. For treatment of vitamin D deficiency, 50,000 IU of vitamin D once a week for 8 weeks raises the circulating concentration of 25(OH)D into the normal range; in the presence of secondary hyperparathyroidism, the circulating concentrations of 1,25$(OH)_2$D can increase to supranormal levels [up to 600 pmol/L (250 pg/mL)]. 25$(OH)D_3$(calcifediol) available in capsules containing either 20 or 50 ug may be useful in treating vitamin D deficiency [low 25(OH)D concentrations] in patients with severe liver dysfunction. Pharmacologic doses are used to treat disorders of 25(OH)D metabolism; in pharmacologic doses, 25$(OH)D_3$is believed to act via interaction with theVDR. Calcitriol is available in capsules containing 0.25 or 0.5 ug and as a solution for intravenous use (1.0 and 2.0 ug/mL). Calcitriol is efficacious in a variety of disorders (Chap. 341), but even low doses can cause hypercalcemia, leading to attempts to develop analogues with less calcemic activity. Two such calcitriol analogues have been approved in the United States for the treatment of renal osteodystrophy; 19-nor-1,25-dihydroxyvitamin D_2, and 24-epi-1,25-dihydroxyvitamin D_2(Fig. 340-7). 1a-Hydroxyvitamin D_3[1$(OH)D_3$] is a potent 1,25$(OH)_2D_3$agonist that is used in Europe and Japan. The structure of this analogue is identical to that of the natural renal hormone with the exception that it lacks a C_{25}OH. In humans, this analogue is rapidly metabolized by the liver to 1,25$(OH)_2D_3$. Topical preparations of calcitriol (3 ug/g) in Europe and calcipotriene (50 ug/g) in Europe and the United States are used for the treatment of psoriasis. When applied over a large surface area, both can potentially cause hypercalcemia and hypercalciuria. Oral calcitriol is also effective for psoriasis and psoriatic arthritis.

When vitamin D is chemically manipulated to rotate the A ring through 180°, the C_3b-OH assumes a geometric position that mimics the C_1a-OH (Fig. 340-7). These compounds, called *pseudo-1a-hydroxyvitamin D analogues*, include the clinically useful dihydrotachysterol (DHT). This analogue is less effective in stimulating intestinal calcium transport on a weight basis than either vitamin D or 1,25$(OH)_2$D. Because it does not require 1a-hydroxylation to be active on intestinal calcium transport, it is 3 to 10 times more potent than vitamin D in disease states that impair renal 25(OH)D-1a-hydroxylase, such as hypoparathyroidism and chronic renal failure. Dihydrotachysterol is efficiently metabolized in the liver to 25-hydroxy-DHT, which is the biologically active form.

RICKETS AND OSTEOMALACIA

Rickets and osteomalacia are disorders in which mineralization of the organic matrix of the skeleton is defective. These disorders are caused by a number of different conditions associated with vitamin D deficiency or resistance (Table 340-7). In *rickets*, the growing skeleton is involved; defective mineralization occurs both in the bone and cartilaginous matrix of the growth plate. The term *osteomalacia* is usually used for this mineralization disorder in the adults in whom the epiphyseal growth plates are closed.

For normal skeletal mineralization, sufficient calcium and phosphate must be present at the mineralization sites. In addition, intact metabolic and transport functions of osteoblasts and chondrocytes and adequate production of cross-linked collagen matrix are required. In cartilage, the initial mineral phase is enclosed in membrane-bound extracellular vesicles. If the osteoblast continues to produce matrix components that cannot be mineralized adequately, rickets or osteomalacia results. A characteristic feature of these disorders is therefore an increase in osteoid volume and thickness (the latter being normally <12 to 14 um) and a decrease in calcification of the mineralization front. This can be detected in unmineralized sections by the fluorescence of previously ingested tetracyclines or by special stains. The inadequate mineralization of the matrix of cartilage in growing children leads to a widening of the epiphyseal plates of the long bones due to a disorganization of the otherwise highly ordered columns of hypertrophied cartilage cells. In addition, the poorly mineralized long bones are incapable of withstanding usual mechanical stresses and tend to undergo bowing deformities. Growth of the epiphyseal plates is diminished, stunting the growth of the long bones. Osteomalacia also compromises the architectural structure and strength of the skeleton in adults, causing an increase in fractures.

PATHOPHYSIOLOGY

A large number of disorders are associated with rickets or osteomalacia, primarily through alterations of vitamin D nutrition or metabolism or because of phosphate wasting (Table 340-7). *Hypovitaminosis D* results from inadequate endogenous production of vitamin D_3 in the skin, from insufficient dietary supplementation, and/or from an inability of the small intestine to absorb adequate amounts of the vitamin from the diet. Resistance to the effects of vitamin D can result from (1) use of drugs that antagonize vitamin D action, (2) alterations in the metabolism of vitamin D, or (3) deficient or defective receptors for $1,25(OH)_2D$. The consequences of hypovitaminosis D include (1) disturbances of mineral ion metabolism and secretion ofPTH, and (2) mineralization defects in the skeleton (e.g., rickets in children, osteomalacia in adults). With an adequate glomerular filtration rate (GFR), the main changes are hypophosphatemia, normal or near-normal serum calcium levels, increased levels of PTH, and low levels of 25(OH)D (Table 340-5).

With regard to calcium metabolism, lack of vitamin D action leads to insufficient intestinal calcium absorption and hypocalcemia. The latter stimulates the secretion ofPTH(secondary hyperparathyroidism), which enhances calcium release from bone, decreases calcium clearance by the kidney, and tends to blunt the hypocalcemia; as a consequence, most patients have a normal or low-normal serum calcium level. (Late in the course of untreated hypovitaminosis D, severe hypocalcemia develops.) Hypophosphatemia is more marked than hypocalcemia, especially in early stages of the deficiency. The efficiency of intestinal phosphate absorption is also decreased. The increased secretion of PTH, although partially effective in minimizing hypocalcemia, leads to urinary phosphate wasting because of decreased renal tubular reabsorption. This latter effect is the most significant factor in causing hypophosphatemia. Aging decreases the responsiveness of the renal 25(OH)D-1-hydroxylase to PTH, decreasing circulating levels of $1,25(OH)_2D$ and contributing to decreased calcium absorption in the elderly.

Although the conversion of vitamin D to 25(OH)D is impaired in severe chronic liver disease, there is not a strong correlation between low serum 25(OH)D levels and osteopenia. Patients with nephrotic syndrome with >4 g/d of proteinuria may have low 25(OH)D levels owing to loss in the urine of the vitamin D-binding protein with its associated tightly bound 25(OH)D. Circulating levels of 25(OH)D may also be decreased when the metabolism of 25(OH)D to $1,25(OH)_2D$ is increased, as in sarcoidosis and hyperparathyroidism. Chronic anticonvulsant therapy can also cause the development of osteomalacia or rickets; mineralization defects are worse in patients receiving multiple drug therapy and when vitamin D intake or exposure to sunlight is inadequate. Anticonvulsant drugs have multiple effects on calcium metabolism. Phenobarbital induces hepatic microsomal enzymes, alters the kinetics of the vitamin D-25-hydroxylase, and stimulates bile secretion, resulting in decreased serum concentrations of vitamin D and 25(OH)D. Phenytoin and phenobarbital inhibit intestinal calcium transport and bone mineral mobilization, independent of effects on vitamin D metabolism.

Glucocorticoids in high doses cause osteoporosis but do not induce osteomalacia and rickets (Chap. 342). Glucocorticoids directly inhibit vitamin D-mediated intestinal calcium absorption and bone mineral mobilization. Patients receiving glucocorticoids chronically may have depressed circulating levels of $1,25(OH)_2D$; the mechanism(s) is unknown. Glucocorticoids also exert direct effects to induce apoptosis of osteoblasts and osteocytes.

A genetic defect in the hepatic 25-hydroxylation of vitamin D has not been described, but in one inherited disorder of calcium and bone metabolism, renal production of $1,25(OH)_2D$ is defective because of recessive mutations 25(OH)D-1a-hydroxylase activity. In this syndrome of pseudovitamin D-deficient rickets (also known as vitamin D-dependent rickets type I), renal production of $1,25(OH)_2D$ is impaired, circulating levels of $1,25(OH)_2D$ are low, but the therapeutic response to physiologic doses of calcitriol (0.25 to 1.0 ug/d) is normal. In patients with a similar phenotype, pseudovitamin D-resistant rickets (vitamin D-dependent rickets type II), mutations in the vitamin D receptor impair its function by altering the binding of the hormone to the receptor or by altering the binding of the receptor heterodimer complex to DNA. Individuals with this disorder have high circulating levels of $1,25(OH)_2D$, but the hormone is ineffective because of the receptor defect. Alopecia is another feature of this disorder, suggesting a role for theVDR in hair follicle development.

Inherited forms of phosphate wasting disorders include X-linked hypophosphatemic rickets and autosomal dominant hypophosphatemic rickets. The gene responsible for the autosomal form is unknown but has been mapped to chromosome 12p13. The X-linked disorder is caused by mutations in the *PHEX* (phosphate-regulating gene with homology to endopeptidases on the X-chromosome) gene. The *PHEX* gene is postulated to encode an osteoblast protein that inactivates phosphatonin, a phosphaturic factor. Consequently, inactivating mutations result in phosphate wasting. The gene is expressed in heterozygotes, suggesting that the disorder is caused by haploinsufficiency. In patients with X-linked hypophosphatemic rickets, serum concentrations of $1,25(OH)_2D$ are normal or low. Since hypophosphatemia is a potent stimulator of the renal 25(OH)D-1a-hydroxylase, levels of $1,25(OH)_2D$ should be high,

which suggests the existence of a functional defect in the 25(OH)D-1a-hydroxylase in this disorder. Therefore, the combination of calcitriol and phosphate supplements is more effective than therapy with phosphate supplements alone.

Patients with hypocalcemia due to hypoparathyroidism or pseudohypoparathyroidism have lower-than-normal mean serum concentrations of $1,25(OH)_2D$, although individual values may be in the normal range. In these patients, small replacement doses of calcitriol (0.25 to 1.0 ug/d) are effective even when the serum 25(OH)D concentrations are elevated. These observations indicate that absent or ineffective action ofPTHdecreases the activity of renal 25(OH)D-1a-hydroxylase. It is not known whether serum $1,25(OH)_2D$ levels would be restored if the hyperphosphatemia were controlled.

Patients with tumor-induced (oncogenic) osteomalacia have low levels of serum phosphorus and $1,25(OH)_2D$. Some of these tumors, especially malignant carcinomas, produce PTHrP (Chap. 341), leading to hypercalcemia as well as hypophosphatemia. Other tumors, particularly more benign neoplasms of vascular or mesenchymal origin, may be responsible for severe hypophosphatemia in the presence of normocalcemia. The mechanism for inhibition of $1,25(OH)_2D$ synthesis remains unknown; after removal of the tumor, however, the serum phosphorus and $1,25(OH)_2D$ levels return to normal.

It has been suggested that alteration of vitamin D receptor levels in target tissues (such as intestine) could affect calcium and bone metabolism, and bone mineral density appears to be associated with specific polymorphisms of theVDRgene. These polymorphisms affect the noncoding intervening DNA sequences (introns) or the coding sequence in a way that does not alter the amino acid sequence of the VDR. Some reports suggest that polymorphisms involving the endonucleases Bsm-I and Taq-I (bb, TT) are associated with higher bone mineral density; other studies have not confirmed these findings. The genetic contribution of VDR polymorphic variants to bone mineral density, as well as a number of other diseases with which they have been associated, require additional, larger-scale studies.

CLINICAL FEATURES

The clinical manifestations of rickets are the result of skeletal deformities, susceptibility to fractures, weakness and hypotonia, and disturbances in growth. As the disorder progresses, particularly that associated with vitamin D deficiency, children are unable to walk without support due to the skeletal deformities in the lower limbs and severe muscle weakness (Fig. 340-8). Abnormal parietal flattening and frontal bossing develops in the skull. The calvariae are softened (*craniotabes*) and sutures may be widened. Prominence of the costochondral junctions is called the *rachitic rosary* and the indentation of the lower ribs at the site of attachment of the diaphragm is known as *Harrison's groove*. If untreated, deformities of the pelvis and extremities progress, with bowing being particularly common in the tibia, femur, radius, and ulna. For women, the flattening of the pelvis increases the risk of maternal and infant morbidity and mortality during childbirth. Fractures are frequent, dental eruption is often delayed, and enamel defects are common.

The presentation of osteomalacia in adults is usually more insidious. Bone pain and muscle weakness are common complaints and may be overlooked as indicators of

vitamin D deficiency. It is estimated in the United States and Europe that>40% of the adult population over the age of 50 are vitamin D deficient. Although the standard lower limit of the normal range for 25(OH)D is 10 ng/mL, several studies suggest that the cutoff for vitamin D deficiency should be increased to 20 ng/mL. This suggestion is based onPTHresponses to various serum levels of 25(OH)D. For example, elevated levels of PTH are frequently seen in individuals with 25(OH)D levels between 10 and 20 ng/mL, and administration of vitamin D (50,000 units of vitamin D once a week for 8 weeks) lowers PTH levels. Defects in skeletal mineralization may accompany these disturbances in vitamin D and mineral metabolism.

Pain in the hips may result in an antalgic gait. Muscle weakness is often associated with osteomalacia but is difficult to distinguish from hesitancy to move because of skeletal pain. Proximal weakness may mimic that of primary muscle disorders and contribute to the waddling gait. Many factors, including secondary hyperparathyroidism, hypophosphatemia, and vitamin D deficiency, contribute to the myopathy. Fractures of the involved bones may occur with minimal trauma. When the ribs are involved, severe deformities may develop in the thorax, and the collapse of the vertebral bodies may produce loss of height.

RADIOLOGIC FEATURES

In rickets, the most prominent radiologic alteration is evident at the growth plate (physis) which is increased in thickness, cupped, and hazy at the metaphyseal border owing to decreased calcification of the hypertrophic zone and inadequate mineralization of the primary spongiosa. The trabecular pattern of the metaphysis is abnormal, the cortices of the diaphysis may be thinned, and the shafts may be bowed.

In osteomalacia, a decrease in bone density is usually associated with loss of trabeculae and thinning of the cortices. Radiologic and bone densitometric changes are indistinguishable from those in osteoporosis (Chap. 342). Trabecular patterns may be blurred, producing a homogeneous "ground glass" appearance. Radiolucent bands, ranging from a few millimeters to several centimeters in length and usually oriented perpendicular to the surface of the bones, suggest the presence of osteomalacia. They are particularly common at the inner aspects of the femur (especially near the femoral neck), in the pelvis, in the outer edge of the scapula, in the upper fibula, and in the metatarsals. These radiolucent bands, called *pseudofractures* or *Looser's zones*, occur most often where major arteries cross the bones and are thought to be due to the pulsation of these vessels in the undermineralized area (Fig. 340-9). Increased rather than decreased density of bones may be observed in patients who have renal tubular disorders rather than vitamin D deficiency and may produce a striking thickening of the cortices and a trabecular pattern of the spongy bone. Despite the increase in bone mass per unit volume, the trabeculae are covered with thickened osteoid seams typical of osteomalacia. Similar findings may occur in patients with chronic renal failure. The reason for the hyperostosis is unknown; the bone is architecturally abnormal and is subject to fracture with minimal trauma.

LABORATORY FINDINGS

Changes in serum concentration of calcium, inorganic phosphorus, 25(OH)D, and

$1,25(OH)_2D$ vary with the different disorders. In vitamin D deficiency, whether due to dietary lack, inadequate sunlight exposure, or intestinal malabsorption, serum calcium levels are normal or low, whereas phosphorus and 25(OH)D levels are consistently low, the latter usually <15 nmol/L (<10 ng/mL) depending on the assay used. In contrast, levels of $1,25(OH)_2D$ may be normal or elevated owing to secondary hyperparathyroidism and the fact that circulating levels of $1,25(OH)_2D$ are 1000-fold less than those of 25(OH)D. Only when vitamin D deficiency is chronic and severe is hypocalcemia observed. It may be sufficiently severe to produce tetany. Mild acidosis and generalized aminoaciduria result from secondary hyperparathyroidism. Patients with renal tubular disorders have normal serum calcium levels and hypophosphatemia. Other laboratory findings such as glucosuria, aminoaciduria, acidosis, and hypouricemia reflect variable degrees of disturbance of proximal tubular function or are features of underlying disease (e.g., low plasma ceruloplasmin in Wilson's disease or abnormalities of immunoglobulins in multiple myeloma). In chronic renal failure, hyperphosphatemia and hypocalcemia are usually accompanied by normal 25(OH)D and low $1,25(OH)_2D$ levels. In nephrotic syndrome, serum 25(OH)D levels can be low owing primarily to urinary losses of vitamin D binding protein-bound 25(OH)D. Serum phosphorus levels are also normal or elevated in hypophosphatasia. Markers of bone resorption increase when secondary hyperparathyroidism and excessive bone resorption are associated with the defect in mineralization. Alkaline phosphatase levels in serum are usually elevated in rickets and osteomalacia.

TREATMENT

In rickets and osteomalacia due to dietary absence of vitamin D or inadequate exposure to sunlight, vitamin D_2(ergocalciferol) or vitamin D_3(cholecalciferol) is given orally in doses of 800 to 4000 IU (0.02 to 0.1 mg) daily for 6 to 12 weeks, followed by daily supplements of 200 to 600 IU, which are adequate to prevent the development of the disorder in otherwise normal persons. In elderly persons with vitamin D deficiency, the administration of 50,000 IU vitamin D by mouth once each week for 8 weeks raises the serum levels of 25(OH)D into the mid-normal range. In infants and children, such treatment causes improvement in muscle tone and strength, an increase in serum calcium and phosphorus levels, and a decrease in alkaline phosphatase levels after several weeks. Radiologic evidence of healing appears within weeks, and healing may be complete by a few months. Calcium supplements and larger initial doses of vitamin D may be necessary in infants and children with tetany. In adults with nutritional osteomalacia, healing of pseudofractures may be evident within 3 to 4 weeks after therapy with as little as 2000 IU (0.5 mg) vitamin D daily. Healing is usually complete by 6 months.

Patients with osteomalacia due to intestinal malabsorption do not respond to small doses of vitamin D. In the presence of active steatorrhea, daily oral doses of vitamin D of 50,000 to 100,000 IU (1.25 to 2.5 mg) and large doses of calcium (e.g., 15 g calcium lactate or 4 g calcium carbonate orally per day) may be required. In some instances, oral vitamin D is ineffective, and the parenteral route is required (e.g., 10,000 IU/d intramuscularly). Another approach is the use of artificial ultraviolet B radiation or exposure to sunlight in addition to supplemental calcium. Small doses of calcitriol (0.5 to 1.0 ug daily) are also usually effective in this form of osteomalacia. Inorganic phosphate therapy is not indicated either in deficiency or in intestinal malabsorption of the vitamin,

since hypocalcemia will develop and intestinal calcium absorption will remain inadequate. In all patients in whom large doses of vitamin D are used, serum calcium and 25(OH)D levels should be monitored periodically. Semiquantitative urinary calcium measurements are inadequate.

In patients treated with multiple anticonvulsant agents, it is usually necessary to continue the drugs while adding 1000 IU/d of vitamin D and to monitor levels of serum calcium and serum 25(OH)D until a therapeutic response (evidence of radiologic healing, improvement in symptoms) is obtained.

Treatment of rickets and osteomalacia in the presence of renal tubular disorders is more difficult. Oral supplements of inorganic phosphate in divided doses of phosphorus (as elemental P), 1.0 to 3.6 g/d (50 mg/kg body weight per day for children), and calcitriol, 0.5 to 2.0 ug/d (30 ng/kg body weight per day for children), constitute the best regimen to restore skeletal growth and heal the bone disease. Patients with nephrotic syndrome and low serum 25(OH)D levels benefit from modest vitamin D supplementation (800 to 1000 IU/d). Small doses of calcitriol are equally effective in treating hypocalcemia and osteodystrophy resulting from chronic renal failure. The recommended initial dose of calcitriol is 0.25 ug/d. If after 2 to 4 weeks on this dose the biochemical parameters are unaltered, the dose is increased by 0.25 ug/d every 2 to 4 weeks until a satisfactory clinical biochemical response (including elevation of serum calcium levels and decrease in PTHlevels) is obtained. The usual dose is 0.5 to 1.0 ug/d. Calcitriol may also be administered intravenously (1.0 to 2.5 ug three times weekly) to patients on dialysis, particularly to treat refractory osteitis fibrosa. Serum calcium levels should be monitored frequently during the first 1 to 2 months of therapy and less frequently once a stable dose has been established.

In patients who have had rickets in childhood, the abnormal mechanical stress of severe deformities may contribute to the development of degenerative joint disease, particularly in the hips and knees. Osteotomies at the proper time after healing may prevent this complication and the requirement for more extensive arthroplasties later in life.

341. DISEASES OF THE PARATHYROID GLAND AND OTHER HYPER- AND HYPOCALCEMIC DISORDERS - *John T. Potts, Jr*

The four parathyroid glands are located posterior to the thyroid gland. They produce parathyroid hormone (PTH), which is the primary regulator of calcium physiology. PTH acts directly on bone, where it induces calcium resorption, and on the kidney, where it stimulates calcium reabsorption and synthesis of 1,25-dihydroxyvitamin D [1,25$(OH)_2$D], a hormone that stimulates gastrointestinal calcium absorption. Serum PTH levels are tightly regulated by a negative feedback loop. Calcium, acting through the calcium-sensing receptor, and vitamin D, acting through its nuclear receptor, inhibit PTH synthesis and release. Understanding the hormone pathways that regulate calcium levels and bone metabolism is essential for effective diagnosis and management of a wide array of hyper- and hypocalcemic disorders.

Hyperparathyroidism, characterized by excess production ofPTH, is a common cause of hypercalcemia and is usually the result of autonomously functioning adenomas or hyperplasia. Surgery for this disorder is highly effective and has been shown recently to reverse some of the deleterious effects of long-standing PTH excess on bone density. Hypercalcemia of malignancy is also common and is usually due to the overproduction of parathyroid hormone-related peptide (PTHrP) by cancer cells. The similarities in the biochemical characteristics of hyperparathyroidism and hypercalcemia of malignancy, first noted by Albright in 1941, are now known to reflect the actions of PTH and PTHrP through the same G protein-coupled (GPC) PTH/PTHrP receptor.

Clarification over the past decade of genetic influences on parathyroid gland and bone cell function helps in constructing a logical approach to hyper- and hypocalcemic disorders. Advances that have occurred include elucidation of the genetic basis of multiple endocrine neoplasia (MEN) types 1 and 2, familial hypocalciuric hypercalcemia (FHH), the different forms of pseudohypoparathyroidism (PHP), Jansen's syndrome, disorders of vitamin D synthesis and action, and the molecular events associated with parathyroid gland neoplasia. The advent of new drugs, including bisphosphonates and selective estrogen receptor modulators (SERMs), offers new avenues for the treatment and prevention of metabolic bone disease. PTH analogues are promising therapeutic agents for the treatment of postmenopausal or senile osteoporosis, and calcimimetic agents, which act through the calcium-sensing receptor, may provide new approaches for PTH suppression.

PARATHYROID HORMONE

PHYSIOLOGY

The primary function ofPTH is to maintain the extracellular fluid (ECF) calcium concentration within a narrow normal range. The hormone acts directly on bone and kidney and indirectly on intestine through its effects on synthesis of 1,25$(OH)_2$D to increase serum calcium concentrations; in turn, PTH production is closely regulated by the concentration of serum ionized calcium. This feedback system is the critical homeostatic mechanism for maintenance of ECF calcium. Any tendency toward hypocalcemia, as might be induced by calcium-deficient diets, is counteracted by an increased secretion of PTH. This in turn (1) acts to increase the rate of dissolution of

bone mineral, thereby increasing the flow of calcium from bone into blood; (2) reduces the renal clearance of calcium, returning more of the calcium filtered at the glomerulus into ECF; and (3) increases the efficiency of calcium absorption in the intestine. Immediate control of blood calcium is probably due to effects of the hormone on bone and, to a lesser extent, on renal calcium clearance. Maintenance of steady-state calcium balance, on the other hand, probably results from the effects of $1,25(OH)_2D$ on calcium absorption (Chap. 340). The renal actions of the hormone are exerted at multiple sites and include inhibition of phosphate transport (proximal tubule), increased reabsorption of calcium (distal tubule), and stimulation of the renal 25(OH)D-1a-hydroxylase. As much as 12 mmol (500 mg) calcium is transferred between the ECF and bone each day (a large amount in relation to the total ECF calcium pool), and PTH has a major effect on this transfer. The homeostatic role of the hormone can preserve calcium concentration in blood acutely at the cost of bone destruction.

PTHhas multiple actions on bone, some direct and some indirect. It increases the rate of calcium release from bone into blood acutely; PTH-mediated changes in bone calcium release can be seen within minutes. The chronic effects of PTH are to increase the number of bone cells, both osteoblasts and osteoclasts, and to increase the remodeling of bone; these effects are apparent within hours after the hormone is given and persist for hours after PTH is withdrawn. Continuous exposure to elevated levels of PTH for days (as in hyperparathyroidism or long-term infusions in animals) leads to increased osteoclast-mediated bone resorption. However, the administration of PTH intermittently over days in animals or osteoporotic patients leads to a net stimulation of bone formation rather than bone breakdown. Striking increases, especially in trabecular bone in the spine and hip, have been reported with the use of PTH in combination with estrogen. PTH as monotherapy caused a highly significant reduction in fracture incidence in a worldwide placebo-controlled trial.

Osteoblasts (or stromal cell precursors), which havePTHreceptors, are crucial to this bone-forming effect of PTH; osteoclasts, which appear to lack PTH receptors, mediate bone breakdown. PTH-mediated stimulation of osteoclasts is believed to be indirect, acting in part through cytokines released from osteoblasts to activate osteoclasts; in experimental studies of bone resorption in vitro, osteoblasts must be present for PTH to activate osteoclasts to resorb bone. The nature of the cytokines that stimulate osteoclasts is a subject of major interest. Insulin-like growth factor 1, interleukin 6, granulocyte-macrophage colony stimulating factor, and possibly other agents are candidates, but the definitive messenger(s) has not been determined. Direct cell-to-cell contact between osteoblasts (stromal cells) and osteoclast precursors is also key to osteoclast function. Cell-associated ligands and receptors, as well as soluble decoy receptors, are involved in these interactions (Chap. 340).

STRUCTURE

PTHis an 84-amino-acid single-chain peptide. The amino acid sequence of PTH has been characterized in multiple mammalian species, revealing marked conservation in the amino-terminal portion, which is critical for many biologic actions of the molecule. Synthetic fragments of the amino-terminal sequence as small as 1-14 residues are sufficient to activate the major receptor (see below). Biologic roles for the

carboxyl-terminal region of PTH are under investigation; a separate receptor may exist for this region of the molecule. Fragments shortened or modified at the amino terminus still bind to the PTH receptor but lose the capacity to stimulate biologic responses. For example, the peptide composed of sequences 7-34 is a competitive inhibitor of active hormone binding to receptors in vitro but is a weak inhibitor in vivo.

BIOSYNTHESIS, SECRETION, AND METABOLISM

Synthesis Parathyroid cells have multiple methods of adapting to increased needs forPTHproduction. Most rapid (within minutes) is secretion of preformed hormone in response to hypocalcemia. Second, within hours, changes in gene activity and increased PTH mRNA are induced by sustained hypocalcemia. Finally, protracted challenge leads within days to cellular replication to increase gland mass.

PTHis initially synthesized as a larger molecule (preproparathyroid hormone, consisting of 115 amino acids), which is then reduced in size by a second cleavage (proparathyroid hormone, 90 amino acids) before secretion as the 84-amino-acid peptide. The hydrophobic regions of the preproparathyroid hormone serve a role in guiding transport of the polypeptide from sites of synthesis on polyribosomes through the endoplasmic reticulum to secretory granules. In one kindred with hypoparathyroidism, a mutation in the preprotein region of the gene disrupts this critical hydrophobic sequence and interferes with hormone secretion.

Studies with cloned and expressedPTHgenes in vitro have demonstrated DNA regions involved in transcriptional control, including sites for interaction and regulation by the vitamin D receptor, as well as sites through which ambient calcium regulates transcription. Suppression of PTH gene activity at the transcriptional level by calcium is nearly maximal at physiologic concentrations; hypercalcemia results in no significant change. Hypocalcemia, however, increases transcriptional activity within hours. $1,25(OH)_2D_3$strongly suppresses PTH gene transcription, though not when chronic hypocalcemia is induced experimentally in animals. In patients with renal failure, however, intravenous administration of supraphysiologic levels of $1,25(OH)_2D_3$or analogues of the active metabolite can dramatically suppress PTH overproduction, which is sometimes difficult to control due to severe secondary hyperparathyroidism. Control over hormone stores is exerted by variation in the rates of proteolytic destruction of preformed hormone under the control ofECFcalcium; high calcium increases and low calcium inhibits the proteolytic destruction of hormone stores. Regulation of hormone precursor processing and proteolytic destruction of preformed hormone (posttranslational regulation of hormone production) is an important mechanism for mediating rapid (minutes) changes in hormone availability.

Regulation of PTH Secretion PTH secretion increases steeply to a maximum value of five times the basal rate of secretion as calcium concentration falls from normal to the range of 1.9 to 2.0 mmol/L (7.5 to 8.0 mg/dL) (measured as total calcium). The ionized fraction of blood calcium is the important determinant of hormone secretion. Magnesium may influence hormone secretion in the same direction as calcium. It is unlikely, however, that physiologic variations in magnesium concentration affect PTH secretion. Severe intracellular magnesium deficiency impairs PTH secretion (see below).

The level of ECF calcium controls PTH secretion by interaction with a calcium sensor, a GPCR for which Ca^{2+} ions act as the ligand (see below). This receptor is a member of a distinctive subfamily of the GPCR superfamily that is characterized by a large extracellular domain suitable for "clamping" the small-molecule ligand. Stimulation of the receptor by high calcium levels leads to suppression of PTH secretion. The intracellular signals generated by the active receptor appear to be inositol triphosphate (IP_3) and diacylglycerol (DAG) formed by activation of phospholipase. The receptor is present in parathyroid glands and the calcitonin-secreting cells (C cells) of the thyroid, brain, and kidney. Genetic evidence has revealed a key biologic role for the calcium-sensing receptor in parathyroid gland responsiveness to calcium and, unexpectedly, in renal calcium clearance. Point mutations associated with loss of function cause a syndrome resembling hyperparathyroidism (FHH) but with hypocalciuria. On the other hand, gain-of-function mutations cause a form of hypocalcemia resembling hypoparathyroidism (see below).

Metabolism The secreted form of PTH is indistinguishable by immunologic criteria and by molecular size from the 84-amino-acid peptide (PTH 1-84) extracted from glands. However, much of the immunoreactive material found in the circulation is smaller than the extracted or secreted hormone. The principal circulating fragments of immunoreactive hormone lack a portion of the critical amino-terminal sequence required for biologic activity and, hence, are biologically inactive fragments (so-called middle- and carboxyl-terminal fragments). Much of the proteolysis of hormone occurs in the liver and kidney. However, fragments corresponding to the middle- and carboxyl-terminal portions have also been detected in effluent blood from the parathyroids and in the peripheral circulation; there is no convincing evidence, however, for circulating amino-terminal fragments. Peripheral metabolism of PTH does not appear to be regulated by physiologic states (high versus low calcium, etc.); hence peripheral metabolism of hormone, although responsible for rapid clearance of secreted hormone, appears to be a high-capacity, metabolically invariant catabolic process.

The rate of clearance of the secreted 84-amino-acid peptide from blood is more rapid than the rate of clearance of the biologically inactive fragment(s) corresponding to the middle- and carboxyl-terminal regions of PTH. Consequently, the interpretation of PTH immunoassays is influenced by the nature of the peptide fragments detected by the antibodies. Before the introduction of double-antibody assays designed to detect intact, biologically active hormone, most immunoassays also measured biologically inert long-lived fragments. Changes in the rate of production or clearance of fragments therefore alter the concentration of immunoreactive hormone.

Although the problems inherent in PTH measurements have been largely circumvented by use of double-antibody assays that detect only the intact molecule, new evidence has revealed the existence of a hitherto unappreciated larger PTH fragment that may affect the interpretation of most currently available double-antibody assays as well. A large amino-terminally truncated form of PTH, possibly PTH(7-84), is present in normal and uremic individuals in addition to PTH(1-84). The concentration of the putative 7-84 fragment relative to that of intact PTH(1-84) is higher with induced hypercalcemia (e.g., in uremic patients) than in eucalcemic or hypocalcemic conditions. The large fragment almost certainly cannot have (on the basis of structure-activity studies with PTH discussed above) much, if any, of the biologic potency of PTH. The suggestion that the

PTH(7-84)-like fragment might act as an inhibitor of PTH action remains to be clarified. The identification of this fragment has clinical significance, particularly in renal failure, as efforts to prevent secondary hyperparathyroidism by a variety of measures (vitamin D analogues, higher calcium intake, and phosphate-lowering strategies) may have led to oversuppression of biologically active intact PTH when the presence of the amino-terminally truncated PTH was not appreciated. The role, if any, of excessive PTH suppression due to inaccurate measurement of PTH in adynamic bone disease in renal failure (see below) is unknown. Newer assays with extreme amino-terminal epitopes are being studied intensively.

PARATHYROID HORMONE-RELATED PROTEIN

The paracrine factor termed *PTHrP* is responsible for most instances of hypercalcemia of malignancy, a syndrome that resembles hyperparathyroidism. Many different cell types producePTHrP, including brain, pancreas, heart, lung, mammary tissue, placenta, endothelial cells, and smooth muscle. In fetal animals, PTHrP directs transplacental calcium transfer, and high concentrations of PTHrP are produced in mammary tissue and secreted into milk. Human and bovine milk, for example, contain very high concentrations of the hormone; the biologic significance of the latter is unknown. PTHrP may also play a role in uterine contraction and other biologic functions, still being clarified in other tissue sites.

PTHandPTHrP, although distinctive products of different genes, exhibit considerable functional and structural homology (Fig. 341-1) and may have evolved from a shared ancestral gene. The structure of the gene for human PTHrP, however, is more complex than that of PTH, containing multiple exons and multiple sites for alternate splicing patterns during formation of the mRNA. Protein products of 141, 139, and 173 amino acids are produced, and other molecular forms may result from tissue-specific degradation at accessible internal cleavage sites. The biologic roles of these various molecular species and the nature of the circulating forms of PTHrP are unclear. It is uncertain whether PTHrP circulates at any significant level in normal human adults; as a paracrine factor, PTHrP may be produced, act, and be destroyed locally within tissues. In adults PTHrP appears to have little influence on calcium homeostasis, except in disease states, when large tumors, especially of the squamous cell type, lead to massive overproduction of the hormone (Fig. 341-1).

PTH AND PTHRP HORMONE ACTION

BecausePTHrPshares a significant homology withPTH in the critical amino terminus, it binds to and activates the PTH/PTHrP receptor, indistinguishably from effects seen with PTH. The 500-amino-acid PTH/PTHrP receptor (also known as the PTH1 receptor) belongs to a subfamily ofGPCRthat includes those for glucagon, secretin, and vasoactive intestinal peptide. The extracellular regions are involved in hormone binding, and the intracellular domains, after hormone activation, bind G protein subunits to transduce hormone signaling into cellular responses through stimulation of second messengers (Fig. 341-2). A second PTH receptor (PTH2 receptor) is expressed in brain, pancreas, and several other tissues. Its amino acid sequence and the pattern of its binding and stimulatory response to PTH and PTHrP differ from those of the PTH1 receptor. The PTH/PTHrP receptor responds equivalently to PTH and PTHrP, whereas

the PTH2 receptor responds only to PTH. The endogenous ligand and the physiologic significance of this receptor are not completely defined.

The PTH1 and PTH2 receptors can be traced backward in evolutionary time to fish. The zebrafish PTH1 and PTH2 receptors exhibit the same selective responses toPTH andPTHrP as do the human PTH1 and PTH2 receptors. The evolutionary conservation of structure and function suggests unique biologic roles for these receptors. Recently, a 39-amino-acid hypothalamic peptide, tubular infundibular peptide (TIP-39), has been characterized and is a likely natural ligand of the PTH2 receptor.

G proteins of the G_s class link thePTH/PTHrPreceptor to adenylate cyclase, an enzyme that generates cyclic AMP, leading to activation of protein kinase A. Coupling to G proteins of the G_q class links hormone action to phospholipase C, an enzyme that generates inositol phosphates (e.g.,IP_3) and DAG, leading to activation of protein kinase C and intracellular calcium release (Fig. 341-2). Studies using the cloned PTH/PTHrP receptor confirm that it can be coupled to more than one G protein and second-messenger kinase pathway, apparently explaining the multiplicity of pathways stimulated by PTH. Incompletely characterized second-messenger responses may be independent of phospholipase C or adenylate cyclase stimulation (the latter, however, is the strongest and best characterized second messenger signaling pathway for PTH).

The details of the biochemical steps by which an increased intracellular concentration of cyclic AMP,IP_3,DAG, and intracellular Ca^{2+}lead to ultimate changes inECFcalcium and phosphate ion translocation or bone cell function are unknown. Stimulation of protein kinases (A and C) and calcium transport channels is associated with a variety of hormone-specific tissue responses. These responses include inhibition of phosphate and bicarbonate transport, stimulation of calcium transport, and activation of renal 1a-hydroxylase in the kidney. The responses in bone include effects on collagen synthesis; increased alkaline phosphatase, ornithine decarboxylase, citrate decarboxylase, and glucose-6-phosphate dehydrogenase activities; DNA, protein, and phospholipid synthesis; and calcium and phosphate transport. Ultimately, these biochemical events lead to an integrated hormonal response in bone turnover and calcium homeostasis.

PTHalso activates Na^+/Ca^{2+}exchanges in renal distal tubular sites and stimulates translocation of preformed calcium transport channels, moving them from the interior to the apical surface to mediate increased tubular uptake of calcium. PTH-dependent stimulation of phosphate excretion (blocking reabsorption -- the opposite effect from actions on calcium in the kidney) involves the sodium-dependent phosphate cotransporter, NPT-2, lowering its apical membrane content (and therefore function). Similar shifts may be involved in other renal tubular transport effects of PTH.

PTHrP exerts important developmental influences on fetal bone development and in adult physiology. A homozygous knockout of the PTHrP gene (or the gene for thePTHreceptor) in mice causes a lethal deformity in which animals are born with severe skeletal deformities resembling chondrodysplasia (Fig. 341-3).

CALCITONIN (See also Chap. 339)

Calcitonin is a hypocalcemic peptide hormone that in several mammalian species acts as the physiologic antagonist toPTH. Calcitonin seems to be of limited physiologic significance in humans, at least in calcium homeostasis, as contrasted with a clearly definable role in calcium metabolism in many other mammalian species. Calcitonin is of medical significance, however, because of its role as a tumor marker in sporadic and hereditary cases of medullary carcinoma and its medical use as an adjunctive treatment in severe hypercalcemia and in Paget's disease of bone.

The hypocalcemic activity of calcitonin is accounted for primarily by inhibition of osteoclast-mediated bone resorption and secondarily by stimulation of renal calcium clearance. These effects are mediated by receptors on osteoclasts and renal tubular cells. Calcitonin exerts additional effects through receptors present in brain, gastrointestinal tract, and the immune system. The hormone, for example, exerts analgesic effects directly on cells in the hypothalamus and related structures, possibly by interacting with receptors for related peptide hormones, such as calcitonin gene-related peptide (CGRP) or amylin. The latter ligands have specific high-affinity receptors and also can bind to and trigger calcitonin receptors. The calcitonin receptors are homologous in structure to thePTH/PTHrPreceptor.

The thyroid is the major source of the hormone, and the cells involved in calcitonin synthesis arise from neural crest tissue. During embryogenesis, these cells migrate into the ultimobranchial body, derived from the last branchial pouch. In submammalian vertebrates, the ultimobranchial body constitutes a discrete organ, anatomically separate from the thyroid gland; in mammals, the ultimobranchial gland fuses with and is incorporated into the thyroid gland.

The naturally occurring calcitonins consist of a peptide chain of 32 amino acids. There is considerable sequence variability among species. Calcitonin from salmon is 10 to 100 times more potent than mammalian forms in lowering serum calcium in animals. Calcitonin is synthesized as a precursor molecule that is four times larger than calcitonin itself. Analysis of the sequence of the coding portions of the gene for rat calcitonin indicates that at least two peptides flank calcitonin. It is likely (by analogy with the common precursor for adrenocorticotropic hormone and endorphin) that these peptides, of still uncharacterized biologic function, are released along with calcitonin.

There are two calcitonin genes,a and b, located on chromosome 11 in the general region of the b-globulin and PTHgenes; the transcriptional control of these genes is complex. Two different mRNA molecules are transcribed from the a gene; one is translated into the precursor for calcitonin, and the other message is translated into an alternative product,CGRP. CGRP is synthesized wherever the calcitonin mRNA is expressed, e.g., in medullary carcinoma of the thyroid. The b, or CGRP-2, gene is transcribed into the mRNA for CGRP in the central nervous system (CNS); this gene does not produce calcitonin, however. CGRP has cardiovascular actions and may serve as a neurotransmitter or play a developmental role in the CNS.

The secretion of calcitonin is under the direct control of blood calcium. The circulating level of calcitonin in humans is lower than that in many other species. In humans, changes in calcium and phosphate metabolism are not seen despite extreme variations in calcitonin production; no definite effects are attributable to calcitonin deficiency (totally

thyroidectomized patients receiving only replacement thyroxine) or excess (patients with medullary carcinoma of the thyroid, a calcitonin-secreting tumor) (Chap. 339). Although there are no obvious abnormalities in calcium metabolism in patients with elevated calcitonin levels, bone remodeling is chronically suppressed. Calcitonin has been a useful pharmacologic agent to suppress bone resorption in Paget's disease (Chap. 343), has had limited use in the treatment of osteoporosis (Chap. 342), and is useful in early phases of treatment of severe hypercalcemia (see below).

HYPERCALCEMIA

Hypercalcemia can be a manifestation of a serious illness such as malignancy or can be detected coincidentally by laboratory testing in a patient with no obvious illness. The number of patients recognized with asymptomatic hypercalcemia, usually hyperparathyroidism, increased in the late twentieth century but is now declining somewhat, perhaps due to decreased use of routine blood calcium measurements or for other unknown reasons.

Whenever hypercalcemia is confirmed, a definitive diagnosis must be established. Although hyperparathyroidism, a frequent cause of asymptomatic hypercalcemia, is a chronic disorder in which manifestations, if any, may be expressed only after months or years, hypercalcemia can also be the earliest manifestation of malignancy, the second most common cause of hypercalcemia in the adult. The causes of hypercalcemia are numerous (Table 341-1), but hyperparathyroidism and cancer account for 90% of cases.

Before undertaking a workup, it is essential to be sure that true hypercalcemia, not a false-positive laboratory test, is present. A false-positive diagnosis of hypercalcemia is usually the result of inadvertent hemoconcentration during blood collection or elevation in serum proteins such as albumin. Hypercalcemia is a chronic problem, and it is cost-effective to obtain several serum calcium measurements; these tests need not be in the fasting state.

Clinical features are helpful in differential diagnosis. Hypercalcemia in an adult who is asymptomatic is usually due to primary hyperparathyroidism. In malignancy-associated hypercalcemia the disease is usually not occult; rather, symptoms of malignancy bring the patient to the physician, and hypercalcemia is discovered during the workup. In such patients the interval between detection of hypercalcemia and death is often<6 months. Accordingly, if an asymptomatic individual has had hypercalcemia or some manifestation of hypercalcemia, such as kidney stones, for >1 or 2 years, it is unlikely that malignancy is the cause. Nevertheless, differentiating primary hyperparathyroidism from *occult* malignancy can occasionally be difficult, and careful evaluation is required, particularly when the duration of the hypercalcemia is unknown. Hypercalcemia not due to hyperparathyroidism or malignancy can result from excessive vitamin D action, high bone turnover from any of several causes, or from renal failure (Table 341-1). Dietary history and a history of ingestion of vitamins or drugs are often helpful in diagnosing some of the less frequent causes.PTHimmunoassays based on double-antibody methods serve as the principal laboratory test in differential diagnosis.

Hypercalcemia from any cause can result in fatigue, depression, mental confusion,

anorexia, nausea, vomiting, constipation, reversible renal tubular defects, increased urination, a short QT interval in the electrocardiogram, and, in some patients, cardiac arrhythmias. There is a variable relation from one patient to the next between the severity of hypercalcemia and the symptoms. Generally, symptoms are more common at calcium levels >2.9 to 3 mmol/L (11.5 to 12.0 mg/dL), but some patients, even at this level, are asymptomatic. When the calcium level is >3.2 mmol/L (13 mg/dL), calcification in kidneys, skin, vessels, lungs, heart, and stomach occurs and renal insufficiency may develop, particularly if blood phosphate levels are normal or elevated due to impaired renal function. Severe hypercalcemia, usually defined as ³3.7 to 4.5 mmol/L (15 to 18 mg/dL) can be a medical emergency; coma and cardiac arrest can occur.

Except in malignancy-associated hypercalcemia, acute management of the hypercalcemia is usually successful prior to definitive therapy. The type of treatment is based on the severity of the hypercalcemia and the nature of associated symptoms.

PRIMARY HYPERPARATHYROIDISM

Natural History and Incidence Primary hyperparathyroidism is a generalized disorder of calcium, phosphate, and bone metabolism due to an increased secretion ofPTH. The elevation of circulating hormone usually leads to hypercalcemia and hypophosphatemia. There is great variation in the manifestations. Patients may present with multiple signs and symptoms, including recurrent nephrolithiasis, peptic ulcers, mental changes, and, less frequently, extensive bone resorption. However, with greater awareness of the disease and wider use of multiphasic screening tests, including blood calcium assays, the diagnosis is frequently made in patients who have no symptoms and minimal, if any, signs of the disease other than hypercalcemia and elevated levels of PTH. The manifestations may be subtle, and the disease may have a benign course for many years or a lifetime. Rarely, hyperparathyroidism develops or worsens abruptly and causes severe complications, such as marked dehydration and coma, so-called hypercalcemic parathyroid crisis.

The annual incidence of the disease is estimated to be as high as 0.2% in patients>60, with an estimated prevalence, including undiscovered asymptomatic patients, of ³1%. The disease has a peak incidence between the third and fifth decades but occurs in young children and in the elderly.

Etiology

Solitary Adenomas The cause of hyperparathyroidism is one or more hyperfunctioning glands. The traditional view has been that a single abnormal gland is the cause in approximately 80% of patients; the abnormality in the gland is usually a benign neoplasm or adenoma and rarely a parathyroid carcinoma. Some surgeons and pathologists report that the enlargement of multiple glands is common; double adenomas are reported. In approximately 15% of patients, all glands are hyperfunctioning; *chief cell parathyroid hyperplasia* is usually hereditary and frequently associated with other endocrine abnormalities.

Multiple Endocrine Neoplasia Hereditary hyperparathyroidism can occur without other endocrine abnormalities but is usually part of a *multiple endocrine neoplasia* syndrome

(Chap. 339).MEN 1 (Wermer's syndrome) consists of hyperparathyroidism and tumors of the pituitary and pancreas, often associated with gastric hypersecretion and peptic ulcer disease (Zollinger-Ellison syndrome). MEN 2A is characterized by pheochromocytoma and medullary carcinoma of the thyroid, as well as hyperparathyroidism; MEN 2B has additional associated features such as multiple neuromas but usually lacks hyperparathyroidism. Each of these MEN syndromes is transmitted in an autosomal dominant manner.

Pathology Adenomas are most often located in the inferior parathyroid glands, but in 6 to 10% of patients, parathyroid adenomas may be located in the thymus, the thyroid, the pericardium, or behind the esophagus. Adenomas are usually 0.5 to 5 g in size but may be as large as 10 to 20 g (normal glands weigh 25 mg on average). Chief cells are predominant in both hyperplasia and adenoma. The adenoma is sometimes encapsulated by a rim of normal tissue. With chief cell hyperplasia, the enlargement may be so asymmetric that some involved glands appear grossly normal. If generalized hyperplasia is present, however, histologic examination reveals a uniform pattern of chief cells and disappearance of fat even in the absence of an increase in gland weight. Thus, microscopic examination of biopsy specimens of several glands is essential to interpret findings at surgery. When an adenoma is present, the other glands are usually normal and contain a normal distribution of all cell types (rather than only chief cells) and normal amounts of fat.

Parathyroid carcinoma is usually not aggressive in character. Long-term survival without recurrence is common if at initial surgery the entire gland is removed without rupture of the capsule. Recurrent parathyroid carcinoma is usually slow-growing with local spread in the neck, and surgical correction of recurrent disease may be feasible. Occasionally, however, parathyroid carcinoma is more aggressive, with distant metastases (lung, liver, and bone) found at the time of initial operation. It may be difficult to appreciate initially that a primary tumor is carcinoma; increased numbers of mitotic figures and increased fibrosis of the gland stroma may precede invasion. The diagnosis of carcinoma is often made in retrospect. Hyperparathyroidism from a parathyroid carcinoma may be indistinguishable from other forms of primary hyperparathyroidism; a potential clue to the diagnosis, however, is provided by the degree of calcium elevation. Calcium values of 3.5 to 3.7 mmol/L (14 to 15 mg/dL) are frequent with carcinoma and may alert the surgeon to remove the abnormal gland with care to avoid capsular rupture.

GENETIC CONSIDERATIONS

Defects Associated with Hyperparathyroidism As in many other types of neoplasia, two fundamental types of genetic defects have been identified in parathyroid gland tumors: (1) overactivity of protooncogenes, and (2) loss of function of tumor suppressor genes. The former, by definition, can lead to uncontrolled cellular growth and function by activation (gain-of-function mutation) of a single allele of the responsible gene, whereas the latter requires loss of function of both allelic copies.

Mutations in the *MENIN* gene locus on chromosome 11q13 are responsible for causingMEN 1; the normal allele of this gene fits the definition of a tumor suppressor gene. A mutation of one allele is inherited; loss of the other allele via somatic cell mutation leads to monoclonal expansion and tumor development in tissues such as the

parathyroids. In approximately 20% of sporadic parathyroid adenomas, the *MENIN* locus on chromosome 11 appears to be deleted, implying that the same defect responsible for MEN 1 can also cause the sporadic disease (Fig. 341-4*A*). Consistent with the Knudson hypothesis for two-step neoplasia in certain inherited cancer syndromes (Chap. 81), the earlier onset of hyperparathyroidism in the hereditary syndromes reflects the statistical probability of only one mutational event triggering the monoclonal outgrowth. In sporadic adenomas, typically occurring later in life, two different somatic events must occur before the *MENIN* gene is silenced.

The *MENIN* gene codes for a novel protein consisting of 610 amino acids. The protein has a nuclear localization signal and appears to interact with the transcription factor Jun D. Most of the mutations are clearly of the inactivating type (nonsense, deletions); there is not, however, a good correlation between clinical features in different kindreds and the specific mutation detected (e.g., penetrance or age of onset of pituitary or pancreatic tumors). This is in contrast to the correlation between genotype and phenotype in MEN 2 (see below).

Other presumptive antioncogenes involved in hyperparathyroidism include a gene mapped to chromosome 1p seen in 40% of sporadic parathyroid adenomas and a gene mapped to chromosome Xp11 in patients with secondary hyperparathyroidism and renal failure, who progressed to "tertiary" hyperparathyroidism, now known to reflect monoclonal outgrowths within previously hyperplastic glands.

The *Rb* gene, a tumor suppressor gene located on chromosome 13q14, was initially associated with retinoblastomas but has since been implicated in many other forms of neoplasia including parathyroid carcinoma. Allelic deletion (with a presumed point mutation in the second allele) has been identified in all parathyroid carcinomas examined; there is also an abnormal staining pattern of the protein product of the gene. Allelic deletion is also seen in 10% of parathyroid adenomas, although the abnormal staining pattern of the Rb protein is not seen. Other gene loci on chromosome 13 may be involved in addition to the *Rb* locus.

There are two rare syndromes associated with hyperparathyroidism that involve one or more genes located on chromosome 1q. The hereditary hyperparathyroidism jaw tumor (HPT-JT) syndrome shows an autosomal dominant inheritance pattern; the jaw tumors are benign, but the parathyroid pathology may involve carcinoma as well as adenoma. Parathyroid carcinoma may also appear in the other syndrome, familial isolated primary hyperparathyroidism (FIPH). Both syndromes have been mapped through linkage studies to the chromosome 1q21-q31 region. Certain findings have led to speculation that this chromosome region might contain a protooncogene rather than an antioncogene.

In some parathyroid adenomas, activation of a protooncogene has been identified (Fig. 341-4*B*). A reciprocal translocation involving chromosome 11 has been identified that juxtaposes thePTH gene promoter upstream of a gene product termed *PRAD-1*, a cyclin D protein that plays a key role in normal cell division. This translocation is found in as many as 15% of parathyroid adenomas, usually in larger tumors. Targeted overexpression of cyclin D_1 in the parathyroid glands of transgenic mice causes the development of hyperparathyroidism, consistent with the role of this cell cycle control

protein in parathyroid neoplasia.

A mutated protooncogene, *RET*, is involved in each of the clinical variants ofMEN2 (Chap. 339). *RET* encodes a tyrosine kinase-type receptor; specific mutations lead to constitutive activity of the receptor, thereby explaining the autosomal dominant mode of transmission and the relatively early onset of neoplasia.

Signs and Symptoms Half or more of patients with hyperparathyroidism are asymptomatic. In series in which patients are followed without operation, as many as 80% are classified as without symptoms. Manifestations of hyperparathyroidism involve primarily the kidneys and the skeletal system. Kidney involvement, due either to deposition of calcium in the renal parenchyma or to recurrent nephrolithiasis, was present in 60 to 70% of patients prior to 1970. With earlier detection, renal complications occur in<20% of patients in many large series. Renal stones are usually composed of either calcium oxalate or calcium phosphate. In occasional patients, repeated episodes of nephrolithiasis or the formation of large calculi may lead to urinary tract obstruction, infection, and loss of renal function. Nephrocalcinosis may also cause decreased renal function and phosphate retention.

The distinctive bone manifestation of hyperparathyroidism is *osteitis fibrosa cystica*, which in series reported 50 years ago occurred in 10 to 25% of patients. In recent years, osteitis fibrosa cystica is very rare in primary hyperparathyroidism, probably due to the increased incidence of mild disease. Histologically, the pathognomonic features are an increase in the giant multinucleated osteoclasts in scalloped areas on the surface of the bone (Howship's lacunae) and a replacement of the normal cellular and marrow elements by fibrous tissue. X-ray changes include resorption of the phalangeal tufts and replacement of the usually sharp cortical outline of the bone in the digits by an irregular outline (subperiosteal resorption).

With the use of multiple markers of bone turnover, such as formation indices (bone-specific alkaline phosphatase, osteocalcin, and type I procollagen peptides) and bone resorption indices (including hydroxypyridinium collagen cross-links and telopeptides of type I collagen), increased skeletal turnover is detected in essentially all patients with established hyperparathyroidism.

Computed tomography (CT) scan and dual-energy x-ray absorptiometry (DEXA) of the spine provide reproducible quantitative estimates (within a few percent) of spinal bone density (Chap. 342). Similarly, cortical bone density in the extremities can be quantified by single-photon densitometry, usually of the distal radius at a site chosen to be primarily cortical. Studies reveal that cortical bone density is reduced while cancellous bone density, especially in the spine, is relatively preserved. Serial studies in patients who choose to be followed without surgery have indicated that in the majority there is little further change over a number of years, consistent with laboratory data indicating relatively unchanged blood calcium andPTHlevels. After an initial loss of bone mass in patients with mild asymptomatic hyperparathyroidism, a new equilibrium may be reached, with bone density and biochemical manifestations of the disease remaining relatively unchanged. This clinical course has led to the recommendations (discussed below) that asymptomatic patients may be safely followed with medical supervision. Certain recent findings have raised questions about the impact of asymptomatic

hyperparathyroidism on the skeleton, however. In one careful, long-term study, parathyroidectomy led to improvements in bone density in the spine and hip in 10 to 15% of patients; the improved bone density has been maintained for a number of years of follow-up. Another group compared fracture incidence in a large cohort of hyperparathyroid patients followed for years without surgery versus those seen in an age- and sex-matched control population. The incidence of fractures of the spine, wrist, and ribs was significantly increased in the hyperparathyroid group (although there were no data available on bone density).

In symptomatic patients, dysfunctions of the central nervous system, peripheral nerve and muscle, gastrointestinal tract, and joints also occur. An awareness of the signs and symptoms of hyperparathyroidism may give the initial clue to the diagnosis. It has been reported that severe neuropsychiatric manifestations may be reversed by parathyroidectomy; it remains unclear, in the absence of controlled studies, whether this improvement has a defined cause-and-effect relationship. Generally, the fact that hyperparathyroidism is common in elderly patients, in whom there are often other problems, suggests the possibility that such coexisting problems as hypertension, renal deterioration, and depression may not be parathyroid-related and suggests caution in recommending parathyroid surgery as a cure for these conditions.

Neuromuscular manifestations may include proximal muscle weakness, easy fatigability, and atrophy of muscles and may be so striking as to suggest a primary neuromuscular disorder. The distinguishing feature is the complete regression of neuromuscular disease after surgical correction of the hyperparathyroidism.

Gastrointestinal manifestations are sometimes subtle and include vague abdominal complaints and disorders of the stomach and pancreas. Again, cause and effect are unclear. InMEN 1 patients with hyperparathyroidism, duodenal ulcer may be the result of associated pancreatic tumors that secrete excessive quantities of gastrin (Zollinger-Ellison syndrome). Pancreatitis has been reported in association with hyperparathyroidism, but the incidence and the mechanism are not established.

Chondrocalcinosis and pseudogout are said to be sufficiently frequent in hyperparathyroidism that screening of such patients is warranted. Occasionally, pseudogout is the initial manifestation.

Diagnosis The diagnosis is typically made by detecting an elevated immunoreactivePTHlevel in a patient with asymptomatic hypercalcemia (see "Differential Diagnosis: Special Tests," below). Serum phosphate is usually low but may be normal, especially if renal failure has developed. Hypophosphatemia is a less specific diagnostic finding than hypercalcemia for two reasons: (1) phosphate levels are influenced by dietary intake, diurnal variations, and other factors; to be useful, samples must be obtained in the morning under fasting conditions; and (2) patients with severe hypercalcemia of any cause may have a low serum phosphate.

Many tests based on renal responses to excessPTH(renal calcium and phosphate clearance; blood phosphate, chloride, magnesium; urinary or nephrogenous cyclic AMP) were used in earlier decades. These tests have low specificity for hyperparathyroidism and are therefore not cost-effective; they have been replaced by PTH immunoassays.

TREATMENT

Medical Treatment Management of hyperparathyroidism involves two separate issues. The critical question is whether the disease should be treated surgically. If severe hypercalcemia [3.7 to 4.5 mmol/L (15 to 18 mg/dL)] is present, surgery is mandatory as soon as the diagnosis can be confirmed by aPTHimmunoassay. However, in most patients with hyperparathyroidism, hypercalcemia is mild and does not require urgent surgical or medical treatment.

Several hundred patients have been closely followed without surgery in attempts to define the natural history of the disease and the benefits of surgery versus the risks of medical observation. Large-scale randomized, prospective clinical trials have not been undertaken, however. Rather, the long-term effects of hyperparathyroidism have been assessed in patients who do not have kidney stones, osteitis fibrosa cystica, or other clear-cut symptoms. Progressive loss of bone mass is a worrisome problem in women who face the problem of age-dependent and estrogen-deficient bone loss in the absence of hyperparathyroidism. The principal concern is that such patients, even though asymptomatic, will suffer sufficient bone loss due toPTHexcess to make them more vulnerable to developing symptomatic osteoporosis.

The National Institutes of Health held a Consensus Conference on Management of Asymptomatic Hyperparathyroidism in 1991. *Asymptomatic hyperparathyroidism* was defined as documented (presumptive) hyperparathyroidism without signs or symptoms attributable to the disease. The consensus was that patients <50 should undergo surgery, given the long surveillance that would be required. Patients>50 are appropriate for medical monitoring if certain criteria are met and the patients wish to avoid surgery. Guidelines for recommending surgery in patients with asymptomatic hyperparathyroidism include the following:

1. Elevation of serum calcium,>0.25 to 0.40 mmol/L (1 to 1.6 mg/dL) above the upper limit of normal for the test laboratory.

2. History of life-threatening hypercalcemia, such as an episode induced by dehydration and recurring illness.

3. Reduction of age-matched creatinine clearance by >30% without a known cause. Presence of kidney stones detected by abdominal radiograph even if they are asymptomatic.

4. Elevation of 24-h urinary calcium excretion >400 mg.

5. Reduction of bone mass more than 2 standard deviations below normal using one of several noninvasive methods.

Other considerations that favor surgery include concern that consistent follow-up would be unlikely or that coexistent illness would complicate management. More recent data indicated that a subgroup of patients had selective vertebral osteopenia out of proportion to bone loss at other sites and responded to surgery with striking restoration

of bone mass (average >20%), suggesting that such patients might also be recommended for surgery. Asymptomatic patients should be monitored regularly. Surgical correction of hyperparathyroidism can always be undertaken when indicated, since the success rate is high (>90%), mortality is low, and morbidity is minimal. The goals of monitoring are early detection of worsening hypercalcemia, deteriorating bone or renal status, or other complications of hyperparathyroidism.

The consensus panel did not make a recommendation as to estrogen use in patients for whom surgery was not elected because there was insufficient cumulative experience with such therapy to balance theoretical risks (breast and endometrial cancer) versus benefits. New medical therapies may change the approach to the disease in the future. Raloxifene (Evista), the first of theSERMS, has been shown to have many of the bone protective effects of estrogen in osteoporotic subjects yet at the same time lowers the incidence of breast cancer; use of this agent has not yet been reported in a series of hyperparathyroid patients, however. Early experience with calcimimetics, drugs that selectively stimulate the calcium sensor and suppressPTHsecretion, indicates that these agents decrease PTH levels for several hours after a single dose.

European investigators have reported serious cardiovascular complications in patients with hyperparathyroidism that reverse, at least in part, after surgery. They also found an increased incidence of malignancy and an absolute increase in age-adjusted mortality due to hyperparathyroidism. These reports clearly describe experiences in a group of patients with more advanced disease, at least based on laboratory tests such as bloodPTHlevels, than the patients followed in the United States. In fact, a recent long-term epidemiologic study of a large cohort of patients in the United States, with a milder form of the disease (fitting the criteria for medical surveillance listed above), had an age-adjusted mortality no different than that of euparathyroid patients and no increased incidence of malignancy.

Surgical Treatment Parathyroid exploration is challenging and is best undertaken by an experienced surgeon with the help of an experienced pathologist. Certain features help in predicting the pathology (e.g., multiple abnormal glands in familial cases). However, some critical decisions regarding management can be made only during the operation. The examination by frozen section of tissue removed at surgery helps direct the subsequent course of the operation.

As discussed above, there are many unresolved issues to consider in surgery for this disease. At the extreme of conservatism, the surgical approach is based on the view that typically only one gland (the adenoma) is abnormal. If an enlarged gland is found, a normal gland should be sought. In this view, if a biopsy of a normal-sized second gland confirms its histologic (and presumed functional) normality, no further exploration, biopsy, or excision is needed. At the other extreme is the minority viewpoint that all four glands be sought and that most of the total parathyroid tissue mass should be removed. The concern with the former approach is that the recurrence rate of hyperparathyroidism may be high if a second abnormal gland is missed; the latter approach could involve unnecessary surgery and an unacceptable rate of hypoparathyroidism. The majority viewpoint, judged by surgical reviews, is in favor of conservative surgery, i.e., removal of what is usually only one enlarged gland but only after four-gland exploration to eliminate the possibility that more than one gland is abnormal. When normal glands are found in

association with one enlarged gland, excision of the single adenoma usually leads to cure or symptom-free disease, although long-term follow-up studies are limited.

Surgical management has been enhanced recently by the use of preoperative ^{99m}Tc sestamibi scans to predict the location of an abnormal gland and intraoperative sampling of PTH before and at 5- to 15-min intervals after removal of a suspected adenoma to confirm a rapid fall (>50%) in PTH levels. In several centers, a combination of preoperative sestamibi imaging, cervical block anesthesia, minimal surgical incision, and intraoperative PTH measurements has allowed successful outpatient surgical management with a clear-cut cost benefit compared to general anesthesia and more extensive neck surgery. The use of these minimally invasive approaches requires clinical judgment to select patients unlikely to have multiple gland disease (e.g., MEN or secondary hyperparathyroidism).

Multiple gland hyperplasia, as predicted in familial cases, poses more difficult questions of surgical management. Once a diagnosis of hyperplasia is established, all the glands must be identified. Two schemes have been proposed for surgical management. One is that three glands be totally removed and the fourth gland be partially excised; care is taken to leave a good blood supply for the remaining gland. Other surgeons advocate total parathyroidectomy with immediate transplantation of a portion of a removed, minced parathyroid gland into the muscles of the forearm, with the view that surgical excision is easier from the ectopic site in the arm if there is recurrent hyperfunction. When parathyroid carcinoma is encountered, the tissue should be widely excised; care must be taken to avoid rupture of the capsule to prevent local seeding of tumor cells.

In a minority of cases, if no abnormal parathyroid glands are found in the neck, the issue of further exploration must be decided. There are documented cases of five or six parathyroid glands and of unusual locations for adenomas, such as in the mediastinum. A variety of techniques have been developed to aid in the preoperative localization of the abnormal parathyroid tissue. Usually these techniques are reserved for patients with initial unsuccessful neck explorations, since the combined success of the localization techniques is not better than that of an experienced parathyroid surgeon in finding the abnormal tissue at the first operation. Noninvasive or minimally invasive techniques include ultrasound, CT scan of the neck and mediastinum, and differential scanning after technetium-sestamibi administration.

When a second parathyroid exploration is indicated, the minimally invasive techniques such as ultrasound, CT scan, and isotope scanning should probably be combined with venous sampling and/or selective digital arteriography in one of the centers specializing in these techniques. Intraoperative monitoring of PTH levels by rapid PTH immunoassays may be useful in guiding the surgery, especially in patients who are reexplored after an initial unsuccessful operation. At one center, long-term cures have been achieved with selective embolization or injection of large amounts of contrast material into the end-arterial circulation feeding the parathyroid tumor.

A decline in serum calcium occurs within 24 h after successful surgery; usually blood calcium falls to low-normal values for 3 to 5 days until the remaining parathyroid tissue resumes hormone secretion. Severe postoperative hypocalcemia is likely only if osteitis fibrosa cystica is present or if injury to all the normal parathyroid glands occurs during

surgery.

In general, patients who do not have symptomatic bone disease or a large deficit in bone mineral and who have good renal and gastrointestinal function have few problems with postoperative hypocalcemia. The extent of postoperative hypocalcemia varies with the surgical approach. If all glands are biopsied, hypocalcemia may be transiently symptomatic and more prolonged. Hypocalcemia is more likely to be symptomatic after second parathyroid explorations, particularly when normal parathyroid tissue was removed at the initial operation and when the manipulation and/or biopsy of the remaining normal glands is more extensive in the search for the missing adenoma.

Patients with hyperparathyroidism have efficient intestinal calcium absorption due to the increased levels of 1,25$(OH)_2$D stimulated by PTH excess. Once hypocalcemia signifies successful surgery, patients can be put on a high-calcium intake or be given oral calcium supplements. Despite mild hypocalcemia, most patients do not require parenteral therapy. If the serum calcium falls to <2 mmol/L (8 mg/dL), *and if the phosphate level rises simultaneously*, the possibility that surgery has caused hypoparathyroidism must be considered. Coexistent hypomagnesemia should be checked for, as it interferes with PTH secretion and causes functional hypoparathyroidism (see below). Parenteral calcium replacement at a low level should be instituted when hypocalcemia is symptomatic. Such indications include a general sense of anxiety and positive Chvostek and Trousseau signs coupled with serum calcium consistently <2 mmol/L (8 mg/dL). For parenteral therapy, calcium (gluconate or chloride) solutions are prepared at a concentration of 1 mg/mL in 5% dextrose in water. The rate and duration of intravenous therapy are determined by the severity of the symptoms and the response of the serum calcium. An infusion of 0.5 to 2 (mg/kg)/h or 30 to 100 mL/h of a 1-mg/mL solution usually suffices to relieve symptoms. Usually, parenteral therapy is required for only a few days. If symptoms worsen or if parenteral calcium is needed for >2 to 3 days, therapy with a vitamin D analogue and/or oral calcium (2 to 4 g/d) should be started (see below). It is cost-effective to use calcitriol (doses of 0.5 to 1.0 ug/d) because of the rapidity of onset and rapidity of cessation of action, in comparison to other forms of vitamin D (see below). A rise in blood calcium after several months of vitamin D replacement may indicate restoration of parathyroid function to normal. It is also appropriate to monitor serum PTH serially to estimate gland function in such patients.

Magnesium deficiency may also complicate the postoperative course. Magnesium deficiency impairs the secretion of PTH, and so hypomagnesemia should be corrected whenever detected. Magnesium chloride is effective by mouth, but this compound is not widely available. Repletion is usually parenteral. Because the depressant effect of magnesium on central and peripheral nerve functions does not occur at levels<2 mmol/L (normal range 0.8 to 1.2 mmol/L), parenteral replacement can be given rapidly. A cumulative dose as great as 0.5 to 1 mmol/kg of body weight can be administered if severe hypomagnesemia is present; often, however, total doses of 20 to 40 mmol are sufficient. The magnesium is given either as an intravenous infusion over 8 to 12 h or in divided doses intramuscularly (magnesium sulfate, USP).

OTHER PARATHYROID-RELATED CAUSES OF HYPERCALCEMIA

Lithium Therapy Lithium, used in the management of bipolar depression and other psychiatric disorders, causes hypercalcemia in approximately 10% of treated patients. The hypercalcemia is dependent on continued lithium treatment, remitting and recurring when lithium is stopped and restarted. The parathyroid adenomas reported in some hypercalcemic patients with lithium therapy may reflect the presence of an independently occurring parathyroid tumor; a permanent effect of lithium on parathyroid gland growth need not be implicated as most patients have complete reversal of hypercalcemia when lithium is stopped. However, long-standing stimulation of parathyroid cell replication by lithium may predispose to development of adenomas (as is documented in secondary hyperparathyroidism and renal failure).

The presence of hypercalcemia does not correlate with plasma lithium level, but the frequency with which hypercalcemia occurs is sufficiently high to support a causal relationship between lithium and the hypercalcemia, particularly the dependence of the hypercalcemia on the continuation of the lithium. At the levels achieved in blood in treated patients, lithium can be shown in vitro to shift thePTHsecretion curve in response to calcium to the right; i.e., higher calcium levels are required to lower PTH secretion, probably acting at the calcium sensor (see below). It is logical to assume that this effect can cause elevated PTH levels and consequent hypercalcemia in otherwise normal individuals. If persistent hypercalcemia is detected during lithium therapy, it may be necessary to try alternative medication for the underlying psychiatric illness. Parathyroid surgery should not be recommended unless hypercalcemia and elevated PTH levels persist after lithium is discontinued.

GENETIC DISORDERS CAUSING HYPERPARATHYROID-LIKE SYNDROMES

Familial Hypocalciuric Hypercalcemia FHH(also called *familial benign hypercalcemia*) is inherited as an autosomal dominant trait. Affected individuals are discovered because of asymptomatic hypercalcemia. This disorder and Jansen's disease (discussed below) are variants of hyperparathyroidism. FHH involves excessive secretion ofPTH, whereas Jansen's disease is caused by excessive biologic activity of the PTH receptor in target tissues. Neither disorder, however, involves a primary growth disorder of the parathyroids.

The pathophysiology ofFHH is now understood. The primary defect is abnormal sensing of the blood calcium by the parathyroid gland and renal tubule, causing inappropriate secretion ofPTH and excessive renal reabsorption of calcium (Fig. 341-5). The calcium sensor is a member of the third family ofGPCR(type C or III) and is located on chromosome 3. The receptor responds to theECFcalcium concentration, suppressing PTH secretion through second messenger signaling, thereby providing negative-feedback regulation of PTH secretion. More than 20 different mutations in the calcium-sensing receptor have been identified in patients with FHH (Fig. 341-6). These mutations lower the capacity of the sensor to bind calcium, and the mutant receptors function as though blood calcium levels are low; excessive secretion of PTH occurs from an otherwise normal gland. Approximately two-thirds of patients with FHH have mutations within the protein-coding region of the gene. The remaining one-third of kindreds may have mutations in the gene promoter or in other regions of the genome identified through mapping studies (e.g., chromosome 19).

Even before elucidation of the pathophysiology ofFHH, abundant clinical evidence served to separate the disorder from primary hyperparathyroidism. Patients with primary hyperparathyroidism have<99% renal calcium reabsorption, whereas most patients with FHH have >99% reabsorption. The hypercalcemia in FHH is often detectable in affected members of the kindreds in the first decade of life, whereas hypercalcemia rarely occurs in patients with primary hyperparathyroidism or theMENsyndromes who are <10.PTH may be elevated in FHH, but the values are usually normal or lower for the same degree of calcium elevation than in patients with primary hyperparathyroidism. Parathyroid surgery in a few patients with FHH led to permanent hypoparathyroidism, but hypocalciuria persisted nevertheless, establishing that hypocalciuria, therefore, is not PTH-dependent (now known to be due to the abnormal calcium sensor in the kidney).

Few clinical signs or symptoms are present in patients withFHH, and other endocrine abnormalities are not present. Most patients are detected as a result of family screening after hypercalcemia is detected in a proband. In those patients inadvertently operated upon, the parathyroids appeared normal or moderately hyperplastic. Parathyroid surgery is not appropriate, nor, in view of the lack of symptoms, does medical treatment seem needed to lower the calcium. Calcimimetic agents that bind to the calcium sensor and elevate the set point are under investigation.

One striking exception to the rule against parathyroid surgery in this syndrome is the occurrence, usually in consanguinous marriages (due to the rarity of gene), of a homozygous or compound heterozygote state, resulting in complete loss of the calcium sensor function. In this condition, neonatal severe hypercalcemia, total parathyroidectomy is mandatory.

Jansen's Disease Mutations in thePTH/PTHrPreceptor have been identified as responsible for this rare autosomal dominant syndrome(Fig. 341-7). Because the mutations lead to constitutive receptor function, one abnormal copy of the mutant receptor is sufficient to cause the disease, thereby accounting for its dominant mode of transmission. The disorder leads to short-limbed dwarfism due to abnormal regulation of the bone growth plate. In adult life, there are numerous abnormalities in bone, including multiple cystic resorptive areas resembling those seen in severe hyperparathyroidism. Hypercalcemia and hypophosphatemia with undetectable or low PTH levels are typically seen. The pathogenesis of the disease has been confirmed by transgenic experiments in which targeted expression of the mutant receptor to the growth plate emulated several features of the disorder.

MALIGNANCY-RELATED HYPERCALCEMIA

Clinical Syndromes and Mechanisms of Hypercalcemia Hypercalcemia due to malignancy is common (occurring with 10 to 15% of certain types of tumor, such as lung carcinoma), often severe and difficult to manage, confusing as to etiology, and sometimes difficult to distinguish from primary hyperparathyroidism. Although malignancy is often clinically obvious, hypercalcemia can occasionally be due to an occult tumor. Previously, hypercalcemia associated with malignancy was thought to be due to local invasion and destruction of bone by tumor cells; many cases are now known to result from the elaboration by the malignant cells of humoral mediators of hypercalcemia.PTHrP is the responsible humoral agent in most cases.

The histologic character of the tumor is more important than the extent of skeletal metastases in predicting hypercalcemia. Small cell carcinoma (oat cell) and adenocarcinoma of the lung, although the most common lung tumors associated with skeletal metastases, rarely cause hypercalcemia. By contrast, as many as 10% of patients with squamous cell carcinoma of the lung develop hypercalcemia. Histologic studies of bone in patients with squamous cell or epidermoid carcinoma of the lung, in sites invaded by tumor as well as areas remote from tumor invasion, reveal bone remodeling, including osteoclastic and osteoblastic activity. In contrast, minimal skeletal metabolic activation occurs even if there are extensive skeletal metastases of small cell (oat cell) carcinoma.

Two main mechanisms of hypercalcemia are operative in cancer hypercalcemia. Many solid tumors associated with hypercalcemia, particularly squamous cell and renal tumors, produce and secrete humoral factors that cause increased bone resorption and mediate the hypercalcemia through systemic actions on the skeleton. Alternatively, direct bone marrow invasion occurs with hematologic malignancies such as leukemia, lymphoma, and multiple myeloma. Lymphokines and cytokines produced by cells involved in the marrow response to the tumors promote resorption of bone through local destruction. Several hormones, hormone analogues, cytokines, and growth factors have been implicated as the result of clinical assays, in vitro tests, or chemical isolation. In some lymphomas, typically B cell lymphomas, there is an increased blood level of $1,25(OH)_2D$, which is probably produced by lymphocytes. The etiologic factor produced by activated normal lymphocytes and by myeloma and lymphoma cells, termed *osteoclast activation factor*, now appears to represent the biologic action of several different cytokines, probably interleukin 1 and lymphotoxin or tumor necrosis factor.

The more common mechanism, humoral hypercalcemia of malignancy, occurs with cancers of the lung and kidney, in particular, in which bone metastases are absent, minimal, or not detectable clinically. The clinical picture resembles primary hyperparathyroidism (hypophosphatemia accompanies hypercalcemia), and elimination or regression of the primary tumor leads to disappearance of the hypercalcemia. The disorder is due to secretion by the tumors of thePTH-like factor,PTHrP, that activates the PTH/PTHrP receptor (see above).

As in hyperparathyroidism, patients with the humoral hypercalcemia of malignancy have elevated urinary nephrogenous cyclic AMP excretion, hypophosphatemia, and increased urinary phosphate clearance. However, in humoral hypercalcemia of malignancy, immunoreactivePTH is undetectable or suppressed, making the differential diagnosis easier. Other features of the disorder differ from those of true hyperparathyroidism. Patients may have high, rather than low, renal calcium clearance (relative to serum calcium when compared to true hyperparathyroidism, unlike the expected elevation) and low to normal levels of $1,25(OH)_2D$. The reason that the humoral syndrome differs from hyperparathyroidism in these parameters is unclear since the biologic actions of PTH andPTHrPare presumably exerted through the same receptor. Other cytokines elaborated by the malignancy may be responsible for these variations from hyperparathyroidism. In some patients with the humoral hypercalcemia of malignancy, osteoclastic resorption is unaccompanied by an osteoblastic or bone-forming response, implying inhibition of the normal coupling of bone formation and

resorption. Thus the interaction of more than one substance may determine whether hypercalcemia develops in a particular patient.

Several different assays (single- or double-antibody, different epitopes) have been developed to detectPTHrP. Most data indicate that circulating PTHrP levels are undetectable (or low) in normal individuals, elevated in most cancer patients with the humoral syndrome, and high in human milk. Despite the discovery of PTHrP, identifying the etiologic mechanisms in cancer hypercalcemia is often complex. For example, in breast carcinoma (metastatic to bone) and in a distinctive type of T cell lymphoma/leukemia initiated by human T cell lymphotropic virus I, hypercalcemia is caused by direct local lysis of bone as well as by a humoral mechanism involving excess production of PTHrP.

Diagnostic Issues Levels ofPTHmeasured by the double-antibody technique are undetectable or extremely low in tumor hypercalcemia, as would be expected with the mediation of the hypercalcemia by a factor other than PTH (the hypercalcemia suppresses the normal parathyroid glands). In a patient with minimal symptoms referred for hypercalcemia, low or undetectable PTH and elevatedPTHrPlevels would focus attention on occult malignancy.

Ordinarily, the diagnosis of cancer hypercalcemia is not difficult because tumor symptoms are prominent when hypercalcemia is detected. Indeed, hypercalcemia may be noted incidentally during the workup of a patient with known or suspected malignancy. Clinical suspicion that malignancy is the cause of the hypercalcemia is heightened when there are other paraneoplastic signs or symptoms, such as weight loss, fatigue, muscle weakness, or unexplained skin rash, or when symptoms specific for a particular tumor are present. Squamous cell tumors are most frequently associated with hypercalcemia, particularly tumors of the lung, kidney, head and neck, and urogenital tract. Radiologic examinations can focus on these areas when clinical evidence is unclear. Bone scans with technetium-labeled bisphosphonate are useful for detection of osteolytic metastases; the sensitivity is high, but specificity is low; results must be confirmed by conventional x-rays to be certain that areas of increased uptake are due to osteolytic metastases per se. Bone marrow biopsies are helpful in patients with anemia or abnormal peripheral blood smears.

TREATMENT

Treatment of the hypercalcemia of malignancy is first directed to control of the tumor; reduction of tumor mass usually corrects hypercalcemia. If a patient has severe hypercalcemia yet has a good chance for effective tumor therapy, treatment of the hypercalcemia should be vigorous while awaiting the results of definitive therapy. If hypercalcemia occurs in the late stages of a tumor that is resistant to therapy, the treatment of the hypercalcemia should be judicious as high calcium levels can have a mild sedating effect. Standard therapies for hypercalcemia (discussed below) are applicable to patients with malignancy.

VITAMIN D-RELATED HYPERCALCEMIA

Hypercalcemia caused by vitamin D can be due to excessive ingestion or abnormal

metabolism of the vitamin. Abnormal metabolism of the vitamin is usually acquired in association with a widespread granulomatous disorder. Vitamin D metabolism is carefully regulated, particularly the activity of renal 1a-hydroxylase, the enzyme responsible for the production of $1,25(OH)_2D$ (Chap. 340). The regulation of 1a-hydroxylase and the normal feedback suppression by $1,25(OH)_2D$ seem to work less well in infants than in adults and to operate poorly, if at all, in sites other than the renal tubule; these phenomena explain the occurrence of hypercalcemia secondary to excessive $1,25(OH)_2D_3$production in infants with Williams' syndrome (see below) and in adults with sarcoidosis or lymphoma.

Vitamin D Intoxication Chronic ingestion of 50 to 100 times the normal physiologic requirement of vitamin D (amounts >50,000 to 100,000 U/d) is usually required to produce significant hypercalcemia in normal individuals. An upper limit of dietary intake of 2000 U/d (50 ug/d) in adults is now recommended because of concerns about potential toxic effects of cumulative supraphysiologic doses. Vitamin D excess increases intestinal calcium absorption and, if severe, also increases bone resorption.

Hypercalcemia in vitamin D intoxication is due to an excessive biologic action of the vitamin, perhaps the consequence of increased levels of 25(OH)D rather than increased levels of the usual active metabolite $1,25(OH)_2D$ (the latter is frequently not elevated in vitamin D intoxication). 25(OH)D has definite, if low, biologic activity in intestine and bone. The production of 25(OH)D is less tightly regulated than is the production of $1,25(OH)_2D$. Hence concentrations of 25(OH)D are elevated several-fold in patients with excess vitamin D intake.

The diagnosis is substantiated by documenting elevated levels of 25(OH)D>100 ng/mL. Hypercalcemia is usually controlled by restriction of dietary calcium intake and appropriate attention to hydration. These measures, plus discontinuation of vitamin D, usually lead to resolution of hypercalcemia. However, vitamin D stores in fat may be substantial, and vitamin D intoxication may persist for weeks after vitamin D ingestion is terminated. Such patients are responsive to glucocorticoids, which in doses of 100 mg/d of hydrocortisone or its equivalent, usually return serum calcium levels to normal over several days; severe intoxication may require intensive therapy.

Sarcoidosis and Other Granulomatous Diseases In patients with sarcoidosis and other granulomatous diseases, such as tuberculosis and fungal infections, excess $1,25(OH)_2D$ is synthesized in macrophages or other cells in the granulomas. Indeed, increased $1,25(OH)_2D$ levels have been reported in anephric patients with sarcoidosis and hypercalcemia. Macrophages obtained from granulomatous tissue convert 25(OH)D to $1,25(OH)_2D$ at an increased rate. There is a positive correlation in patients with sarcoidosis between 25(OH)D levels (reflecting vitamin D intake) and the circulating concentrations of $1,25(OH)_2D$, whereas normally there is no increase in $1,25(OH)_2D$ with increasing 25(OH)D levels due to multiple feedback controls on renal 1a-hydroxylase (Chap. 340). The usual regulation of active metabolite production by calcium orPTH does not operate in these patients; hypercalcemia does not lead to a reduction in the blood levels of $1,25(OH)_2D$ in patients with sarcoidosis. Clearance of $1,25(OH)_2D$ from blood may be decreased in sarcoidosis as well. PTH levels are usually low and $1,25(OH)_2D$ levels are elevated, but primary hyperparathyroidism and sarcoidosis may coexist in some patients.

Management of the hypercalcemia can often be accomplished by avoiding excessive sunlight exposure and limiting vitamin D and calcium intake. Presumably, however, the abnormal sensitivity to vitamin D and abnormal regulation of $1,25(OH)_2D$ synthesis will persist as long as the disease is active. Alternatively, glucocorticoids in the equivalent of £100 mg/d of hydrocortisone control hypercalcemia. Glucocorticoids appear to act by blocking excessive production of $1,25(OH)_2D$ as well as the response to it in target organs.

Idiopathic Hypercalcemia of Infancy This rare disorder, usually referred to as *Williams' syndrome*, is an autosomal dominant disorder characterized by multiple congenital development defects, including supravalvular aortic stenosis, mental retardation, and an elfin facies, in association with hypercalcemia due to abnormal sensitivity to vitamin D. The syndrome was first recognized in England after the fortification of milk with vitamin D. Levels of $1,25(OH)_2D$ are elevated, ranging from 46 to 120 nmol/L (150 to 500 pg/mL). The mechanism of the abnormal sensitivity to vitamin D and of the increased circulating levels of $1,25(OH)_2D$ is still unclear. Studies suggest that mutations involving the elastin locus and perhaps other genes on chromosome 7 may play a role in the pathogenesis.

HYPERCALCEMIA ASSOCIATED WITH HIGH BONE TURNOVER

Hyperthyroidism As many as 20% of hyperthyroid patients have high-normal or mildly elevated serum calcium concentrations; hypercalciuria is even more common. The hypercalcemia is due to increased bone turnover, with bone resorption exceeding bone formation. Severe calcium elevations are not typical, and the presence of such suggests a concomitant disease such as hyperparathyroidism. Usually, the diagnosis is obvious, but signs of hyperthyroidism may occasionally be occult, particularly in the elderly (Chap. 330). Hypercalcemia is managed by treatment of the hyperthyroidism.

Immobilization Immobilization is a rare cause of hypercalcemia in adults in the absence of an associated disease but may cause hypercalcemia in children and adolescents, particularly after spinal cord injury and paraplegia or quadriplegia. With resumption of ambulation, the hypercalcemia in children usually returns to normal.

The mechanism appears to involve a disproportion between bone formation and bone resorption. Hypercalciuria and increased mobilization of skeletal calcium can develop in normal volunteers subjected to extensive bed rest, although hypercalcemia is unusual. Immobilization of an adult with a disease associated with high bone turnover, such as Paget's disease, may cause hypercalcemia.

Thiazides Administration of benzothiadiazines (thiazides) can cause hypercalcemia in patients with high rates of bone turnover, such as patients with hypoparathyroidism treated with high doses of vitamin D. Traditionally, thiazides are associated with aggravation of hypercalcemia in primary hyperparathyroidism, but this effect can be seen in other high-bone-turnover states as well. The mechanism of thiazide action is complex. Chronic thiazide administration leads to reduction in urinary calcium; the hypocalciuric effect appears to reflect the enhancement of proximal tubular resorption of sodium and calcium in response to sodium depletion. Some of this renal effect is due to

augmentation ofPTHaction and is more pronounced in individuals with intact PTH secretion. However, thiazides cause hypocalciuria in hypoparathyroid patients on high-dose vitamin D and oral calcium replacement if sodium intake is restricted. This finding is the rationale for the use of thiazides as an adjunct to therapy in hypoparathyroid patients, as discussed below. Thiazide administration to normal individuals causes a transient increase in blood calcium (usually within the high-normal range) that reverts to preexisting levels after a week or more of continued administration. If hormonal function and calcium and bone metabolism are normal, homeostatic controls are reset to counteract the calcium-elevating effect of the thiazides. In the presence of hyperparathyroidism or increased bone turnover from another cause, homeostatic mechanisms are ineffective. The abnormal effects of the thiazide on calcium metabolism disappear within days of cessation of the drug.

Vitamin A Intoxication Vitamin A intoxication is a rare cause of hypercalcemia and is most commonly a side effect of dietary faddism (Chap. 75). Calcium levels can be elevated into the 3 to 3.5 mmol/L (12 to 14 mg/dL) range after the ingestion of 50,000 to 100,000 units of vitamin A daily (10 to 20 times the minimum daily requirement). Typical features of severe hypercalcemia include fatigue, anorexia, and, in some, severe muscle and bone pain. Excess Vitamin A intake is presumed to increase bone resorption.

The diagnosis can be established by history and by measurement of vitamin A levels in serum, which may be severalfold above normal. Occasionally, skeletal x-rays reveal periosteal calcifications, particularly in the hands. Withdrawal of the vitamin is usually associated with prompt disappearance of the hypercalcemia and reversal of the skeletal changes. As in vitamin D intoxication, administration of 100 mg/d hydrocortisone or its equivalent leads to a rapid return of the serum calcium to normal.

HYPERCALCEMIA ASSOCIATED WITH RENAL FAILURE

Severe Secondary Hyperparathyroidism Secondary hyperparathyroidism occurs when partial resistance to the metabolic actions ofPTHleads to excessive production of the hormone. Parathyroid gland hyperplasia occurs because resistance to the normal level of PTH leads to hypocalcemia, which, in turn, is a stimulus to parathyroid gland enlargement. This concept is supported by studies of the treatment of patients treated with bisphosphonates, which block the skeletal resorptive response. Because a portion of PTH secretion by each parathyroid cell is not suppressible by any degree of elevation of blood calcium, larger glands (more cells) have a higher hormone output at the hypercalcemic end of the dose-response curve.

Secondary hyperparathyroidism occurs not only in patients with renal failure but also in those with osteomalacia due to multiple causes (Chap. 340), including deficiency of vitamin D action, and PHP(deficient response toPTH at the level of the receptor). Hypocalcemia seems to be the common denominator in initiating secondary hyperparathyroidism. Only in patients with renal failure, however, is hypercalcemia sometimes encountered despite appropriate medical management regimens (see below). Primary and secondary hyperparathyroidism can be distinguished conceptually by the autonomous growth of the parathyroid glands in primary hyperparathyroidism (presumably irreversible) and the adaptive response of the parathyroids in secondary

hyperparathyroidism (typically reversible). In fact, reversal over weeks from an abnormal pattern of secretion, presumably accompanied by involution of parathyroid gland mass to normal, occurs in patients who have been treated effectively to reverse the resistance to PTH (such as with calcium and vitamin D in osteomalacia).

Patients with secondary hyperparathyroidism may develop bone pain, ectopic calcification, and pruritus. The bone disease seen in patients with secondary hyperparathyroidism and renal failure is termed *renal osteodystrophy*. Osteomalacia (predominantly due to vitamin D and calcium deficiency) and/or osteitis fibrosa cystica (excessivePTHaction on bone) may occur.

Two other skeletal disorders are associated with long-term dialysis in patients with renal failure. Aluminum deposition (see below) is associated with an osteomalacia-like picture. The other entity is a low-bone-turnover state termed "aplastic" or "adynamic" bone disease;PTHlevels are lower than in typical secondary hyperparathyroidism. It is believed that the condition is caused, at least in part, by excessive PTH suppression, which may be even greater than previously appreciated in light of evidence that some of the immunoreactive PTH detected by most commercially available PTH assays is not the full-length biologically active molecule (as discussed above).

TREATMENT

Medical therapy to reverse secondary hyperparathyroidism includes reduction of excessive blood phosphate by restriction of dietary phosphate, the use of nonabsorbable antacids, and careful, selective addition of calcitriol (0.25 to 2.0 ug/d); calcium carbonate is preferred over aluminum-containing antacids to prevent aluminum toxicity. Intravenous calcitriol, administered as several pulses each week, helps control secondary hyperparathyroidism. Aggressive but carefully administered medical therapy can often, but not always, reverse hyperparathyroidism and its symptoms and manifestations.

Occasional patients develop severe manifestations of secondary hyperparathyroidism, including hypercalcemia, pruritus, extraskeletal calcifications, and painful bones, despite aggressive medical efforts to suppress the hyperparathyroidism.PTHhypersecretion no longer responsive to medical therapy, a state of severe hyperparathyroidism in patients with renal failure that requires surgery, has been referred to as *tertiary hyperparathyroidism*. Parathyroid surgery is necessary to control this condition. Based on genetic evidence from examination of tumor samples in these patients, the emergence of autonomous parathyroid function is due to a monoclonal outgrowth of one or more previously hyperplastic parathyroid glands.

Aluminum Intoxication Aluminum intoxication (and often hypercalcemia as a complication of medical treatment) may occur in patients on chronic dialysis; manifestations include acute dementia and unresponsive and severe osteomalacia. Bone pain, multiple nonhealing fractures, particularly of the ribs and pelvis, and a proximal myopathy may occur. Hypercalcemia develops when these patients are treated with vitamin D or calcitriol because of impaired skeletal responsiveness. Aluminum is present at the site of osteoid mineralization, osteoblastic activity is minimal, and calcium incorporation into the skeleton is impaired. Prevention is accomplished by avoidance of

aluminum excess in the dialysis regimen; treatment of established disease involves mobilizing aluminum through the use of the chelating agent deferoxamine (Chap. 348).

Milk-Alkali Syndrome The milk-alkali syndrome is due to excessive ingestion of calcium and absorbable antacids such as milk or calcium carbonate. It is much less frequent since nonabsorbable antacids and other treatments became available for peptic ulcer disease. However, the increased use of calcium carbonate in the management of osteoporosis has led to reappearance of the syndrome. Several clinical presentations -- acute, subacute, and chronic -- have been described, all of which feature hypercalcemia, alkalosis, and renal failure. The chronic form of the disease, termed *Burnett's syndrome*, is associated with irreversible renal damage. The acute syndromes reverse if the excess calcium and absorbable alkali are stopped.

Individual susceptibility is important in the pathogenesis, as many patients are treated with calcium carbonate alkali regimens without developing the syndrome. One variable is the fractional calcium absorption as a function of calcium intake. Some individuals absorb a high fraction of calcium, even with intakes as high as 2 g or more of elemental calcium per day, instead of reducing calcium absorption with high intake, as occurs in most normal individuals. Resultant mild hypercalcemia after meals in such patients is postulated to contribute to the generation of alkalosis. Development of hypercalcemia causes increased sodium excretion and some depletion of total-body water. These phenomena and perhaps some suppression of endogenousPTHsecretion due to mild hypercalcemia lead to increased bicarbonate resorption and to alkalosis in the face of continued calcium carbonate ingestion. Alkalosis per se selectively enhances calcium resorption in the distal nephron, thus aggravating the hypercalcemia. The cycle of mild hypercalcemia® bicarbonate retention® alkalosis ® renal calcium retention ® severe hypercalcemia perpetuates and aggravates hypercalcemia and alkalosis as long as calcium and absorbable alkali are ingested.

DIFFERENTIAL DIAGNOSIS: SPECIAL TESTS

Differential diagnosis of hypercalcemia is best achieved by using clinical criteria, but the immunoassay forPTH is especially useful in distinguishing among major causes (Fig. 341-8). The clinical features that deserve emphasis are the presence or absence of symptoms or signs of disease and evidence of chronicity. If one discounts fatigue or depression,>90% of patients with primary hyperparathyroidism have *asymptomatic hypercalcemia*; symptoms of malignancy are usually present in cancer-associated hypercalcemia. Disorders other than hyperparathyroidism and malignancy cause <10% of cases of hypercalcemia, and some of the nonparathyroid causes are associated with clear-cut manifestations such as renal failure.

Hyperparathyroidism is the likely diagnosis in patients with *chronic hypercalcemia*. If hypercalcemia has been manifest for >1 year, malignancy can usually be excluded as the cause. A striking feature of malignancy-associated hypercalcemia is the rapidity of the course, whereby signs and symptoms of the underlying malignancy are evident within months of the detection of hypercalcemia. A careful history of dietary supplements and drug use may suggest intoxication with vitamins D or vitamin A or the use of thiazides.

Although clinical considerations are helpful in arriving at the correct diagnosis of the cause of hypercalcemia, appropriate laboratory testing is essential for definitive diagnosis. The immunoassay forPTHshould separate hyperparathyroidism from all other causes of hypercalcemia. Patients with hyperparathyroidism have elevated PTH levels despite hypercalcemia, whereas patients with malignancy and the other causes of hypercalcemia (except for disorders mediated by PTH such as lithium-induced hypercalcemia) have levels of hormone below normal or undetectable. Assays based on the double-antibody method for PTH exhibit very high sensitivity (especially if serum calcium is simultaneously evaluated) and specificity for the diagnosis of primary hyperparathyroidism (Fig. 341-9).

In summary,PTHvalues are elevated in >90% of parathyroid-related causes of hypercalcemia, undetectable or low in malignancy-related hypercalcemia, and undetectable or normal in vitamin D-related and high-bone-turnover causes of hypercalcemia. In view of the specificity of the PTH immunoassay and the high frequency of hyperparathyroidism in hypercalcemic patients, it is cost-effective to measure the PTH level in all hypercalcemic patients unless malignancy or a specific nonparathyroid disease is obvious. False-positive PTH assay results are rare. There are very rare reports of ectopic production of excess PTH by nonparathyroid tumors. Immunoassays forPTHrPare helpful in diagnosing certain types of malignancy-associated hypercalcemia. AlthoughFHH is parathyroid-related, the disease should be managed distinctively from hyperparathyroidism. Clinical features and the low urinary calcium excretion can help make the distinction. Because the incidence of malignancy and hyperparathyroidism both increase with age, they can coexist as two independent causes of hypercalcemia.

$1,25(OH)_2D$ levels are elevated in many (but not all) patients with primary hyperparathyroidism. In other disorders associated with hypercalcemia, concentrations of $1,25(OH)_2D$ are low or, at the most, normal. However, this test is of low specificity and is not cost-effective, as not all patients with hyperparathyroidism have elevated $1,25(OH)_2D$ levels, and not all nonparathyroid hypercalcemic patients have suppressed $1,25(OH)_2D$. Measurement of $1,25(OH)_2D$ is, however, critically valuable in establishing the cause of hypercalcemia in sarcoidosis and certain B cell lymphomas.

A useful general approach is outlined inFig. 341-8. If the patient is *asymptomatic* and there is evidence of *chronicity* to the hypercalcemia, hyperparathyroidism is almost certainly the cause. IfPTHlevels (usually measured at least twice) are elevated, the clinical impression is confirmed and little additional evaluation is necessary. If there is only a short history or no data as to the duration of the hypercalcemia, *occult malignancy* must be considered; if the PTH levels are not elevated, then a thorough workup must be undertaken for malignancy, including chest x-ray,CT of chest and abdomen, and bone scan. Immunoassays forPTHrPmay be especially useful in such situations. Attention should also be paid to clues for underlying hematologic disorders such as anemia, increased plasma globulin, and abnormal serum immunoelectrophoresis; bone scans can be negative in some patients with metastases, such as in multiple myeloma. Finally, if a patient with chronic hypercalcemia is asymptomatic and malignancy therefore seems unlikely on clinical grounds, but PTH values are not elevated, it is useful to search for other chronic causes of hypercalcemia, such as occult sarcoidosis.

TREATMENT

Hypercalcemic States The approach to medical treatment of hypercalcemia varies with its severity. Mild hypercalcemia, <3.0 mmol/L (12 mg/dL), can be managed by hydration. More severe hypercalcemia [levels of 3.2 to 3.7 mmol/L (13 to 15 mg/dL)] must be managed aggressively; above that level, hypercalcemia can be life-threatening and requires emergency measures. By using a combination of approaches, the serum calcium concentration can be decreased by 0.7 to 2.2 mmol/L (3 to 9 mg/dL) within 24 to 48 h in most patients, enough to relieve acute symptoms, prevent death from hypercalcemic crisis, and permit diagnostic evaluation. Therapy can then be directed at the underlying disorder -- the second priority.

Hypercalcemia develops because of excessive skeletal calcium release, increased intestinal calcium absorption, or inadequate renal calcium excretion. Understanding the particular pathogenesis helps guide therapy. For example, hypercalcemia in patients with malignancy is primarily due to excessive skeletal calcium release and is, therefore, minimally improved by restriction of dietary calcium. On the other hand, patients with vitamin D hypersensitivity or vitamin D intoxication have excessive intestinal calcium absorption, and restriction of dietary calcium is beneficial. Decreased renal function orECFdepletion decreases urinary calcium excretion. In such situations, rehydration may rapidly reduce or reverse the hypercalcemia, even though increased bone resorption persists. As outlined below, the more severe the hypercalcemia, the greater the number of combined therapies that should be used. Rapid acting (hours) approaches -- rehydration, forced diuresis, and calcitonin -- can be used with the most effective antiresorptive agents, such as bisphosphonates (since severe hypercalcemia usually involves excessive bone resorption).

Hydration, Increased Salt Intake, Mild and Forced Diuresis The first principle of treatment is to restore normal hydration. Many hypercalcemic patients are dehydrated because of vomiting, inanition, and/or hypercalcemia-induced defects in urinary concentrating ability. The resultant drop in glomerular filtration rate is accompanied by an additional decrease in renal tubular sodium and calcium clearance. Restoring a normalECFvolume corrects these abnormalities and increases urine calcium excretion by 2.5 to 7.5 mmol/d (100 to 300 mg/d). Increasing urinary sodium excretion to 400 to 500 mmol/d increases urinary calcium excretion even further than simple rehydration. After rehydration has been achieved, saline can be administered or furosemide or ethacrynic acid can be given twice daily to depress the tubular reabsorptive mechanism for calcium (care must be taken to prevent dehydration). The combined use of these therapies can increase urinary calcium excretion to[3]12.5 mmol/d (500 mg/d) in most hypercalcemic patients. Since this is a substantial percentage of the exchangeable calcium pool, the serum calcium concentration usually falls 0.25 to 0.75 mmol/L (1 to 3 mg/dL) within 24 h. Precautions should be taken to prevent potassium and magnesium depletion; calcium-containing renal calculi are a potential complication.

Under life-threatening circumstances, the preceding approach can be pursued more aggressively, giving as much as 6 L isotonic saline (900 mmol sodium) daily plus furosemide or equivalent in doses up to 100 mg every 1 to 2 h or ethacrynic acid in doses to 40 mg every 1 to 2 h. Urinary calcium excretion may exceed 25 mmol/d (1000

mg/d), and the serum calcium may decrease by ³1 mmol/L (4 mg/dL) within 24 h. Depletion of potassium and magnesium is inevitable unless replacements are given; pulmonary edema can be precipitated. The potential complications can be reduced by careful monitoring of central venous pressure and plasma or urine electrolytes; catheterization of the bladder may be necessary. This treatment approach should be supplemented with agents to block bone resorption. Though these agents do not become effective for several days, forced diuresis is difficult to sustain even in patients with good cardiopulmonary and renal function.

Bisphosphonates The bisphosphonates are analogues of pyrophosphate, with high affinity for bone, especially in areas of increased bone turnover, where they are powerful inhibitors of bone resorption. These bone-seeking compounds are stable in vivo because phosphatase enzymes cannot hydrolyze the central carbon-phosphorus-carbon bond. The bisphosphonates are concentrated in areas of high bone turnover and are taken up by and inhibit osteoclast action; the mechanism of action is complex. Bisphosphonates alter osteoclast proton pump function or impair the release of acid hydrolases into the extracellular lysosomes contiguous with mineralized bone. They may also inhibit the differentiation of monocyte-macrophage precursors into osteoclasts and possibly have effects on osteoblasts as well. The bisphosphonate molecules that contain amino groups in the side chain structure (see below) interfere with prenylation of proteins and can lead to cellular apoptosis. The highly active non-amino group-containing bisphosphonates are also metabolized to cytotoxic products.

The initial bisphosphonate widely used in clinical practice, etidronate, was effective but had several disadvantages, including the capacity to inhibit bone formation as well as blocking resorption. Subsequently, a number of second-generation compounds have become the mainstays of antiresorptive therapy for treatment of hypercalcemia. The most widely used, pamidronate, is a potent inhibitor of osteoclast-mediated skeletal resorption yet does not cause mineralization defects at ordinary doses. Several additional bisphosphonates (alendronate, tiludronate, and risedronate) are potent and also have a highly favorable ratio of blocking resorption versus inhibiting bone formation. Though the bisphosphonates have similar structures, the routes of administration, efficacy, toxicity, and side effects vary. The potency of the compounds for inhibition of bone resorption varies a thousandfold in the order of etidronate, tiludronate, pamidronate, alendronate, and risedronate. Oral alendronate is approved for the therapy of osteoporosis in the United States, and in Europe oral preparations of these bisphosphonates are used in the chronic treatment of hypercalcemia. Only the intravenous use of pamidronate is approved for this purpose in the United States; between 30 and 90 mg pamidronate, given as a single intravenous dose over a few hours, returns serum calcium to normal within 24 to 48 h with an effect that lasts for weeks in 80 to 100% of patients.

Pamidronate causes low-grade fever in as many as 20% of patients, likely related to release of cytokines from osteoclasts, monocytes, and macrophages (Table 341-2). This effect is usually seen only with the initial doses. Etidronate causes hyperphosphatemia through a direct renal mechanism, whereas hypophosphatemia is seen after therapy with other bisphosphonates. Overall, second-generation bisphosphonates are now the agents of choice in severe hypercalcemia, particularly that

associated with malignancy. Zoledronate, a third-generation bisphosphonate, is claimed to be 100 to 800 times more potent than pamidronate and to normalize calcium more quickly and for longer periods.

Calcitonin Calcitonin acts within a few hours of its administration, through receptors on osteoclasts, to block bone resorption and, in addition, to increase urinary calcium excretion by inhibition of renal tubular calcium reabsorption. However, calcitonin leads to variable and usually minimal lowering of calcium. Tachyphylaxis, a known phenomenon with this drug, may explain the variable results. However, in life-threatening hypercalcemia, calcitonin can be used effectively within the first 24 h in combination with rehydration and saline diuresis while waiting for more sustained effects from a simultaneously administered bisphosphonate such as pamidronate. Usual doses of calcitonin are 2 to 8 U/kg of body weight intravenously, subcutaneously, or intramuscularly every 6 to 12 h.

Other Therapies *Plicamycin* (mithramycin), which inhibits bone resorption, has been a useful therapeutic agent but is now little used because of the effectiveness of bisphosphonates. Plicamycin must be given intravenously, either as a bolus injection or by slow infusion. The usual dose is 25 ug/kg body weight. Major side effects include thrombocytopenia, hepatocellular necrosis with increased lactic acid dehydrogenase (LDH) and aspartate aminotransferase (AST) levels, and decreased levels of clotting factors with resultant epistaxis, bruising, hemorrhage, and bleeding gums.

Gallium nitrate exerts a hypocalcemic action by inhibiting bone resorption and altering the structure of bone crystals. Major disadvantages include the 5-day duration of infusion and the potential for nephrotoxicity and relatively shorter duration of action than bisphosphonates. Accordingly it is not often used because of superior alternatives.

Glucocorticoids increase urinary calcium excretion and decrease intestinal calcium absorption when given in pharmacologic doses, but they also cause negative skeletal calcium balance. In normal individuals and in patients with primary hyperparathyroidism, glucocorticoids neither increase nor decrease the serum calcium concentration. In patients with hypercalcemia due to certain osteolytic malignancies, however, glucocorticoids may be effective as a result of antitumor effects. The malignancies in which hypercalcemia responds to glucocorticoids include multiple myeloma, leukemia, Hodgkin's disease, other lymphomas, and carcinoma of the breast, at least early in the course of the disease. Glucocorticoids are also effective in treating hypercalcemia due to vitamin D intoxication and sarcoidosis. In all the preceding situations, the hypocalcemic effect develops over several days, and the usual glucocorticoid dosage is 40 to 100 mg prednisone (or its equivalent) daily in four divided doses. The side effects of chronic glucocorticoid therapy may be acceptable in some circumstances.

Dialysis is often the treatment of choice for hypercalcemia complicated by renal failure, which is difficult to manage. Peritoneal dialysis with calcium-free dialysis fluid can remove 5 to 12.5 mmol (200 to 500 mg) of calcium in 24 to 48 h and lower the serum calcium concentration by 0.7 to 3 mmol/L (3 to 12 mg/dL). Large quantities of phosphate are lost during dialysis, and serum inorganic phosphate concentrations usually fall, thus aggravating hypercalcemia. Therefore, the serum inorganic phosphate concentration should be measured after dialysis, and phosphate supplements should be added to the

diet or to dialysis fluids if necessary.

Phosphate therapy, oral or intravenous, has a limited role in certain circumstances. Patients with primary hyperparathyroidism are frequently hypophosphatemic, and hypercalcemia of other causes also may be complicated by hypophosphatemia. Hypophosphatemia decreases the rate of calcium uptake into bone, increases intestinal calcium absorption, and directly and indirectly stimulates bone breakdown. These effects aggravate hypercalcemia, and correcting hypophosphatemia lowers the serum calcium concentration. The usual treatment is 1 to 1.5 g phosphorus per day for several days, given in four divided doses to minimize the chances of developing hyperphosphatemia. Such therapy has been administered for prolonged periods in selected patients. It is generally believed, but not established, that toxicity does not occur if therapy is limited to restoring serum inorganic phosphate concentrations to normal.

Raising the serum inorganic phosphate concentration above normal decreases serum calcium levels, sometimes strikingly. Intravenous phosphate is one of the most dramatically effective treatments available for severe hypercalcemia but is toxic and even dangerous (fatal hypocalcemia). For these reasons, it is used rarely and only in severely hypercalcemic patients with cardiac or renal failure. A phosphate phosphorus dose of ³1500 mg intravenously over 6 to 8 h leads to a prompt decrease in serum calcium of as much as 1.2 to 2.5 mmol/L (5 to 10 mg/dL) in patients with initially normal serum inorganic phosphate concentrations. This therapy should be employed only in extreme emergencies. Inorganic phosphate is commercially available for oral use in liquid, powder, and capsule form and as a liquid for intravenous use. It is important to calculate doses in terms of phosphate phosphorus.

Summary The various therapies for hypercalcemia are listed inTable 341-2. The choice depends on the underlying disease, the severity of the hypercalcemia, the serum inorganic phosphate level, and the renal, hepatic, and bone marrow function. Mild hypercalcemia [£3 mmol/L (12 mg/dL)] can usually be managed by hydration. Severe hypercalcemia [3.7 mmol/L (15 mg/dL)] requires rapid correction. Calcitonin should be given for its rapid, albeit short-lived, blockade of bone resorption, and intravenous pamidronate should be administered, although its onset of action is delayed for 1 to 2 days. In addition, for the first 24 to 48 h, aggressive sodium-calcium diuresis with intravenous saline and large doses of furosemide and ethacrynic acid following initial hydration should be initiated, but only if appropriate monitoring is available and cardiac and renal function are adequate. Otherwise, dialysis may be necessary. Intermediate degrees of hypercalcemia between 3.0 and 3.7 mmol/L (12 and 15 mg/dL) should be approached with vigorous hydration and then the most appropriate selection for the patient of the combinations used with severe hypercalcemia.

HYPOCALCEMIA

PATHOPHYSIOLOGY OF HYPOCALCEMIA: CLASSIFICATION BASED ON MECHANISM

Chronic hypocalcemia is less common than hypercalcemia; causes include chronic renal failure, hereditary and acquired hypoparathyroidism, vitamin D deficiency,PHP,

and hypomagnesemia.

Critically ill patients may have transient hypocalcemia with severe sepsis, burns, acute renal failure, and extensive transfusions with citrated blood. Acute hypocalcemia with certain medications is usually transient and may produce no symptoms. Although as many as half of patients in an intensive care setting are reported to have calcium concentrations <2.1 mmol/L (8.5 mg/dL),<10% have a reduction in ionized calcium. Patients with severe sepsis may have a decrease in ionized calcium (true hypocalcemia), but in other severely ill individuals, hypoalbuminemia is the primary cause of the reduced total calcium concentration. Alkalosis increases calcium binding to proteins, and in this setting direct measurements of ionized calcium should be made.

Medications such as protamine, heparin, and glucagon may cause transient hypocalcemia. These forms of hypocalcemia are usually not associated with tetany and resolve with improvement in the overall medical condition. The hypocalcemia after repeated transfusions of citrated blood usually resolves quickly.

Patients with *acute pancreatitis* have hypocalcemia that persists during the acute inflammation and varies in degree with the severity of the pancreatitis. The cause of hypocalcemia remains unclear.PTHvalues are reported to be low, normal, or elevated, and both resistance to PTH and impaired PTH secretion have been postulated. Occasionally, a chronic low total calcium and low ionized calcium concentration are detected in an elderly patient without obvious cause and with a paucity of symptoms; the pathogenesis is unclear.

Chronic hypocalcemia, however, is usually symptomatic and requires treatment. Neuromuscular and neurologic manifestations of chronic hypocalcemia include muscle spasms, carpopedal spasm, facial grimacing, and, in extreme cases, laryngeal spasm and convulsions. Respiratory arrest may occur. Increased intracranial pressure occurs in some patients with long-standing hypocalcemia, often in association with papilledema. Mental changes include irritability, depression, and psychosis. The QT interval on the electrocardiogram is prolonged, in contrast to its shortening with hypercalcemia. Arrhythmias occur, and digitalis effectiveness may be reduced. Intestinal cramps and chronic malabsorption may occur. Chvostek's or Trousseau's sign can be used to confirm latent tetany.

The classification of hypocalcemia shown inTable 341-3 is based on the premise thatPTH is responsible for minute-to-minute regulation of plasma calcium concentration and, therefore, that the occurrence of hypocalcemia must mean a failure of the homeostatic action of PTH. Failure of the PTH response can occur due to hereditary or acquired parathyroid gland failure, if PTH is ineffective in target organs, or if the action of the hormone is overwhelmed by the loss of calcium from theECF at a rate faster than it can be replaced.

PTH ABSENT

Whether hereditary or acquired, hypoparathyroidism has a number of common components. Acute and chronic symptoms of untreated hypocalcemia are shared by both types of hypoparathyroidism, although the onset of hereditary hypoparathyroidism

is more gradual and is often associated with other developmental defects. Basal ganglia calcification and extrapyramidal syndromes are more common and earlier in onset in hereditary hypoparathyroidism. In earlier decades, acquired hypoparathyroidism secondary to surgery in the neck was more common than hereditary hypoparathyroidism, but the frequency of surgically induced parathyroid failure has diminished as a result of improved surgical techniques that spare the parathyroid glands and increased use of nonsurgical therapy for hyperthyroidism.PHP, an example of ineffective PTH action rather than a failure of parathyroid gland production, may share several features with hypoparathyroidism, including extraosseous calcification and extrapyramidal manifestations such as choreoathetotic movements and dystonia.

Papilledema and raised intracranial pressure may occur in both hereditary or acquired hypoparathyroidism, as do chronic changes in fingernails and hair and lenticular cataracts, the latter usually reversible with treatment of hypocalcemia. Certain skin manifestations, including alopecia and candidiasis, are characteristic of hereditary hypoparathyroidism associated with autoimmune polyglandular failure (Chap. 339).

Hypocalcemia associated with hypomagnesemia is associated with both deficientPTHrelease and impaired responsiveness to the hormone. Patients with hypocalcemia secondary to hypomagnesemia have absent or low levels of circulating PTH, indicative of diminished hormone release despite maximum physiologic stimulus by hypocalcemia. Plasma PTH levels return to normal with correction of the hypomagnesemia. Thus hypoparathyroidism with low levels of PTH in blood can be due to hereditary gland failure, acquired gland failure, or acute but reversible gland dysfunction (hypomagnesemia).

Genetic Abnormalities and Hereditary Hypoparathyroidism Hereditary hypoparathyroidism can occur as an isolated entity without other endocrine or dermatologic manifestations (idiopathic hypoparathyroidism); more typically, it occurs in association with other abnormalities such as defective development of the thymus or failure of function of other endocrine organs such as the adrenal, thyroid, or ovary (Chap. 339). Idiopathic and hereditary hypoparathyroidism are often manifest within the first decade but may appear later.

A rare form of hypoparathyroidism associated with defective development of both the thymus and the parathyroid glands is termed the *DiGeorge syndrome* (DGS), or the *velocardiofacial syndrome* (VCFS). Congenital cardiovascular, facial, and other developmental defects are present, and most patients die in early childhood with severe infections, hypocalcemia and seizures, or cardiovascular complications. Some survive into adulthood, and milder, incomplete forms occur. Most cases are sporadic, but an autosomal dominant form involving microdeletions of chromosome 22q11.2 has been described. Smaller deletions in this region are seen in incomplete forms of the DGS syndrome, appearing in childhood or adolescence, that are manifest primarily by parathyroid gland failure.

Hypoparathyroidism can occur in association with a complex hereditary autoimmune syndrome involving failure of the adrenals, the ovaries, the immune system, and the parathyroids in association with recurrent mucocutaneous candidiasis, alopecia, vitiligo, and pernicious anemia (Chap. 339). The responsible gene on chromosome 21q22.3 has

been identified. The protein product, which resembles a transcription factor, has been termed the *AIRE* (autoimmune regulator). A stop codon mutation occurs in many Finnish families with the disorder, commonly referred to as *polyglandular autoimmune type 1 deficiency*.

Gain-of-function mutations in the calcium-sensing receptor cause *autosomal dominant hypocalcemia* (ADH). These mutations induce constitutive receptor functions that lead to features that are the inverse ofFHH. The activated receptor suppressesPTH, leading to hypocalcemia; receptor activation in the kidney results in excessive renal calcium excretion. Recognition of the syndrome is important because efforts to treat the hypocalcemia of these patients with vitamin D analogues and increased oral calcium exacerbate the already excessive urinary calcium secretion (several grams or more per 24 h), leading to irreversible renal damage from stones and ectopic calcification.

Hypoparathyroidism is seen in two disorders associated with mitochondrial dysfunction and myopathy, one termed the *Kearns-Sayre syndrome* (KSS), with ophthalmaplegia and pigmentary retinopathy, and the other termed the *MELAS syndrome*, *m*itochondrial *e*ncephalopathy, *l*actic *a*cidosis, and *s*troke-like episodes. Mutations or deletions in mitochondrial genes have been identified (Chap. 67).

The two other rare forms of hypoparathyroidism with other multisystem developmental abnormalities follow either an autosomal dominant pattern, with deafness and/or renal dysplasia, or an autosomal recessive pattern, with growth retardation and dysmorphic features.

Hereditary hypoparathyroidism occurs also as an isolated entity without any other defects. The pattern of inheritance varies and includes autosomal dominant, autosomal recessive, and X-linked inheritance patterns. In one family in which the disorder is transmitted as an autosomal dominant trait, a structural abnormality in thePTH gene has been identified. A defect in the signal sequence needed for processing of the hormone impairs PTH secretion. In another kindred with autosomal recessive inheritance, the mutant allele in the first intron of the PTH gene causes a splicing defect in mRNA production. An X-linked recessive form of hypoparathyroidism has been described in males from two kindreds that are probably related. The locus of the defect has been located to chromosome Xq26-q27.

Acquired Hypoparathyroidism *Acquired chronic hypoparathyroidism* is usually the result of inadvertent surgical removal of all the parathyroid glands; in some instances, not all the tissue is removed, but the remainder undergoes vascular supply compromise secondary to fibrotic changes in the neck after surgery. In the past, the most frequent cause of acquired hypoparathyroidism was surgery for hyperthyroidism. Hypoparathyroidism now usually occurs after surgery for hyperparathyroidism when the surgeon, facing the dilemma of removing too little tissue and thus not curing the hyperparathyroidism, removes too much. Parathyroid function may not be totally absent in all patients with postoperative hypoparathyroidism.

Even rarer causes of acquired chronic hypoparathyroidism include radiation-induced damage subsequent to radioiodine therapy of hyperthyroidism and glandular damage in patients with hemochromatosis or hemosiderosis after repeated blood transfusions.

Infection may involve one or more of the parathyroids but usually does not cause hypoparathyroidism because all four glands are rarely involved.

Transient hypoparathyroidism is frequent following surgery for hyperparathyroidism. After a variable period of hypoparathyroidism, normal parathyroid function may return due to hyperplasia or recovery of remaining tissue. Occasionally, recovery occurs months after surgery.

TREATMENT

Treatment of acquired and hereditary hypoparathyroidism involves replacement with vitamin D or 1,25$(OH)_2D_3$(calcitriol) combined with a high oral calcium intake. In most patients, blood calcium and phosphate levels are satisfactorily regulated, but some patients show resistance and a brittleness with a tendency to alternate between hypocalcemia and an overshoot hypercalcemia. For many patients, vitamin D in doses of 1 to 3 mg/d (40,000 to 120,000 U/d) combined with³1 g elemental calcium is satisfactory. The wide dosage range reflects the variation encountered from patient to patient; precise regulation of each patient is required. Compared to typical daily requirements in euparathyroid patients of 200 U/d, the high dose of vitamin D reflects the reduced conversion of vitamin D to 1,25$(OH)_2D$. Many physicians now use 0.5 to 1.0 ug of calcitriol in management of such patients, especially if they are difficult to control. When vitamin D (because of storage in fat) is withdrawn, weeks are required for the disappearance of the biologic effects, compared with a few days for calcitriol, which has a rapid turnover.

Oral calcium and vitamin D restore the overall calcium-phosphate balance but do not reverse the lowered urinary calcium reabsorption typical of hypoparathyroidism. Therefore, care must be taken to avoid excessive urinary calcium excretion after vitamin D and calcium replacement therapy; otherwise, kidney stones can develop. Thiazide diuretics lower urine calcium by as much as 100 mg/d in hypoparathyroid patients on vitamin D, provided they are maintained on a low-sodium diet. Use of thiazides seems to be of benefit in mitigating hypercalciuria and easing the daily management of these patients.

Hypomagnesemia Severe hypomagnesemia is associated with hypocalcemia (Chap. 340). Restoration of the total-body magnesium deficit leads to rapid reversal of hypocalcemia. There are at least two causes of the hypocalcemia -- impairedPTHsecretion and reduced responsiveness to PTH.

Hypomagnesemia is generally classified as primary or secondary; primary hypomagnesemia is due to hereditary defects in intestinal absorption or renal reabsorption of magnesium. Secondary hypomagnesemia, a more common condition, occurs on a nutritional basis or as a result of acquired intestinal or renal disorders. The most common causes of the secondary disorder are chronic alcoholism with poor nutritional intake, intestinal malabsorption syndromes, and parenteral nutrition when magnesium replacement is omitted.

The effects of magnesium onPTHsecretion are similar to those of calcium; hypermagnesemia suppresses and hypomagnesemia stimulates PTH secretion. The

effects of magnesium on PTH secretion are normally of little significance, however, because the calcium effects dominate. Greater change in magnesium than in calcium is needed to influence hormone secretion. Nonetheless, hypomagnesemia might be expected to increase hormone secretion. It is therefore surprising to find that severe hypomagnesemia is associated with blunted secretion of PTH. The explanation for the paradox is that severe, chronic hypomagnesemia leads to intracellular magnesium deficiency, which interferes with secretion and peripheral responses to PTH. The mechanism of the cellular abnormalities caused by hypomagnesemia is unknown, although effects on adenylate cyclase (for which magnesium is a cofactor) have been proposed.

Serum magnesium must usually fall below 0.4 mmol/L (1.0 mg/dL) to cause hypocalcemia.PTHlevels are undetectable or inappropriately low despite the stimulus of severe hypocalcemia, and acute repletion of magnesium leads to a rapid increase in PTH level. Serum phosphate levels are often not elevated, in contrast to the situation with acquired or idiopathic hypoparathyroidism, probably because phosphate deficiency is a frequent accompaniment of hypomagnesemia.

Diminished peripheral responsiveness toPTH also occurs in some patients, as documented by subnormal response in urinary phosphorus and urinary cyclic AMP excretion after administration of exogenous PTH to patients who are hypocalcemic and hypomagnesemic. Both blunted PTH secretion and lack of renal response to administered PTH can occur in the same patient. When acute magnesium repletion is undertaken, the restoration of PTH levels to normal or supranormal may precede restoration of normal serum calcium by several days.

TREATMENT

Repletion of magnesium cures the condition, and attention must be given to restoring the intracellular deficiency, which may be considerable. Repletion should be parenteral. After intravenous magnesium administration, serum magnesium may return transiently to the normal range, but unless replacement therapy is adequate serum magnesium will again fall. If renal function is normal, urinary magnesium excretion is a useful indicator of magnesium repletion, as magnesium is retained by the kidney until the deficiency is corrected. Intracellular deficits can be ^{3}50 mmol. Parenteral administration of 10 to 14 mmol magnesium usually reverses the signs of magnesium deficiency, but greater amounts may occasionally be required if the deficit is large. If the cause of the hypomagnesemia is renal magnesium wasting, magnesium may have to be given chronically to prevent recurrence (Chap. 340).

PTHINEFFECTIVE

PTH is ineffective when the hormone receptor-guanyl nucleotide-binding protein complex is defective (PHP, discussed below), when PTH action to promote calcium absorption from the diet is impaired because of vitamin D deficiency or because vitamin D is ineffective (receptor or synthesis defects), or in chronic renal failure in which the calcium-elevating action of PTH is impaired.

Typically, hypophosphatemia is more severe than hypocalcemia in vitamin D deficiency

states because of the increased secretion ofPTH, which, although only partly effective in elevating blood calcium, is capable of promoting phosphaturia.

PHP, on the other hand, has a pathophysiology different from the other disorders of ineffectivePTHaction. PHP resembles hypoparathyroidism (in which PTH synthesis is deficient) and is manifested by hypocalcemia and hyperphosphatemia. The cause of the disorder is defective hormone activation of guanyl nucleotide-binding proteins, resulting in failure of PTH to increase intracellular cyclic AMP (see below).

Chronic Renal Failure Improved medical management of chronic renal failure and/or a more indolent course of the renal disease now allow many patients to survive long enough to develop features of renal osteodystrophy. Phosphate retention and impaired production of $1,25(OH)_2D$ are the principal factors that cause calcium deficiency, secondary hyperparathyroidism, and bone disease. The uremic state also causes impairment of intestinal absorption by mechanisms other than defects in vitamin D metabolism. Nonetheless, treatment with supraphysiologic amounts of vitamin D or calcitriol corrects the impaired calcium absorption.

Hyperphosphatemia in renal failure lowers blood calcium levels by several mechanisms, including extraosseous deposition of calcium and phosphate, impairment of the bone-resorbing action ofPTH, and reduction in $1,25(OH)_2D$ production by remaining renal tissue. Low levels of $1,25(OH)_2D$ due to hyperphosphatemia and destruction of renal tissue and are critical in the development of hypocalcemia.

TREATMENT

Therapy of chronic renal failure (Chap. 270) involves appropriate management of patients prior to dialysis and adjustment of regimens once dialysis is initiated. Attention should be paid to restriction of phosphate in the diet; use of calcium-containing salts as phosphate-binding antacids is preferable, rather than aluminum, to avoid the problem of aluminum intoxication; provision of an adequate calcium intake by mouth, usually 1 to 2 g/d; and supplementation with 0.25 to 1.0 ug/d calcitriol. Each patient must be monitored closely. The aim of therapy is to restore normal calcium balance to prevent osteomalacia and secondary hyperparathyroidism. Reduction of hyperphosphatemia and restoration of normal intestinal calcium absorption by calcitriol can improve blood calcium levels and reduce the manifestations of secondary hyperparathyroidism. Since adynamic bone disease can occur in association with lowPTHlevels, it is important to avoid excessive suppression of the parathyroid glands while recognizing the beneficial effects of controlling the secondary hyperparathyroidism. These patients should probably be closely monitored with PTH assays that detect only the full-length PTH 1-84 to avoid interference by biologically inactive amino-terminally truncated PTH.

Vitamin D Deficiency due to Inadequate Diet and/or Sunlight Vitamin D deficiency due to inadequate intake of dairy products enriched with vitamin D, lack of vitamin supplementation, and reduced sunlight exposure in the elderly, particularly during winter in northern latitudes, is more common in the United States than previously recognized. Biopsies of bone in elderly patients with hip fracture (documenting osteomalacia) and abnormal levels of vitamin D metabolites,PTH, calcium, and phosphate indicate that vitamin D deficiency may occur in as many as 25% of elderly patients, particularly in

areas where there is little ambient sunlight. Concentrations of 25(OH)D are low or low-normal in these patients. Quantitative histomorphometry of bone biopsy specimens reveals widened osteoid seams consistent with osteomalacia. PTH hypersecretion compensates for the tendency for the blood calcium to fall but also induces renal phosphate wasting and results in osteomalacia.

Treatment involves adequate replacement with vitamin D and calcium until the deficiencies are corrected. Severe hypocalcemia rarely occurs in moderately severe vitamin D deficiency of the elderly, but vitamin D deficiency must be considered in the differential diagnosis of mild hypocalcemia.

Defective Vitamin D Metabolism

Anticonvulsant therapy Anticonvulsant therapy with any of several agents induces acquired vitamin D deficiency by increasing the conversion of vitamin D to inactive compounds. The more marginal the vitamin D intake in the diet, the more likely that anticonvulsant therapy will lead to abnormal mineral and bone metabolism (Chap. 340).

Although $1,25(OH)_2D$ levels are lower in patients treated with chronic anticonvulsants than in the normal population, there is a great deal of variation. The greater prevalence of the disorder in some European populations and in the mentally retarded may reflect the lower vitamin D intake of those groups. Restoration of bone mineral mass and reversal of hypocalcemia can be accomplished with vitamin D replacement plus oral calcium. Administration of 50,000 units of vitamin D monthly may be preventive if anticonvulsant therapy needs to be given chronically.

Vitamin D-dependent rickets type I Rickets can be due to *resistance to the action* of vitamin D as well as to vitamin D deficiency. Vitamin D-dependent rickets type I, previously termed *pseudo-vitamin D-resistant rickets*, differs from true vitamin D-resistant rickets (vitamin D-dependent rickets type II, see below) in that it is less severe and the biochemical and radiographic abnormalities can be reversed with appropriate doses of the vitamin or the active metabolite, $1,25(OH)_2D_3$.

Clinical features include hypocalcemia, often with tetany or convulsions, hypophosphatemia, secondary hyperparathyroidism, and osteomalacia, often associated with skeletal deformities and increased alkaline phosphatase. Physiologic amounts of calcitriol cure the disease (Chap. 340). This finding fits with the pathophysiology as the disorder, which is autosomal recessive, is now known to be caused by a series of mutations in the gene for the 25(OH)D-1a-hydroxylase. Over 20 different mutations have been identified. All patients have both alleles inactivated, but often the genetic pattern is that of a compound heterozygote. Response to high doses of vitamin D or calcifediol, as noted in prior years, is probably due to direct effects of 25(OH)D at high levels. Treatment begins with 1 to 2 ug/d calcitriol, but maintenance is satisfactory with physiologic doses of calcitriol (0.5 to 1.0 ug/d). Careful adjustment of calcitriol dose is required, particularly during growth periods.

Vitamin D Ineffective

Intestinal Malabsorption Mild hypocalcemia, secondary hyperparathyroidism, severe

hypophosphatemia, and a variety of nutritional deficiencies occur with gastrointestinal diseases. Hepatocellular dysfunction can lead to reduction in 25(OH)D levels, as in portal or biliary cirrhosis of the liver, and malabsorption of vitamin D and its metabolites, including $1,25(OH)_2D$, may occur in a variety of bowel diseases, hereditary or acquired. Hypocalcemia itself can lead to steatorrhea, due to deficient production of pancreatic enzymes and bile salts. Depending on the disorder, vitamin D or its metabolites can be given parenterally, guaranteeing adequate blood levels of active metabolites.

Vitamin D-dependent rickets type II Vitamin D-dependent rickets type II results from end-organ resistance to the active metabolite $1,25(OH)_2D_3$. The clinical features resemble those of the type I disorder and include hypocalcemia, hypophosphatemia, secondary hyperparathyroidism, and rickets. A clear distinction is partial or total alopecia in type II. Plasma levels of $1,25(OH)_2D$ are at least three times normal, in keeping with the refractoriness of the end organs. Some patients respond to very high doses of vitamin D or vitamin D metabolites (e.g., 17 to 20 ug/d calcitriol). Earlier suggestions that there were both receptor and postreceptor defects are incorrect. All of the genetically characterized phenotypes have mutations in the gene for the vitamin D receptor. Nineteen mutations have been identified that affect different regions of the receptor primarily in the DNA binding domain (with normal ligand binding: these were the so-called postreceptor defects detected by earlier indirect methods) or in the ligand-binding domain (classified previously as receptor negative).

Pseudohypoparathyroidism PHP is a hereditary disorder characterized by symptoms and signs of hypoparathyroidism, typically in association with distinctive skeletal and developmental defects. The hypoparathyroidism is due to a deficient end-organ response toPTH. Hyperplasia of the parathyroids, a response to hormone resistance, causes elevation of PTH levels. Studies, both clinical and basic, have clarified some aspects of this syndrome, including the variable clinical spectrum, the pathophysiology, the genetic defects, and the inheritance.

A working classification of the various forms ofPHP is given in Table 341-4. The classification scheme is based on the signs of ineffectivePTHaction (low calcium and high phosphate), urinary cyclic AMP response to exogenous PTH, the presence or absence of *Albright's hereditary osteodystrophy* (AHO), and assays of the concentration of the $G_s$asubunit of the adenylate cyclase enzyme. Using these criteria, there are four types: PHP type I, subdivided into a and b categories; PHP-II; and pseudopseudohypoparathyroidism (PPHP).

PHP-Ia and PHP-Ib Individuals withPHP-I, the most common of the disorders, show a deficient urinary cyclic AMP response to administration of exogenousPTH. Patients with PHP-I are divided into type a, who have reduced amounts of G_sa in vitro assays with erythrocytes, and type b, with normal amounts of G_sa in erythrocytes. There is a third type (PHP-Ic, reported in a few patients) that differs from PHP-Ia only in having normal erythroycte levels of $G_s$adespite havingAHO, hypocalcemia, and decreased urinary cyclic AMP responses to PTH (presumably with a post-$G_s$adefect in adenyl cyclase stimulation).

Most patients show characteristic features ofAHO, consisting of short stature, round face, skeletal anomalies (brachydactyly), and heterotopic calcification. Patients have low

calcium and high phosphate levels, as with true hypoparathyroidism.PTHlevels, however, are elevated, reflecting resistance to hormone action.

Amorphous deposits of calcium and phosphate are found in the basal ganglia in about half of patients. The defects in metacarpal and metatarsal bones are sometimes accompanied by short phalanges as well, possibly reflecting premature closing of the epiphyses. The typical findings are short fourth and fifth metacarpals and metatarsals. The defects are usually bilateral. Exostoses and radius curvus are frequent. Impairments in olfaction and taste and unusual dermatoglyphic abnormalities have been reported.

PPHP The initial view that the defect responsible forPHP-Ia was simply the deficiency of $G_s$asubunits was temporarily confounded by the subsequent discovery that the same 50% reduction in $G_s$asubunits was seen in patients withPPHP, who have typical features of the hereditary osteodystrophy syndrome despite normal serum calcium levels and normal response of urinary cyclic AMP to exogenousPTH.

Multiple defects have now been identified in the *GNAS-1* gene inPHP-Ia and PPHPpatients. This gene, which is located on chromosome 20q13, encodes the stimulatory G protein subunit G_sa, among other products (see below). Mutations include abnormalities in splice junctions associated with deficient mRNA production and point mutations that result in a protein with defective function as well as the 50% reduction in $G_s$alevels in erythrocytes.

Detailed analyses of disease transmission in affected kindreds have clarified many features ofPHP-Ia,PPHP, and PHP-Ib (Fig. 341-10). The former two entities, traced through multiple kindreds, have an inheritance pattern consistent with gene imprinting -- only females, not males, can transmit the full disease with hypocalcemia -- and PHP and PPHP do not coexist in the same generation. The phenomenon of gene imprinting involves selective inactivation of either the maternal or the paternal allele (Chap. 65). In the case of the $G_s$agene, it is paternally imprinted (silenced) so that the disease PHP-Ia is never inherited from the father carrying the defective allele but only from the mother. On the other hand, the defective allele is not imprinted or silenced in all tissues. It seems possible, therefore, that theAHOphenotype recognized in PPHP as well as PHP-Ia reflects haplotype insufficiency. In the renal cortex, however, it is postulated that only the maternal allele is normally active, such that lack of activity from a defective paternal allele is not of consequence. This explains the occurrence in PHP-Ia of hypocalcemia, hyperphosphatemia, and other stigmata such as variable resistance to other hormones (if similar tissue-specific imprinting occurs in other organs). Strong evidence favoring this overall hypothesis comes from gene knockout studies in the mouse (ablating exon 2 of the gene). Mice inheriting the mutant allele from the female had undetectable $G_s$aprotein in renal cortex and were hypocalcemic and resistant to renal actions ofPTH. Offspring inheriting the mutant allele from the male showed no evidence of PTH resistance or hypercalcemia.

The complex mechanisms that control the GNAS-1 gene also contribute to challenges involved in unraveling the pathogenesis of these disorders. Alternative splicing patterns produce three different transcripts that encode distinct proteins. In addition to G_sa, this gene encodes a second protein product with a unique NH_2-terminus (the XL exon); XL_as

includes exons 2-13. It is unknown whether this protein can function as a stimulatory G protein, but the mRNA encoding it is expressed in numerous endocrine tissues and is transcribed from only the paternal allele. A third transcript is transcribed from only the maternal allele and encodes the protein product, NESP55, which contains no homology with $XL_{a}s$ or $G_{s}a$.

PHP-Ib, lacking theAHOphenotype, shares with PHP-Ia the resistance toPTHaction and a blunted urinary cyclic AMP response to administered PTH, a standard test for hormone resistance (Table 341-4). PHP-Ib patients, however, show normal levels of $G_{s}a$ in erythrocytes. Bone responsiveness may be excessive rather than blunted in PHP-Ib compared to PHP-Ia patients, based on case reports that have emphasized an osteitis fibrosa-like pattern in some PHP patients who lack the AHO phenotype. The inheritance patterns in PHP-Ib kindreds are clearly consistent with paternal imprinting and lack male transmission of symptomatic disease; gene cloning studies have narrowed the responsible region to chromosome 20, close to -- if not within -- the *GNAS-1* gene locus. Elucidation of the responsible genetic and pathogenetic mechanisms in this disorder may further illuminate the function of the complex *GNAS-1* gene and the role of its products in hormonal signaling.

PHP-II refers to patients with hypocalcemia and hyperphosphatemia who have a normal urinary cyclic AMP response toPTH. These patients are assumed to have a defect in the response to PTH at a locus distal to cyclic AMP production, although at least some patients may instead have occult vitamin D deficiency.

The diagnosis of these hormone-resistant states can usually be made without difficulty when there is a positive family history for developmental defects and/or the presence of developmental anomalies, including brachydactyly, in association with the signs and symptoms of hypoparathyroidism. In all categories -- PHP-Ia, -Ib, and -II -- serumPTHlevels are elevated, particularly when patients are hypocalcemic. However, patients with PHP-Ib or PHP-II do not have phenotypic abnormalities, only hypocalcemia with high PTH levels, confirming hormone resistance. In PHP-Ib, the response of urinary cyclic AMP to the administration of exogenous PTH is blunted. Levels of G_{s}asubunits in erythrocyte membranes are, however, normal in those with PHP-Ib. The diagnosis of PHP-II is more complex, in that cyclic AMP responses in urine are, by definition, normal. Since vitamin D deficiency itself can dissociate phosphaturic and urinary cyclic AMP responses to exogenous PTH, vitamin D deficiency must be excluded before the diagnosis of PHP-II can be entertained.

TREATMENT

Treatment of PHPis similar to that of hypoparathyroidism, except that the doses of vitamin D and calcium are usually lower than those required in true hypoparathyroidism, presumably because the defect in PHP is only partial because of imprinting in specific tissues (renal cortex vs. renal medulla). Variability in response makes it necessary to establish the optimal regimen for each patient, based on maintaining the appropriate blood calcium level and urinary calcium excretion.

PTHOverwhelmed Occasionally, loss of calcium from the ECF is so severe that PTH cannot compensate. Such situations include acute pancreatitis and severe, acute

hyperphosphatemia, often in association with renal failure, conditions in which there is rapid efflux of calcium from extracellular fluid. Severe hypocalcemia can occur quickly; PTH rises in response to hypocalcemia but does not return blood calcium to normal.

Severe, Acute Hyperphosphatemia Severe hyperphosphatemia is associated with extensive tissue damage or cell destruction (Chap. 340). The combination of increased release of phosphate from muscle and impaired ability to excrete phosphorus because of renal failure causes moderate to severe hyperphosphatemia, the latter causing calcium loss from the blood and mild to moderate hypocalcemia. Hypocalcemia is usually reversed with tissue repair and restoration of renal function as phosphorus and creatinine values return to normal. There may even be a mild hypercalcemic period in the oliguric phase of renal function recovery. This sequence, severe hypocalcemia followed by mild hypercalcemia, reflects widespread deposition of calcium in muscle and subsequent redistribution of some of the calcium to theECFafter return of phosphate levels to normal.

Other causes of hyperphosphatemia include hypothermia, massive hepatic failure, and hematologic malignancies, either because of high cell turnover of malignancy or because of cell destruction by chemotherapy.

TREATMENT

Treatment is directed toward lowering of blood phosphate by the administration of phosphate-binding antacids or dialysis, often needed for the management of renal failure. Although calcium replacement may be necessary if hypocalcemia is severe and symptomatic, calcium administration during the hyperphosphatemic period tends to increase extraosseous calcium deposition and aggravate tissue damage. The levels of $1,25(OH)_2D$ may be low during the hyperphosphatemic phase and return to normal during the oliguric phase of recovery.

Osteitis Fibrosis after Parathyroidectomy Severe hypocalcemia after parathyroid surgery is less common now that osteitis fibrosa cystica is an infrequent manifestation of hyperparathyroidism. When osteitis fibrosa cystica is severe, however, bone mineral deficits can be large. After parathyroidectomy, hypocalcemia can persist for days if calcium replacement is inadequate. Treatment may require parenteral administration of calcium; addition of calcitriol and oral calcium supplementation is sometimes needed for weeks to a month or two until bone defects are filled (which, of course, is of therapeutic benefit in the skeleton), making it possible to discontinue parenteral calcium and/or reduce the amount.

DIFFERENTIAL DIAGNOSIS OF HYPOCALCEMIA

Care must be taken to ensure that true hypocalcemia is present; in addition, acute transient hypocalcemia can be a manifestation of a variety of severe, acute illnesses, as discussed above. *Chronic hypocalcemia*, however, can usually be ascribed to a few disorders associated with absent or ineffectivePTH. Important clinical criteria include the duration of the illness, signs or symptoms of associated disorders, and the presence of features that suggest a hereditary abnormality. A nutritional history can be helpful in recognizing a low intake of vitamin D and calcium in the elderly, and a history of

excessive alcohol intake may suggest magnesium deficiency.

Hypoparathyroidism andPHP are typically lifelong illnesses, usually (but not always) appearing by adolescence; hence a recent onset of hypocalcemia in an adult is more likely due to nutritional deficiencies, renal failure, or intestinal disorders that result in deficient or ineffective vitamin D. Neck surgery, even long past, however, can be associated with a delayed onset of postoperative hypoparathyroidism. A history of seizure disorder raises the issue of anticonvulsive medication. Developmental defects, particularly in childhood and adolescence, may point to the diagnosis of PHP. Rickets and a variety of neuromuscular syndromes and deformities may indicate ineffective vitamin D action, either due to defects in vitamin D metabolism or to vitamin D deficiency.

A pattern of *low calcium with high phosphorus* in the absence of renal failure or massive tissue destruction almost invariably means hypoparathyroidism orPHP. A *low calcium and low phosphorus* points to absent or ineffective vitamin D, thereby impairing the action ofPTH on calcium metabolism (but not phosphate clearance). The relative ineffectiveness of PTH in vitamin D deficiency, anticonvulsant therapy, gastrointestinal disorders, and hereditary defects in vitamin D metabolism leads to secondary hyperparathyroidism as a compensation. The relatively unopposed action of the excess PTH on renal tubule phosphate transport, which is less dependent on vitamin D than calcium transport, accounts for renal phosphate wasting and hypophosphatemia.

Exceptions to these patterns may occur. Most forms of hypomagnesemia are due to long-standing nutritional deficiency as seen in chronic alcoholics. Despite the fact that the hypocalcemia is principally due to an acute absence ofPTH, phosphate levels are usually low, rather than elevated as in hypoparathyroidism. Chronic renal failure is often associated with hypocalcemia and hyperphosphatemia, despite secondary hyperparathyroidism.

Diagnosis is usually established by application of thePTHimmunoassay, tests for vitamin D metabolites, and measurements of the urinary cyclic AMP response to exogenous PTH. In hereditary and acquired hypoparathyroidism and in severe hypomagnesemia, PTH is either undetectable or in the normal range. This finding in a hypocalcemic patient is supportive of hypoparathyroidism, as distinct from ineffective PTH action, in which even mild hypocalcemia is associated with elevated PTH levels. Hence a failure to detect elevated PTH levels establishes the diagnosis of hypoparathyroidism; elevated levels suggest the presence of secondary hyperparathyroidism, as found in many of the situations in which the hormone is ineffective due to associated abnormalities in vitamin D action. Assays for 25(OH)D and $1,25(OH)_2D$ can be helpful. Low or low normal 25(OH)D indicates vitamin D deficiency due to lack of sunlight, inadequate vitamin D intake, or intestinal malabsorption. A low level of $1,25(OH)_2D$ in the presence of elevated concentrations of PTH suggests ineffective PTH action in disorders such as chronic renal failure, severe vitamin D deficiency, vitamin D-dependent rickets type I, andPHP. Recognition that mild hypocalcemia, rickets, and hypophosphatemia are due to anticonvulsant therapy is made by history.

TREATMENT

Hypocalcemic States The management of hypoparathyroidism,PHP, chronic renal failure, and hereditary defects in vitamin D metabolism involves the use of vitamin D or vitamin D metabolites and calcium supplementation. Vitamin D itself is the least expensive form of vitamin D replacement and is frequently used in the management of uncomplicated hypoparathyroidism and some disorders associated with ineffective vitamin D action. When vitamin D is used prophylactically, as in the elderly or in those with chronic anticonvulsant therapy, there is a wider margin of safety than with the more potent metabolites. However, most of the conditions in which vitamin D is administered chronically for hypocalcemia require amounts 50 to 100 times the daily replacement dose because the formation of $1,25(OH)_2D$ is deficient. In such situations, vitamin D is no safer than the active metabolite because intoxication can occur with high-dose therapy (because of storage in fat). Calcitriol is more rapid in onset of action and also has a short biologic half-life.

Vitamin D (5 ug/d) or calcifediol and lower doses of calcitriol (0.25 to 1.0 ug/d) are required to prevent rickets in normal individuals. In contrast, 1 to 3 mg (1000 to 3000 ug of vitamin D_2 or D_3 is typically required in hypoparathyroidism; doses of calcifediol are also high (several hundred micrograms per day). The dose of calcitriol is unchanged in hypoparathyroidism, since the defect is in hydroxylation by the 25(OH)D-1a-hydroxylase.

Patients with hypoparathyroidism should be given 2 to 3 g elemental calcium by mouth each day. The two agents, vitamin D or calcitriol and oral calcium, can be varied independently. If hypocalcemia alternates with episodes of hypercalcemia in more brittle patients with hypoparathyroidism, administration of calcitriol and use of thiazides, as discussed above, may make management easier.

342. OSTEOPOROSIS - *Robert Lindsay, Felicia Cosman*

Osteoporosis, characterized by decreased bone strength, is prevalent among postmenopausal women but also occurs in men and women with underlying conditions or major risk factors associated with bone demineralization. Its chief clinical manifestations are vertebral and hip fractures. Osteoporosis affects>10 million individuals in the United States, but only 10 to 20% are diagnosed and treated.

DEFINITION

Osteoporosis is defined as a reduction of bone mass (or density) or the presence of a fragility fracture. This reduction in bone tissue is accompanied by deterioration in the architecture of the skeleton, leading to a markedly increased risk of fracture. Osteoporosis is defined operationally as a bone density that falls 2.5 standard deviations (SD) below the mean -- also referred to as a *T-score* of-2.5. Those who fall at the lower end of the young normal range (a T-score of >1 SD below the mean) have low bone density and are considered to be at increased risk of osteoporosis.

EPIDEMIOLOGY

In the United States, as many as 8 million women and 2 million men have osteoporosis (T-score <-2.5), and an additional 18 million individuals have bone mass levels that put them at increased risk of developing osteoporosis (e.g., bone mass T-score <-1.0). Osteoporosis occurs more frequently with increasing age as bone tissue is progressively lost. In women, the loss of ovarian function at menopause (typically after age 50) precipitates rapid bone loss such that most women meet the criteria for osteoporosis by age 70.

The epidemiology of fractures follows similar trends as the loss of bone density. Fractures of the distal radius increase in frequency before age 50 and plateau by age 60, with only a modest age-related increase thereafter. In contrast, incidence rates for hip fractures double every 5 years after age 70 (Fig. 342-1). This distinct epidemiology may be related to the way people fall as they age, with fewer falls on an outstretched hand. At least 1.5 million fractures occur each year in the United States as a consequence of osteoporosis. As the population continues to age, the total number of fractures will continue to escalate.

About 300,000 hip fractures occur each year in the United States, most of which require hospital admission and surgical intervention. The probability that a 50-year-old white individual will have a hip fracture during his or her lifetime is 14% for women and 5% for men; the risk for African Americans is much lower (about half these rates). Hip fractures are associated with a high incidence of deep vein thrombosis and pulmonary embolism (20 to 50%) and a mortality rate between 5 and 20% during the few months after surgery.

There are about 500,000 vertebral crush fractures per year in the United States. Only a fraction of these are recognized clinically, since many are relatively asymptomatic and are identified incidentally during radiography for other purposes (Fig. 342-2). Vertebral fractures rarely require hospitalization but are associated with long-term morbidity and a

slight increase in mortality. Multiple fractures lead to height loss (often of several inches), kyphosis, and secondary pain and discomfort related to altered biomechanics of the back. Thoracic fractures can be associated with restrictive lung disease, whereas lumbar fractures are associated with abdominal symptoms including distention, early satiety, and constipation.

Approximately 200,000 wrist fractures occur in the United States each year. Fractures of other bones also occur with osteoporosis, which is not surprising given that bone loss is a systemic phenomenon. Fractures of the pelvis and proximal humerus are clearly associated with osteoporosis. Although some fractures are clearly the result of major trauma, the threshold for fracture is reduced for an osteoporotic bone (Fig. 342-3). A list of common risk factors for osteoporotic fractures is summarized inTable 342-1. Prior fractures, a family history of osteoporotic fractures, and low body weight are each independent predictors of fracture. Chronic diseases that increase the risk of falling or frailty, including dementias, Parkinson's disease, and multiple sclerosis, also increase fracture risk.

In the United States and Europe, osteoporosis-related fractures are more common among women than men, presumably due to a lower peak bone mass as well as postmenopausal bone loss in women. However, this gender difference in bone density and age-related increase in hip fractures is not as apparent in some other cultures, possibly due to genetics, physical activity level, or diet.

PATHOPHYSIOLOGY

Bone Remodeling Osteoporosis results from bone loss due to normal age-related changes in bone remodeling as well as extrinsic and intrinsic factors that exaggerate this process. These changes may be superimposed on a low peak bone mass. Consequently, the bone remodeling process is fundamental for understanding the pathophysiology of osteoporosis (Chap. 340). The skeleton increases in size by linear growth and by apposition of new bone tissue on the outer surfaces of the cortex (Fig. 342-4). This latter process is the phenomenon of modeling, which also allows the long bones to adapt in shape to the stresses placed upon them. Increased sex hormone production at puberty is required for maximum skeletal maturation, which reaches maximum mass and density in early adulthood. Nutrition and lifestyle also play an important role in growth, though genetic factors are the major determinants of peak skeletal mass and density. Numerous genes control skeletal growth, peak bone mass, and body size, but it is likely that separate genes control skeletal structure and density. Heritability estimates of 50 to 80% for bone density and size have been derived based on twin studies. Though peak bone mass is often lower among individuals with a family history of osteoporosis, association studies of candidate genes [vitamin D receptor; Type I collagen, the estrogen receptor (ER), interleukin (IL) 6; and insulin-like growth factor (IGF) I] have not been consistently replicated. Linkage studies suggest that a genetic locus on chromosome 11 is associated with high bone mass.

Once peak skeletal mass has been attained, the process of remodeling becomes the principal metabolic activity of the skeleton. This process has three primary functions: (1) to repair microdamage within the skeleton, (2) to maintain skeletal strength, and (3) to supply calcium from the skeleton to maintain serum calcium. Acute demands for calcium

involve osteoclast-mediated resorption as well as calcium transport by osteocytes. The activation of remodeling may be induced by microdamage to bone due to excessive or accumulated stress.

Bone remodeling is also regulated by several circulating hormones, including estrogens, androgens, vitamin D, and parathyroid hormone (PTH), as well as locally produced growth factors such asIGF-I and -II, transforming growth factor (TGF) b, parathyroid hormone-related peptide (PTHrP),ILs, prostaglandins, tumor necrosis factor (TNF), and osteoprotegrin ligand (Fig. 342-5). Additional influences include include nutrition (particularly calcium intake) and physical activity level. The end result of this remodeling process is that the resorbed bone is replaced by an equal amount of new bone tissue. Thus, the mass of the skeleton remains constant after peak bone mass is achieved in adulthood. After age 30 to 45, however, the resorption and formation processes become imbalanced, and resorption exceeds formation. This imbalance may begin at different ages and varies at different skeletal sites; it becomes exaggerated in women after menopause. Excessive bone loss can be due to an increase in osteoclastic activity and/or a decrease in osteoblastic activity. In addition, an increase in remodeling activation frequency can magnify the small imbalance seen at each remodeling unit.

In trabecular bone, if the osteoclasts are sufficiently aggressive to penetrate trabeculae, they leave no template for new bone formation to occur and, consequently, may cause rapid bone loss. In cortical bone, increased activation of remodeling creates more porous bone. The effect of this increased porosity on cortical bone strength may be modest if the overall diameter of the bone is not changed. However, decreased apposition of new bone on the periosteal surface coupled with increased endocortical resorption of bone decreases the biomechanical strength of long bones. Even a slight exaggeration in normal bone loss patterns increases the risk of osteoporotic fracture.

Calcium Nutrition Peak bone mass may be impaired by inadequate calcium intake during growth, thereby leading to increased risk of osteoporosis in later life. During the adult phase of life, calcium deprivation induces secondary hyperparathyroidism and an increase in the rate of remodeling.PTHstimulates the hydroxylation of vitamin D in the kidney, leading to increased levels of 1,25-dihydroxyvitamin D [1,25$(OH)_2$D] and enhanced gastrointestinal calcium absorption. PTH also reduces renal calcium loss. Though these are appropriate short-term homeostatic responses for improving calcium economy, the long-term effects are detrimental to the skeleton because of the ongoing imbalance at remodeling sites.

Total daily calcium intakes of<400 mg are likely to be detrimental to the skeleton, but there is more doubt about intakes in the 600- to 800-mg range, which is the average intake among adults in the United States. The recommended daily required intake of 1000 to 1200 mg for adults accomodates population heterogeneity in controlling calcium balance (Chap. 73).

Vitamin D (See also Chap. 340) Severe vitamin D deficiency causes rickets in children or osteomalacia in adults. There is accumulating evidence that vitamin D deficiency may be more prevalent than previously thought, particularly among individuals at increased risk, such as the elderly; those living in northern latitudes; and in individuals with poor nutrition, malabsorption, or chronic liver or renal disease. Modest vitamin D deficiency

leads to compensatory secondary hyperparathyroidism and is an important risk factor for osteoporosis and fractures. Some studies have shown that>50% of inpatients on a general medical service exhibit biochemical features of vitamin D deficiency, including increased levels of PTH and alkaline phosphatase and lower levels of ionized calcium. In women living in northern latitudes, it has been shown that vitamin D levels decline during the winter months. This is associated with a striking seasonal bone loss, reflecting increased bone turnover. Treatment with vitamin D and calcium supplementation prevents this seasonal effect on bone metabolism. Reduced fracture rates have also been documented among individuals in northern latitudes who have greater vitamin D intake and have higher 25-hydroxyvitamin D [25(OH)D] levels (see below).

Estrogen Status Estrogen deficiency probably causes bone loss by two distinct but interrelated mechanisms: (1) activation of new bone remodeling sites, and (2) exaggeration of the imbalance between bone formation and resorption. The change in activation frequency causes a transient bone loss until a new steady state between resorption and formation is achieved. The remodeling imbalance, however, results in a permanent decrement in mass that can only be corrected by a remodeling event during which bone formation exceeds resorption. In addition, the very presence of more remodeling sites in the skeleton increases the probability that trabeculae will be penetrated, thereby eliminating the template upon which new bone can be formed and accelerating the loss of bony tissue.

The most frequent estrogen-deficient state is the cessation of ovarian function at the time of menopause, which occurs on average at the age of 51. Thus, with current life expectancy, an average woman will spend about 30 years without ovarian supply of estrogen. The mechanism by which estrogen deficiency causes bone loss is summarized inFig. 342-5. Marrow cells (macrophages, monocytes, osteoclast precursors, mast cells) as well as bone cells (osteoblasts, osteocytes, osteoclasts) expressERsa and b. The net effect of estrogen deficiency is increased osteoclast recruitment and perhaps activity. Estrogen may also play an important role in determining the life span of bone cells by controlling the rate of apoptosis. Thus, in situations of estrogen deprivation, the life span of osteoblasts may be decreased whereas the longevity of osteoclasts is increased.

Since remodeling is initiated at the surface of bone, it follows that trabecular bone -- which has a considerably larger surface area (80% of the total) than cortical bone -- will be preferentially affected by estrogen deficiency. Fractures occur earliest at sites where trabecular bone contributes most to bone strength; consequently, vertebral fractures are the most common early consequence of estrogen deficiency.

Physical Activity Inactivity, such as prolonged bed rest or paralysis, results in significant bone loss. Concordantly, athletes have higher bone mass than the general population. These changes in skeletal mass are most marked when the stimulus begins during growth and before the age of puberty. Adults are less capable than children of increasing bone mass following restoration of physical activity. Epidemiologic data support the beneficial effects on the skeleton of chronic high levels of physical activity. Fracture risk is lower in rural communities and in countries where physical activity is maintained into old age. However, when exercise is initiated during adult life, the effects

of moderate exercise are modest, with a bone mass increase of 1 to 2%. It is argued that more active individuals are less likely to fall and are more capable of protecting themselves upon falling, thereby reducing fracture risk.

Chronic Disease Various genetic and acquired diseases are associated with an increase in the risk of osteoporosis (Table 342-2). Mechanisms that contribute to bone loss are unique for each disease and typically result from multiple factors including nutrition, reduced physical activity levels, and factors that affect bone-remodeling rates.

Medications A large number of medications used in clinical practice have potentially detrimental effects on the skeleton (Table 342-3). *Glucocorticoids* are a common cause of medication-induced osteoporosis. It is often not possible to determine the extent to which osteoporosis is related to the glucocorticoid or to other factors, as treatment is superimposed on the effects of the primary disease, which may itself be associated with bone loss (e.g., rheumatoid arthritis). Excessive doses of thyroid hormone can accelerate bone remodeling and result in bone loss.

Other medications have less detrimental effects upon the skeleton than pharmacologic doses of glucocorticoids. *Anticonvulsants* are thought to increase the risk of osteoporosis, although many affected individuals have concomitant vitamin D insufficiency, as anticonvulsants that induce the cytochrome P450 system alter vitamin D metabolism. Patients undergoing transplantation are at high risk for rapid bone loss and fracture not only from glucocorticoids but also from treatment with other *immunosuppressants*, such as cyclosporine and tacrolimus (FK506). In addition, these patients often have underlying metabolic abnormalities, such as hepatic or renal failure, that predispose to osteopenia.

Cigarette Consumption The use of cigarettes over a long period has detrimental effects on bone mass. These effects may be mediated directly, by toxic effects on osteoblasts, or indirectly by modifying estrogen metabolism. On average, cigarette smokers reach menopause 1 to 2 years earlier than the general population. Cigarette smoking also has secondary effects on bone growth, such as illness, frailty, decreased exercise, and the need for additional medications (e.g., glucocorticoids for lung disease).

MEASUREMENT OF BONE MASS

Several noninvasive techniques are now available for estimating skeletal mass or density. These include dual-energy x-ray absorptiometry (DXA), single-energy xray absorptiometry (SXA), quantitative computed tomography (CT), and ultrasound.

DXAis a highly accurate x-ray technique that has become the standard for measuring bone density in most centers. Though it can be used for measurements of any skeletal site, clinical determinations are usually made of the lumbar spine and hip. Portable DXA machines have been developed that measure the heel (calcaneus), forearm (radius and ulna), or finger (phalanges), and DXA can also be used to measure body composition. In the DXA technique, two x-ray energies are used to estimate the area of mineralized tissue, and the mineral content is divided by the area, which partially corrects for body size. However, this correction is only partial since DXA is a two-dimensional scanning

technique and cannot estimate the depths or posteroanterior length of the bone. Thus, small people tend to have lower-than-average bone mineral density (BMD). Bone spurs, which are frequent in osteoarthritis, tend to falsely increase bone density of the spine. Because DXA instrumentation is provided by several different manufacturers, the output varies in absolute terms. Consequently, it has become standard practice to relate the results to "normal" values using T-scores, which compare individual results to those in a young population that is matched for race and gender. Alternatively, Z-scores compare individual results to those of an age-matched population that is also matched for race and gender. Thus, a 60-year-old woman with a Z-score of -1 (1 SD below mean for age) could have a T-score of -2.5 (2.5 SD below mean for a young control group) (Fig. 342-6).

CTis used primarily to measure the spine, and peripheral CT is used to measure bone in the forearm or tibia. Research into the use of CT for measurement of the hip is ongoing. The results obtained from CT are different from all others currently available since this technique specifically analyzes trabecular bone and can provide a true density (mass of bone per unit volume) measurement. However, CT remains expensive, involves greater radiation exposure, and is less reproducible.

Ultrasound is used to measure bone mass by calculating the attenuation of the signal as it passes through bone or the speed with which it traverses the bone. It is unclear whether ultrasound assesses bone quality, but this may be an advantage of the technique. Because of its relatively low cost and mobility, ultrasound is amenable for use as a screening procedure.

All of these techniques for measuringBMD have been approved by the U.S. Food and Drug Administration (FDA) based upon their capacity to predict fracture risk. The hip is the preferred site of measurement in most individuals, since it directly assesses bone mass at an important fracture site. When hip measurements are performed byDXA, the spine can be measured at the same time. In younger individuals, such as perimenopausal women, spine measurements may be the most sensitive indicator of bone loss.

When to Measure Bone Mass Clinical guidelines developed by the National Osteoporosis Foundation recommend bone mass measurements in postmenopausal women, assuming they have risk factors for osteoporosis in addition to age, gender, and estrogen deficiency. The guidelines further recommend that bone mass measurement be considered in *all* women by age 60 to 65. Criteria approved for Medicare reimbursement of BMDare summarized in Table 342-4.

When to Treat Based Upon Bone Mass Results The guidelines developed by the National Osteoporosis Foundation suggest that patients be considered for treatment whenBMD> 2.5 SD below the mean value for young adults (T-score £ -2.5). Treatment should also be considered in women with risk factors in addition to menopause, if measurement of BMD of the hip gives a T score< -2.0. Because the fracture risk increases continuously as T-scores decline, there is no critical threshold and treatment decisions must be individualized. Cost-benefit analyses in this area are changing rapidly because of the availability of new drugs [e.g., bisphosphonates, selective estrogen receptor modulators (SERMs)] and the results of trials [e.g., the Heart and

Estrogen-Progestin Replacement Study (HERS)] examining the long-term cardiovascular effects of hormone replacement therapy (HRT).

Approach to the Patient

The perimenopausal transition is a good opportunity to initiate discussion about risk factors for osteoporosis and to consider indications for aBMDtest. A careful history and physical examination should be performed to identify risk factors for osteoporosis. As noted above, a low Z-score increases the suspicion of a secondary disease. Height loss >2.5 to 3.8 cm (1 to 1.5 in.) is an indication for radiography to rule out asymptomatic vertebral fractures, as is the presence of significant kyphosis or back pain, particularly if it began after menopause. For patients who present with fractures, it is important to ensure that the fractures are truly due to trauma or osteoporosis and not to secondary underlying malignancy. Usually this is clear on routine radiography, but on occasion,CT, magnetic resonance imaging, or radionuclide scans may be helpful. Severe unremitting back pain also raises the suspicion of other causes such as malignancy (especially myeloma).

Routine Laboratory Evaluation There is no established algorithm for the evaluation of women presenting with osteoporosis. A general evaluation that includes complete blood count, serum calcium, and perhaps urine calcium is helpful for identifying selected secondary causes of low bone mass, particularly for women with fractures or very low Z-scores. An elevated serum calcium level suggests hyperparathyroidism or malignancy, whereas a reduced serum calcium level may reflect malnutrition and osteomalacia. In the presence of hypercalcemia, a serumPTHlevel differentiates between hyperparathyroidism (PTH-) and malignancy (PTH^{-}), and a highPTHrPlevel can help document the presence of humoral hypercalcemia of malignancy (Chap. 341). A low urine calcium (<50 mg/24 h) suggests osteomalacia, malnutrition, or malabsorption; a high urine calcium (>300 mg/24 h) is indicative of hypercalciuria and must be investigated further. Hypercalciuria occurs primarily in three situations: (1) a renal calcium leak, which is more frequent in males with osteoporosis; (2) absorptive hypercalciuria, which can be idiopathic or associated with increased $1,25(OH)_2D$ in granulomatous disease; or (3) hematologic malignancies or conditions associated with excessive bone turnover such as Paget's disease, hyperparathyroidism, and hyperthyroidism.

When there is clinical suspicion of hyperthyroidism or Cushing's syndrome, thyroid stimulating hormone (TSH) or urinary free cortisol levels should be measured. When bowel disease, malabsorption, or malnutrition is suspected, serum albumin, cholesterol, and a complete blood count should be checked. Asymptomatic malabsorption might be suspected if there is anemia (macrocytic -- vitamin B_{12} or folate deficiency; or microcytic -- iron deficiency), or low serum cholesterol or urinary calcium levels. If these or other features suggest malabsorption, further evaluation is required. Asymptomatic celiac sprue with selective malabsorption is not uncommon; the diagnosis requires antigliadin and antiendomysial antibody tests and often a small-bowel biopsy. A trial of a gluten-free diet may be confirmatory (Chap. 286).

Myeloma can masquerade as generalized osteoporosis, although it more commonly presents with bone pain and characteristic "punched-out" lesions on radiography.

Serum and urine electrophoresis and evaluation for light chains in urine are required to exclude this diagnosis. A bone marrow biopsy may be required to rule out myeloma (in patients with equivocal electrophoretic results) and can also be used to exclude mastocytosis, leukemia, and other marrow infiltrative disorders, such as Gaucher's disease.

Bone Biopsy Although the use of bone biopsy is rarely required today, it remains an important tool in clinical research. Tetracycline labeling of the skeleton allows determination of the rate of remodeling as well as evaluation for other metabolic bone diseases. The current use ofBMDtests, in combination with hormonal evaluation and biochemical markers of bone remodeling, has largely replaced bone biopsy.

Biochemical Markers Several biochemical tests are now available that provide an index of the overall rate of bone remodeling (Table 342-5). Biochemical markers are usually characterized as those related primarily to *bone formation* or *bone resorption*. These tests measure the overall state of bone remodeling at a single point in time. Clinical use of these tests has been hampered by biologic variability (in part related to circadian rhythm) as well as to analytical variability.

For the most part, remodeling markers do not predict rates of bone loss well enough to use this information clinically. However, markers of bone resorption may help in the prediction of fracture risk, particularly in older individuals. In women³65 years, when bone density results are greater than the usual treatment thresholds noted above, a high level of bone resorption should prompt consideration of treatment. The primary use of biochemical markers is for monitoring the response to treatment. With the introduction of antiresorptive therapeutic agents, bone remodeling declines rapidly, with the fall in resorption occurring earlier than the fall in formation. Inhibition of bone resorption is maximal within 3 to 6 months. Thus, measurement of bone resorption prior to initiating therapy and 4 to 6 months after starting therapy provides an earlier estimate of patient response than does bone densitometry. A decline in resorptive markers can be ascertained after treatment with bisphosphonates andHRT; this effect is less marked after treatment with either raloxifene or intranasal calcitonin. A biochemical marker response to therapy is particularly useful for asymptomatic patients and helps to ensure long-term compliance. When agents that stimulate bone formation become available, bone remodeling markers may be useful to help select therapy. However, since all current therapeutic approaches reduce bone turnover, this strategy currently has little value.

TREATMENT

Management of Osteoporotic Fractures Treatment of the patient with osteoporosis frequently involves management of acute fractures as well as treatment of the underlying disease. Hip fractures almost always require surgical repair if the patient is to become ambulatory again. Depending on the location and severity of the fracture, condition of the neighboring joint, and general status of the patient, procedures may include open reduction and internal fixation with pins and plates, hemiarthroplasties, and total arthroplasties. These surgical procedures are followed by intense rehabilitation in an attempt to return patients to their prefracture functional level. Long bone fractures often require either external or internal fixation. Other fractures (e.g., vertebral, rib, and

pelvic fractures) are usually managed with only supportive care, requiring no specific orthopedic treatment.

Only ~25 to 30% of vertebral compression fractures present with sudden-onset back pain. For acutely symptomatic fractures, treatment with analgesics is required, including nonsteroidal anti-inflammatory agents and/or acetaminophen, sometimes with the addition of a narcotic agent (codeine or oxycodone). A few small, randomized clinical trials have demonstrated that calcitonin may reduce pain related to acute vertebral compression fracture. A recently developed, but still experimental, technique involves percutaneous injection of artificial cement (polymethylmethacrylate) into the vertebral body (vertebroplasty or kyphoplasty); this has been reported to offer significant immediate pain relief in the majority of patients. Short periods of bed rest may be helpful for pain management, but, in general, early mobilization is recommended as it helps prevent further bone loss associated with immobilization. Occasionally, use of a soft elastic-style brace may facilitate earlier mobilization. Muscle spasms often occur with acute compression fractures and can be treated with muscle relaxants and heat treatments.

Severe pain usually resolves within 6 to 10 weeks. Chronic pain is probably not bony in origin; instead, it is related to abnormal strain on muscles, ligaments, and tendons and to secondary facet-joint arthritis associated with alterations in thoracic and/or abdominal shape. Chronic pain is difficult to treat effectively and may require analgesics, sometimes including narcotic analgesics. Frequent intermittent rest in a supine or semireclining position is often required to allow the soft tissues, which are under tension, to relax. Back-strengthening exercises (paraspinal) may be beneficial. Heat treatments help relax muscles and reduce the muscular component of discomfort. Various physical modalities, such as ultrasound and transcutaneous nerve stimulation, may be beneficial in some patients. Pain also occurs in the neck region, not as a result of compression fractures (which almost never occur in the cervical spine as a result of osteoporosis) but because of chronic strain associated from trying to elevate the head in a person with a severe thoracic kyphosis.

Multiple vertebral fractures are often associated with psychological symptoms, not always commonly appreciated. The changes in body configuration and back pain can lead to marked loss of self-image and a secondary depression. Altered balance, precipitated by the kyphosis and the anterior movement of the body's center of gravity, leads to a fear of falling, a consequent tendency to remain indoors, and the onset of social isolation. These symptoms can sometimes be alleviated by family support and/or psychotherapy. Medication may be necessary when depressive features are present.

Management of the Underlying Disease

Risk Factor Reduction Patients should be thoroughly educated to reduce the likelihood of any risk factors associated with bone loss and falling. Medications should be reviewed to ensure that any glucocorticoid medication is truly indicated and is being given in doses as low as possible. For those on thyroid hormone replacement,TSHtesting should be performed to ensure that an adequate, but not excessive, dose is being used, as excess can be associated with increased bone loss. In patients who smoke, efforts should be made to facilitate smoking cessation. Reducing

risk factors for falling also includes alcohol abuse treatment and a review of the medical regimen for any drugs that might be associated with orthostatic hypotension and/or sedation, including hypnotics and anxiolytics. If nocturia occurs, the frequency should be reduced, if possible (e.g., by decreasing or modifying diuretic use), as arising in the middle of sleep is a common precipitant of a fall. Patients should be instructed about environmental safety with regard to eliminating exposed wires, curtain strings, slippery rugs, and mobile tables. Avoiding stocking feet on wood floors, checking carpet condition (particularly on stairs), and providing good light in paths to bathrooms and outside the home are good preventive measures. Treatment for impaired vision is recommended, particularly a problem with depth perception, which is specifically associated with increased falling risk. Elderly patients with neurologic impairment (e.g., stroke, Parkinson's disease, Alzheimer's disease) are particularly at risk of falling and require specialized supervision and care.

Nutritional Recommendations

CALCIUM A large body of data indicates that optimal calcium intake reduces bone loss and suppresses bone turnover. Recommended intakes from a recent report from the Institute of Medicine are shown inTable 342-6. The National Health and Nutritional Evaluation Studies (NHANES) have consistently documented that average calcium intakes fall considerably short of these recommendations. The preferred source of calcium is from dairy products and other foods, but many patients require additional calcium supplementation. Food sources of calcium are dairy products (milk, yogurt, and cheese) and fortified foods such as certain cereals, waffles, snacks, juices, and crackers. Some of these fortified foods contain as much calcium per serving as milk.

If a calcium supplement is required, it should be taken in doses£600 mg at a time, as the calcium absorption fraction decreases at higher doses. Calcium supplements should be calculated based on the elemental calcium content of the supplement, not the weight of the calcium salt (Table 342-7). Calcium supplements containing carbonate are best taken with food since they require acid for solubility. Calcium citrate supplements can be taken at any time.

Several controlled clinical trials of calcium plus vitamin D have confirmed reductions in clinical fractures, including fractures of the hip (~20 to 30% risk reduction). All recent studies of pharmacologic agents have been conducted in the context of calcium replacement (± vitamin D). Thus, it is standard practice to ensure an adequate calcium and vitamin D intake in patients with osteoporosis, whether they are receiving additional pharmacologic therapy or not.

Although side effects from supplemental calcium are minimal, individuals with a history of kidney stones should have a 24-h urine calcium determination before starting increased calcium to avoid hypercalciuria. Furthermore, a thiazide-containing diuretic might be indicated in some patients to increase renal tubular calcium reabsorption and to reduce urine calcium levels.

VITAMIN D Vitamin D is synthesized in skin under the influence of heat and ultraviolet light (Chap. 340). However, large segments of the population do not obtain sufficient vitamin D to maintain what is now considered an adequate supply [serum 25(OH)D

consistently >15 to 20 ng/mL]. Since vitamin D supplementation at doses that would achieve these serum levels is safe and inexpensive, it is now routine to recommend supplemental vitamin D. The Institute of Medicine recommends daily intakes of 200 IU for adults <50 years of age, 400 IU for those from 50 to 70 years, and 600 IU for those >70 years. Multivitamin tablets usually contain 400 IU, and many calcium supplements also contain vitamin D.

OTHER NUTRIENTS Other nutrients such as salt and caffeine may have modest effects on calcium excretion or absorption. Adequate vitamin K states is required for optimal carboxylation of osteocalcin. States in which vitamin K nutrition or metabolism is impaired, such as with long-term coumadin therapy, have been associated with reduced bone mass.

Magnesium is abundant in foods, and magnesium deficiency is quite rare in the absence of a serious chronic disease. Magnesium supplementation may be warranted in patients with inflammatory bowel disease, celiac sprue, chemotherapy, severe diarrhea, malnutrition, or alcoholism. Phytoestrogens may impact skeletal health, although the degree of this effect is unclear. Dietary phytoestrogens, which are derived primarily from soy products and legumes (e.g., garbanzo beans, chickpeas, and lentils), are insufficiently potent to justify their use in place of a pharmacologic agent in the treatment of osteoporosis.

Patients with hip fracture are often frail and relatively malnourished. Some data suggest an improved outcome in such patients when they are provided calorie and protein supplementation.

Exercise Exercise in young individuals increases the likelihood that they will attain the maximal genetically determined peak bone mass. Meta-analyses of studies performed in postmenopausal women indicate that weight-bearing exercise prevents bone loss but does not appear to result in substantial bone gain. When the exercise is discontinued, any effects on bone mass wane. It is important to note, however, that exercise also has beneficial effects on neuromuscular function. Exercise can improve coordination, balance, and strength and thereby reduce the risk of falling, as well as the severity of injury upon a fall. Therefore, the beneficial effects of exercise on muscle mass and reduced risk of falling justify its recommendation for all age groups. A walking program is a practical way to start. Other activities such as dancing, racquet sports, cross-country skiing, and use of gym equipment are also recommended, depending on the patient's personal preference. Even women who cannot walk benefit from swimming or water exercises, not so much for the effects on bone, which are quite minimal, but because of effects on muscle. Exercise habits should be consistent, optimally at least three times a week.

Pharmacologic Therapies Until fairly recently, estrogen treatment, either by itself or in concert with a progestin, was the primary therapeutic agent for prevention or treatment of osteoporosis. Over the past 5 years, a number of new drugs have appeared, and more are expected in the near future. Some are agents that specifically treat osteoporosis (bisphosphonates, calcitonin); others, such as tissue-selective estrogens (orSERMs), have broader effects. The availability of these drugs allows therapy to be tailored to the needs of an individual patient. The evidence supporting the effectiveness

of each remedy is variable, in part because these treatments are new.

Estrogens A large body of clinical trial data indicates that various types of estrogens (conjugated equine estrogens, estradiol, estrone, esterified estrogens, ethinyl estradiol, and mestranol) reduce bone turnover, prevent bone loss, and induce small increases in bone mass of the spine, hip, and total body. The effects of estrogen are seen in women with natural or surgical menopause and in late postmenopausal women with or without established osteoporosis. Estrogens are efficacious when administered orally, buccally, vaginally, percutaneously, subcutaneously, and transdermally. For both oral and transdermal routes of administration, combined estrogen/progestin preparations are now available in many countries, obviating the problem of taking two tablets or using a patch and oral progestin. One large study, referred to as PEPI (Postmenopausal Estrogen/ Progestin Intervention Trial), indicated that C-21 progestins alone do not augment the effect of estrogen on bone mass (Fig. 342-7).

DOSE OF ESTROGEN For oral estrogens, the recommended dose is 0.3 mg/d for esterified estrogens, 0.625 mg/d for conjugated equine estrogens, and 5 ug/d for ethinyl estradiol. For transdermal estrogen, the commonly used dose supplies 50 ug estradiol per day, but a lower dose may be appropriate for some individuals. Dose-response data are not available for other routes of administration.

FRACTURE DATA In contrast to the body of clinical trial data evaluating the effects of estrogen on bone mass, its effects on fracture occurrence have been less well studied. Epidemiologic databases indicate that women who take estrogen replacement have a 50% reduction, on average, of osteoporotic fractures, including hip fractures. The beneficial effect of estrogen is greatest among those who start replacement early and continue the treatment; the benefit wanes after discontinuation such that there is no residual protective effect against fracture by 10 years after discontinuation. There are no clinical trial data confirming that estrogen administration reduces the risk of hip fracture. In fact, theHERStrial of women with established coronary artery disease showed no reduction in the risk of hip or clinical fractures in the estrogen-progestin arm relative to the placebo group. These data may not be definitive, however, since the women were not chosen for osteoporosis risk and were at unknown risk of osteoporotic fracture. Furthermore, radiographic vertebral fractures were not assessed in this study. One clinical study which looked at all nonvertebral fractures suggested a reduction in HRT-treated women.

A few clinical trials have evaluated spine fracture occurrence as an outcome with estrogen therapy. One that used high doses of estrogen (2.5 mg conjugated equine estrogen per day) indicated marked vertebral fracture reduction in estrogen-treated women. Several other small studies, using lower estrogen doses, have consistently shown that estrogen treatment reduces the incidence of vertebral compression fracture. The ongoing Women's Health Initiative will provide additional data about the effects of estrogen on the risk of other osteoporosis-related fractures.

Long-term estrogen use may be associated with an increase in the risk of venous thromboembolism and gallbladder, uterine, and breast cancer; in observational studies, estrogens have been associated with a significant reduction in myocardial infarction, although this was not so in HERS. The WHI will provide further information.

MODE OF ACTION Two subtypes ofERs,a and b, have been identified in bone and other tissues. Cells of monocyte lineage express both ERa and -b, as do osteoblasts. Estrogen-mediated effects vary depending on the receptor type. Using ER knockout mouse models, elimination of ERaproduces a modest reduction in bone mass, whereas ERbnull animals had very little abnormality, except greater cortical bone mass. A male patient with a homozygous mutation of ERa had markedly decreased bone density as well as abnormalities in epiphyseal closure, confirming the important role of ERa in bone biology. The mechanism of estrogen action in bone is an area of active investigation (Fig. 342-5). Though data are conflicting, estrogens appear to inhibit osteoclasts directly. However, the majority of estrogen (and androgen) effects on bone resorption are mediated indirectly through paracrine factors produced by osteoblasts. These actions include: (1) increasingIGF-1 andTGF-b, and (2) suppressingIL-1 (a and b), IL-6,TNF-a, and osteocalcin synthesis. The consequence of these effects is primarily to decrease bone resorption.

Progestins In women with a uterus, daily progestin or cyclical progestins at least 12 days per month are prescribed in combination with estrogens to reduce the risk of uterine cancer. Medroxyprogesterone acetate and norethindrone acetate blunt the high-density lipoprotein response to estrogen, but micronized progesterone does not. Neither medroxyprogesterone acetate nor micronized progesterone appears to have an independent effect on bone; at lower doses, norethindrone acetate might have an additive benefit. On breast tissue, progestins may increase the risk of breast cancer, though this is by no means definite.

Tissue-Selective Estrogens, or SERMs TwoSERMsare currently being used in postmenopausal women: raloxifene, which is approved for prevention and treatment of osteoporosis, and tamoxifen, which is approved for the prevention and treatment of breast cancer.

Tamoxifen reduces bone turnover and bone loss in postmenopausal women compared to placebo groups. These findings support the concept that tamoxifen acts as an estrogenic agent in bone. There are limited data on the effect of tamoxifen on fracture risk, but the Breast Cancer Prevention study indicated a possible reduction in clinical vertebral, hip, and Colles' fractures. The major benefit of tamoxifen is on breast cancer occurrence. The breast cancer prevention trial indicated that tamoxifen administration over 4 to 5 years reduced the incidence of new invasive and noninvasive breast cancer by approximately 45% in women at increased risk of breast cancer. The incidence ofER-positive breast cancers was reduced by 65%.

Raloxifene (60 mg/d) has effects on bone turnover and bone mass that are very similar to those of tamoxifen, indicating that this agent is also estrogenic on the skeleton. The effect of raloxifene on bone density (+1.4 to 2.8% versus placebo in the spine, hip, and total body) is somewhat less than that seen with standard doses of estrogens. Raloxifene reduces the occurrence of vertebral fracture by 30 to 50%, depending on the subpopulation.

Raloxifene, like tamoxifen and estrogen, has effects throughout other organ systems. The most positive effect appears to be a reduction in invasive breast cancer (mainly

decreasedER-positive) occurrence of about 70% in women who take raloxifene compared to placebo. In contrast to tamoxifen, raloxifene is not associated with an increase in the risk of uterine cancer or benign uterine disease. Raloxifene increases the occurrence of hot flashes. Although raloxifene reduces serum total and low-density lipoprotein cholesterol, lipoprotein(a), and fibrinogen, no studies including cardiovascular disease or cerebrovascular disease endpoints are available.

MODE OF ACTION OF SERMS AllSERMsbind to theER, but each agent produces a unique receptor conformation. As a result, specific coactivator or corepressor proteins are bound to the receptor (Chap. 327), resulting in differential effects on gene transcription that vary according to other transcription factors present in the cell. Another aspect of selectivity is the affinity of each SERM for the different ERa and bsubtypes, which are expressed differentially in various tissues. These tissue-selective effects of SERMs offer the possibility of tailoring estrogen therapy to best meet the needs and risk factor profile of an individual patient.

Bisphosphonates Both alendronate and risendronate are approved for the prevention and treatment of postmenopausal osteoporosis and treatment of steroid-induced osteoporosis. Risedronate is also approved for the prevention of steroid-induced osteoporosis.

Alendronate has been shown to have dramatic effects in patients with osteoporosis, decreasing bone turnover and increasing bone mass in the spine by up to 8% versus placebo and by 6% versus placebo in the hip (Fig. 342-8). Multiple trials have evaluated the effect of alendronate on fracture occurrence. The Fracture Intervention Trial provided evidence in over 2000 women with prevalent vertebral fractures that daily alendronate treatment (5 mg/d for 2 years and 10 mg/d for 9 months afterwards) reduces vertebral fracture risk by about 50%, multiple vertebral fractures by up to 90%, and hip fractures by up to 50% (Fig. 342-9). Several subsequent trials have confirmed these findings. For example, in a study of >1900 women with low bone mass treated with alendronate (10 mg/d) versus placebo, the incidence of all nonvertebral fractures was reduced by ~47% after just 1 year.

Alendronate (5 to 10 mg/d) should be given with a full glass of water before breakfast, as bisphosphonates are poorly absorbed. Because of the potential for esophageal irritation, alendronate is contraindicated in patients who have stricture or inadequate emptying of the esophagus. It is recommended that patients remain upright for at least 30 min after taking the medication to avoid esophageal irritation. Cases of esophagitis, esophageal ulcer, and esophageal stricture have been described, but the incidence appears to be low. In clinical trials, overall gastrointestinal symptomatology was no different with alendronate compared to placebo.

Risedronate produces a dramatic reduction in bone turnover and an increase in bone mass. Controlled clinical trials have demonstrated >40% reduction in vertebral fracture risk over 3 years, accompanied by a 33% reduction in clinical nonspine fractures. Reports from several studies show a 40% reduction in hip fracture in patients with osteoporosis, with a somewhat greater effect in patients with prevalent vertebral fractures. Patients should take risedronate (5.0 mg orally) with a full glass of plain water [0.18 to 0.25 L (6 to 8 oz)], to facilitate delivery to the stomach, and should not lie down

for 30 min after taking the drug. The incidence of gastrointestinal side effects in these trials with risedronate was similar to that of placebo.

Etidronate was the first bisphosphonate to be approved, initially for use in Paget's disease and hypercalcemia. This agent has also been used in osteoporosis trials of smaller magnitude than those performed for alendronate and risedronate. Etidronate probably has some efficacy against vertebral fracture when given as an intermittent cyclical regimen (2 weeks on, 2 1/2 months off).

MODE OF ACTION Bisphosphonates are structurally related to pyrophosphates, compounds that are incorporated into bone matrix. Through mechanisms that remain to be fully elucidated, bisphosphonates specifically impair osteoclast function and reduce osteoclast number, in part by the induction of apoptosis. Recent evidence suggests that the nitrogen-containing bisphosphonates also inhibit protein prenylation, one of the end products in the mevalonic acid pathway. This effect disrupts intracellular protein trafficking and may ultimately lead to apoptosis. Bisphosphonates have very long retention in the skeleton and may exert long-term effects.

Calcitonin Calcitonin is a polypeptide hormone produced by the thyroid gland (Chap. 341). Its physiologic role is unclear as no skeletal disease has been described in association with calcitonin deficiency or calcitonin excess. Calcitonins are approved by theFDAapproved for Paget's disease, hypercalcemia, and osteoporosis in women>5 years past menopause.

Injectable calcitonin produces small increments in bone mass of the lumbar spine. However, difficulty of administration and frequent reactions, including nausea and facial flushing, make general use limited. In 1995, a nasal spray containing calcitonin (200 IU/d) was approved for treatment of osteoporosis in postmenopausal women. Several studies indicate that nasal calcitonin produces small increments in bone mass and a small reduction in new vertebral fractures in calcitonin-treated patients versus those on calcium alone.

Calcitonin is not indicated for prevention of osteoporosis and is not sufficiently potent to prevent bone loss in early postmenopausal women. As mentioned above, calcitonin might have an analgesic effect on bone pain, both in the subcutaneous and possibly the nasal form.

MODE OF ACTION Calcitonin suppresses osteoclast activity by direct action on the osteoclast calcitonin receptor. Osteoclasts exposed to calcitonin cannot maintain their active ruffled border, which normally maintains close contact with underlying bone. Calcitonin also affects osteoclast mobility and the movement of enzyme-containing cytoplasmic granules.

Experimental Agents

PARATHYROID HORMONE EndogenousPTH is an 84-amino-acid peptide that is largely responsible for calcium homeostasis (Chap. 341). Although chronic elevation of PTH, as occurs in hyperparathyroidism, is associated with bone loss (particularly cortical bone), PTH can also exert anabolic effects on bone. Consistent with this, some

observational studies have indicated that mild elevations in PTH are associated with maintenance of trabecular bone mass. On the basis of these findings, preclinical and early clinical studies have been performed using an exogenous PTH analogue (1-34 PTH). The first randomized controlled trial in postmenopausal women showed that PTH, when superimposed on ongoing estrogen therapy, produced substantial increments in bone mass (13% over a 3-year period compared to estrogen alone). This increment in bone mass was also associated with a reduction in risk of vertebral compression deformity (Fig. 342-10). More recent studies have confirmed the ability of combined treatment with estrogen and PTH to induce striking increases in bone mass.

PTHuse may be limited by its mode of administration, which currently requires subcutaneous injection. Alternative modes of delivery are being investigated, including transdermal and inhalation routes. The optimal frequency of administration also remains to be established, and it is possible that PTH might also be effective when used in high doses, 1 month out of every 3.

MODE OF ACTION Exogenously administeredPTHappears to have direct actions on osteoblast activity, with biochemical and histomorphometric evidence of de novo bone formation early in response to PTH, prior to activation of bone resorption. Subsequently, PTH activates bone remodeling but still appears to favor bone formation over bone resorption. PTH stimulatesIGF-I and collagen production and appears to increase osteoblast number by inhibiting apoptosis and stimulating replication.

FLUORIDE Fluoride has been available for many years and is a potent stimulator of osteoprogenitor cells when studied in vitro. It has been used in multiple osteoporosis studies with conflicting results, in part related to use of varying doses and preparations. Fluoride produces marked effects on bone mass, especially in the spine, where gains of around 10% per year have been observed. However, despite increments in bone mass, there is no consistent effect of fluoride on vertebral or nonvertebral fracture, which might actually increase when high doses of fluoride are used. Furthermore, animal data suggest that there is reduced biomechanical strength when fluoride is incorporated into bone as fluoroapatite, with excess osteoid accumulation and evidence of woven rather than lamellar bone formation, especially at high doses. For these reasons, fluoride remains an experimental agent, despite its long history and multiple studies.

OTHER POTENTIAL ANABOLIC AGENTS Several small studies of growth hormone (GH), alone or in combination with other agents, have not shown consistent or substantial positive effects on skeletal mass. Many of these studies are relatively short-term, and the effects of GH and the IGFsare still under investigation. Anabolic steroids, mostly derivatives of testosterone, act primarily as antiresorptive agents to reduce bone turnover but may also stimulate osteoblastic activity. Effects on bone mass remain unclear but appear weak, in general, and use is limited by masculinizing side effects. Several recent observational studies suggest that the statin drugs, currently used to treat hypercholesterolemia, may be associated with increased bone mass and reduced fractures, but there are not clinical trial data.

Nonpharmacologic Approaches Protective pads worn around the outer thigh, which cover the trochanteric region of the hip can prevent hip fractures in elderly residents in nursing homes. The use of hip protectors is limited largely by compliance and comfort,

but new devices are being developed that may circumvent these problems and provide adjunctive treatments.

Treatment Monitoring There are currently no well-accepted guidelines for monitoring treatment of osteoporosis. Because most osteoporosis treatments produce small or moderate bone mass increments on average, it is reasonable to considerBMD as a monitoring tool. As with any biologic or assay determination, there is precision error with repeated measurements. Changes must exceed ~4% in the spine and 6% in the hip to be considered significant in any individual. The hip is the preferred site due to larger surface area and greater reproducibility. Medication-induced increments may require several years to produce changes of this magnitude (if they do at all). Consequently, it can be argued that BMD should not be repeated at intervals <2 years. Only significant BMD reductions should prompt a change in medical regimen, as it is expected that many individuals will not show responses greater than the detection limits of the current measurement techniques.

Biochemical markers of bone turnover may prove useful for treatment monitoring, but there is currently little hard evidence to support this concept; it remains unclear which endpoint is most useful. If bone turnover markers are used, a determination should be made before starting therapy and repeated³4 months after therapy is initiated. In general, a change in bone turnover markers must be 30 to 40% lower than the baseline to be significant because of the biologic and technical variability in these tests. A positive change in biochemical markers and/or bone density can be useful to help patients adhere to treatment regimens.

GLUCOCORTICOID-INDUCED OSTEOPOROSIS

Osteoporotic fractures are a well-characterized consequence of the hypercortisolism associated with Cushing's syndrome. However, the therapeutic use of glucocorticoids is by far the most common form of glucocorticoid-induced osteoporosis. Glucocorticoids are widely used in the treatment of a variety of disorders, including chronic lung disorders, rheumatoid arthritis and other connective tissue diseases, inflammatory bowel disease, and posttransplantation. Osteoporosis and related fractures are serious side effects of chronic glucocorticoid therapy. Because the effects of glucocorticoids on the skeleton are often superimposed upon the consequences of aging and menopause, it is not surprising that women and the elderly are most frequently affected. The skeletal response to steroids is remarkably heterogeneous, however, and even young, growing individuals treated with glucocorticoids can present with fractures.

The risk of fractures depends on the dose and duration of glucocorticoid therapy. Thus, cumulative dose is an important determinant of fracture risk. Bone loss is more rapid during the early months of treatment, and trabecular bone is more severely affected than cortical bone. Bone loss has been documented with the use of oral prednisone at doses that are generally considered to be less than replacement levels, and the lower threshold is not known. High-dose inhaled glucocorticoids can produce systemic effects on the skeleton, as can intraarticular injections. Alternate-day delivery does not appear to ameliorate the skeletal effects of glucocorticoids. The prevalence of vertebral fractures in asthmatic patients treated for 1 year with glucocorticoids is 11%, and increased risk of fractures has been demonstrated in most other disease states treated

with glucocorticoids.

Pathophysiology Glucocorticoids increase bone loss by multiple mechanisms including: (1) inhibition of osteoblast function and potential increase in osteoblast apoptosis, resulting in impaired synthesis of new bone; (2) stimulation of bone resorption, probably as a secondary effect; (3) impairment of the absorption of calcium across the intestine, probably by a vitamin D-independent effect; (4) increase of urinary calcium loss and induction of some degree of secondary hyperparathyroidism; (5) reduction of adrenal androgens and suppression of ovarian and testicular secretion of estrogens and androgens; and (6) potential induction of glucocorticoid myopathy, which may exacerbate effects on skeletal and calcium homeostasis, as well as increase the risk of falls.

Evaluation of the Patient Because of the prevalence of glucocorticoid-induced osteopenia, it is important to evaluate the status of the skeleton in all patients being initiated on or already receiving long-term glucocorticoid therapy. Modifiable risk factors should be identified, including those for falls. Examination should include height and muscle strength testing. Laboratory evaluation should include an assessment of 24-h urinary calcium. A task force of the American College of Rheumatology recommends that all patients who are being initiated on glucocorticoids and patients already on long-term (>6 months) glucocorticoids have measurement of bone mass at both the spine and hip usingDXA. If only one skeletal site can be measured, it is best to assess the spine in individuals <60 years and the hip for those>60 years.

Prevention Bone loss caused by glucocorticoids can be prevented, and the risk of fractures significantly reduced. Strategies must include using the lowest dose of glucocorticoid for disease management. Topical and inhaled routes of administration are preferred, where appropriate. Risk factor reduction is important, including smoking cessation, limitation of alcohol consumption, and participation in weight-bearing exercise, where appropriate. All patients should receive an adequate calcium and vitamin D intake from the diet or from supplements.

TREATMENT

Only bisphosphonates have been demonstrated in large clinical trials to reduce the risk of fractures in patients being treated with glucocorticoids. Risedronate has been shown to prevent bone loss and to reduce vertebral fracture risk by about 70%. Similar beneficial effects are observed in studies of alendronate and etidronate. Controlled trials ofHRT have shown bone-sparing effects, and calcitonin also has some protective effect. Thiazides reduce urine calcium loss, but their role in prevention of fractures is unclear.

343. PAGET'S DISEASE AND OTHER DYSPLASIAS OF BONE - *Stephen M. Krane*, *Alan L. Schiller*

PAGET'S DISEASE OF BONE

Paget's disease of bone (osteitis deformans) is characterized by excessive resorption of bone by osteoclasts, followed by the replacement of normal marrow by vascular, fibrous connective tissue. At some stage and to a variable degree, the resorbed bone is replaced by coarse-fibered, dense trabecular bone organized in haphazard fashion. The irregular and often rapid deposition of this new bone, to a great extent still lamellar, results in an increase in the number of prominent, irregular cement lines that give the bone its characteristic "mosaic" pattern. Most lesions show both excessive resorption and chaotic new bone formation. The disorder is usually focal but may be widespread.

INCIDENCE

The prevalence is difficult to determine because the disease is often asymptomatic. It is frequently detected when roentgenograms are obtained for other reasons or because of a high level of alkaline phosphatase on routine blood screening. On the basis of autopsy examination, the incidence is estimated to be about 3% in individuals over age 40; the likelihood of occurrence increases with age. The incidence varies in different parts of the world. Radiologic surveys indicate that the frequency in adults is <1% in the United States, Great Britain, and Australia. In India, Japan, the Middle East, and Scandinavia, the disease is rare.

ETIOLOGY

The cause is unknown. Some of the manifestations can be suppressed with glucocorticoids, salicylates, and cytotoxic drugs, but there is no convincing evidence that the fundamental lesion is inflammatory. Intranuclear inclusions have been found by electron microscopy in osteoclasts in pagetic bone. Some of the inclusions resemble nucleocapsids of viruses belonging to the measles group. Indirect immunofluorescence studies using antibodies to measles virus suggest that the inclusions are indeed measles virus nucleocapsids. The presence of mutations in specific regions of the viral genome is consistent with persistent infection. In some individuals with Paget's disease, osteoclasts and bone marrow mononuclear cells contain nucleocapsids of respiratory syncytial virus alone or in addition to nucleocapsids of measles virus; in some areas of Britain, canine distemper virus sequences have been identified in pagetic bone cells. Thus, different paramyxoviruses may have roles in the initiation or propagation of Paget's disease. Further evidence supporting the potential role of measles virus in the pathogenesis of the excessive bone resorption in Paget's disease has been obtained from studies of osteoclast precursors in vitro. Normal bone marrow-derived CD34+ cells transduced with a measles virus nucleocapsid gene differentiate into abnormal multinucleated osteoclasts that can resorb bone.

There is renewed interest in genetic factors that might be important in the predisposition to and pathogenesis of Paget's disease. Several large kindreds have been identified in which Paget's disease affects two or more generations with a pattern of inheritance consistent with autosomal dominant transmission. A rare Paget's disease-like disorder,

familial expansile osteolysis, has been mapped to chromosome 18q21-22; Paget's disease was mapped to the same locus in several families. However, in other families with Paget's disease, there is no linkage to 18q21-22, indicating genetic heterogeneity. In some sporadic osteosarcomas, there is constitutional loss of heterozygosity mapped to the same region of chromosome 18, and the rare sarcomas associated with Paget's disease (see below) also exhibit loss of heterozygosity in this region. It is of great interest that the gene within the 18q21-22 locus (*TNFRS-F11A* gene) responsible for familial expansile osteolysis encodes the receptor activator of NfkB (RANK), a member of the tumor necrosis factor (TNF) superfamily crucial for osteoclast differentiation (see below). The mutation results in constitutive activation of RANK. It is unknown whether similar mutations occur in some individuals with Paget's disease.

PATHOPHYSIOLOGY

The characteristic feature is increased resorption of bone accompanied by an increase in bone formation. In the early phase, bone resorption predominates (e.g., in the variant *osteoporosis circumscripta*) and the bones are very vascular. This has been termed the *osteoporotic*, *osteolytic*, or *destructive phase* of disease. Body calcium balance may be negative. Commonly, the excessive resorption is followed closely by formation of new pagetic bone. In this so-called mixed phase of the disease, the rate of bone formation is so geared to that of bone resorption that the magnitude of the increase in bone turnover is not reflected in the overall calcium balance. As the activity decreases, the resorptive rate may decline progressively relative to formation, eventually leading to development of hard, dense, less vascular bone (the so-called *osteoplastic* or *sclerotic phase*) and a positive calcium balance. The rates of bone turnover may be increased enormously in the early phases of the disease, occasionally more than 20 times normal.

Increased generation and overactivity of osteoclasts are considered the major abnormality. The osteoclasts are larger than normal and contain multiple pleomorphic nuclei. Increased numbers of osteoclast-like multinucleated cells are generated from hematopoietic precursors in long-term marrow cultures from individuals with Paget's disease. Production of interleukin (IL) 6 by the pagetic bone (marrow) cells is increased, and the cells are more sensitive than normal to the pro-resorptive effects of $1,25(OH)_2D_3$.

The calcification rate is characteristically increased in pagetic bone. Bone turnover correlates with the increased plasma level of bone alkaline phosphatase, which is higher in Paget's disease than in any other condition except for hereditary hyperphosphatasia. Although increased bone resorption enhances release of calcium and phosphate ions from bone, the plasma concentrations of these ions are usually normal, presumably because of mineral deposition in new bone and because of feedback control of parathyroid hormone secretion. The concentration of phosphate in the plasma is normal or slightly elevated. When the imbalance between bone formation and resorption favors resorption, as after prolonged immobilization or fractures, urinary calcium excretion may be increased and on occasion hypercalcemia may occur. If, on the other hand, bone formation exceeds resorption (relatively uncommon), circulating levels of parathyroid hormone may be increased. Significant increases in trabecular bone resorption and osteoid surfaces in normal bone from patients with Paget's disease may be due to compensatory, secondary hyperparathyroidism. Resorption involves both the organic

and mineral phases of bone. While the inorganic ions of the mineral phase are reutilized for bone formation, amino acids such as hydroxyproline and hydroxylysine and the hydroxypyridinium cross-link compounds are released during resorption of the collagen matrix of bone and are not reutilized for collagen biosynthesis. The increased urinary excretion of small peptides containing hydroxyproline reflects increased bone resorption. The pyridinium cross-link compounds pyridinoline (Pyr) and deoxypyridinoline (D-Pyr) are released from bone collagen during osteoclastic bone resorption and can be measured in urine by several commercial assays. The C- and N-telopeptide measurements are also useful for monitoring therapy, but measurements of serum alkaline phosphatase activity alone are usually sufficient.

RADIOLOGIC CHANGES

The pelvic bones are most commonly involved, followed by the femur, skull, tibia, lumbosacral spine, dorsal spine, clavicles, and ribs; small bones are not as frequently diseased. The lytic phase of the disease may be overlooked except when it occurs in the skull as osteoporosis circumscripta, with areas of sharply demarcated radiolucency in the frontal, parietal, and occipital bones. In the long bones, the lytic areas are usually first seen at one end and progress toward the other end with a V-shaped advancing edge. The lesion may cause expansion of the cortex and exhibit features suggesting malignancy. Usually lysis is followed by a zone of increased density, representing the new bone formation of the mixed phase of the disease. In general, the bone enlarges with an irregularly widened cortex in a coarse, striated pattern and with increased density, occasionally focal in distribution. Perpendicular lines of radiolucency (cortical infractions) are frequent and occur on the convex side of bowed long bones, particularly the femur and tibia. The remodeling of the pagetic bone usually follows the lines of stress produced by muscle pull or gravity, accounting for the characteristic lateral bowing of the femur or anterior bowing of the tibia and the tendency for most of the dense bone to be deposited on the concave side of the bowed bone. In the mixed stage, there is enlargement and thickening of the skull, especially of the outer table, with irregular, spotty areas of increased density (Fig. 343-1). The changes in the pelvis reflect the varying degrees of bone resorption and new bone formation and are frequently accompanied by a characteristic thickening of the pelvic brim. In the sclerotic phase of the disease, the bone may show uniform increase in density, often in the absence of striations. This feature is common in the facial bones but occasionally occurs in the vertebrae, where a homogeneous, dense pattern gives an "ivory" appearance similar to that typical of Hodgkin's disease, although the involved vertebrae in Hodgkin's disease are not enlarged. Computed tomography (CT) and magnetic resonance imaging (MRI) are useful in defining atypical lesions, particularly when neoplastic involvement is suspected. Technetium 99m diphosphonate bone scans are useful in documenting the extent of disease when therapy is contemplated or to confirm the diagnosis when radiologic findings are inconclusive.

CLINICAL MANIFESTATIONS

The clinical presentation is a function of the extent of the disease, the particular bones involved, and the presence of complications. Many patients are asymptomatic. In these individuals the disorder is discovered during radiologic examination of the pelvis or spine for another problem or because of the finding of an elevated level of plasma alkaline

phosphatase. Other individuals may gradually become aware of a swelling or deformity of a long bone or develop a disturbance in gait due to unequal length of the lower extremities. Enlargement of the skull is often not noticed by the patients, except by awareness of increasing hat size. Facial pain and headache are initial complaints in some; backache and leg pain are common. The pain is usually dull but may be shooting or knifelike. Back pain is most common in the lumbar region and may radiate into the buttocks or lower extremities. This pain can be due to the pagetic process itself, to distortion of articular facets, or to secondary osteoarthritis. Pain in the lower extremities may be associated with the transverse cortical infractions along the convex lateral surface of the femur or the anterior surface of the tibia. New lytic lesions detected on bone scan may be the most painful. Pain may also be due to involvement of the hip joint resembling degenerative joint disease, which is characterized by narrowing of the joint space, bony lipping at the margin of the acetabulum, and deepening of the acetabulum. Angioid streaks may be present in the retina. Hearing loss can be due to direct involvement of the ossicles of the inner ear, involvement of bone in the region of the cochlea, or impingement on the eighth cranial nerve in the auditory foramen. More serious neurologic complications can result from overgrowth of bone at the base of the skull (platybasia) and compression of the brainstem. Compression of the spinal cord can cause paraplegia, particularly with involvement of the mid-dorsal spine. Pathologic fractures of vertebrae may also produce spinal cord lesions.

COMPLICATIONS

Blood flow may be markedly increased in extremities involved with Paget's disease. There is proliferation of blood vessels in pagetic bone, but anatomic and functional studies have not confirmed the presence of arteriovenous fistulas. Although blood flow is increased in bone, cutaneous vasodilatation in the pagetic extremities accounts for the increased warmth noted clinically. When the disease is widespread, involving one-third or more of the skeleton, the increased blood flow raises *cardiac output* and rarely leads to high-output heart failure. However, heart disease in individuals with Paget's disease is usually due to the same conditions that occur in other patients of similar age. *Pathologic fracture* may occur at any stage but is more common in the destructive phase of the disease. In the weight-bearing bones fractures are often incomplete, multiple, and on the convex side of the bone. They may occur spontaneously or after slight trauma. Though many lesions heal with no major disability, more serious fractures also occur. Complete fractures are often transverse as if the bone was snapped like a piece of chalk.

There is no characteristic level of urinary calcium excretion, but it tends to be higher when the resorptive phase predominates, possibly accounting for the somewhat higher incidence of *urinary stones* in these patients. *Hyperuricemia* and gout are common in men with Paget's disease, and calcific periarthritis may occur.

Sarcoma is the dread complication. The incidence is probably £1%, although higher incidence has been noted in series that include many patients with polyostotic involvement. The sarcomas most frequently arise in the femur, humerus, skull, facial bones, and pelvis and rarely in the vertebrae. Pagetic osteosarcomas are lytic in appearance on radiographs, in contrast to the sclerotic appearance of radiation-induced osteosarcomas. The tumors are multicentric in about 20% of patients. Fibrosarcomas

and chondrosarcomas have also been found. Pain and swelling are the common complaints that lead to recognition of the sarcomas. The extent and character of the neoplastic involvement are established byCTand/orMRI. In occasional patients, an "explosive rise" of the phosphatase level may accompany the growth of the sarcoma, whereas in patients with limited Paget's disease, phosphatase levels may be only slightly elevated and give no clue to the development of the malignant lesion. The prognosis is poor following the development of sarcomas, and ablative surgery is rarely successful. In contrast to the successful treatment of some osteosarcomas in children, chemotherapy has little effect on survival of patients with pagetic osteosarcomas. Reparative granulomas resembling giant cell tumors may cause local destruction, but they do not metastasize.

TREATMENT

Most patients require no treatment, since the disease is localized and does not cause symptoms. Indications for therapy include persistent pain in involved bones, neural compression, rapidly progressive deformity resulting in disabling disturbance of posture and/or gait, high-output congestive heart failure, hypercalcemia, severe hypercalciuria with or without formation of renal stones, repeated fractures or nonunion, and preparation for major orthopedic surgery. Nonsteroidal anti-inflamatory drugs, such as one of the COX2 inhibitors or acetaminophen, may be useful to relieve pain, especially that involving the hip joints. Patients with severe hip or knee pain, unrelieved by analgesics and not responsive to therapy with agents that inhibit bone resorption, are candidates for total joint replacement. Results of joint replacement are often excellent, although patients with Paget's disease have an increased risk of ectopic bone formation around the operative site. Osteotomies are also useful in patients with bowing deformities of the tibia. In patients who have undergone surgical procedures, early ambulation and adequate fluid intake are important to prevent the development of hypercalciuria and hypercalcemia.

Potent bisphosphonates can inhibit bone resorption and are usually well tolerated. They appear to act by adsorbing to the surface of the calcium/phosphate mineral phase of bone and inhibiting osteoclast function. Bisphosphates are chemically stable analogues of inorganic pyrophosphate and are available in two classes: nitrogen-containing and non-nitrogen-containing. The non-nitrogen-containing bisphosphates (e.g., clodronate and etidronate) are metabolically incorporated into nonhydrolyzable analogues of ATP that may inhibit ATP-mediated reactions. The nitrogen-containing bisphosphates (e.g., pamidronate, alendronate, and risedronate) do not form ATP compounds, but they do inhibit enzymes in the mevalonate pathway, particularly enzymes involved in the synthesis of farnesyl pyrophosphate and geranylgeranyl pyrophosphate. The latter compounds are involved in protein prenylation reactions.

The first bisphosphate available for treatment of Paget's disease in the United States, editronate, was moderately effective in alleviating symptoms but did not decrease biochemical indices to the normal range. Editronate also inhibits mineralization of bone and produces osteomalacia. The newer bisphosphonates such as alendronate, pamidronate, risedronate, and tiludronate are more potent than etidronate and do not produce mineralization defects. Consequently, editronate is no longer indicated for treatment of Paget's disease. In the United States, pamidronate is approved for

intravenous use, and alendronate and risedronate are approved for oral administration.

The bisphosphonates as a class are poorly absorbed from the gastrointestinal tract. Alendronate should be given orally with water after an overnight fast 30 to 60 min before breakfast; the dose is 40 mg/d for 6 months. Risedronate is administered at 30 mg/d for 2 to 3 months. Gastric irritability and rarely esophageal ulcerations may occur. Several regimens are advocated for the intravenous administration of pamidronate. For example, pamidronate is used intravenously as an infusion of 30 mg/d over 3 to 4 h in 5% glucose in water or normal saline on three or four successive days. Responses are usually rapid, with decreases in urinary excretion of hydroxyproline and pyridinium cross-link compounds within days to weeks, followed by a fall in levels of serum alkaline phosphatase. Flulike symptoms accompanied by fever may occur but usually subside rapidly.

Patients given bisphosphonates should also be given daily calcium supplements of 1 to 1.5 g and approximately 400 IU of vitamin D. Clinical and biochemical improvement often lasts for more than a year after bisphosphonate therapy. Clinical evaluation and assessment of alkaline phosphatase levels at 3-month intervals are useful for assessing the need for retreatment. Radiographs at 6-month intervals may be indicated for evaluation of lytic lesions, which usually heal with these agents.

Calcitonin therapy has largely been replaced by bisphosphonates for primary treatment of severe disease, but calcitonin may still be useful in patients who cannot tolerate alendronate or residronate because of gastrointestinal side effects or who prefer to avoid intravenous therapy with pamidronate. The administration of porcine, salmon, and human *calcitonins* for prolonged periods decreases plasma alkaline phosphatase and urinary hydroxyproline excretion. Treatment with calcitonin variably decreases bone pain due to suppression of the pagetic lesion as well as to an independent, centrally mediated analgesic effect. The calcitonins are probably most useful in patients with pain in areas of pagetic involvement not due to associated joint disease. The dose of salmon calcitonin is 50 to 100 MRC units daily given subcutaneously. In most cases, it is possible to reduce the dose to three times weekly. Some patients develop a sensation of warmth and/or nausea 30 min to several hours after injection. Nasal spray formulations of calcitonin can be administered at doses of 200 IU/d. Cytotoxic drugs such as plicamycin and dactinomycin no longer have a place in therapy.

Although the bisphosphonates and calcitonins act primarily to decrease bone resorption, the rate of new bone formation subsequently falls. As a result, the state of high bone turnover is shifted to a state of lower turnover, where rates of formation and resorption are still apparently geared to each other. In this lower turnover state, collagen fibers of the bone matrix are deposited in a more orderly fashion similar to normal bone.

HYPEROSTOSIS

A number of disease states have in common an increase in the mass of bone per unit volume (*hyperostosis*) (Table 343-1). This increase in bone mass is often associated with disturbance in the architecture of the tissue. The additional bone may be located at the periosteum, within the compact bone of the cortex, or in the trabeculae of the cancellous regions. In some diseases, the increase in bone mass may be spotty, as in

osteopoikilosis, whereas in others, most of the skeleton may be involved, as in the malignant form of osteopetrosis in children. The increase in mass is usually not due to an excessive amount of mineral relative to matrix, except in disorders where islands of calcified cartilage may persist such as osteopetrosis. In some diseases, such as the osteosclerosis of untreated renal insufficiency, bone mass and radiodensity may be increased, even though the new bone formed is poorly mineralized and contains widened osteoid seams.

Although hyperostosis is usually due to decreased numbers of osteoclasts or altered osteoclast function, dysfunction of osteoblasts can also occur. For example, an engineered null mutation of the osteocalcin gene in mice results in a higher bone mass due to increased bone formation without change in bone resorption. Infection of newborn mice also produces an osteopetrosis-like phenotype in which osteoblast progenitors appear to induce increased bone formation. In human osteopetrosis of the relatively benign and sporadic type, viral nucleocapsid particles have been found in osteoclasts, and it is possible that viral infection accounts for the excessive bone mass.

OSTEOPETROSIS

Also known as Albers-Schonberg or marble bone disease, osteopetrosis is clinically, biochemically, and genetically heterogeneous. Although osteopetrosis has many causes, a defect in bone resorption is always the underlying mechanism.

Several inherited forms of osteopetrosis occur in rodents, some of which can be cured by bone marrow transplantation from a normal littermate and are probably due to stem cell defects. The osteopetrosis in *op/op* mice and in *tl/tl* toothless rats is not cured by bone marrow transplantation, however. These animals have few osteoclasts, and those that are present appear to be defective. The *op/op* mice have a defect in the coding region of the gene for macrophage colony stimulating factor (M-CSF). The skeletal defects in these animals and in *tl/tl* rats can be reversed by treatment with M-CSF. Another form of osteopetrosis has been produced in mice by targeted disruption of the c-*src* gene, which is normally expressed at high levels in osteoclasts. These *src-/-*mice still have osteoclasts on bone surfaces, but they fail to form a ruffled border at the bone-resorbing surface. Disruption of the c-*fos* gene results in osteopetrosis in which osteoclasts are absent.

Important advances have also been made in understanding the interactions between osteoblasts/stromal cells and hemopoietic osteoclast precursor cells that lead to osteoclastogenesis (Fig. 343-2). A novel member of theTNFreceptor superfamily, referred to as *osteoprotegerin* (OPG; also known as *osteoclastogenesis inhibitory factor*, OCIF) functions as a soluble decoy receptor that binds, and presumably neutralizes,RANKligand, a transmembrane ligand expressed on osteoblasts/stromal cells. RANK ligand binds to RANK, a transmembrane receptor on hemopoietic osteoclast precursor cells, to activate osteoclast differentiation and function (Chap. 340). The RANK receptor binds to intracellular signaling molecules called *TNF receptor-associated factors* (TRAFs) that activate NFkB, a transcription factor known to be required for normal osteoclast function. Genetic models in mice are beginning to unravel this complex signaling pathway. Expression of a soluble version of RANK ligand stimulates osteoclast differentiation. Overexpression of OPG in transgenic mice leads to

osteopetrosis, apparently by blocking RANK ligand. Mice deficient in RANK lack osteoclasts and develop severe osteopetrosis (as well as T cell immunologic defects). TRAF6-deficient mice also develop osteopetrotic features because of defective osteoclast function. It is clear, based on these and other lines of evidence, that the RANK ligand/OPG/RANK/TRAF/NFkB pathway plays a pivotal role in the control of osteoclast development and function.

In humans the infantile autosomal recessive form of osteopetrosis, until recently, has been of unknown cause. It is a severe bone disease that is usually fatal within the first decade of life. Osteoclasts are usually present in normal or increased numbers. In addition, since bone resorption is markedly suppressed, it has been assumed that the defect is not in genes responsible for osteoclast differentiation but in those responsible for osteoclast function. This form of osteopetrosis is manifested in utero and progresses after birth with anemia, hepatosplenomegaly, hydrocephalus, cranial nerve involvement, and death, often due to infections. Transplantation of bone marrow from allogeneic donors to provide normal osteoclast precursor cells has been successful in several patients, in whom osteopetrotic bone was repopulated with donor osteoclasts that produced radiologic and/or bone-biopsy evidence of bone resorption. Nearly 100 bone marrow transplantations have been reported over the past 15 years. If the transplants are successful, markers of donor cells can be found in bone resorbing areas and skeletal improvement persists for years. Although restoration of visual acuity usually does not occur with successful transplantation, this is the only means of approaching cure even in mild cases. The genetic defect in about half of the subjects studied has now been identified. The gene in the human disease was mapped to chromosome 11q13, a region that contains several potential candidate genes. In mice, introduction of a null mutation in one of the genes in this region, *Tcirg1*, that encodes the osteoclast-specific (*OC116*) subunit of the vacuolar proton pump ([V]-type H^+-ATPase) responsible for acidification of the extracellular compartment adjacent to the brush border, results in osteopetrosis with abundant osteoclasts. Furthermore a deletion of the 5¢ portion of the gene is the cause for the defect in *oc/oc* mice with spontaneous osteopetrosis. In approximately half of the human subjects with the autosomal recessive form of osteopetrosis so far examined, missense, frameshift, or potential splicing mutations have just been identified in the homologous gene, *TC1RG1*. Thus, mutations in *TG1RG1* are a frequent, although not the sole, cause of this form of osteopetrosis.

Less fulminant forms of osteopetrosis occur in older children and adults. In some the disorder appears to be sporadic, and in others the osteopetrosis is inherited as an autosomal dominant trait and progresses with age; anemia is not as severe, neurologic abnormalities are not as frequent, and recurrent pathologic fractures are the main feature. Although the disorder is most common in infants and children, the diagnosis may be made in adults when roentgenograms are obtained because of fractures or unrelated diseases.

An "intermediate" form of autosomal recessive osteopetrosis has been described in kindreds in which the skeletal abnormality is associated with renal tubular acidosis and cerebral calcification. This form is compatible with long survival and is associated with profound impairment of the activity of one of the isoenzymes of carbonic anhydrase (carbonic anhydrase II). Carbonic anhydrase II is a major component of the system that generates the acid environment adjacent to the ruffled border of the osteoclast.

Deficiency of the enzyme impairs bone resorption. The defect in remodeling results in disorganization of bone structure, with thickened cortices and lack of funnelization of metaphyses. Despite increased density, the bone may be abnormal mechanically and can fracture readily. Osteomalacia or rickets is sometimes a component of osteopetrosis in children.

Roentgenograms reveal uniformly dense, sclerotic bone, often with no distinction between the cortical and cancellous regions (Fig. 343-3). In the severe infantile form, there is persistence of the primary spongiosa with central calcified cartilage cores surrounded by woven bone. Osteoclasts may be increased in number but do not function normally due to the acidification defect that results from the mutated vacuolar proton pump. In other forms of osteopetrosis, there may be different morphologic abnormalities such as loss of ruffled borders. The variability may reflect heterogeneity in this syndrome, as in the osteopetrosis in rodents. The long bones are usually involved, with increased density along the entire shaft. The metaphyses have a characteristic clubbed or splayed appearance. Alternating horizontal bands of increased and decreased density in the long bones and vertebrae suggest that the defect is intermittent during periods of growth. The skull, pelvis, ribs, and other bones may be involved. The phalanges and the distal humerus are usually spared.

Encroachment of bone on the marrow cavity, particularly in the severe infantile disorder, is associated with anemia of the myelophthisic type with extramedullary hematopoiesis in liver, spleen, and lymph nodes and enlargement of these organs. Neurologic abnormalities caused by encroachment on cranial nerves include optic atrophy, nystagmus, papilledema, exophthalmos, and impairment of extraocular muscles. Facial paralysis and deafness are frequent; trigeminal lesions and anosmia are less common. In infants, macrocephaly, hydrocephalus, and convulsions may occur, and infections such as osteomyelitis are frequent. Renal tubular acidosis is a feature of the osteopetrosis associated with carbonic anhydrase II deficiency.

In the less severe forms, about half of patients have no symptoms, and the disorder is discovered incidentally on roentgenograms. Others present with fractures, bone pain, osteomyelitis, and cranial nerve palsies.

Fractures may occur with trivial trauma. Healing of such fractures is usually slow but satisfactory. When the disease is manifested first in adult life, fractures may be the only clinical problem. Levels of calcium and alkaline phosphatase in the plasma are usually normal in adults, but hypophosphatemia and moderate hypocalcemia may occur in children. Serum acid phosphatase levels are usually increased.

As mentioned, in children with severe osteopetrosis, bone marrow transplantation from allogeneic donors or HLA-identical siblings has resulted in histologic and radiologic increases in bone resorption and variable improvement in anemia, vision, hearing, and growth and development. Unfortunately, it is not always possible to find appropriate donors, or patients may not be good candidates for bone marrow transplantation. In some patients with the lethal forms of the disorder, calcitriol therapy is associated with the appearance of osteoclasts with normal ruffled borders and other evidence of increased bone resorption.

PYKNODYSOSTOSIS

Pyknodysostosis is an autosomal recessive form of osteosclerosis that superficially resembles osteopetrosis. It is a form of short-limbed dwarfism associated with bone fragility and a tendency to fracture with minimal trauma. Nevertheless, life span is usually normal. In addition to a generalized increase in bone density, features include short stature; separated cranial sutures; hypoplasia of the mandible; kyphoscoliosis and deformities of the trunk; persistence of deciduous teeth; progressive acroosteolysis of the terminal phalanges; high, arched palate; proptosis; blue sclerae; and a pointed, beaked nose. Patients usually present because of frequent fractures. The disorder is caused by mutations in a gene on chromosome 1q21 that encodes cathepsin K, a cysteine protease that is expressed in normal osteoclasts. Null mutations in the cathepsin K gene in mice result in a phenotype with many features of pyknodysostosis. Osteoclasts are present but do not function normally since there is no proteinase secreted into the area adjacent to the ruffled border where bone collagen resorption normally takes place.

OSTEOMYELOSCLEROSIS

In osteomyelosclerosis, the marrow cells are replaced by diffuse fibroplasia, occasionally accompanied by osseous metaplasia and increased skeletal density on roentgenograms. In early stages woven bone may be found in intratrabecular locations, whereas in more advanced stages, woven bone is observed in the medulla. The disorder is probably a phase in the course of the myeloproliferative disorders and is characteristically accompanied by extramedullary hematopoiesis.

Hyperostosis corticalis generalisata (van Buchem's disease) is characterized by osteosclerosis of the skull (base and calvaria), lower jaw, clavicles, and ribs and thickening of the diaphyseal cortices of the long and short bones. Alkaline phosphatase levels in the serum are elevated, and the disorder may be due to increased formation of bone of normal structure. The major manifestations are due to neural compression and consist of optic atrophy, facial paralysis, and perception deafness. In *hyperostosis generalisata with pachydermia* (Uehlinger), the sclerosis is due to increased formation of subperiosteal spongy bone and involves the epiphyses, metaphyses, and diaphyses. Pain, swelling of joints, and thickening of the skin of the lower arms are common.

HEREDITARY HYPERPHOSPHATASIA

This disorder is characterized by structural deformities of the skeleton, with increased thickness of the calvaria, increased density at the base of the skull, and widening and loss of normal architecture of the shafts and the epiphyses of the long and short bones. The failure to deposit normal bone and the haphazard orientation of lamellae suggest active remodeling that resembles that of Paget's disease. Osteoclasts with multiple nuclei characteristic of Paget's disease and the typical "mosaic" pattern of faceted units of lamellar bone are not found, however. Levels of plasma alkaline phosphatase and urinary excretion of hydroxyproline peptides and other collagen-degradation products are increased. The disorder is apparently inherited as an autosomal recessive trait. Treatment with bisphosphonates or calcitonin therapy may be of value.

PROGRESSIVE DIAPHYSEAL DYSPLASIA (CAMURATI-ENGELMANN DISEASE)

This is an autosomal dominant disorder in which a symmetric thickening and increased diameter of the diaphyses of long bones occurs, particularly in the femur, tibia, fibula, radius, and ulna. Pain over affected areas, fatigue, abnormal gait, and muscle wasting are the major manifestations. Serum alkaline phosphatase levels may be elevated, and, on occasion, hypocalcemia and hyperphosphatemia may be found. Other abnormalities include anemia, leukopenia, and an elevated erythrocyte sedimentation rate. Linkage studies have localized a candidate gene (*DPD1*) to chromosome 19q13.2. Clinical and biochemical improvement may result from the use of glucocorticoids.

MELORHEOSTOSIS

This rare, sporadic condition usually begins in childhood and is characterized by a slowly progressive linear hyperostosis in one or more bones of one limb, usually in a lower extremity. All segments of the bone may be involved, with sclerotic areas that have a "flowing" distribution. The involved limb is often extremely painful. Soft tissue masses, not connected to bone, are often mineralized and are composed of osseous or cartilaginous tissue. Other types of soft tissue masses are associated with joint contractures or consist of fibrofatty, lymphatic, or vascular tissue.

OSTEOPOIKILOSIS

This is a benign autosomal dominant trait usually discovered by chance. In some families, the occurrence of melorheostosis suggests that these disorders may involve the same genetic locus. Osteopoikilosis is characterized by dense spots of trabecular bone <1 cm in diameter, usually of uniform density, located in the epiphyses and adjacent parts of the metaphyses. All bones may be involved except the skull, ribs, and vertebrae.

HYPEROSTOSIS FRONTALIS INTERNA

This is an abnormality of the inner table of the frontal bones of the skull consisting of smooth, rounded enostoses covered by dura and projecting into the cranial cavity. These enostoses are usually <1 cm at their greatest diameter and do not extend posteriorly beyond the coronal suture. The abnormality is found almost exclusively in women who are frequently obese, hirsute, and may have a variety of neuropsychiatric complaints (Morgagni-Stewart-Morel syndrome). The disorder also occurs in women with no obvious illness or particular associated disease. The finding in the skull may be a manifestation of a generalized metabolic disorder.

FIBROUS DYSPLASIA (MCCUNE-ALBRIGHT SYNDROME)

The bony lesions of fibrous dysplasia are characterized by proliferation of fibroblast-like cells that in some areas have features of osteoblasts, with production of an extracellular matrix that may be calcified and have the appearance of woven bone. In other areas the cells have features of chondrocytes and produce a cartilage-like extracellular matrix. The lesions of fibrous dysplasia are usually focal and have a radiolucent appearance; they may be monostotic or polyostotic. The disorder occurs with equal frequency in both

sexes. Some individuals have distinctive areas of skin pigmentation and precocious puberty (McCune-Albright syndrome) (Chap. 336). These diverse manifestations are the consequence of postzygotic mutations in the gene encoding the regulatory G_{sa}proteins.

INCIDENCE

The monostotic form is the most common type of fibrous dysplasia. The lesions can be asymptomatic, can be associated with local pain, or predispose to pathologic fracture. Most of the lesions are in the ribs or in the craniofacial bones, especially the maxillae. Other bones that may be affected include metaphyseal or diaphyseal portions of the proximal femurs or tibias. Monostotic fibrous dysplasia is most often diagnosed in patients between 20 and 30 years of age. There are usually no associated skin lesions. Approximately one-quarter of the individuals with the polyostotic form have more than half the skeleton involved by disease. One side of the body may be affected, and the lesions may be distributed segmentally in a limb, particularly in the lower extremities. Craniofacial lesions are present in approximately half of patients with the polyostotic form. Whereas the monostotic form is usually detected in young adults, fractures and skeletal deformities occur in childhood in the polyostotic form; early-onset disease is generally more severe. Lesions, especially monostotic lesions, can become quiescent at puberty and worsen during pregnancy. McCune-Albright syndrome (polyostotic fibrous dysplasia, multiple cafe au lait spots, and sexual precocity) is more common (10:1) in females. Short stature is due to premature closure of the epiphyses.

PATHOPHYSIOLOGY

Histologically, the lesions contain benign-appearing fibroblastic tissue arranged in a loose whorled pattern (Fig. 343-4). Malignant transformation of either monostotic or polyostotic fibrous dysplasia occurs with a frequency of<1%. The malignant change is usually detected in the third or fourth decade in individuals who have had lesions first identified in childhood. In about one-third of the cases the neoplasms arise in previously irradiated lesions. Ossifying fibroma of long bones is a peculiar fibroosseous cortical lesion that may be a variant of fibrous dysplasia. It is most common in the tibial shaft in teenagers. Although benign, the lesion has a tendency to recur if not adequately excised.

Fibrous dysplasia and McCune-Albright syndrome represent a phenotypic spectrum of disorders caused by activating mutations in the *GNAS1* gene, which encodes the G_{sa}protein. Because these postzygotic mutations occur at different stages in early development, the extent and type of tissues affected by the mutations are variable, explaining the mosaic pattern of skin and bone changes. The mutations occur in regions (e.g., Arg 201) of G_{sa}that selectively inhibit its GTPase activity. Because the GTP-bound form of the regulatory protein confers its active state (Chap. 341), the mutations confer constitutive stimulation of the cyclic AMP-protein kinase A signal transduction pathway. The mutations in *GNAS1* are also found in patients with fibrous dysplasia without manifestations of the McCune-Albright syndrome. Thus, in the boney lesions these mutations result in abnormalities in osteoblastic differentiation and the production of abnormal bone. In addition, there is an associated increase in osteoclastic bone resorption that provides a rationale for therapy with the bisphosphonate, pamidronate. Other tissues in which growth control and function are strongly regulated by

G_{sa}protein-coupled receptors are particularly susceptible to the mutations. In addition to bone (parathyroid hormone receptor) and skin (melanocyte-stimulating hormone receptor), various endocrine glands, including the ovary (follicle-stimulating hormone receptor), thyroid (thyroid-stimulating hormone receptor), adrenal (ACTH-receptor), and pituitary (growth hormone-releasing hormone receptor), are commonly affected by the G_{sa}mutations. It is of interest that the genetic abnormality in Albright's hereditary osteodystrophy (pseudohypoparathyroidism) is the opposite of that found in the McCune-Albright syndrome. In the former, alterations in G_{sa}function or expression result in *deficient* activity and decreased responsiveness to hormones that function through cyclic AMP-mediated signal transduction pathways (Chap. 341).

RADIOLOGIC CHANGES

The roentgenographic appearance of the lesions is that of a radiolucent area with a well-delineated, smooth or scalloped border, typically associated with focal thinning of the cortex of the bone (Fig. 343-5). Fibrous dysplasia can cause bones to become larger than normal, a feature characteristic of Paget's disease as well. The "ground-glass" appearance is due to the thin spicules of calcified woven bone. Deformities can include coxa vara, shepherd's-crook deformity of the femur, bowing of the tibia, Harrison's grooves, and protrusio acetabuli. Involvement of facial bones, usually with lesions of increased radiodensity, may create a leonine appearance (*leontiasis ossea*). Fibrous dysplasia of the temporal bones can cause progressive loss of hearing and obliteration of the external ear canal. Advanced skeletal age in girls is correlated with sexual precocity but can occur in boys without sexual precocity. Occasionally, a focus of fibrous dysplasia may undergo cystic degeneration, with an enormous distortion of the shape of the bone, and mimic the so-called aneurysmal bone cyst.

CLINICAL MANIFESTATIONS

The clinical course is variable. Skeletal lesions are usually detected because of localized pain, deformities, or fractures. Other symptoms ascribable to bone involvement are headache, seizures, cranial nerve abnormalities, hearing loss, narrowing of the external ear canal, or even spontaneous scalp hemorrhages if there is craniofacial bone disease. On rare occasions the onset of sexual precocity is the first clinical manifestation of the McCune-Albright syndrome. Serum calcium and phosphorus values are usually normal. In approximately one-third of patients with the polyostotic form, bone turnover is increased, as reflected by high levels of serum alkaline phosphatase and increased urinary excretion of collagen breakdown products. In some patients high cardiac output resembles that in extensive Paget's disease. Widespread disease does not usually develop when the disease is mild at the outset.

The cutaneous pigmentation in most patients with McCune-Albright syndrome consists of isolated dark-brown to light-brown macules that tend to be located on one side of the midline (Fig. 343-6). The border is usually, although not always, irregular or jagged ("coast of Maine"), in contrast to the smooth borders of the pigmented macules of neurofibromatosis ("coast of California"). As a rule, there are fewer than six of the lesions, which range in size from 1 cm to very large lesions, covering areas such as the back, buttocks, or sacral regions. When the lesions are in the scalp, the overlying hair may be more deeply pigmented. Localized alopecia is associated with osteomas of the

skin, and such lesions tend to overly skeletal lesions. The pigmentation also tends to be on the same side as the skeletal lesions and actually to overlie them. Occasionally, neurofibromatosis and fibrous dysplasia coexist.

Sexual precocity occurs more commonly in girls than in boys. Premature vaginal bleeding, breast development, and growth of axillary and pubic hair are the usual features. Sexual precocity is due to autonomous end-organ activity, not to pituitary or hypothalamic dysfunction. Thus, girls have high estrogen levels and low or undetectable gonadotropins. The characteristic pigmented macules are usual but not invariable. Hyperthyroidism occurs with increased frequency, and rare associations include Cushing's syndrome, acromegaly, pulmonary lesions, and soft tissue myxomas. Hypophosphatemic osteomalacia may also accompany fibrous dysplasia and resembles the disorder associated with other skeletal and nonskeletal tumors.

Although the lytic lesions of fibrous dysplasia resemble the brown tumors of hyperparathyroidism, the age of the patient, normal calcium levels, increased density of bone in the skull, and areas of cutaneous pigmentation identify the former condition. Fibrous dysplasia and hyperparathyroidism may coexist, however. Neurofibromas may involve bone and produce cutaneous pigmentation as well as nodules in the skin. The pigmented macules of neurofibromatosis are more numerous and more widely distributed than in fibrous dysplasia, usually have smooth borders, and tend to involve areas such as the axillary folds. Other lesions that have roentgenographic features similar to those of isolated fibrous dysplasia are unicameral bone cysts, aneurysmal bone cysts, and nonossifying fibromas. Leontiasis ossea is most often due to fibrous dysplasia, although other disorders may also produce this appearance, such as craniometaphyseal dysplasia, hyperphosphatasia, and, in adults, Paget's disease.

TREATMENT

Fibrous dysplasia is not curable. The skeletal lesions, however, can be improved by orthopedic procedures such as casting, osteotomy with internal fixation, curettage, and bone grafting, depending on the lesion and the age of the patient. Indications for such procedures include progressive deformity, nonunion of fractures, and pain unresponsive to conservative treatment. Calcitonin may be effective in treatment of widespread disease associated with bone pain and high serum alkaline phosphatase levels. Pamidronate (0.5 to 1 mg/kg per day intravenously for 2 to 3 days) at 6-month or yearly intervals has been shown to reduce bone pain with refilling of osteolytic lesions in about half of patients and to decrease elevated levels of serum alkaline phosphatase and urinary hydroxyproline excretion. Precocious puberty does not respond to long-acting gonadotropin-releasing hormone (GnRH) analogues, consistent with the autonomous function of the gonads. Aromatase inhibitors, such as testolactone (22 mg/kg per day), have been used to block estrogen production, but with limited efficacy. Promising initial results have been seen with estrogen antagonists, such as tamoxifen. In addition to preventing pubertal progression, blockade of estrogen action is helpful to prevent early epiphyseal closure and short stature.

OTHER DYSPLASIAS OF BONE AND CARTILAGE

A variety of diseases of bone and cartilage have been called *dystrophies* or *dysplasias*.

The *osteochondrodysplasias* are heritable disorders of connective tissue characterized by primary abnormalities of cartilage that lead to disturbances in cartilage and bone growth and development. They comprise several hundred distinct entities, which can be distinguished on the basis of clinical, genetic, and radiologic features. The molecular defects in a number of these disorders have been identified utilizing positional cloning and screening of candidate genes. Several of the disorders are due to mutations in collagen genes.**For discussion of chondrodysplasias, see Chap. 351.*

SPONDYLOEPIPHYSEAL DYSPLASIA

The *spondyloepiphyseal dysplasias* are disorders in which abnormalities of growth occur in various bones, including the vertebrae, pelvis, carpal and tarsal bones, and the epiphyses of tabular bones. On the basis of roentgenographic findings, this group can be divided into (1) those with generalized platyspondyly, (2) those with multiple epiphyseal dysplasias, and (3) those with epiphysometaphyseal dysplasias. *Morquio's syndrome*, in which there is a defect in degradation of glycosaminoglycans (therefore, a "mucopolysaccharidosis"), is inherited as an autosomal recessive trait and is associated with corneal opacities, dental defects, variable disturbances in intellect, and increased urinary excretion of keratosulfate; it belongs in the first group (Chap. 349). Other forms of spondyloepiphyseal dysplasia, some of which are accounted for by defects in type II collagen, may not be recognized until late in childhood or young adult life. Flat vertebral bodies are associated with other abnormalities in shape and alignment. The disordered development of the capital femoral epiphyses leads to irregularities in shape and flattening of the femoral heads and early onset of osteoarthritis of the hips.

ACHONDROPLASIA

This disorder is among the more common types of dwarfism (1 in 15,000 to 1 in 40,000 live births). It is inherited as an autosomal dominant trait, although most cases are sporadic and due to new fibroblast growth factor receptor 3 (FGFR3) mutations (see below). The appearance of short limbs, particularly the proximal portions, with a normal trunk is characteristically accompanied by a large head, a saddle nose, and an exaggerated lumbar lordosis. The length of the spine is almost always normal. Features of the disorder are usually recognizable at birth. Those who survive infancy usually have normal mental and sexual development, and life span may be normal. Spinal deformity nevertheless may lead to a cord compression and nerve root encroachment, especially in those with kyphoscoliosis. Homozygous achondroplasia is a more serious disorder and a cause of neonatal death.

The most common mutation responsible for achondroplasia substitutes an arginine for glycine in the transmembrane domain ofFGFR3and causes a gain-of-function, implying that fibroblast growth factor normally acts via the FGFR3 to inhibit chondrocyte proliferation in the growth plate. The abnormal proliferation at the growth plate, leaving other areas relatively unaffected in the tubular bones, causes production of short bones that are proportionately thick. Formation and maturation of the secondary ossification centers and articular cartilage are not disturbed. Appositional growth at the metaphysis continues, with resulting flare in this region of the bone; intramembranous bone formation at the periosteum is normal. Consistent with the inhibitory role of the FGFR3, a null mutation of the *Fgfr3* gene in mice causes increased growth in the physis.

Mutations in other domains of the *FGFR3* gene have been described in thanatophoric dysplasia, the most severe and lethal dysplasia. In several types of the so-called craniosynostosis syndromes (Pfeiffer, Crouzon, Jackson-Weiss, and Apert syndromes), mutations have been identified in the *FGFR1* or *FGFR2* genes.

Pseudoachondroplasia clinically resembles achondroplasia with respect to the limb deformities but there are no skull abnormalities. Affected individuals have mutations in the gene encoding a non-collagenous component of cartilage called cartilate oligomeric matrix protein (COMP). Mutations in the *COMP* gene have also been described in one of the less severe forms of multiple epiphyseal dysplasia (EDM1).

ENCHONDROMATOSIS (DYSCHONDROPLASIA, OLLIER'S DISEASE)

This is also a disorder of the growth plate in which the hypertrophic cartilage is not resorbed and ossified normally. It results in masses of cartilage with disorderly arrangement of the chondrocytes showing variable proliferative and hypertrophic changes. These masses are located in the metaphyses in close association with the growth plate in children but may be diaphyseal in teenagers and young adults. The disorder is usually recognized in childhood by the appearance of deformities or retardation in growth. The most common sites of involvement are the ends of long bones, usually in the region where rate of growth is most marked. The pelvis is often involved, but ribs, sternum, and skull are seldom affected. There is a tendency toward unilateral involvement. Chondrosarcoma develops occasionally in the enchondromata. The association of enchondromatosis and cavernous hemangiomata in the soft tissues including the skin is known as *Maffucci's syndrome*. Both Ollier's disease and Maffuci's syndrome have been associated with other primary malignancies as diverse as granulosa cell tumor of the ovary and cerebral gliomas.

MULTIPLE EXOSTOSES (DIAPHYSEAL ACLASIS OR OSTEOCHONDROMATOSIS)

This is a disorder of the metaphysis, transmitted in an autosomal dominant manner, in which areas of the growth plate become displaced, presumably by growing through a defect in the perichondrium, or so-called ring of Ranvier. The spongiosa forms within the mass as vessels invade the cartilage. Therefore, the diagnostic radiographic finding is the direct continuity of the mass to the marrow cavity of the parent bone with absence of underlying cortex. Usually the growth of these exostoses ceases when growth of the adjacent plate ceases. The lesions may be solitary or multiple and are usually located in the metaphyseal areas of long bones, with the apex of the exostosis directed toward the diaphysis. Often the lesions produce no symptoms, but occasionally, interference with the function of a joint or tendon or compression of nerves may result. Dwarfism may occur. The metacarpals may be shortened, resembling those seen in Albright's hereditary osteodystrophy. Multiple exostoses are sometimes seen in patients with pseudohypoparathyroidism.

An exostosis may suddenly begin to enlarge long after growth should have ceased, and rarely, chondrosarcomas may develop from the cartilage cap of an exostosis. Although pregnancy may stimulate growth of an exostosis that clinically may mimic malignancy, the lesion merely undergoes exuberant endochondral ossification and cartilage hyperplasia without malignant changes.

Multiple inactivating mutations or deletions have been identified in the *EXT1* or *EXT2* genes in patients with hereditary multiple exostoses. The *EXT* genes probably function normally as a tumor suppressor, and mutations in *EXT* could contribute both to the development of the exostoses and to the malignant transformation to chondrosarcoma that sometimes occurs. Mutations in *EXT* genes apparently cause abnormal processing the cytoskeletal proteins in chondrocytes.

SECTION 3 -DISORDERS OF INTERMEDIARY METABOLISM

344. DISORDERS OF LIPOPROTEIN METABOLISM - *Henry N. Ginsberg,, Ira J. Goldberg*

Lipoproteins are macromolecular complexes that carry hydrophobic plasma lipids, particularly cholesterol and triglyceride, in the plasma. More than half of the coronary heart disease (CHD) in the United States is attributable to abnormalities in the levels and metabolism of plasma lipids and lipoproteins. Some premature CHD is due to mutations in major genes involved in lipoprotein metabolism. However, elevated lipoprotein levels in most patients with CHD reflect the adverse impact of a sedentary lifestyle, excess body weight, and diets high in total and saturated fat superimposed on a genetic background that confers susceptibility to increased circulating lipids. A large body of evidence indicates that lifestyle changes and drug treatment strategies that correct hyperlipidemias reduce CHD risk (Chap 242). More than 70 clinical trials examining the effects of cholesterol reduction have been reported, including several large-scale studies using the potent cholesterol-lowering HMG-CoA reductase inhibitors (also known as statins). These studies unequivocally demonstrate that lowering low-density lipoprotein (LDL) cholesterol reduces fatal and nonfatal heart attacks (Table 344-1).

This chapter focuses on the major lipid disorders, including both the dyslipoproteinemias caused by single-gene defects and the disorders that are likely to be multifactorial in origin. A practical approach is provided to assist in the identification, evaluation, and treatment of patients with increased risk ofCHD.

LIPID AND LIPOPROTEIN TRANSPORT

LIPOPROTEIN STRUCTURE

Lipoproteins are spherical particles made up of hundreds of lipid and protein molecules. They are smaller than red blood cells and visible only by electron microscopy. However, when the larger, triglyceride-rich lipoproteins are present in high concentration, plasma can appear turbid or milky to the naked eye. The major lipids of the lipoproteins are cholesterol, triglycerides, and phospholipids. Triglycerides and the esterified form of cholesterol (cholesteryl esters) are nonpolar lipids that are insoluble in aqueous environments (hydrophobic) and comprise the core of the lipoproteins. Phospholipids and a small quantity of free (unesterified) cholesterol, which are soluble in both lipid and aqueous environments (amphipathic), cover the surface of the particles, where they act as the interface between the plasma and core components. A family of proteins, the apolipoproteins, also occupies the surface of the lipoproteins; the apolipoproteins play crucial roles in the regulation of lipid transport and lipoprotein metabolism.

Lipoproteins have been classified on the basis of their densities into five major classes:(1) chylomicrons, (2) very low density lipoproteins (VLDL), (3) intermediate-density lipoproteins (IDL), (4)LDL, and (5) high-density lipoproteins (HDL). The physical-chemical characteristics of the major lipoprotein classes are presented inTable 344-2.

APOLIPOPROTEINS

The apolipoproteins (apos) provide structural stability to the lipoproteins and determine the metabolic fate of the particles upon which they reside. They were named in an arbitrary alphabetical order and, for the purposes of this discussion, will be described in relation to their association with lipoprotein classes (Table 344-3).

There are two forms of apo B -- apo B100 and apo B48. Apo B100 is the major apolipoprotein ofVLDL,IDL, andLDL, comprising approximately 30, 60, and 95% of the protein in these lipoproteins, respectively. Apo B100 has a molecular mass of about 545 kDa and is synthesized in the liver. It is essential for the assembly and secretion of VLDL from the liver and is the ligand for the removal of LDL by the LDL receptor. The LDL receptor is a cell-surface protein that binds and internalizes lipoproteins that contain apo B100 or apo E. The LDL receptor binding domain of apo B100 is the sequence between amino acids 3200 and 3600, a region that is absent in apo B48.

Apo B48 is essential for the assembly and secretion of chylomicrons. Apo B48 is encoded by the same gene and messenger ribonucleic acid (mRNA) as Apo B100. However, the mRNA is edited in an unusual way: A cytidine deaminase in the intestine changes a cytidine to a uridine in base 6666 of the apo B100 mRNA to produce a stop codon so that apo B48 contains only the N-terminal 48% of the full-length apo B100. In contrast, the apo B100 mRNA in human liver is not edited. The role of apo B48 in the metabolism of chylomicrons in plasma is unclear. Individuals with mutations that interfere with the normal synthesis of apo B have absent or very low levels of chylomicrons,VLDL,IDL andLDL.

The apolipoproteins of the C series are synthesized in the liver and are present in all plasma lipoproteins (trace amounts inLDL). Individual apo Cs have different metabolic roles, but all inhibit the removal of plasma chylomicrons andVLDLremnants by the liver. Overexpression of apo CI in transgenic mice inhibits the uptake of chylomicron and VLDL remnants by the liver. Apo CI under- or overexpression has not been described in humans. Apo CII is an essential activator of the enzyme lipoprotein lipase (LPL), which hydrolyzes triglycerides in chylomicrons and VLDL; individuals lacking apo CII have severe hypertriglyceridemia. Apo CIII inhibits LPL, and apo CIII overexpression in transgenic mice causes severe hypertriglyceridemia. Humans who lack apo CIII have accelerated rates of VLDL triglyceride lipolysis.

Apo E is synthesized mainly in hepatocytes but is also made in other cells, including macrophages, neurons, and glial cells. It is found in chylomicrons,IDL,VLDL, and HDLand mediates the uptake of these lipoproteins in the liver by both theLDLreceptor and the LDL receptor-related protein (LRP). Apo E also binds to heparin-like proteoglycan molecules on the surface of all cells. There are three major apo E alleles: E2, E3, and E4; these isoforms differ in sequence at two positions and have frequencies of about 0.12, 0.75, and 0.13, respectively, in the general population. Apo E2 binds to the LDL receptor with lower affinity than apo E3 or E4. Individuals who are homozygous for apo E2 may develop severe hyperlipidemia (type III dysbetalipoproteinemia); complete absence of apo E increases plasma levels of chylomicron and VLDL remnants and causes early atherosclerosis.

Apo AI, apo AII, and apo AIV are found primarily onHDL. Apo AI and apo AII are synthesized in the small intestine and the liver; apo AIV is made only in the intestine. Apo AI comprises about 70 to 80% of the protein of HDL and plays a critical structural role in HDL particles. Individuals with a profound deficiency of apo AI also lack HDL. Apo AI activates the enzyme lecithin:cholesterol acyltransferase (LCAT), which esterifies free cholesterol in plasma. Plasma levels of HDL cholesterol and apo AI are inversely related to risk forCHD, and some patients with apo AI deficiency develop early, severe atherosclerosis. Transgenic mice that overexpress human apo AI are resistant to atherosclerosis. Apo AII is the second most abundant apoprotein in HDL, but its function has not been determined; transgenic mice that overexpress apo AII have high plasma levels of both HDL cholesterol and triglycerides but may be susceptible to atherosclerosis. Apo AII knockout mice have low levels of HDL, indicating that apo AII is also necessary for the integrity of HDL particles. Apo AIV, a minor component of HDL and chylomicrons may play a role in the activation of LCAT.

Apoprotein(a), a large glycoprotein that shares a high degree of sequence homology with plasminogen, is made by hepatocytes and is secreted into plasma where it forms a covalent linkage with the apo B100 ofLDL to form lipoprotein(a). The physiologic role of lipoprotein(a) is not known, but elevated levels are associated with an increased risk for atherosclerosis.

ENZYMES INVOLVED IN LIPOPROTEIN METABOLISM

LPLis synthesized in fat and muscle, secreted into the interstitial space, transported across endothelial cells, and bound to proteoglycans on the luminal surfaces in the adjacent capillary beds. LPL mediates the hydrolysis of the triglycerides of chylomicrons andVLDL to generate free fatty acids and glycerol. The free fatty acids diffuse into adjacent tissues to be burned for energy or stored as fat. Most circulating LPL is associated withLDL. Insulin stimulates the synthesis and secretion of LPL; reduced LPL activity in diabetes mellitus can lead to impaired triglyceride clearance. Homozygotes for mutations that impair LPL have severe hypertriglyceridemia that usually manifests in childhood (type I hyperlipidemia). Heterozygotes for LPL defects have mild to moderate fasting hypertriglyceridemia but may have marked hypertriglyceridemia after consuming a high-fat meal. LPL is also expressed in macrophages, including cholesteryl ester-laden macrophages (foam cells) in atherosclerotic lesions. In this setting, secreted LPL may associate with LDL, causing retention of the lipoprotein in the subendothelial space.

Hepatic triglyceride lipase (HTGL), a member of a family of enzymes that includesLPL and pancreatic lipase, is synthesized in the liver and interacts with lipoproteins in hepatic sinusoids. HTGL removes triglycerides fromVLDLremnants (IDL), thus promoting the conversion of VLDL toLDL. It may also play a role in the clearance of chylomicron remnants and in the conversion of$HDL_2$to HDL_3in the liver by hydrolyzing the triglyceride and phospholipid in HDL (see below). Severe hypertriglyceridemia in individuals with genetic deficiency of HTGL is due to the accumulation of chylomicron and VLDL remnants in plasma. In contrast to most patients with hypertriglyceridemia, however, individuals with HTGL deficiency have normal levels of HDL.

LCATis synthesized in the liver and secreted into plasma where it is bound

predominantly toHDL. LCAT mediates the transfer of linoleate from lecithin to free cholesterol on the surface of HDL to form cholesteryl esters that are then transferred toVLDL and eventuallyLDL. Apo AI is a cofactor for esterification of free cholesterol by LCAT. Deficiency of LCAT can be caused by mutations in the enzyme or in Apo A1. LCAT deficiency causes low levels of cholesteryl esters and HDL, and it can lead to corneal clouding and renal insufficiency.

Cholesteryl ester transfer protein (CETP) is synthesized primarily in the liver and circulates in plasma in association withHDL. CETP mediates the exchange of cholesteryl esters from HDL with triglyceride from chylomicrons orVLDL. This exchange can explain much of the inverse relationship between plasma levels of triglycerides and HDL cholesterol.LDLcholesteryl ester can also be exchanged with triglyceride from chylomicrons and VLDL, leading to the generation of small, dense LDL. Individuals who are homozygotes for mutations in the CETP gene have marked elevations of HDL cholesterol and apo AI. Heterozygotes for these mutations have slight elevations of HDL, indicating that CETP plays an important role in the removal of cholesteryl esters from HDL.

Phospholipid transfer protein (PLTP) is synthesized in the liver and lung. The production of matureHDLparticles depends on PLTP, which provides phospholipid to the enlarging particles.

TRANSPORT OF EXOGENOUS (DIETARY) LIPIDS

Exogenous lipid transport in chylomicrons and chylomicron remnants is depicted inFig. 344-1*A*. In western societies, where individuals ordinarily consume 50 to 100 g of fat and 0.5 g of cholesterol during three or four meals, transport of dietary fats is essentially continual. Normolipidemic individuals dispose of most dietary fat in the bloodstream within 8 h of the last meal, but some individuals with dyslipidemia, particularly those with elevated fasting levels ofVLDLtriglyceride, have measurable levels of intestinally derived lipoproteins in the circulation as long as 24 h after the last meal.

In the intestinal mucosa dietary triglyceride and cholesterol are incorporated into the core of nascent chylomicrons. The surface coat of the chylomicron is composed of phospholipid, free cholesterol, apo B48, apo AI, apo AII, and apo AIV. The chylomicron, essentially a fat droplet containing 80 to 95% triglycerides, is secreted into lacteals and transported to the circulation via the thoracic duct. In the plasma, apo C proteins are transferred to the chylomicron fromHDL. Apo CII mediates hydrolysis of triglycerides by activatingLPL on capillary endothelial cells in fat and muscle. After the triglyceride core has been hydrolyzed, apo CII and apo CIII recirculate back to HDL. The addition of apo E allows the chylomicron remnant to bind first to heparan sulfate proteoglycans within the space of Disse and then to hepatic LDL receptors and/or LDL receptor-related protein. As a consequence, dietary triglyceride is delivered to adipocytes and muscle cells as fatty acids, and dietary cholesterol is taken up by the liver where it can be used for bile acid formation, incorporated into membranes, resecreted as lipoprotein cholesterol back into the circulation, or excreted as cholesterol into bile. Dietary cholesterol also regulates endogenous hepatic cholesterol synthesis.

Abnormal transport and metabolism of chylomicrons may predispose to atherosclerosis,

and postprandial hyperlipidemia may be a risk factor forCHD. Chylomicrons and their remnants can be taken up by cells of the vessel wall, including monocyte-derived macrophages that migrate into the vessel wall from plasma. Cholesteryl ester accumulation by these macrophages transforms them into foam cells, the earliest cellular lesion of the atherosclerotic plaque (Chap. 241). If the postprandial levels of chylomicrons or their remnants are elevated, or if their removal from plasma is prolonged, cholesterol delivery to the artery wall may be increased.

TRANSPORT OF ENDOGENOUS LIPIDS

The endogenous lipid transport system, which conveys lipids from the liver to peripheral tissues and from peripheral tissues back to the liver, can be separated into two subsystems: the apo B100 lipoprotein system (VLDL,IDL, andLDL) and the apo AI lipoprotein system (HDL).

The Apo B100 Lipoprotein System (SeeFig. 344-1*B*) In the liver, triglycerides are made from fatty acids that are either taken up from plasma or synthesized de novo within the liver. Cholesterol can also be synthesized by the liver or delivered to the liver via lipoproteins, particularly chylomicron remnants. These core lipids are packaged together with apo B100 and phospholipids intoVLDL and secreted into plasma where apos CI, CII, CIII, and E are added to the nascent VLDL particles. Triglycerides make up the bulk of the VLDL (55 to 80% by weight), and the size of the VLDL is determined by the amount of triglyceride available. Hence, very large triglyceride-rich VLDL are secreted in situations where excess triglycerides are synthesized, such as in states of caloric excess, in diabetes mellitus, and after alcohol consumption. Small VLDL are secreted when fewer triglycerides are available. Although VLDL are the principal hepatic lipoprotein secreted by most individuals, VLDL and cholesteryl ester-enrichedIDLand/orLDL-like particles may be secreted by the liver in individuals with combined hyperlipidemia (see below).

In the plasma, triglycerides are hydrolyzed byLPL andVLDLparticles are converted to VLDL remnants (IDL). In contrast to chylomicron remnants, VLDL remnants can either enter the liver or give rise toLDL. Larger VLDL particles carry more triglycerides and are likely to be removed directly from plasma without being converted to LDL; apo E in the VLDL remnants binds to the LDL receptor to mediate removal from the plasma. Smaller, more dense VLDL particles are more efficiently converted to LDL; apo E andHTGLplay important roles in this process. Individuals with deficiency of either apo E2 or HTGL accumulate IDL in plasma. Apo B100 is the only protein that remains on the surface of the LDL particle.

The half-life ofLDL in plasma is determined principally by the availability (or "activity") of LDL receptors. Most plasma LDL is taken up by the liver, and the remainder is delivered to peripheral tissues, including the adrenals and gonads, which utilize cholesterol as a precursor for steroid hormone synthesis. The adrenals have the highest concentration of LDL receptors per cell in the body. Overall, about 70 to 80% of LDL catabolism occurs via LDL receptors, and the remainder is removed by fluid endocytosis and possibly by other receptors.

TheLDLreceptor, a glycoprotein with a molecular mass of approximately 160 kDa, is

present on the surfaces of nearly all cells in the body. Goldstein and Brown characterized the molecular genetics and cell biology of the LDL receptor and defined its role in cholesterol metabolism. They showed that cholesterol delivered to the cytoplasm by LDL regulates both the rate of cholesterol synthesis in the liver and the number of LDL receptors on the surface of hepatocytes. LDL receptor synthesis is mediated by sterol response element regulatory proteins (SREBPs). These transcription factors are activated in the absence of cholesterol, proteolytically cleaved, and transferred from the endoplasmic reticulum into the nucleus where they stimulate LDL receptor gene expression. Though the LDL receptor is a major factor in determining plasma LDL cholesterol levels, the rates of entry ofVLDLinto plasma and the efficiency with which VLDL is converted to LDL also influence steady-state LDL concentrations in plasma.

Increased levels of plasmaLDLcholesterol and apo B100 are risk factors for atherosclerosis. Normal LDL does not cause foam cell formation when incubated with cultured macrophages or smooth-muscle cells. But, when LDL undergoes lipid peroxidation, it becomes a ligand for alternative, scavenger receptors that are present on endothelial cells and macrophages. Uptake of modified (oxidized) lipoproteins by these receptors in macrophages results in formation of cholesterol-laden foam cells. In addition to inducing foam cell formation, oxidized LDL acts in the vessel wall to stimulate the secretion of cytokines and growth factors by endothelial cells, smooth-muscle cells, and monocyte-derived macrophages (Chap. 242). The consequence is recruitment of more monocytes to the lesion and proliferation of smooth-muscle cells, which synthesize and secrete increased amounts of extracellular matrix, such as collagen. The critical role of LDL in atherosclerosis has been confirmed in genetically altered mice. Although mice are normally resistant to atherosclerosis, increased plasma levels of remnant lipoproteins or LDL lead to atherosclerosis in this species.

The role ofVLDL in atherogenesis is less certain. The major reason for this uncertainty derives from the inverse relationship between elevated levels of triglyceride-rich lipoproteins and reduced levels of the antiatherogenicHDLcholesterol. It is possible, for example, that hypertriglyceridemia may not be directly atherogenic but rather the surrogate of other lipoprotein abnormalities. If postprandial hyperlipidemia is a risk factor forCHD, individuals who have normal fasting plasma triglyceride levels but develop postprandial hypertriglyceridemia after consumption of a fat load would be misclassified as "normal" in studies in which only fasting blood samples are analyzed. It is clear that cholesteryl ester-enriched VLDL, isolated from cholesterol-fed animals, can be taken up by receptors on macrophages and smooth-muscle cells and cause foam cell formation. These cholesteryl ester-laden VLDLs are enriched in apo E and are probably representative of VLDL remnants. Thus, the risk of atherosclerosis from hypertriglyceridemia and elevated VLDL levels may be determined by the level of cholesteryl ester-enriched VLDL remnants. The atherogenic potential ofIDL is probably similar to that of VLDL remnants.

Apo AI-Containing Lipoproteins (See Fig. 344-1*C*) In contrast to atherogenic apo B lipoproteins, the apo AI-containingHDLappear to be antiatherogenic. In fact, in some studies, HDL cholesterol levels are as strong an indicator of protection fromCHD asLDLcholesterol levels are an indicator of risk. Although a great deal is known about the HDL transport system, the mechanism by which these lipoproteins protect against

atherosclerosis is poorly defined.

HDLparticles are formed in plasma from the coalescence of individual phospholipid-apolipoprotein complexes. Apo AI appears to be the crucial, structural apoprotein for HDL, and apo AI/phospholipid complexes probably fuse with other phospholipid vesicles that contain apo AII and apo AIV to form the various types of HDL. The C apoproteins can be added to HDL after their secretion as phospholipid complexes or by their transfer from triglyceride-rich lipoproteins. This may involve the action ofPLTP. These small, cholesterol-poor HDL particles are heterogeneous in size and content and are referred to as HDL_3. Free cholesterol is transferred from cell membranes to HDL_3; a cholesterol transporter called ABC1 mediates this important first step in reverse cholesterol transport. Free cholesterol in HDL_3 is converted to cholesteryl ester byLCAT, and the cholesteryl ester moves into the core of the HDL. Formation of cholesteryl ester increases the capacity of the HDL_3 to accept more free cholesterol and enlarge to form the more buoyant class of HDL particles termed *HDL_2*. HDL_2 can be metabolized by two pathways: (1) cholesteryl esters can be transferred from HDL_2 to apo B lipoproteins or cells, or (2) the entire HDL_2particle can be removed from plasma. The transfer of cholesteryl ester from HDL to triglyceride-rich apo B lipoproteins (chylomicrons andVLDL in the fed and fasted states, respectively) is mediated byCETP. Triglyceride is transferred to HDL in this process and is a substrate for lipolysis byLPLand/orHTGL. As a result, HDL_2 is converted back into HDL_3. When the apo B lipoproteins are removed by the liver, reverse cholesterol transfer is complete. HDL cholesteryl ester may also be transferred selectively to cells via interaction of HDL with the scavenger receptor B-1, a receptor expressed by hepatocytes and steroid-producing cells. HDL-mediated reverse cholesterol transport (from peripheral tissues to the liver) is thought to be the primary mechanism by which HDL protects against atherosclerosis.

Rarely, low plasmaHDL is due to a genetic deficiency of one of the structural components of HDL (such as apo AI). However, low HDL cholesterol levels are usually the secondary consequence of increased plasma levels ofVLDL andIDL (or chylomicrons and their remnants). Mutations in the *ABC1* gene (see above) are associated with Tangier's disease, a rare form of low HDL. Low levels of HDL cholesterol and apo AI may increase atherosclerosis risk by any of several mechanisms. HDL could remove cholesterol from foam cells in atherosclerotic lesions or protectLDL from oxidative modification. Alternatively, the atherosclerotic risk of low HDL may be due to the commonly associated elevations of apo B-containing lipoproteins, which accept HDL cholesteryl esters and deliver cholesteryl esters to the vessel wall.

THE HYPERLIPOPROTEINEMIAS (See Table 344-4)

HYPERCHOLESTEROLEMIA

Elevated levels of fasting plasma total cholesterol in the presence of normal levels of triglycerides are almost always associated with increased concentrations of plasmaLDLcholesterol (type IIa), as LDL carries about 65 to 75% of total plasma cholesterol. A rare individual with markedly elevatedHDLcholesterol may also have increased plasma total cholesterol levels. Elevations of LDL cholesterol can result from single-gene defects, polygenic disorders, or from the secondary effects of other disease

states.

Familial Hypercholesterolemia (FH) FH is a codominant genetic disorder that occurs in the heterozygous form in approximately 1 in 500 individuals. FH is due to mutations in the gene for theLDLreceptor and is genetically heterogeneous, >200 different mutations in the gene having been described. Plasma levels of LDL cholesterol are elevated at birth and remain so throughout life. In untreated adults, total cholesterol levels range from 7 to 13 mmol/L (275 to 500 mg/dL). Plasma triglyceride levels are typically normal, andHDLcholesterol levels are normal or reduced. As would be expected of a disorder with decreased numbers of LDL receptors, the fractional clearance of LDL apo B is reduced. LDL production is increased because the liver secretes moreVLDL andIDL and more IDL particles are converted to LDL rather than taken up by the hepatic LDL receptors. FH heterozygotes usually develop severe atherosclerosis in early or middle age. *Tendon xanthomas*, which are due to both intracellular and extracellular deposits of cholesterol, most commonly involve the Achilles tendons and the extensor tendons of the knuckles; they are found in about 75% of adults with FH (Fig. 344-CD1). *Tuberous xanthomas*, which are softer, painless nodules on the elbows and buttocks, and *xanthelasmas*, which are barely elevated deposits of cholesterol on the eyelids, are common in heterozygous FH (Figs. 344-CD2 and344-CD3).CHDdevelops in men by the fourth decade of life or earlier.

The homozygous form ofFHoccurs in 1 out of 1 million individuals and is associated with a marked increase of plasma cholesterol levels (>13 mmol/L;>500 mg/dL), large xanthelesmas, and prominent tendon and planar xanthomas. These individuals have severe, prematureCHD that can be manifested in childhood.

Familial Defective Apo B100 This autosomal dominant disorder is a phenocopy ofFH and is due to a missense mutation at amino acid 3500 that reduces the affinity ofLDL for the LDL receptor and, thus, impairs LDL catabolism. The prevalence and manifestations of both the heterozygous and homozygous forms are similar to those produced by mutations of the LDL receptor.

Polygenic Hypercholesterolemia Most moderate hypercholesterolemia [plasma cholesterol levels between 6.5 and 9 mmol/L (240 and 350 mg/dL)] is polygenic in origin. Multiple genes interact with environmental factors to contribute to the hypercholesterolemia, and both overproduction and reduced catabolism ofLDL are thought to play roles in the pathophysiology. The severity is probably affected by the consumption of saturated fat and cholesterol, age, and the level of physical activity. Plasma triglyceride andHDLcholesterol levels are usually normal. These individuals are at increased risk of atherosclerosis. Tendon xanthomas are not present. Genes involved in cholesterol and bile acid metabolism may be involved in the pathogenesis.

HYPERTRIGLYCERIDEMIA

The diagnosis of hypertriglyceridemia is made by determining plasma lipids after an overnight fast. Because of the less certain association of triglycerides withCHD(compared toLDLcholesterol), plasma concentrations greater than the 90th or 95th percentile for age and sex have been used to define hypertriglyceridemia. Some studies show, however, that plasma triglyceride levels >130 to 150 mg/dL are

associated with lowHDLcholesterol levels and small, dense LDL particles. Furthermore, a meta-analysis of several prospective population studies confirms that triglyceride concentrations are independent predictors of CHD risk. Isolated elevations of plasma triglycerides can be due to increased levels ofVLDL(type IV) or combinations of VLDL and chylomicrons (type V). Rarely, only chylomicron levels are elevated (type I). Plasma is usually clear when triglyceride levels are <4.5 mmol/L (<400 mg/dL) and cloudy when levels are higher and VLDL (and/or chylomicron) particles become large enough to scatter light. When chylomicrons are present, a creamy layer floats to the top of plasma after refrigeration for several hours. Tendon xanthomas and xanthelasmas do not occur with isolated hypertriglyceridemia, but eruptive xanthomas (small orange-red papules) (Fig. 344-CD4) can appear on the trunk and extremities when triglyceride levels are >11.5 mmol/L (>1000 mg/dL) (i.e., when chylomicronemia is present). At these high levels of triglycerides, the retinal vessels can appear to be orange-yellow in color (lipemia retinalis). Pancreatitis is the major risk associated with plasma triglyceride concentrations>11 mmol/L (>1000 mg/dL).

Elevations in plasma triglycerides are usually associated with increased synthesis and secretion ofVLDLtriglycerides by the liver. Hepatic triglyceride synthesis is regulated by substrate flow (the availability of free fatty acids), energy balance (the level of glycogen stores in the liver), and hormonal status (the balance between insulin and glucagon). Obesity, excessive consumption of simple sugars and saturated fats, inactivity, alcohol consumption, and insulin resistance are commonly associated with hypertriglyceridemia. In most of these situations, increased free fatty acid flux from adipose tissue to the liver stimulates the assembly and secretion of VLDL. When VLDL triglyceride levels are markedly elevated [>11.5 mmol/L (>1000 mg/dL)],LPL may be saturated so that an acquired LPL deficiency develops during the postprandial period even if there is no underlying genetic disorder. The addition of chylomicrons to the circulation may cause dramatic increases in plasma triglycerides.

Familial Hypertriglyceridemia Familial hypertriglyceridemia appears to be transmitted as an autosomal dominant disorder, though the underlying mutation(s) have not been identified. The pathophysiology is complex: both reduced catabolism of triglyceride-rich lipoproteins and overproduction ofVLDLhave been reported. Elevated levels of fasting plasma triglycerides in the range of 2.3 to 8.5 mmol/L (200 to 750 mg/dL) are usually associated with increased levels of VLDL triglycerides only. When VLDL triglyceride levels are markedly elevated (regardless of etiology), chylomicron triglycerides can also be present, even after a 14-h fast. A 20-year follow-up of individuals with familial hypertriglyceridemia demonstrated a moderate increase inCHDrisk.

Familial Lipoprotein Lipase Deficiency This autosomal recessive disorder is due to the severe impairment or absence ofLPL, leading to massive accumulation of chylomicrons in plasma. Manifestations begin in infancy and include pancreatitis, eruptive xanthomas, hepatomegaly, splenomegaly, foam cell infiltration of the bone marrow, and, when the level of triglycerides is >11 mmol/L (1000 mg/dL), lipemia retinalis. Atherosclerosis is not accelerated. The diagnosis is suspected by finding a creamy layer (chylomicrons) at the top of plasma that has incubated overnight at 4°C; it is confirmed by demonstrating that LPL levels in plasma do not increase after the administration of heparin (which normally releases LPL from endothelial surfaces). Manifestations recede dramatically when patients are placed on fat-free diets.

LPLlevels are within the normal range in most patients with moderate hypertriglyceridemia [2.8 to 5.6 mmol/L (250 to 500 mg/dL)]. Heterozygous mutations in the LPL gene are present in 5 to 10% of hypertriglyceridemic individuals; LPL activity may be reduced by 20 to 50% in these individuals. Heterozygotes for LPL deficiency may also present with severe hypertriglyceridemia if they have poorly controlled diabetes, are pregnant, consume excessive quantities of alcohol, take exogenous estrogen, or are obese.

Familial Apoprotein CII Deficiency This rare autosomal recessive disorder causes a functional deficiency ofLPL and clinical manifestations similar to those of familial LPL deficiency. Deficiency of apoprotein CII impairs hydrolysis of chylomicrons andVLDL so that either, or both, lipoproteins accumulate in blood. The diagnosis is suspected in children or adults with recurrent attacks of pancreatitis and confirmed by demonstrating the absence of apo CII on gel electrophoresis and that plasma transfusion (which contains abundant apo CII) causes a dramatic fall in plasma triglycerides. Heterozygotes have half-normal levels of apo CII, may have mild elevations of triglycerides, and are asymptomatic. Dietary fat restriction should be life-long.

Hepatic Lipase Deficiency Total deficiency ofHTGL is a rare autosomal recessive disorder that impairs the final catabolism and/or remodeling of smallVLDL andIDL. Subjects with HTGL deficiency often have elevated levels of VLDL remnants;HDL_2levels may be elevated because HTGL participates in the conversion of HDL_2 to HDL_3. HTGL activity is frequently increased in hypertriglyceridemic individuals, but the meaning of this association is unclear.

HYPERCHOLESTEROLEMIA WITH HYPERTRIGLYCERIDEMIA

Concomitant hypercholesterolemia and hypertriglyceridemia occurs in two disorders -- familial combined hyperlipidemia (FCHL) and dysbetalipoproteinemia.

Familial Combined Hyperlipidemia FCHL is transmitted as an autosomal dominant disorder. Probands (the initial case discovered within a family) typically have combined hyperlipidemia, isolated hypertriglyceridemia, or isolated elevated levels ofLDLcholesterol. The diagnosis requires documentation at some time of combined hyperlipidemia in the proband or, if the proband has isolated hypercholesterolemia or hypertriglyceridemia, the various lipid phenotypes in first-degree relatives at risk. The lipoprotein phenotype in affected individuals may change over time. The underlying defect in this disorder is not known, though mutations or polymorphisms in theLPL gene and in the gene cluster for apo AI, apo CIII, and apo AIV may contribute to the disorder in some families. Insulin resistance is present in many individuals with FCHL; the link may result from increased free fatty acid flux driving assembly and secretion of apo B100 lipoproteins.

FCHLis associated with increased secretion ofVLDLparticles, as determined by the flux of VLDL apo B. The lipoprotein patterns associated with the disorder are most likely determined by genetic polymorphisms in genes that regulate the metabolism of VLDL. For example, if the affected individual also has a defect inLPL, hypertriglyceridemia will be present. Since the hydrolysis of VLDL triglycerides also regulates the generation

ofLDL in plasma, individuals with FCHL who have inefficient catabolism of VLDL may also have reduced levels of LDL cholesterol and high VLDL cholesterol. Finally, individuals with FCHL who synthesize normal quantities of triglycerides and secrete VLDL that carries normal amounts of triglyceride generate increased numbers of LDL particles and present with isolated elevations of plasma LDL cholesterol. These variations in VLDL catabolism, together with additional genetic heterogeneity and environmental variability, form the basis for the variable phenotype in this disorder. FCHL may occur in as many as 0.5 to 1.0% of Americans and is the most common familial lipid disorder in survivors of myocardial infarction. The increased risk for atherosclerosis is due to the presence of increased numbers of small, atherogenic VLDLs and the conversion of VLDL to the more atherogenicIDL and LDL. Persons with FCHL usually have clear plasma and do not have xanthomas or xanthelasma.

Dysbetalipoproteinemia This rare disorder affects 1 in 10,000 persons and is due to homozygosity for apo E2, the binding-defective form of apo E. Because apo E plays a crucial role in the catabolism of chylomicron andVLDLremnants, affected individuals have elevations in both VLDL triglyceride and VLDL cholesterol, and chylomicron remnants are present in fasting plasma. The ratio of total cholesterol to triglyceride approximates 1.0, and the ratio of VLDL cholesterol to triglyceride is greater than 0.25.LDL andHDLcholesterol levels are usually low. Although 1% of the population is homozygous for apo E2, most have normal plasma triglyceride and cholesterol levels. Thus, a second defect in lipid metabolism must be present in the 0.01% of individuals with dysbetalipoproteinemia. These individuals may have tuberous xanthomas and deposits of cholesterol in the palmar creases (striae palmaris); the latter, appearing as yellow-orange lines, are specific for dysbetalipoproteinemia. The risk for atherosclerosis and its complications is increased, with onset in the fourth and fifth decades. The incidence of peripheral vascular disease is higher than inFH.

REDUCED HDL CHOLESTEROL

Low levels ofHDLcholesterol can be defined as <0.9 mmol/L (<35 mg/dL) in men and<1 to 1.2 mmol/L (<40 to 45 mg/dL) in women. Low concentrations of HDL cholesterol are usually associated with coexistent hypertriglyceridemia, though "primary hypoalphalipoproteinemia" has been identified in both individuals and families. The relationship between hypertriglyceridemia and low HDL levels probably derives from: (1)CETP-mediated transfer of cholesteryl ester from the core of HDL toVLDL; (2) shift of surface components, particularly phospholipids apo CII, and apo CIII, from HDL to VLDL; and (3) increased fractional catabolism of the cholesteryl ester-poor apoAI that results from the first two processes. The complexity of the relationship between HDL and triglyceride levels is highlighted by the fact that HDL levels do not return to normal when fasting plasma triglycerides are reduced in most persons with hypertriglyceridemia and low HDL cholesterol levels. Low HDL is clinically silent, and the plasma is usually clear (it can be cloudy or creamy if there is concomitant hypertriglyceridemia).

Primary hypoalphalipoproteinemia refers to the state whereHDLcholesterol concentrations are markedly reduced but plasma triglyceride concentrations are normal. Many individuals with this phenotype have had hypertriglyceridemia in the past or have an older (or more obese) first-degree relative who has both low HDL and increased triglyceride levels. Hence, both family studies and long-term follow-up may be required

to identify individuals with primary reductions in HDL cholesterol. Rare mutations have been described in the apo AI gene that lead to reductions in apo AI synthesis or increases in catabolism. One mutation that is common in Italy, apo AI-Milano, is associated with a high fractional clearance rate of apo AI but is not associated with increased risk for atherosclerosis.

Some rare genetic disorders of lipid metabolism are summarized in Table 344-5.

SECONDARY CAUSES OF HYPERLIPOPROTEINEMIA (See Table 344-6)

Diabetes Mellitus Diabetes can affect lipid and lipoprotein metabolism through several mechanisms (Chap. 333). In type 1 diabetes mellitus (DM) (formerly called insulin-dependent diabetes mellitus), plasma lipids are usually normal when control of diabetes with insulin is adequate. In diabetic ketoacidosis, hypertriglyceridemia can be severe due to increases in both VLDL and chylomicrons. These abnormalities are associated with overproduction of VLDL and LPL deficiency secondary to insulinopenia. They usually improve with tight control of the diabetes. In type 2 DM (formerly called non-insulin-dependent diabetes mellitus), insulin resistance and obesity combine to cause mild to moderate hypertriglyceridemia and low HDL cholesterol levels. In general, this pattern of dyslipidemia is due to overproduction of VLDL. LDL cholesterol is usually normal in type 2 DM, though the LDLs are small, dense, and perhaps more atherogenic. Treatment of type 2 DM and weight reduction improve, but usually do not completely correct, the dyslipidemia (particularly the low HDL cholesterol levels). Therapy of hyperlipidemia should not be delayed in patients with type 2 DM, as they are at increased risk for CHD. It is recommended that patients with diabetes should be treated as if they already have CHD, i.e., the treatment goal is to reduce their LDL to <2.6 mmol/L (<100 mg/dL) (Fig. 344-2).

Hypothyroidism Hypothyroidism accounts for about 2% of all cases of hyperlipidemia and is second only to DM as a cause of secondary hyperlipidemia. Levels of LDL cholesterol can be elevated, even in patients with subclinical disease in whom thyroid-stimulating hormone (TSH) levels are elevated but other thyroid function tests are normal. Hypertriglyceridemia can occur if obesity is present. Hypothyroidism is also associated with increased levels of HDL cholesterol, probably because of reduced HTGL activity. Correction of hypothyroidism reverses the lipid abnormalities.

Renal Disease Renal disease causes a wide range of lipid abnormalities. The nephrotic syndrome can be accompanied by elevations in LDL, VLDL, or both. The severity of the hyperlipidemia correlates with the degree of hypoproteinemia. Renal failure is associated with hypertriglyceridemia and low HDL cholesterol concentrations.

Ethanol The metabolism of ethanol enhances the level of NADH in the liver which, in turn, stimulates the synthesis of fatty acids and their incorporation into triglycerides. Moderate ethanol consumption raises plasma VLDL levels, with the degree of elevation dependent on the baseline level. Severe hypertriglyceridemia and pancreatitis usually develop on the background of a genetic hyperlipidemia and heavy alcohol intake. Because ethanol also stimulates the synthesis of apo AI and inhibits CETP, ethanol-associated hypertriglyceridemia is usually accompanied by normal or elevated levels of HDL cholesterol.

Liver Disease Primary biliary cirrhosis and extrahepatic biliary obstruction can cause hypercholesterolemia and elevated levels of plasma phospholipids associated with increased levels of an abnormal lipoprotein (lipoprotein X;Chap. 299) andLDL. Severe liver injury often leads to a decrease in levels of both cholesterol and triglyceride. Acute hepatitis can cause elevated levels ofVLDL and impairment ofLCATformation.

AIDS Use of protease inhibitor therapies has been associated with a generalized metabolic syndrome that includes hypertriglyceridemia, alterations in fat distribution, and occasionally type 2DM(Chap. 309).

DIAGNOSIS

Although the initial indication of an abnormality in lipoprotein metabolism is via blood measurements of triglyceride and cholesterol, the disorders are due to abnormalities of specific lipoproteins. Thus, lipoprotein analysis should assessVLDL,LDL, andHDLlevels. Direct measurements of plasma LDL require laborious centrifugation techniques. However, LDL cholesterol concentrations can be estimated indirectly in individuals with triglyceride levels <4.5 mmol/L (<400 mg/dL) by subtracting the HDL and VLDL cholesterol from the total plasma cholesterol. HDL cholesterol is determined after chemical precipitation of VLDL and LDL. VLDL cholesterol is estimated to be the plasma triglyceride level divided by five. Therefore

where all values are measured in milligrams per deciliter.

In persons with triglyceride levels >4.5 mmol/L (>400 mg/dL), the ratio of triglyceride to cholesterol inVLDL is>5, and this equation cannot be used to calculate the plasmaLDLcholesterol level. The other disorder that is not detected with this method is dysbetalipoproteinemia because the ratio of triglyceride to cholesterol in the VLDL is <<5. In these two situations, direct measurement of LDL cholesterol must be performed in ultracentrifuged plasma. Commercial methods for the measurement of "direct LDL" are available. Although these methods appear to be precise and accurate, the measured values for LDL cholesterol are 0.06 to 0.17 mmol/L (5 to 15 mg/dL) less than estimated LDL because the estimated value is actually the combination ofIDL and LDL. If a "direct LDL" measurement is used, the National Cholesterol Education Program (NCEP) guidelines (based on estimated LDL) must be adjusted before therapeutic decisions are made.

Because plasma triglyceride levels rise and bothHDL andLDLcholesterol levels fall modestly after a fat-containing meal (due to the action ofCETP), it is preferable to measure plasma lipids after a 12-h fast. Measuring cholesterol levels alone will not detect individuals with isolated low HDL; screening forCHDshould therefore include measurement of HDL. Because serum lipid levels vary from day to day, at least two to three measurements should be made days or weeks apart before initiating therapy. Some experts advocate the use of total cholesterol/HDL ratios as a better assessment of individual risk. This is a reasonable approach provided both the patient and physician are aware that the treatment goal is to reduce LDL. In addition, rare patients with very

high or very low levels of both LDL and HDL have ratios that are not interpretable on the basis of population studies. Although some laboratories offer measurements of individual apoproteins (e.g., apo B100 and apo AI), or size estimates of LDL, this information is not generally helpful in decision-making. Measurement of lipoprotein (a) levels can provide an indication of risk that cannot be gleaned from lipid measurements. Lipoprotein electrophoresis is not useful except for the diagnosis of dysbetalipoproteinemia, a diagnosis that otherwise requires ultracentrifugation methods. Apo E genotyping is also helpful in the diagnosis of dysbetalipoproteinemia (although rarely the disorder can be due to other defects in the apo E gene).

BothLDL andHDLcholesterol levels are temporarily decreased for several weeks after myocardial infarction or acute inflammatory states but can be accurately measured if blood is obtained within 8 h of the event.

Approach to the Patient

Elevated LDL Cholesterol Treatment of elevated LDL cholesterol can have either of two aims -- *primary prevention* of the complications of atherosclerosis or *secondary treatment* after complications have occurred. The rationale for primary prevention is based on the large body of data linking elevated levels of LDL cholesterol with increasedCHD risk and an impressive body of clinical and experimental data demonstrating that reducing LDL cholesterol slows progression and may actually induce regression of atherosclerotic lesions (Chap. 242). Both primary and secondary intervention trials indicate that total mortality can be reduced when the LDL cholesterol is lowered (Table 344-1). A meta-analysis of four randomized trials (4S, CARE, AFCAPS/TexCAPS, LIPID) comparing HMG-CoA reductase inhibitors to control included 30,817 participants and found that HMG-CoA reductase inhibitor treatment was associated with: (1) a 20% decrease in total cholesterol, a 28% decrease in LDL cholesterol, a 13% decrease in triglycerides, and a 5% increase in HDLcholesterol; (2) a 31% decrease in major coronary events and a 21% decrease in all-cause mortality; (3) similar risk reduction in women and men; and (4) no effect on noncardiovascular mortality. Unexpectedly, the risk of stroke was also reduced 19 to 32% by HMG-CoA reductase inhibitor treatment, even though previous observational studies show a relatively weak association between cholesterol level and stroke risk.

Dietary Alterations A fundamental starting point for both primary prevention and secondary treatment involves counseling to modify diet, exercise, smoking, and other life-style factors that increase the risk of CHD. The typical American diet derives about 35% of its calories from fat (14 to 15% from saturated fat) and contains 400 to 500 mg/d of cholesterol. Individuals with hyperlipidemia should be encouraged to eat a diet lower in cholesterol and saturated fat. TheNCEPStep 1 diet, which is recommended for all Americans above age 2, provides 30% of calories from fat, <10% of calories from saturated fat, and <300 mg/d of cholesterol (Table 344-7). Carbohydrate is the typical nutrient used to replace fat in patients with isolated hypercholesterolemia. In general, whole-milk dairy products, egg yolks, meats, palm oil, and coconut oil should be replaced with fresh fruits and vegetables, complex carbohydrates (especially whole-grain products), and low-fat dairy products. Shellfish are low in fat content and, except for shrimp, also have low cholesterol levels; shrimp, in moderation, is acceptable. Portion size needs to be stressed; the protein and fat-rich portion of meat in

a given meal should be<115 g (4 oz), the size of a deck of cards. Substitutions with any food low in saturated fat such as bran, nuts, and olive oil will have positive effects onLDL. Hydrogenation of vegetable oils increases the saturation of the fatty acids. In particular, trans-fatty acids, mainly found in commercially hydrogenated vegetable oils, raise LDL and can lowerHDLcholesterol levels. Use of stanol-containing margarines has, by contrast, lowered LDL cholesterol about 5 to 10% by blocking cholesterol absorption in the small intestine. When further diet therapy is indicated, the NCEP Step 2 diet provides 30% of calories as fat but <7% of calories from saturated fat, and <200 mg/d of cholesterol. After changing from the average American diet to the Step 1 diet, the LDL cholesterol usually drops 8 to 10%; an additional reduction of 5 to 7% can be achieved by advancing to the Step 2 diet. There is, however, great individual variability in diet responsiveness, and several values should be obtained before judging the efficacy of any diet treatment.

Primary Prevention The NCEPAdult Treatment Panel recommends measuring plasma cholesterol in all adults older than age 20 at least every 5 years. Ideally, this testing involves a lipoprotein profile to allow better risk stratification. Primary prevention goals includeLDLcholesterol <3.36 mmol/L (<130 mg/dL), triglycerides<1.7 mmol/L (<150 mg/dL), andHDLcholesterol >1.03 mmol/L (>40 mg/dL) for men and>1.29 mmol/L (>50 mg/dL) for women. In individuals withoutDM or known CHD, treatment recommendations for primary prevention are outlined inFig. 344-2. Assessment of risk factors in addition to LDL cholesterol is an essential part of this decision-making process. Risk factors include: (1) family history of prematureCHD(<55 years in a male parent or sibling or<65 in female relatives), (2) hypertension (even if it is controlled with medications), (3) cigarette smoking (>10 cigarettes per day), (4) DM, and (5) low HDL [<0.9 mmol/L (<35 mg/dL)]. In addition, because CHD is more prevalent in older individuals, age (men >45 years, women>55 years, or younger women with premature menopause without estrogen replacement) is also an important risk factor. HDL cholesterol >1.6 mmol/L (>60 mg/dL) is a negative risk factor, i.e., one other risk factor can be negated by a high HDL cholesterol level.

In individuals with fewer than two risk factors, life-style modifications alone and follow-up testing may be used ifLDL is<4.14 mmol/L (<160 mg/dL). For those with LDL >4.91 mmol/L (>190 mg/dL), drug treatment is indicated. If two or more risk factors are present, drug treatment in addition to life-style modifications should be instituted if LDL cholesterol is>3.36 mmol/L (>130 mg/dL). HMG-CoA reductase inhibitors are first-line medications for most patients; niacin and resins are second-line treatments (see below).

Secondary Prevention TheNCEPguidelines are stringent for the secondary treatment of patients withCHD. Patients with CHD should be screened for lipid abnormalities during and after their initial diagnoses. A goal of lowering plasmaLDLconcentrations to <2.6 mmol/L (<100 mg/dL) is advocated for such individuals as well as for patients withDM(Fig. 344-2). As described below, this requires modifications of diet in addition to the use of one or more medications.

If a patient withCHD has only a modestly elevatedLDLcholesterol level [e.g., <3.36 mol/L (<130 mg/dL)], a 4- to 6-week period of Step 1 diet therapy can precede the addition of drugs. In such a patient, moving to the Step 2 diet, which provides the same total fat but <7% of calories from saturated fat, can be useful. If, however, the LDL

cholesterol is >3.36 mmol/L (>130 mg/dL), drug therapy should be instituted along with diet therapy (Fig. 344-2).

High Triglycerides and Low HDL The evidence that treatment to reduce plasma triglyceride levels or increase levels of HDL cholesterol leads to long-term health benefits is less compelling than that for treatment of high LDL levels. Two recent clinical trials have shown, however, that lowering triglycerides (using fibric acids) or lowering LDL (HMG-CoA reductase inhibitors) decreases CHD events in these patients. There have been no intervention trials in which only increases in HDL cholesterol concentrations have been achieved. Beneficial effects of niacin have been attributed, in part, to its HDL-raising effect and its action to reduce triglycerides and LDL. Even with drugs that primarily affect LDL cholesterol levels, such as bile acid-binding resins and HMG-CoA reductase inhibitors, some of the benefits achieved may be related to increases in HDL cholesterol levels.

In patients with isolated elevations of triglyceride levels or with hypertriglyceridemia and high LDL cholesterol, life-style modifications should be introduced as described above, and weight reduction should be strongly encouraged if obesity is present. Fat intake should be decreased, but the concomitant increase in carbohydrate intake may raise triglyceride and lower HDL cholesterol levels. If this occurs, replacing some of the saturated fat with monounsaturated fat, which will not raise LDL cholesterol, may be valuable. Severe hypertriglyceridemia and hyperchylomicronemia require very low fat diets, avoidance of free sugars, and decreased alcohol intake. Patients with genetic LPL deficiency are instructed to prepare their food using medium-chain triglycerides, which are not incorporated into chylomicrons. Fish oils decrease triglyceride synthesis, and high doses may be used for severe hypertriglyceridemia.

The management of hypertriglyceridemia focuses on the associated LDL and HDL concentrations as guidelines for therapy. Thus, the overall risk profile can be used to set goals for LDL cholesterol, using a low HDL level (commonly associated with hypertriglyceridemia) as a concomitant major risk factor for atherosclerosis. However, when triglyceride levels are>5.6 mmol/L (>500 mg/dL), the risk of developing pancreatitis increases, and a direct focus on lowering triglycerides is recommended. Thus, triglyceride levels>5.6 mmol/L (>500 mg/dL) are generally treated with drugs, whereas lower levels [2.2 to 5.6 mmol/L (200 to 500 mg/dL)] are not treated unless other CHD risk factors are present (Fig. 344-2).

TREATMENT

Three classes of lipid-lowering agents are recommended as first-line therapy against hypercholesterolemia: (1) the HMG-CoA reductase inhibitors; (2) niacin; and (3) the bile acid-binding resins (Table 344-8). Fibric acid derivatives are second-line agents for hypercholesterolemia and are most effective for lowering triglycerides.

HMG-CoA Reductase Inhibitors This class of drugs, which include lovastatin, simvastatin, pravastatin, fluvastatin, atorvastatin, and cerivastatin, inhibits the rate-limiting step in hepatic cholesterol biosynthesis (the conversion of HMG-CoA to mevalonate), causing an increase in LDL receptor levels in hepatocytes and enhanced receptor-mediated clearance of LDL cholesterol from the circulation. At usual doses, the

HMG-CoA reductase inhibitors decrease total cholesterol by 20 to 30% and LDL cholesterol by 25 to 40%. Larger reductions may be achieved with higher doses. Treatment with reductase inhibitors often reduces triglycerides by 10 to 20%, possibly due to reduced secretion ofVLDL by the liver. Higher doses of more potent reductase inhibitors, which can lower LDL cholesterol by 45 to 60%, can lower triglycerides by 30 to 45%.HDLcholesterol levels rise about 5 to 10%. In comparison with other lipid-lowering agents, HMG-CoA reductase inhibitors are relatively free of side effects. Mild, transient elevations in liver enzymes occur with all of the agents at the highest doses, but elevations in serum aminotransferases to more than three times the upper limits of normal occur in <2% of patients. Therapy should be discontinued when elevations of this magnitude occur. A rare but potentially serious adverse effect of HMG-CoA reductase inhibitors is myopathy, manifest by muscle pain with elevation of serum creatine phosphokinase (CPK). This occurs in <1% of patients treated with reductase inhibitors alone but is more common (about 2 to 3%) when used in combination with gemfibrozil, niacin, or cyclosporine.

Niacin The mechanism of action of niacin is not fully understood, but it appears to inhibit the secretion of lipoproteins containing apo B100 from the liver. Niacin decreases both total andLDLcholesterol approximately 15 to 25%, reducesVLDLlevels by 25 to 35%, and raisesHDLcholesterol levels by as much as 15 to 25%. Thus, niacin exerts favorable changes on the three major lipoproteins (VLDL, LDL, and HDL). Efficacy of monotherapy was confirmed in a long-term secondary prevention trial in which niacin significantly reduced the incidence of myocardial infarction. An even longer-term follow-up of that study (15 years total) showed an 11% decrease in all-cause mortality among patients randomized to niacin. Because of its ability to reduce VLDL synthesis, niacin is also a first-line drug for treatment of hypertriglyceridemia.

Niacin is safe, having been in use for almost 30 years, but unpleasant side effects, including cutaneous flushing with or without pruritus, may limit patient acceptability. The cutaneous symptoms tend to subside after several weeks and may be minimized by initiating therapy at low doses or by administering aspirin 30 min before the niacin dose. Less common adverse effects include elevations of liver enzymes, gastrointestinal distress, impaired glucose tolerance, and elevated serum uric acid levels with or without gouty arthritis. Liver enzymes may be elevated in 3 to 5% of patients on full doses of niacin (>2 g/d). Because of its propensity to worsen the control of blood sugar, niacin should be used with caution in patients withDM. Niaspan, an intermediate-release form of niacin, appears to exhibit lipid-altering activity similar to regular niacin.

Bile Acid-Binding Resins Cholestyramine and colestipol have been in use as lipid-lowering agents for almost three decades. These drugs interfere with reabsorption of bile acids in the intestine, resulting in a compensatory increase in bile acid synthesis and upregulation ofLDLreceptors in hepatocytes. The bile acid sequestrants are useful in the treatment of patients with elevated levels of LDL cholesterol and normal triglycerides. Sequestrants produce dose-dependent decreases on the order of 15 to 25% in total cholesterol and of 20 to 35% in LDL cholesterol. The agents cause modest increases inHDLcholesterol. A limitation of the sequestrants is their tendency to raise triglyceride levels through compensatory increases in hepatic synthesis ofVLDL; they should not be given to hypertriglyceridemic individuals. Bile acid-binding resins are efficacious and safe and are recommended for young adult men and premenopausal

women with moderate cholesterol elevations. Patient compliance is low, in part because of the need to dissolve these powdered agents in fluid; the availability of colestipol as a tablet may alleviate this problem. Gastrointestinal side effects include constipation, bloating, and gas.

Combination Therapy Combinations of bile acid-binding resins and reductase inhibitors are effective for the treatment of severe, isolated elevations ofLDLcholesterol. Combinations of reductase inhibitors and niacin, or resins and niacin, are useful for the treatment of high LDL and lowHDLcholesterol levels, though the former combination carries an increased risk of myositis (2 to 3%). If triglyceride and LDL levels are both elevated (HDL is usually reduced as well), resins and niacin are an excellent combination, with resins and gemfibrozil (see below) as an alternative. The combination of a reductase inhibitor and gemfibrozil can be useful when LDL cholesterol is very high in the face of concomitant hypertriglyceridemia, but the risk of myositis (about 2 to 3%) must be considered. Combinations of reductase inhibitors with either niacin or gemfibrozil might best be reserved for patients withCHD and combined hyperlipidemia.

LDL Apheresis In patients with homozygousFH and in ordinary FH patients who respond poorly to diet and drug therapy or who cannot tolerate drugs, apheresis at 7- to 14-day intervals can cause profound lowering of LDL cholesterol levels. Diet and drug regimens are continued during treatment. This approach should be considered for patients with few therapeutic options.

Fibric Acids Gemfibrozil and fenofibrate stimulate the activity of a liver transcription factor termed *PPARa* that increasesLPLactivity and production of apo AI. Moreover, these drugs reduceVLDLtriglyceride entry into plasma and reduce synthesis of apo CIII, which might improve LPL-induced lipolysis or reduce VLDL secretion. Stimulation of peroxisomal fatty acid oxidation by fibrates may also contribute to the triglyceride-lowering actions. Gemfibrozil and fenofibrate treatment is associated with 25 to 40% reductions in plasma triglyceride levels. Postprandial triglyceride levels, which are linked to fasting concentrations, are also reduced. HDL cholesterol levels increase 5 to 15% with fibrate treatment. Fibric acids and a low-fat diet are particularly useful in the treatment of dysbetalipoproteinemia and are first-line therapy for this disorder except in postmenopausal women, who should initially be given estrogen replacement (if not contraindicated).

Significant increases inLDLcholesterol can accompany otherwise potentially beneficial falls in triglycerides and increases inHDLcholesterol during fibrate therapy. Such rises may require a change to another drug or addition of a second agent.

In the short term, these drugs are well tolerated; mild gastrointestinal distress in the form of epigastric pain is the major side effect. Elevations of liver enzymes occur in 2 to 3% of patients but do not usually require cessation of treatment. Rarely, hepatitis can occur. Fibrates appear to make the bile more lithogenic, and long-term use is probably associated with a twofold increase in gallstone formation. Myopathy with myositis is a rare occurrence with the fibrates, either alone or in combination with HMG CoA reductase inhibitors.

Fish Oils Large doses of omega-3 fatty acids reduce triglyceride levels by diminishing

their production. In the United States, omega-3 fatty acid capsules contain 40 to 60% omega-3 fatty acids; the rest of the fatty acids are omega-6. Therefore, to consume 2 to 4 g of omega-3 fatty acids, an individual must take 5 to 10 capsules per day.

HYPOCHOLESTEROLEMIA

A low total cholesterol concentration [<2.6 mmol/L (<100 mg/dL)] in an adult can be due to rare hereditary traits or secondary to a number of diseases. As described earlier, mutations in the gene for apo B100 that disrupt synthesis or produce truncated forms of apo B100 are associated with hypobetalipoproteinemia. These mutations are inherited as codominant traits; heterozygotes have plasma cholesterol levels in the range of 1.3 to 2.6 mmol/L (50 to 100 mg/dL), with reducedLDLcholesterol levels but normal plasmaHDLcholesterol levels. Heterozygotes are asymptomatic, whereas hypolipoproteinemia homozygotes (or compound heterozygotes) have even lower total and LDL cholesterol concentrations and may have malabsorption of fats and fat-soluble vitamins similar to that in abetalipoproteinemia.

Abetalipoproteinemia (Table 344-5) is a rare, autosomal recessive disorder in which there are mutations in the microsomal triglyceride transfer protein (MTP) gene. Individuals who are homozygous for this disorder have total cholesterol levels <1.3 mmol/L (<50 mg/dL) and essentially noVLDL,IDL,LDL, or chylomicrons. Because dietary fat and vitamins A and E are transported from the intestine in chylomicrons, these patients may have malabsorption of fat and fat-soluble vitamins. Vitamin E deficiency in infancy and early childhood can result in neurologic problems (Chap. 75). If vitamin replacement is adequate, individuals with abetalipoproteinemia can live normal, healthy lives.

Moderately low levels of total cholesterol may also be associated with extreme reductions inHDLcholesterol. As noted above, these are almost always secondary to mutations in the gene for apo AI and a lack of apo AI in plasma.

A number of systemic diseases can cause low cholesterol concentrations. Malnutrition, often associated with alcoholism or gastrointestinal disease, can cause low levels of total andLDLcholesterol. Hyperthyroidism, particularly when severe, can reduce cholesterol levels. Patients with uncontrolled AIDS may have total cholesterol levels<2.1 mmol/L (<80 mg/dL), usually associated with severe wasting, diarrhea, and a poor prognosis. Several neoplasms, particularly those involving the hematopoietic system, are associated with hypocholesterolemia. Patients with acute and chronic myelogenous leukemia and myeloid metaplasia with splenomegaly can have severe reductions in both LDL andHDLlevels. Other diseases with concomitant splenomegaly, including lipid storage diseases such as Gaucher's disease and Niemann-Pick disease, can cause very low LDL and HDL cholesterol concentrations due to increased lipoprotein catabolism.

345. HEMOCHROMATOSIS - *Lawrie W. Powell, Kurt J. Isselbacher*

DEFINITION

Hemochromatosis is a common disorder of iron storage in which an appropriate increase in intestinal iron absorption results in deposition of excessive amounts of iron in parenchymal cells with eventual tissue damage and impaired function of organs, especially the liver, pancreas, heart, joints, and pituitary. The disease was termed *hemochromatosis* and the iron-storage pigment was called *hemosiderin* because it was believed that the pigment was derived from the blood. The terms *hemosiderosis* and *siderosis* are often used to describe the presence of stainable iron in tissues, but tissue iron must be quantified to assess body iron status (see below andChap. 105). *Hemochromatosis* implies potentially severe progressive iron overload leading to fibrosis and organ failure. Cirrhosis of the liver, diabetes mellitus, arthritis, cardiomyopathy, and hypogonadotrophic hypogonadism are common manifestations.

Although there is debate about definitions, it seems logical to use the following terminology:

1. *Hereditary* or *genetic hemochromatosis*: This disorder is most often caused by inheritance of a mutant *HFE* gene, which is tightly linked to the HLA-A locus on chromosome 6p (see below). The genetic disease can be recognized during its early stages when iron overload and organ damage are minimal. At this stage the disease is best referred to as *early* or *precirrhotic hemochromatosis* (Fig. 345-1).

2. *Secondary iron overload*: Tissue injury usually occurs secondary to an iron-loading anemia such as thalassemia or sideroblastic anemia, in which increased erythropoiesis is ineffective. In the acquired iron-loading disorders, massive iron deposits in parenchymal tissues can lead to the same clinical and pathologic features as in hemochromatosis.

PREVALENCE

Hemochromatosis is one of the most common genetic diseases, although its prevalence varies in different ethnic groups. It is most common in populations of northern European extraction in whom approximately 1 in 10 persons are heterozygous carriers and 0.3 to 0.5% are homozygotes. However, expression of the disease is modified by several factors, especially dietary iron intake, blood loss associated with menstruation and pregnancy, and blood donation. The clinical expression of the disease is 5 to 10 times more frequent in men than in women. Nearly 70% of affected patients develop the first symptoms between ages 40 and 60. The disease is rarely evident before age 20, although with family screening (see below) and periodic health examinations, asymptomatic subjects with iron overload can be identified, including young menstruating women. A recent study in a European non-blood bank population revealed that 30% of homozygous individuals did not have evidence of iron overload. Thus, the penetrance of the mutation is variable.

GENETIC BASIS AND MODE OF INHERITANCE

The gene involved in the most common form of hemochromatosis was cloned in 1996 and is termed *HFE*. A homozygous G®A mutation resulting in a cysteine to tyrosine substitution at position 282 (C282Y) is the most common mutation. It was identified in 85 to 100% of patients with hereditary hemochromatosis in populations of northern European descent but was found in only 60% of cases from Mediterranean populations (e.g., southern Italy). A second, relatively common *HFE* mutation has also been identified. This results in an amino acid substitution of histidine to aspartic acid at position 63 (H63D). Some compound heterozygotes (e.g., one copy each of C282Y and H63D) have increased body iron stores. Thus, *HFE*-associated hemochromatosis is inherited as an autosomal recessive trait; heterozygotes have no, or minimal, increase in iron stores. However, in some cases this slight increase in hepatic iron acts as a cofactor that aggravates other diseases such as porphyria cutanea tarda (PCT) and nonalcoholic steatohepatitis.

Mutations in other genes, currently unidentified, are responsible for non-*HFE* associated hemochromatosis, including juvenile hemochromatosis, which affects subjects in the second and third decade of life (Table 345-1).

PATHOGENESIS

Normally, the body iron content of 3 to 4 g is maintained such that intestinal mucosal absorption of iron is equal to iron loss. This amount is approximately 1 mg/d in men and 1.5 mg/d in menstruating women. In hemochromatosis, mucosal absorption is inappropriate to body needs and amounts to 4 mg/d or more. The progressive accumulation of iron causes an early elevation in plasma iron, an increased saturation of transferrin, and progressive elevation of plasma ferritin level (Fig. 345-1).

The *HFE* gene encodes a 343 amino acid protein that is structurally related to MHC class I proteins. The basic defect in hemochromatosis is a lack of cell surface expression of HFE (due to the C282Y mutation). The normal (wild type) HFE protein forms a complex withb_2-microglobulin and transferrin, and the C282Y mutation completely abrogates this interaction. As a result, the mutant HFE protein remains trapped intracellularly, reducing transferrin receptor-mediated iron uptake by the intestinal crypt-cell. This is postulated to upregulate the divalent metal transporter (DMT-1) on the brush border of the villous cells, leading to inappropriately increased intestinal iron absorption. In advanced disease, the body may contain 20 g or more of iron that is deposited mainly in parenchymal cells of the liver, pancreas, and heart. Iron may be increased 50- to 100-fold in the liver and pancreas and 5- to 25-fold in the heart. Iron deposition in the pituitary causes hypogonadotropic hypogonadism in both men and women. Tissue injury may result from disruption of iron-laden lysosomes, from lipid peroxidation of subcellular organelles by excess iron, or from stimulation of collagen synthesis by activated stellate cells.

Secondary iron overload with deposition in parenchymal cells occurs in chronic disorders of erythropoiesis, particularly in those due to defects in hemoglobin synthesis or ineffective erythropoiesis such as sideroblastic anemia and thalassemia (Chap. 106). In these disorders, the absorption of iron is increased. Moreover, these patients require blood transfusions and are also frequently treated inappropriately with iron.PCT, a disorder characterized by a defect in porphyrin biosynthesis (Chap. 346), is also

sometimes associated with excessive parenchymal iron deposits. The magnitude of the iron load in PCT is usually insufficient to produce tissue damage. However, recent reports have found that many patients with PCT also have mutations in the *HFE* gene, and some have associated hepatitis C infection. Although the relationship among these disorders remains to be clarified, iron overload accentuates the inherited enzyme deficiency in PCT and should be avoided along with other agents (alcohol, estrogens, haloaromatic compounds) that may exacerbate PCT. Another cause of hepatic parenchymal iron overload is hereditary aceruloplasminemia. In this disorder, impairment of iron mobilization due to deficiency of ceruloplasmin (a ferroxidase) causes iron overload in hepatocytes.

Alcoholic subjects with end-stage chronic liver disease may have increased tissue iron stores of the degree seen in hemochromatosis. The increased iron may be caused by cell death and uptake of the released iron, as well as by hemolysis associated with spur-cell anemia (Chap. 108). Hemochromatosis in a heavy drinker can be distinguished from alcoholic liver disease by the presence of the C282Y mutation.

Excessive iron ingestion over many years rarely results in hemochromatosis. An important exception has been reported in South Africa among groups who brew fermented beverages in vessels made of iron. Hemochromatosis has on occasion been described in apparently normal subjects who have taken medicinal iron over many years, but such individuals probably have a genetic disorder.

The common denominator in all patients with hemochromatosis is *excessive amounts of iron in parenchymal tissues*. Parenteral administration of iron in the form of blood transfusions or iron preparations results predominantly in reticuloendothelial cell iron overload. This appears to lead to less tissue damage than iron loading of parenchymal cells.

PATHOLOGY

At autopsy, the enlarged nodular liver and pancreas are rusty in color. Histologically, iron is increased in amount in many organs, particularly in the liver, heart, and pancreas, and to a lesser extent in the endocrine glands. The epidermis of the skin is thin, and melanin is increased in the cells of the basal layer. Deposits of iron are present around the synovial lining cells of the joints.

In the liver of patients with hemochromatosis, parenchymal iron is in the form of ferritin and hemosiderin. In the early stages these deposits are seen in the periportal parenchymal cells, especially within lysosomes in the pericanalicular cytoplasm of the hepatocytes. This stage progresses to perilobular fibrosis and eventually to deposition of iron in bile duct epithelium, Kupffer cells, and fibrous septa. In the advanced stage, a macronodular or mixed macro- and micronodular cirrhosis develops.

CLINICAL MANIFESTATIONS

Initial symptoms include weakness, lassitude, weight loss, change in skin color, abdominal pain, loss of libido, and symptoms of diabetes mellitus. Hepatomegaly, increased pigmentation, spider angiomas, splenomegaly, arthropathy, ascites, cardiac

arrhythmias, congestive heart failure, loss of body hair, testicular atrophy, and jaundice are prominent in advanced disease.

The *liver* is usually the first organ to be affected, and hepatomegaly is present in more than 95% of symptomatic patients. Hepatic enlargement may exist in the absence of symptoms or of abnormal liver function tests. Indeed, over half of patients with symptomatic hemochromatosis have little laboratory evidence of functional impairment of the liver, in spite of hepatomegaly and fibrosis. Loss of body hair, palmar erythema, testicular atrophy, and gynecomastia are common. Manifestations of portal hypertension and esophageal varices occur less commonly than in cirrhosis from other causes. Hepatocellular carcinoma develops in about 30% of patients with cirrhosis, and it is the most common cause of death in treated patients; hence the importance of early diagnosis and therapy. Its incidence increases with age, is more common in men, and occurs almost exclusively in cirrhotic patients. Splenomegaly occurs in approximately half of symptomatic cases.

Excessive skin pigmentation is present in over 90% of symptomatic patients at the time of diagnosis. The characteristic metallic or slate gray hue is sometimes referred to as bronzing and results from increased melanin and iron in the dermis. Pigmentation usually is diffuse and generalized, but it may be more pronounced on the face, neck, extensor aspects of the lower forearms, dorsa of the hands, lower legs, genital regions, and in scars.

Diabetes mellitus occurs in about 65% of patients and is more likely to develop in those with a family history of diabetes, suggesting that direct damage to the pancreatic islets by iron deposition occurs in combination with a genetic predisposition. The management is similar to that of other forms of diabetes, although pronounced insulin resistance is more common in association with hemochromatosis. Late complications are the same as seen in other causes of diabetes mellitus.

Arthropathy develops in 25 to 50% of patients. It usually occurs after age 50, but may occur as a first manifestation, or long after therapy. The joints of the hands, especially the second and third metacarpophalangeal joints, are usually the first joints involved, a feature that helps to distinguish the chondrocalcinosis associated with hemochromatosis from the idiopathic form (Chap. 322). A progressive polyarthritis involving wrists, hips, ankles, and knees also may ensue. Acute brief attacks of synovitis may be associated with deposition of calcium pyrophosphate (chondrocalcinosis or pseudogout), mainly in the knees. Radiologic manifestations include cystic changes of the subchondral bones, loss of articular cartilage with narrowing of the joint space, diffuse demineralization, hypertrophic bone proliferation, and calcification of the synovium. The arthropathy tends to progress despite removal of iron by phlebotomy. Although the relation of these abnormalities to iron metabolism is not known, the fact that similar changes occur in other forms of iron overload suggests that iron is directly involved.

Cardiac involvement is the presenting manifestation in about 15% of patients. The most common manifestation is congestive heart failure, which occurs in about 10% of young adults with the disease, especially those with juvenile hemochromatosis. Symptoms of congestive failure may develop suddenly, with rapid progression to death if untreated. The heart is diffusely enlarged and may be misdiagnosed as idiopathic cardiomyopathy

if other overt manifestations are absent. Cardiac arrhythmias include premature supraventricular beats, paroxysmal tachyarrhythmias, atrial flutter, atrial fibrillation, and varying degrees of atrioventricular block.

Hypogonadism occurs in both sexes and may antedate other clinical features. Manifestations include loss of libido, impotence, amenorrhea, testicular atrophy, gynecomastia, and sparse body hair. These changes are primarily the result of decreased production of gonadotropins due to impairment of hypothalamic-pituitary function by iron deposition; however, primary testicular dysfunction may be seen in some cases. Adrenal insufficiency, hypothyroidism, and hypoparathyroidism may also occur.

DIAGNOSIS

The association of (1) hepatomegaly, (2) skin pigmentation, (3) diabetes mellitus, (4) heart disease, (5) arthritis, and (6) hypogonadism should suggest the diagnosis. However, a parenchymal iron overload of comparatively short duration or modest degree may exist with none or only some of these manifestations [e.g., in young subjects (Fig. 345-1)]. Therefore, a high index of suspicion is needed to make the diagnosis early. This is particularly important because treatment before there is permanent organ damage can reverse the iron toxicity and restore life expectancy to normal (see below).

The history should be particularly detailed in regard to disease in other family members, alcohol ingestion, iron intake, and ingestion of large doses of ascorbic acid, which promotes iron absorption (Chap. 75). Appropriate tests should be performed to exclude iron deposition due to hematologic disease. The presence of liver, pancreatic, cardiac, and joint disease should be confirmed by physical examination, roentgenography, and standard function tests of these organs. The degree of increase in total-body iron stores should be assessed with particular attention to an increase in parenchymal iron concentration, with or without tissue damage.

The methods available for assessing parenchymal iron stores include (1) measurement of serum iron and the percent saturation of transferrin (or the unsaturated iron-binding capacity); (2) measurement of serum ferritin concentration; (3) liver biopsy with measurement of the iron concentration and calculation of the hepatic iron index (Table 345-2), (4) estimation of chelatable iron stores following the administration of deferoxamine; and (5) computed tomography (CT) and/or magnetic resonance imaging (MRI) of the liver. Each has its advantages and limitations. The serum iron level and percent saturation of transferrin are elevated early in the course, but their specificity is reduced by significant false-positive and false-negative rates. For example, serum iron concentration may be increased in patients with alcoholic liver disease without iron overload; in this situation, however, the hepatic iron index is usually not increased as in hemochromatosis (Table 345-1). In otherwise healthy persons, a fasting serum transferrin saturation greater than 50% is abnormal and suggests homozygosity for hemochromatosis.

The serum ferritin concentration is usually a good index of body iron stores, whether decreased or increased. In fact, an increase of 1 ug/L in serum ferritin level reflects an

increase of about 65 mg in body stores. In most untreated patients with hemochromatosis, the serum ferritin level is greatly increased (Fig. 345-1 andTable 345-1). However, in patients with inflammation and hepatocellular necrosis, serum ferritin levels may be elevated out of proportion to body iron stores due to increased release from tissues. A repeat determination of serum ferritin should therefore be carried out after acute hepatocellular damage has subsided, e.g., in alcoholic liver disease. Ordinarily, the combined measurements of the percent transferrin saturation and serum ferritin level provide a simple and reliable screening test for hemochromatosis, including the precirrhotic phase of the disease. If either of these tests is abnormal, genetic testing for hemochromatosis should be performed (Fig. 345-2).

The role of liver biopsy in the diagnosis and management of hemochromatosis is being reassessed as a result of the widespread availability of genetic testing for the C282Y mutation. The absence of severe fibrosis can be accurately predicted in most patients using clinical and biochemical variables. Thus, there is virtually no risk of severe fibrosis in a C282Y homozygous subject with: (1) serum ferritin level less than 1000 ug/L; (2) normal serum alanine amino transaminase values; (3) no hepatomegaly; and (4) no excess alcohol intake. However, it should be emphasized that liver biopsy is the only reliable method for establishing or excluding the presence of hepatic cirrhosis, which is the critical factor determining prognosis and the risk of developing hepatocellular carcinoma. Biopsy also permits histochemical estimation of tissue iron and measurement of hepatic iron concentration. Increased density of the liver due to iron deposition can be demonstrated byCT orMRI. A retrospective assessment of body iron storage is also provided by performing weekly phlebotomy and calculating the amount of iron removed before iron stores are exhausted (1 mL blood = approximately 0.5 mg iron).

SCREENING FOR HEMOCHROMATOSIS

When the diagnosis of hemochromatosis is established, it is important to counsel and screen other family members (Chap. 68). Asymptomatic as well as symptomatic family members with the disease usually have an increased saturation of transferrin and an increased serum ferritin concentration. These changes occur even before the iron stores are greatly increased (Fig. 345-1). All first-degree relatives of patients with hemochromatosis should be tested for the C282Y and H63D mutations and advised appropriately. In affected individuals, it is important to confirm or exclude the presence of cirrhosis, and begin therapy as early as possible. When children of a proband are affected, a homozygote-heterozygote mating is most likely.

The role of population screening for hemochromatosis is controversial. Hemochromatosis fulfills the criteria established by the World Health Organization for population screening, and DNA testing could, in principle, be performed along with other neonatal tests. However, because iron overload does not develop until the second, third, or fourth decades, and the degree of penetrance is still uncertain, screening by phenotypic expression is more practical at present (Fig. 345-2).

TREATMENT

The therapy of hemochromatosis involves removal of the excess body iron and

supportive treatment of damaged organs. Iron removal is best begun by weekly or twice-weekly phlebotomy of 500 mL. Although there is an initial modest decline in the volume of packed red blood cells to about 35 mL/dL, the level stabilizes after several weeks. The plasma transferrin saturation remains increased until the available iron stores are depleted. In contrast, the plasma ferritin concentration falls progressively, reflecting the gradual decrease in body iron stores. Since one 500-mL unit of blood contains 200 to 250 mg iron and about 25 g iron should be removed, weekly phlebotomy may be required for 1 or 2 years. When the transferrin saturation and ferritin level become normal, phlebotomies are performed at appropriate intervals to maintain levels within the normal range. The measurements promptly become abnormal with iron reaccumulation. Usually one phlebotomy every 3 months will suffice.

Chelating agents such as deferoxamine, when given parenterally, remove 10 to 20 mg iron per day, which is much less than that mobilized by once-weekly phlebotomy. Phlebotomy is also less expensive, more convenient, and safer for most patients. However, chelating agents are indicated when anemia or hypoproteinemia is severe enough to preclude phlebotomy. Subcutaneous infusion of deferoxamine using a portable pump is the most effective means of administration.

The management of hepatic failure, cardiac failure, and diabetes mellitus is similar to conventional therapy for these conditions. Loss of libido and change in secondary sex characteristics are partially relieved by parenteral testosterone or gonadotropin therapy (Chap. 335).

PROGNOSIS

The principal causes of death in untreated patients are cardiac failure (30%), hepatocellular failure or portal hypertension (25%), and hepatocellular carcinoma (30%).

Life expectancy is improved by removal of the excessive stores of iron and maintenance of these stores at near-normal levels. The 5-year survival rate with therapy increases from 33 to 89%. With repeated phlebotomy, the liver and spleen decrease in size, liver function improves, pigmentation of skin decreases, and cardiac failure may be reversed. Diabetes improves in about 40%, but removal of excess iron has little effect on hypogonadism or arthropathy. Hepatic fibrosis may decrease, but cirrhosis is irreversible. End-stage liver disease can be treated with orthotopic liver transplantation, but the results are suboptimal unless excess iron stores are first corrected. Hepatocellular carcinoma usually occurs as a late sequela in patients who are cirrhotic at presentation. The apparent increase in its incidence in treated patients is probably related to their increased life span. Hepatocellular carcinoma does not appear to develop if the disease is treated in the precirrhotic stage. Indeed, the life expectancy of homozygotes treated before the development of cirrhosis is normal.

The importance of family screening and early therapy cannot be emphasized too strongly. Asymptomatic subjects detected by family studies should have phlebotomy therapy if iron stores are moderately to severely increased. Assessment of iron stores at appropriate intervals is also important. With this management approach, most manifestations of the disease can be prevented.

346. THE PORPHYRIAS - *Robert J. Desnick*

The porphyrias are inherited or acquired disorders of specific enzymes in the heme biosynthetic pathway (Fig. 346-1). These disorders are classified as either *hepatic* or *erythropoietic* depending on the primary site of overproduction and accumulation of the porphyrin precursor or porphyrin (Tables 346-1 and346-2), although some have overlapping features. The major manifestations of the hepatic porphyrias are neurologic, including neuropathic abdominal pain, neuropathy, and mental disturbances, whereas the erythropoietic porphyrias characteristically cause cutaneous photosensitivity. The reason for neurologic involvement in the hepatic porphyrias is poorly understood. Cutaneous sensitivity to sunlight is due to the fact that excitation of excess porphyrins in the skin by long-wave ultraviolet light leads to cell damage, scarring, and deformation. Steroid hormones, drugs, and nutrition influence the production of porphyrin precursors and porphyrins, thereby precipitating or increasing the severity of some porphyrias. Thus, the porphyrias are multifactorial genetic disorders, in which environmental, physiologic, and genetic factors interact to cause disease (Chap. 68).

Because many symptoms of the porphyrias are nonspecific, diagnosis is often delayed. Laboratory testing is required to confirm or exclude the various types of porphyria (Table 346-2). Urinaryd-aminolevulinic acid (ALA) and porphobilinogen (PBG) are easily quantitated by chemical methods; the urinary porphyrin isomers can be separated and quantitated by high-performance liquid chromatography. The diagnostic profile of accumulated precursors and/or porphyrins in each disorder can also be defined by extraction and thin-layer chromatography of fecal porphyrins. However, a definite diagnosis requires demonstration of the specific enzyme deficiency or gene defect. The isolation and characterization of the cDNAs encoding the heme biosynthetic enzymes have permitted identification of the genetic basis of each porphyria. Molecular genetic analyses now make it possible to provide precise heterozygote identification and prenatal diagnoses in families with known mutations or with informative polymorphisms.

HEME BIOSYNTHESIS

The first and last three enzymes in the heme biosynthetic pathway are located in the mitochondrion, whereas the other four are in the cytosol (Fig. 346-1). The first enzyme,d-aminolevulinate synthase (ALAsynthase), catalyzes the condensation of glycine, activated by pyridoxal phosphate and succinyl coenzyme A, to form ALA. In the liver, this rate-limiting enzyme can be induced by a variety of drugs, steroids, and other chemicals. Distinct erythroid-specific and nonerythroid (e.g., housekeeping) forms of ALA synthase are encoded by separate genes; defects in the erythroid form cause X-linked sideroblastic anemia (XLSA).

The second enzyme, d-aminolevulinate dehydratase (ALAdehydratase), catalyzes the condensation of two molecules of ALA to formPBG. Four molecules of PBG condense to form the tetrapyrrole uroporphyrinogen (URO) III by a two-step process catalyzed by hydroxymethylbilane (HMB) synthase (also known as PBG deaminase or URO I synthase) and URO III synthase. HMB synthase catalyzes the head-to-tail condensation of four PBG molecules by a series of deaminations to form the linear tetrapyrrole HMB. URO synthase catalyzes the rearrangement and rapid cyclization of HMB to form the asymmetric, physiologic, octacarboxylate porphyrinogen URO III isomer.

The fifth enzyme in the pathway,UROdecarboxylase, catalyzes the sequential removal of the four carboxyl groups from the acetic acid side chains of URO III to form coproporphyrinogen (COPRO) III, a tetracarboxylate porphyrinogen. This compound then enters the mitochondrion, where COPRO oxidase, the sixth enzyme, catalyzes the decarboxylation of two of the four propionic acid groups to form the two vinyl groups of protoporphyrinogen (PROTO) IX, a dicarboxylate porphyrinogen. Next, PROTO oxidase oxidizes PROTO IX to protoporphyrin IX by the removal of six hydrogen atoms. The product of the reaction is a porphyrin (oxidized form), in contrast to the preceding tetrapyrrole intermediates, which are porphyrinogens (reduced forms). Finally, ferrous iron is inserted into protoporphyrin IX to form heme, a reaction catalyzed by the eighth enzyme in the pathway, ferrochelatase (also known as heme synthetase or protoheme ferrolyase).

Each of the heme biosynthetic enzymes is encoded by a separate gene. Full-length human cDNAs for each of the enzymes, including those for both forms ofALAsynthase, have been isolated and sequenced, and the chromosomal locations of the genes have been identified (Table 346-3).

REGULATION OF HEME BIOSYNTHESIS

About 85% of the heme produced in the body is synthesized in erythroid cells to provide heme for hemoglobin; most of the remainder is produced in the liver, where the biosynthetic pathway is under negative feedback control (Chap. 104). "Free" heme in the liver regulates the synthesis and mitochondrial translocation of the housekeeping form ofALAsynthase. Heme represses the synthesis of the ALA synthase mRNA and interferes with the transport of the enzyme from the cysotol into mitochondria. ALA synthase is increased by many of the same chemicals that induce the cytochrome P450 enzymes in the endoplasmic reticulum of the liver. Because most of the heme in the liver is used for the synthesis of cytochrome P450 enzymes, hepatic ALA synthase and the cytochrome P450s are regulated in a coordinated fashion.

Different regulatory mechanisms control production of heme for hemoglobin. The erythroid-specificALAsynthase encoded on the X chromosome is expressed at higher levels than the hepatic enzyme, and an erythroid-specific control mechanism regulates iron transport into erythroid cells. During erythroid differentiation, the activities of the heme biosynthetic enzymes are increased.

THE HEPATIC PORPHYRIAS

The acute hepatic porphyrias are characterized by the rapid onset of neurologic manifestations. During the acute attack, individuals have markedly elevated plasma and urinary concentrations of the porphyrin precursorsALA andPBG, which originate from the liver.

ALA DEHYDRATASE-DEFICIENT PORPHYRIA

This is a rare autosomal recessive disorder that has been described in only a few patients. Onset and severity of the disease are variable, presumably depending on the

amount of residual ALA dehydratase activity. Treatment and prevention of the neurologic complications are the same as for other acute porphyrias (see below).

Clinical Features The clinical presentation is variable. The first reported cases were in two unrelated German men who had clinical onset during adolescence of abdominal pain and neuropathy, resembling acute intermittent porphyria (AIP; see below). A Swedish infant presented with failure to thrive and required transfusions and parenteral nutrition. Presumably, the earlier age of onset and more severe manifestations reflect a more complete enzyme deficiency. A Belgian man developed an acute motor polyneuropathy and polycythemia at age 63. Recently a Japanese woman was described who had her first acute attack and the syndrome of inappropriate secretion of antidiuretic hormone at age 69.

Diagnosis Patients have increased urinary levels ofALA and coproporphyrin. ALA dehydratase activity in erythrocytes is<5% of normal. Because either succinylacetone (which accumulates in hereditary tyrosinemia and is structurally similar to ALA) or lead can inhibit ALA dehydratase, increase urinary excretion of ALA, and cause manifestations that resemble those of the acute porphyrias, lead intoxication and hereditary tyrosinemia (fumarylacetoacetase deficiency) should be considered in the differential diagnosis of ALA dehydratase-deficient porphyria. Immunologic studies in the reported cases demonstrated the presence of nonfunctional enzyme proteins that cross-reacted with anti-ALA dehydratase antibodies. DNA analysis revealed different missense mutations that resulted in the amino acid substitutions G133R and V275M in the infantile-onset patient, and R240W and A274T in a juvenile-onset patient.

Heterozygotes are clinically asymptomatic and do not excrete increased levels ofALA, but they can be detected by demonstration of intermediate levels of erythrocyte ALA dehydratase activity or by demonstrating a specific mutation in the *ALA dehydratase* gene. Prenatal diagnosis of this disorder has not been achieved but should be possible by determination of the ALA dehydratase activity in cultured chorionic villi or amniocytes.

TREATMENT

Treatment is similar to that ofAIP (see below). The severely affected infant was supported by hyperalimentation and periodic blood transfusions. Continued failure to thrive led to liver transplantation, which did not improve the hematologic manifestations.

ACUTE INTERMITTENT PORPHYRIA

This hepatic porphyria is an autosomal dominant condition resulting from the half-normal level ofHMBsynthase (also termedPBGdeaminase) activity. The disease is widespread but is especially common in Scandinavia and perhaps Great Britain. The enzyme deficiency can be demonstrated in most heterozygous individuals, but clinical expression is highly variable. Activation of the disease is related to environmental or hormonal factors, such as drugs, diet, and steroid hormones, which can precipitate the manifestations. Attacks can be prevented by avoiding known precipitating factors.

Clinical Features Most heterozygotes remain clinically asymptomatic (latent) unless

exposed to factors that increase the production of porphyrins. Endogenous and exogenous gonadal steroids, porphyrinogenic drugs, alcohol ingestion, and low-calorie diets, usually instituted for weight loss, are common precipitating factors.Table 346-4 lists the major drugs that are harmful inAIP [and also in hereditary coproporphyria (HCP) and variegate porphyria (VP)] and some drugs and anesthetic agents known to be safe. More extensive lists of drugs considered harmful or safe are available (see the bibliography), but information is incomplete for many of them. Attacks also can be provoked by infections and by surgery.

Because the neurovisceral symptoms rarely occur before puberty and are often nonspecific, a high index of suspicion is required to make the diagnosis. The disease can be disabling but is rarely fatal. Abdominal pain, the most common symptom, is usually steady and poorly localized but may be cramping. Ileus, abdominal distention, and decreased bowel sounds are common. However, increased bowel sounds and diarrhea may occur. Abdominal tenderness, fever, and leukocytosis are usually absent or mild because the symptoms are neurologic rather than inflammatory. Nausea, vomiting, constipation, tachycardia, hypertension, mental symptoms, pain in the limbs, head, neck, or chest, muscle weakness, sensory loss, dysuria, and urinary retention are characteristic. Tachycardia, hypertension, restlessness, tremors, and excess sweating are due to sympathetic overactivity.

The peripheral neuropathy is due to axonal degeneration (rather than demyelinization) and primarily affects motor neurons. Significant neuropathy does not occur with all acute attacks; abdominal symptoms are usually more prominent. Motor neuropathy affects the proximal muscles initially, more often in the shoulders and arms. The course and degree of involvement are variable. Deep tendon reflexes may be normal or hyperactive but are usually decreased or absent with advanced neuropathy. Motor weakness can be asymmetric and focal and may involve cranial nerves. Sensory changes such as paresthesia and loss of sensation are less prominent. Progressive muscle weakness can lead to respiratory and bulbar paralysis and death when diagnosis and treatment are delayed. Sudden death may result from sympathetic overactivity and cardiac arrhythmia.

Mental symptoms such as anxiety, insomnia, depression, disorientation, hallucinations, and paranoia can occur in acute attacks. Seizures can be due to neurologic effects or to hyponatremia. Treatment of seizures is difficult because virtually all antiseizure drugs (except bromides) may exacerbateAIP(clonazepam may be safer than phenytoin or barbiturates). Hyponatremia results from hypothalamic involvement and inappropriate vasopressin secretion or from electrolyte depletion due to vomiting, diarrhea, poor intake, or excess renal sodium loss. Persistent hypertension and impaired renal function may occur. When an attack resolves, abdominal pain may disappear within hours, and paresis begins to improve within days and may continue to improve over several years.

Diagnosis ALA andPBGlevels are increased in plasma and urine during acute attacks. Urinary PBG excretion is usually 220 to 880 umol/d (50 to 200 mg/d) [normal, 0 to 18 umol/d (0 to 4 mg/d)], and urinary ALA excretion is 150 to 760 umol/d (20 to 100 mg/d) [normal, 8 to 53 umol/d (1 to 7 mg/d)]. The excretion of these compounds generally decreases with clinical improvement, particularly after hematin infusions (see below). A normal urinary PBG level effectively excludesAIP as a cause for current symptoms.

Fecal porphyrins are usually normal or minimally increased in AIP, in contrast toHCP andVP. Most asymptomatic ("latent") heterozygotes withHMBsynthase deficiency have normal urinary excretion of ALA and PBG. Therefore, measurement of HMB synthase in erythrocytes is useful to confirm the diagnosis and to screen asymptomatic family members.

The enzyme deficiency is detectable in erythrocytes from mostAIPheterozygotes (*classic AIP*). Note that the activity is higher in young erythrocytes and may increase into the normal range in AIP when erythropoiesis is increased due to a concurrent condition. However, patients with the rare erythroid form of AIP (*erythroid, or variant, AIP*) have normal enzyme levels in erythrocytes and deficient activity in nonerythroid tissues (see below). The erythroid and housekeeping forms ofHMBsynthase are encoded by a single gene, which has two promoters: one promoter generates the ubiquitously expressed housekeeping mRNA; the other promoter transcribes the erythroid-specific mRNA. Several deletions and over 150 different point mutations have been found in the coding region of the gene in unrelated AIP families (Fig. 346-2). These mutations alter the kinetic properties and/or stability of the mutant enzymes or create premature termination codons. Mutations that cause erythroid AIP variants with half-normal enzyme in nonerythroid tissues, but normal activity in erythrocytes, include point mutations in the initiation methionine codon (which prevent translation) or in the 5¢ donor splice site of intron 1 (which cause abnormal splicing of the HMB synthase transcript).

Heterozygotes can be identified using various polymorphic sites in the*HMB synthase* gene. Efforts are now under way to identify the specific mutations in the *HMB synthase* gene in allAIPfamilies; this information will make it possible to identify all heterozygotes in affected families and to advise them to avoid the factors that cause acute attacks. The prenatal diagnosis of a fetus at risk can be made with cultured amniotic cells or chorionic villi.

TREATMENT

During acute attacks, narcotic analgesics may be required for abdominal pain, and phenothiazines are useful for nausea, vomiting, anxiety, and restlessness. Chloral hydrate can be given for insomnia, and benzodiazepines are probably safe in low doses, if a minor tranquilizer is required. Although intravenous glucose (at least 300 g/d) can be effective in acute attacks of porphyria, a more complete parenteral nutritional regimen may be beneficial if oral feeding is not possible for a prolonged period. However, intravenous heme is more effective than glucose in reducing porphyrin precursor excretion and probably leads to more rapid recovery. The response to heme therapy is reduced if therapy is delayed. Therefore, 3 to 4 mg of heme, in the form of hematin (Abbott Laboratories), heme albumin, or heme arginate (Leiras Oy, Turku, Finland), may be infused daily for 4 days beginning as soon as possible after onset of an attack. Heme arginate and heme albumin are chemically stable and are less likely than hematin to produce phlebitis or an anticoagulant effect. The rate of recovery from an acute attack depends on the degree of neuronal damage and may be rapid (1 to 2 days) with prompt therapy. Recovery from severe motor neuropathy may require months or years. Identification and avoidance of inciting factors can hasten recovery from an attack and prevent future attacks. Multiple inciting factors may contribute to a

symptomatic episode. Frequent clear-cut cyclical attacks occur in some women and can be prevented with a long-acting gonadotropin-releasing hormone analogue (this indication is not approved by the U.S. Food and Drug Administration) (Chap. 336).

PORPHYRIA CUTANEA TARDA

Porphyria cutanea tarda (PCT), the most common of the porphyrias, can be sporadic (type I) or familial (types II and III) and can also develop after exposure to halogenated aromatic hydrocarbons. HepaticURODecarboxylase is deficient in all types of PCT. In type I PCT, URO decarboxylase activity is normal in erythrocytes. In type II PCT, an autosomal dominant disorder, the enzyme is deficient in erythrocytes and other tissues. In type III PCT, deficiency of the enzyme is limited to the liver. Deficient hepatic URO decarboxylase and a porphyrin pattern resembling PCT can be produced by exposure of normal individuals to a number of halogenated aromatic hydrocarbons. Hepatoerythropoietic porphyria (HEP) is an autosomal recessive form of porphyria that results from marked systemic deficiency of URO decarboxylase activity.

Clinical Features Cutaneous photosensitivity is the major clinical feature. Neurologic manifestations are not observed. Fluid-filled vesicles and bullae develop on sun-exposed areas such as the face, the dorsa of the hands and feet, the forearms, and the legs. The skin in these areas is friable, and minor trauma may lead to the formation of bullae. The appearance of small white plaques, termed *milia*, may precede or follow vesicle formation. Bullae and denuded skin heal slowly and are subject to infection. Other features include hypertrichosis and hyperpigmentation, especially of the face, and thickening, scarring, and calcification resembling the cutaneous changes of systemic sclerosis.

A number of factors contribute to the development of hepaticURODecarboxylase deficiency, including excess alcohol, iron, and estrogens. The importance of excess hepatic iron as a precipitating factor is underscored by the finding that the incidence of the common hemochromatosis-causing mutations, *HFE* C282Y and H63D, are increased in patients with types I and IIPCT(Chap. 345). Various chemicals can also induce PCT; an epidemic of PCT occurred in eastern Turkey in the 1950s as a consequence of wheat contaminated with the fungicide hexachlorobenzene. PCT also occurs after exposure to other chemicals, including di- and trichlorophenols and 2,3,7,8-tetrachlorodibenzo-(*p*)-dioxin (TCDD, dioxin). Patients with PCT characteristically have liver damage and are at risk for hepatocellular carcinoma. These carcinomas do not produce porphyrins.

HEPresembles congenital erythropoietic porphyria (CEP) and usually presents with blistering skin lesions, hypertrichosis, scarring, and red urine in infancy or childhood.

Diagnosis Porphyrins are increased in the liver, plasma, urine, and stool. The urinaryALAlevel may be slightly increased, but thePBGlevel is normal. Urinary porphyrins consist mostly of uroporphyrin and 7-carboxylate porphyrin, with lesser amounts of coproporphyrin and 5- and 6-carboxylate porphyrins. Plasma porphyrins are also increased in a pattern that resembles that in urine. Isocoproporphyrins are increased in feces and sometimes in plasma and urine. The finding of increased isocoproporphyrins is diagnostic for a deficiency of hepaticURODecarboxylase.

Type IIPCT andHEP can be distinguished by finding decreasedURO decarboxylase in erythrocytes. URO decarboxylase activity in liver, erythrocytes, and cultured skin fibroblasts in type II PCT is approximately 50% of normal in affected individuals and in family members with latent disease. In HEP, the URO decarboxylase activity is markedly deficient, with typical levels of 3 to 10% of normal. Several point mutations have been identified in the coding region of the *URO decarboxylase* gene from unrelated type II PCT and HEP patients (Fig. 346-3). Excess hepatic iron contributes to development of sporadic and familial forms of PCT. As noted above, coinheritance of *HFE* mutations that cause hemochromatosis increases susceptibility to PCT-precipitating factor. In the familial forms (types II and III), iron inhibits the residual normal enzyme, so that enzymatic activity in liver is<50% of normal. In type I PCT the decreased hepatic URO decarboxylase activity is not accompanied by a decrease in the amount of enzyme protein, suggesting that the enzyme is present in an inactive form; hepatic URO decarboxylase activity gradually increases after a remission is induced by phlebotomy.

TREATMENT

Alcohol, estrogens, iron supplements, and, if possible, any drugs that may exacerbate the disease should be discontinued, but this step does not always lead to improvement. A complete response can almost always be achieved by repeated phlebotomy to reduce hepatic iron. A unit (450 mL) of blood can be removed every 1 to 2 weeks. Because iron overload is not marked in most cases, remission may occur after only five or six phlebotomies. Hemoglobin levels or hematocrits and serum ferritin should be followed closely to prevent development of iron deficiency and anemia. After remission, continued phlebotomy may not be needed even if ferritin levels return to normal. Relapses are treated by additional phlebotomy.

PCTcan also be treated with chloroquine or hydroxychloroquine, both of which complex with the excess porphyrins and promote their excretion. Small doses (e.g., 125 mg chloroquine phosphate twice weekly) should be given, because standard doses can induce transient, sometimes marked increases in photosensitivity and hepatocellular damage. Hepatic imaging can diagnose or exclude complicating hepatocellular carcinoma. Treatment of PCT in patients with end-stage renal disease is facilitated by administration of erythropoietin.

HEREDITARY COPROPORPHYRIA

HCPis an autosomal dominant form of hepatic porphyria that results from half-normal levels ofCOPROoxidase activity. Photosensitivity may occur. A few cases of homozygous HCP have been reported.

Clinical Features HCP is influenced by the same factors that cause attacks inAIP. The disease is latent before puberty, and symptoms are more common in women. Neurovisceral symptoms and other manifestations are virtually identical to those of AIP. Photosensitivity may resemble that inPCT andVP. Cutaneous lesions may begin in childhood in rare homozygous cases.

Diagnosis Coproporphyrin is markedly increased in the urine and feces in symptomatic disease and sometimes when there are no symptoms. UrinaryALA andPBGlevels are increased during acute attacks but may return to normal when symptoms resolve. Although the diagnosis can be confirmed by measuringCOPROoxidase activity, these assays are not widely available and require cells other than erythrocytes.

TREATMENT

Neurologic symptoms are treated as inAIP (see above). Phlebotomy and chloroquine are ineffective when cutaneous lesions are present.

VARIEGATE PORPHYRIA

VP, a hepatic porphyria that results from the deficient activity ofPROTOoxidase, is transmitted in an autosomal dominant manner and can present with neurologic symptoms, photosensitivity, or both.

Clinical Features Neurovisceral signs and symptoms develop after puberty and are similar to those ofAIP orHCP (see above). Attacks are provoked by the same drugs, steroids, and nutritional factors that are detrimental in AIP. Skin manifestations are more common than in HCP but usually occur apart from the neurovisceral symptoms. Because the skin lesions inVP, HCP, and PCTare not distinguishable by clinical examination or biopsy, these conditions must be diagnosed by assay of porphyrins and porphyrin precursors in blood, urine, and feces.

VPis particularly common in South Africa, where 3 of every 1000 whites have the disorder. Most are descendants of a couple who emigrated from Holland to South Africa in 1688. Homozygous VP is associated with photosensitivity, neurologic symptoms, and developmental disturbances, including growth retardation, in infancy or childhood; all cases had increased erythrocyte levels of zinc protoporphyrin, a characteristic finding in all homozygous porphyrias so far described.

Dual porphyria, the simultaneous occurrence ofVP and familialPCT, has been documented in several kindreds. *Chester porphyria* was described in a large British family in which individuals had acute porphyric attacks and deficiency of bothPROTOoxidase andHMBsynthase. Photosensitivity was not observed. It is unclear whether Chester porphyria is a variant of VP orAIP.

Diagnosis When VPis symptomatic, levels of fecal protoporphyrin and coproporphyrin and of urinary coproporphyrin are increased. UrinaryALA andPBGlevels are increased during acute attacks. Plasma levels of porphyrins are increased, particularly when there are cutaneous lesions. VP can be distinguished rapidly from all other porphyrias by examining the fluorescence emission spectrum of porphyrins in plasma at neutral pH. This test is particularly useful for differentiating VP fromPCT.

Assays of PROTOoxidase activity in cultured fibroblasts or lymphocytes are not widely available. Some latent cases ofVP can be diagnosed by measurement of fecal porphyrins in relatives of VP patients.

TREATMENT

Acute attacks are treated with hematin as inAIP. Other than avoiding sun exposure, there are few effective measures for treating the skin lesions. b-Carotene, phlebotomy, and chloroquine are not helpful.

THE ERYTHROPOIETIC PORPHYRIAS

In the erythropoietic porphyrias, porphyrins from bone marrow erythrocytes and plasma are deposited in the skin and lead to cutaneous photosensitivity.

X-LINKED SIDEROBLASTIC ANEMIA

XLSAresults from the deficient activity of the erythroid form ofALAsynthase and is associated with ineffective erythropoiesis, weakness, and pallor.

Clinical Features Typically, males withXLSAdevelop refractory hemolytic anemia, pallor, and weakness during infancy. They have secondary hypersplenism, become iron overloaded, and can develop hemosiderosis. The severity depends on the level of residual erythroidALAsynthase activity and on the responsiveness of the specific mutation to pyridoxal 5¢-phosphate supplementation (see below). Peripheral blood smears reveal a hypochromic, microcytic anemia with striking anisocytosis, poikilocytosis, and polychromasia; the leukocytes and platelets appear normal. Hemoglobin content is reduced, and the mean corpuscular volume and mean corpuscular hemoglobin concentration are decreased. Patients with milder, late-onset disease have been reported recently.

Diagnosis Bone marrow examination reveals hypercellularity with a left shift and megaloblastic erythropoiesis with an abnormal maturation. A variety of Prussian blue-staining sideroblasts are observed. Levels of urinary porphyrin precursors and of both urinary and fecal porphyrins are normal. The level of erythroidALAsynthase is decreased in bone marrow, but this enzyme is difficult to measure in the presence of the normal ALA synthase housekeeping enzyme. Definitive diagnosis requires the demonstration of mutations in the *erythroid ALA synthase* gene.

TREATMENT

The severe anemia may respond to pyridoxine supplementation. This cofactor is essential forALAsynthase activity, and mutations in the pyridoxine binding site of the enzyme have been found in several responsive patients. Cofactor supplementation may make it possible to eliminate or reduce the frequency of transfusion. Unresponsive patients may be transfusion-dependent and require chelation therapy.

CONGENITAL ERYTHROPOIETIC PORPHYRIA

CEPis an autosomal recessive disorder, also known as *Gunther's disease*, that is due to the markedly deficient activity ofUROsynthase; it is associated with hemolytic anemia and cutaneous lesions. CEP is characterized by accumulation of uroporphyrin I and coproporphyrin I isomers.

Clinical Features Severe cutaneous photosensitivity begins in early infancy. The skin over sun-exposed areas is friable, and bullae and vesicles are prone to rupture and infection. Skin thickening, focal hypo- and hyperpigmentation, and hypertrichosis of the face and extremities are characteristic. Secondary infection of the cutaneous lesions can lead to disfigurement of the face and hands. Porphyrins are deposited in teeth and in bones. As a result, the teeth are reddish brown and fluoresce on exposure to long-wave ultraviolet light. Hemolysis is probably due to the marked increase in erythrocyte porphyrins and leads to splenomegaly. Adults with a milder form of the disease have been described.

Diagnosis Uroporphyrin and coproporphyrin (mostly type I isomers) accumulate in the bone marrow, erythrocytes, plasma, urine, and feces. The diagnosis should be confirmed by demonstration of markedly deficientURO synthase activity. The disease can be detected in utero by measuring porphyrins in amniotic fluid and URO synthase activity in cultured amniotic cells or chorionic villi. Molecular analyses of the mutant alleles from over 20 unrelated patients have revealed the presence of gene rearrangements, an mRNA processing defect, and several point mutations that cause amino acid substitutions.

TREATMENT

The transfusion of sufficient blood to suppress erythropoiesis is effective but results in iron overload. Splenectomy may reduce hemolysis and decrease transfusion requirements. Protection from sunlight and from minor skin trauma is important. b-Carotene may be of some value. Complicating bacterial infections should be treated promptly. Recently, bone marrow transplantation has proven effective in several transfusion-dependent children, providing the rationale for stem-cell gene therapy.

ERYTHROPOIETIC PROTOPORPHYRIA

Erythropoietic protoporphyria (EPP) is an autosomal dominant disorder due to the partial deficiency of ferrochelatase activity. Protoporphyrin accumulates in erythroid cells and plasma and is excreted in bile and feces. EPP is the most common erythropoietic porphyria and, afterPCT, the second most common porphyria.

Clinical Features Skin photosensitivity usually begins in childhood. The skin manifestations differ from those of other porphyrias. Vesicular lesions are uncommon. Redness, swelling, burning, and itching can develop within minutes of sun exposure and resemble angioedema. Symptoms may seem out of proportion to the visible skin lesions. Sparse vesicles and bullae occur in 10% of cases. Chronic skin changes may include lichenification, leathery pseudovesicles, labial grooving, and nail changes. Severe scarring is rare, as are pigment changes, friability, and hirsutism.

The primary source of excess protoporphyrin is the bone marrow reticulocyte. Erythrocyte protoporphyrin is free (not complexed with zinc) and is mostly bound to hemoglobin. In plasma, protoporphyrin is bound to albumin. Hemolysis and anemia are usually absent or mild.

Liver function is usually normal, but in some patients accumulation of protoporphyrin causes chronic liver disease that can progress to liver failure and death. The hepatic complications are often preceded by increasing levels of erythrocyte and plasma protoporphyrin and probably result, in part, from protoporphyrin accumulation in the liver. Protoporphyrin is insoluble, forms crystalline structures in liver cells, and can decrease hepatic bile flow. Gallstones composed at least in part of protoporphyrin occur in some patients.

Some obligate heterozygotes are asymptomatic and have little or no increase in erythrocyte protoporphyrin. Thus there is phenotypic variation in this disease.

Diagnosis Protoporphyrin levels are increased in bone marrow, circulating erythrocytes, plasma, bile, and feces. Urinary levels of porphyrin and porphyrin precursors are normal. Ferrochelatase activity in cultured lymphocytes or fibroblasts is decreased.

TREATMENT

Oralb-carotene (120 to 180 mg/d) improves tolerance to sunlight in many patients. The dosage may need to be adjusted to maintain serum carotene levels in the recommended range of 10 to 15 umol/L (600 to 800 ug/dL). Mild skin discoloration due to carotenemia is the only significant side effect. The beneficial effects of b-carotene may involve quenching of singlet oxygen or free radicals. Unfortunately, this drug is less effective in other forms of porphyria associated with photosensitivity.

Treatment of hepatic complications is difficult. However, cholestyramine and other porphyrin absorbents such as activated charcoal may interrupt the enterohepatic circulation of protoporphyrin and promote its fecal excretion, leading to some improvement. Splenectomy may be helpful when the disease is accompanied by hemolysis and significant splenomegaly. Caloric restriction and drugs or hormones that may induce the heme pathway or impair hepatic excretory function should be avoided. Iron deficiency should be prevented or treated. Transfusions or intravenous heme therapy may suppress erythroid and hepatic protoporphyrin production and are sometimes beneficial. Liver transplantation has been carried out in some patients with severe liver complications.

347. DISORDERS OF PURINE AND PYRIMIDINE METABOLISM - *Robert L. Wortmann*

Purines and pyrimidines are the bases that, when linked to sugars (ribose or deoxyribose) and phosphate groups, create the nucleic acids that comprise the building blocks of RNA and DNA. The main purine bases are adenine and guanine; the pyrimidine bases include cytosine, thymine, and uracil. In addition, purines participate in diverse cellular functions, including intracellular energy metabolism (e.g., ATP), cell signaling pathways (e.g., GTP), and intercellular communication (e.g., adenosine). The nucleotides therefore serve fundamental roles in the replication of genetic material, gene transcription, protein synthesis, and cellular metabolism. Disorders that involve abnormalities of nucleotide metabolism range from relatively common diseases such as hyperuricemia and gout, in which there is increased production or impaired excretion of a metabolic end product of purine metabolism (uric acid), to rare enzyme deficiencies that affect purine and pyrimidine synthesis or degradation. Understanding these biochemical pathways has led, in some instances, to the development of specific forms of treatment, such as the use of allopurinol to reduce uric acid production.

URIC ACID METABOLISM

Uric acid is the final breakdown product of purine degradation in humans. It is a weak acid with pK_as of 5.75 and 10.3. Urates, the ionized forms of uric acid, predominate in plasma extracellular fluid and synovial fluid, with approximately 98% existing as monosodium urate at pH 7.4. Monosodium urate is easily dialyzed from plasma. Binding of urate to plasma proteins has little physiologic significance.

Plasma is saturated with monosodium urate at a concentration of 415 umol/L (6.8 mg/dL) at 37°C. At higher concentrations, plasma is therefore supersaturated, creating the potential for urate crystal precipitation. However, precipitation sometimes does not occur even at plasma urate concentrations as high as 4800 umol/L (80 mg/dL), perhaps because of the presence of solubilizing substances in plasma.

Uric acid is more soluble in urine than in water, possibly because of the presence of urea, proteins, and mucopolysaccharides. The pH of urine greatly influences its solubility. At pH 5.0, urine is saturated with uric acid at concentrations ranging from 360 to 900 umol/L (6 to 15 mg/dL). At pH 7.0, saturation is reached at concentrations between 9480 and 12,000 umol/L (158 and 200 mg/dL). Ionized forms of uric acid in urine include mono- and disodium, potassium, ammonium, and calcium urates.

Although purine nucleotides are synthesized and degraded in all tissues, urate is produced only in tissues that contain xanthine oxidase, primarily the liver and small intestine. The amount of urate in the body is the net result of the amount produced and the amount excreted (Fig. 347-1). Urate production varies with the purine content of the diet and the rates of purine biosynthesis, degradation, and salvage. Normally, two-thirds to three-fourths of urate is excreted by the kidneys, and most of the remainder is eliminated through the intestines. A four-component model describes the renal handling of uric acid in humans and includes: (1) glomerular filtration, (2) tubular reabsorption, (3) secretion, and (4) postsecretory reabsorption (Fig. 347-2). Approximately 8 to 12% of urate filtered by the glomeruli is excreted in the urine as uric acid. After filtration, 98 to

100% of the urate is reabsorbed; about half the reabsorbed urate is secreted back into the proximal tubule, and about 40% of that is again reabsorbed.

Serum urate levels vary with age and sex. Most children have serum urate concentrations of 180 to 240 umol/L (3.0 to 4.0 mg/dL). Levels begin to rise during puberty in males but remain low in females until menopause. Although the cause of this gender variation is not completely understood, it is due in part to a higher excretion of urate in females. Mean serum urate values of adult men and premenopausal women are 415 and 360 umol/L (6.8 and 6.0 mg/dL), respectively. After menopause, values for women increase to approximate those of men. In adulthood, concentrations rise steadily over time and vary with height, body weight, blood pressure, renal function, and alcohol intake.

HYPERURICEMIA

Hyperuricemia can result from increased production or decreased excretion of uric acid or from a combination of the two processes. When sustained hyperuricemia exists, plasma and extracellular fluids are supersaturated with respect to urate, and total body urate is increased. Sustained hyperuricemia predisposes some individuals to develop clinical manifestations including gouty arthritis (Chap. 322) and renal dysfunction (see below).

Hyperuricemia may be defined as a plasma (or serum) urate concentration >420 umol/L (7.0 mg/dL). This definition is based on physicochemical, epidemiologic, and disease-related criteria. Physicochemically, hyperuricemia is the concentration of urate in the blood that exceeds the solubility limits of monosodium urate in plasma, 415 umol/L (6.8 mg/dL). In epidemiologic studies, hyperuricemia is defined as the mean plus 2 standard deviations of values determined from a randomly selected healthy population. When measured in unselected individuals, 95% have serum urate concentrations <420 umol/L (7.0 mg/dL). Finally, hyperuricemia can be defined in relation to the risk of disease. The risk of developing gouty arthritis or urolithiasis increases with urate levels >420 umol/L (7.0 mg/dL) and escalates in proportion to the degree of elevation. Hyperuricemia is present in between 2.0 and 13.2% of ambulatory adults and somewhat more frequently in hospitalized individuals.

CAUSES OF HYPERURICEMIA

Hyperuricemia may be classified as primary or secondary depending on whether the cause is innate or is the result of an acquired disorder (Table 347-1). However, it is more useful to classify hyperuricemia in relation to the underlying pathophysiology, i.e., whether it results from increased production, decreased excretion, or a combination of the two (Fig. 347-1,Table 347-2).

Increased Urate Production Diet provides an exogenous source of purines and, accordingly, contributes to the serum urate in proportion to its purine content. Strict restriction of purine intake reduces the mean serum urate level by about 60 umol/L (1.0 mg/dL) and urinary uric acid excretion by approximately 1.2 mmol/d (200 mg/d). Because about 50% of ingested RNA purine and 25% of ingested DNA purine appear in the urine as uric acid, foods high in nucleic acid content have a significant effect on the

serum urate level. Such foods include liver, "sweetbreads" (i.e., thymus and pancreas), kidney, and anchovy.

Endogenous sources of purine production also influence the serum urate level (Fig. 347-3). De novo purine biosynthesis, the formation of a purine ring from nonring structures, is an 11-step process that results in formation of inosine monophosphate (IMP). The first step combines phosphoribosylpyrophosphate (PRPP) and glutamine and is catalyzed by amidophosphoribosyltransferase (amidoPRT). The rates of purine biosynthesis and urate production are determined, for the most part, by this enzyme. AmidoPRT is regulated by the substrate PRPP, which drives the reaction forward, and by the end products of biosynthesis (IMP and other ribonucleotides), which provide feedback inhibition. A secondary regulatory pathway is the salvage of purine bases by hypoxanthine phosphoribosyltransferase (HPRT). HPRT catalyzes the combination of the purine bases hypoxanthine and guanine with PRPP to form the respective ribonucleotides IMP and guanosine monophosphate (GMP). Increased salvage activity thus retards de novo synthesis by reducing PRPP levels and increasing concentrations of inhibitory ribonucleotides.

Serum urate levels are closely coupled to the rates of de novo purine biosynthesis, which is driven in part by the level ofPRPP, as evidenced by two inborn errors of purine metabolism. Both increased PRPP synthetase activity andHPRTdeficiency are associated with overproduction of purines, hyperuricemia, and hyperuricaciduria (see below for clinical descriptions). An X-linked disorder that causes an increase in activity of the enzyme PRPP synthetase leads to increased PRPP production and accelerated de novo biosynthesis. PRPP is a substrate and allosteric activator ofamidoPRT, the first enzyme in the de novo pathway. HPRT deficiency is also X-linked and enhances urate biosynthesis in two ways. PRPP is accumulated as a result of decreased utilization in the salvage pathway and, in turn, provides increased substrate for amidoPRT and de novo biosynthesis. In addition, decreased formation of the nucleoside monophosphates,IMP andGMP, via the salvage pathway impairs feedback inhibition on amidoPRT, further enhancing de novo biosynthesis.

Accelerated purine nucleotide degradation can also cause hyperuricemia, i.e., with conditions of rapid cell turnover, proliferation, or cell death, as in leukemic blast crises, cytotoxic therapy for malignancy, hemolysis, or rhabdomyolysis. Nucleic acids released from cells are hydrolyzed by the sequential activities of nucleases and phosphodiesterases, forming nucleoside monophosphates, which in turn are degraded to nucleosides, bases, and urate. Hyperuricemia can result from excessive degradation of skeletal muscle ATP after strenuous physical exercise or status epilepticus and in glycogen storage diseases types III, V, and VII (Chap. 350). The hyperuricemia of myocardial infarction, smoke inhalation, and acute respiratory failure may also be related to accelerated breakdown of ATP.

Decreased Uric Acid Excretion Over 90% of individuals with sustained hyperuricemia have a defect in the renal handling of uric acid. In hyperuricemia with gout the renal defect is evidenced by a lower than normal ratio of urate clearance to glomerular filtration rate (or urate to insulin clearance rate) over a wide range of filtered loads. As a result, gouty individuals excrete approximately 40% less uric acid than nongouty individuals for any given plasma urate concentration. Uric acid excretion increases in

gouty and nongouty individuals when plasma urate levels are raised by purine ingestion or infusion, but in those with gout, plasma urate concentrations must be 60 to 120 umol/L (1 to 2 mg/dL) higher than normal to achieve equivalent uric acid excretion rates.

Altered uric acid excretion could theoretically result from decreased glomerular filtration, decreased tubular secretion, or enhanced tubular reabsorption. Decreased urate filtration does not appear to cause primary hyperuricemia but does contribute to the hyperuricemia of renal insufficiency. Although hyperuricemia is invariably present in chronic renal disease, the correlation between serum creatinine, urea nitrogen, and urate concentration is poor. Uric acid excretion per unit of glomerular filtration rate increases progressively with chronic renal insufficiency, but tubular secretory capacity tends to be preserved, tubular reabsorptive capacity is reduced, and extrarenal clearance of uric acid increases as renal damage becomes more severe.

Decreased tubular secretion of urate causes the secondary hyperuricemia of acidosis. Diabetic ketoacidosis, starvation, ethanol intoxication, lactic acidosis, and salicylate intoxication are accompanied by accumulations of organic acids (b-hydroxybutyrate, acetoacetate, lactate, or salicylates) that compete with urate for tubular secretion. Hyperuricemia may be due to enhanced reabsorption of uric acid distal to the site of secretion. This mechanism is known to be responsible for the hyperuricemia of extracellular volume depletion that occurs with diabetes insipidus or diuretic therapy.

Combined Mechanisms Both increased urate production and decreased uric acid excretion may contribute to hyperuricemia. Individuals with a deficiency of glucose-6-phosphatase, the enzyme that hydrolyzes glucose-6-phosphate to glucose, are hyperuricemic from infancy and develop gout early in life (Chap. 350). Increased urate production results from accelerated ATP degradation during fasting or hypoglycemia. In addition, the lower levels of nucleoside monophosphates decrease feedback inhibition ofamidoPRT, thereby accelerating de novo biosynthesis. Glucose-6-phosphatase-deficient individuals may also develop hyperlacticacidemia, which blocks uric acid excretion by decreasing tubular secretion.

Patients with hereditary fructose intolerance caused by fructose-1-phosphate aldolase deficiency also develop hyperuricemia by both mechanisms. In homozygotes, vomiting and hypoglycemia after fructose ingestion can lead to hepatic failure and proximal renal tubular dysfunction. Ingestion of fructose, the substrate for the enzyme, causes accumulation of fructose-1-phosphate. This action results in ATP depletion, accelerated purine nucleotide catabolism, and hyperuricemia. Both lactic acidosis and renal tubular acidosis contribute to urate retention. Heterozygous carriers develop hyperuricemia, and perhaps one-third develop gout. The heterozygous state has a prevalence of 0.5 to 1.5%, suggesting that fructose-1-phosphate aldolase deficiency may be a relatively common cause of familial gout.

Alcohol also promotes hyperuricemia by both mechanisms. Excessive alcohol consumption accelerates hepatic breakdown of ATP and increases urate production. Alcohol consumption can also induce hyperlacticacidemia, which blocks uric acid secretion. The higher purine content in some alcoholic beverages such as beer may also be a factor.

EVALUATION OF HYPERURICEMIA

Hyperuricemia does not necessarily represent a disease, nor is it a specific indication for therapy. Rather, the finding of hyperuricemia is an indication to determine its cause. The decision to treat depends on the cause and the potential consequences of the hyperuricemia in each individual.

Quantification of uric acid excretion can be used to determine whether hyperuricemia is caused by overproduction or decreased excretion. On a purine-free diet, men with normal renal function excrete <3.6 mmol/d (600 mg/d). Thus, the hyperuricemia of individuals who excrete uric acid above this level while on a purine-free diet is due to purine overproduction, whereas it is due to decreased excretion in those who excrete lower amounts on the purine-free diet. If the assessment is performed while the patient is on a regular diet, the level of 4.2 mmol/d (800 mg/d) can be used as the discriminating value. With renal insufficiency, less urate is filtered in the glomeruli and less uric acid appears in the urine. Consequently, a lower 24-h urinary uric acid value in the presence of renal insufficiency does not necessarily rule out urate overproduction, but an elevated value provides strong evidence of urate overproduction. Spuriously high values can occur if a uricosuric agent is being taken at the time of urine collection. Glucocorticoids, ascorbic acid, salicylates in doses >2 g/d, and other agents that promote urate excretion interfere with the interpretation of results.

Assessment of the ratio of uric acid to creatinine (or the ratio of uric acid clearance to creatinine clearance) in spot or random urine samples is not a reliable method to screen for urate overproduction. However, this is a useful tool for evaluating individuals with acute renal failure suspected of having acute uric acid nephropathy (see below).

Pyrazinamide, which has a suppressive action on tubular secretion, can be used to investigate presecretory reabsorption of uric acid. Probenecid, an agent that inhibits postsecretory reabsorption, can be used to evaluate tubular secretion and postsecretory reabsorption.

COMPLICATIONS OF HYPERURICEMIA

The most recognized complication of hyperuricemia is *gouty arthritis*. In the general population the prevalence of hyperuricemia ranges between 2.0 and 13.2%, and the prevalence of gout is between 1.3 and 3.7%. The higher the serum urate level, the more likely an individual is to develop gout. In one study, the incidence of gout was 4.9% for individuals with serum urate concentrations>540 umol/L (9.0 mg/dL) compared with 0.5% for those with values between 415 and 535 umol/L (7.0 and 8.9 mg/dL). The complications of gout correlate with both the duration and severity of hyperuricemia.*For further discussion of gout, see Chap. 322.

Hyperuricemia also causes several renal problems: (1) nephrolithiasis; (2) urate nephropathy, a rare cause of renal insufficiency attributed to monosodium urate crystal deposition in the renal interstitium; and (3) uric acid nephropathy, a reversible cause of acute renal failure resulting from deposition of large amounts of uric acid crystals in the renal collecting ducts, pelvis, and ureters.

Nephrolithiasis Uric acid nephrolithiasis occurs most commonly, but not exclusively, in individuals with gout. In gout, the prevalence of nephrolithiasis correlates with the serum and urinary uric acid levels, reaching approximately 50% with serum urate levels of 770 umol/L (13 mg/dL) or urinary uric acid excretion>6.5 mmol/d (1100 mg/d).

Uric acid stones can develop in individuals with no evidence of arthritis, only 20% of whom are hyperuricemic. Uric acid can also play a role in other types of kidney stones. Some nongouty individuals with calcium oxalate or calcium phosphate stones have hyperuricemia or hyperuricaciduria. Uric acid may act as a nidus on which calcium oxalate can precipitate or lower the formation product for calcium oxalate crystallization.

Urate Nephropathy Urate nephropathy, sometimes referred to as *urate nephrosis*, is a late manifestation of severe gout and is characterized histologically by deposits of monosodium urate crystals surrounded by a giant cell inflammatory reaction in the medullary interstitium and pyramids. The disorder is now rare and cannot be diagnosed in the absence of gouty arthritis. The lesions may be clinically silent or cause proteinuria, hypertension, and renal insufficiency.

Uric Acid Nephropathy This reversible cause of acute renal failure is due to precipitation of uric acid in renal tubules and collecting ducts that causes obstruction to urine flow. Uric acid nephropathy develops following sudden urate overproduction and marked hyperuricaciduria. Factors that favor uric acid crystal formation include dehydration and acidosis. This form of acute renal failure occurs most often during an aggressive "blastic" phase of leukemia or lymphoma prior to or coincident with cytolytic therapy but has also been observed in individuals with other neoplasms, following epileptic seizures, and after vigorous exercise with heat stress. Autopsy studies have demonstrated intraluminal precipitates of uric acid, dilated proximal tubules, and normal glomeruli. The initial pathogenic events are believed to include obstruction of collecting ducts with uric acid and obstruction of distal renal vasculature.

If recognized, uric acid nephropathy is potentially reversible. Appropriate therapy has reduced the mortality from about 50% to practically nil. Serum levels cannot be relied on for diagnosis because this condition has developed in the presence of urate concentrations varying from 720 to 4800 umol/L (12 to 80 mg/dL). The distinctive feature is the urinary uric acid concentration. In most forms of acute renal failure with decreased urine output, urinary uric acid content is either normal or reduced, and the ratio of uric acid to creatinine is<1. In acute uric acid nephropathy the ratio of uric acid to creatinine in a random urine sample or 24-h specimen is>1, and a value that high is essentially diagnostic.

TREATMENT

Asymptomatic Hyperuricemia Hyperuricemia is present in approximately 5% of the population and in up to 25% of hospitalized individuals. The vast majority are asymptomatic with regard to their hyperuricemia and are at no clinical risk because of it. Elevated serum urate concentrations have been associated with insulin resistance, obesity, hypertension, dyslipidemia (sometimes referred to as syndrome X), and atherosclerotic disease. However, urate does not appear to have a causal role in the development of coronary heart disease or death from cardiovascular disease. In the

past, the association of hyperuricemia with cardiovascular disease and renal failure led to the use of urate-lowering agents for people with asymptomatic hyperuricemia. This practice is no longer recommended with the exception of individuals receiving cytolytic therapy for neoplastic disease, in which treatment is given in an effort to prevent uric acid nephropathy.

Hyperuricemic individuals are at risk to develop gouty arthritis, especially those with higher serum urate levels. However, treatment of asymptomatic hyperuricemia to prevent the first attack of gouty arthritis is not indicated because most hyperuricemic people never develop gout. Furthermore, neither structural kidney damage nor tophi are identifiable before the first attack. Reduced renal function cannot be attributed to asymptomatic hyperuricemia, and treatment of asymptomatic hyperuricemia does not alter the progression of renal dysfunction in patients with renal disease. Although nephrolithiasis is common in gouty patients, and a number of individuals with nephrolithiasis are hyperuricemic, increased risk of stone formation in people with asymptomatic hyperuricemia is not established.

Thus, because treatment with antihyperuricemic agents entails inconvenience, cost, and potential toxicity, routine treatment of asymptomatic hyperuricemia cannot be justified other than for prevention of acute uric acid nephropathy. In addition, routine screening for asymptomatic hyperuricemia is not recommended. If hyperuricemia is diagnosed, however, the cause should be determined. Causal factors should be corrected if the condition is secondary, and associated problems such as hypertension, hypercholesterolemia, diabetes mellitus, and obesity should be treated.

Symptomatic Hyperuricemia (SeeChap. 322 for treatment of gout)

Nephrolithiasis Antihyperuricemic therapy is recommended for the individual who has both gouty arthritis and either uric acid- or calcium-containing stones, both of which may occur in association with hyperuricaciduria. Regardless of the nature of the calculi, fluid ingestion should be sufficient to produce a daily urine volume>2 L. Alkalinization of the urine with sodium bicarbonate or acetazolamide may be justified to increase the solubility of uric acid. Specific treatment of uric acid calculi requires reducing the urine uric acid concentration with allopurinol. Allopurinol administration decreases the serum urate concentration and the urinary excretion of uric acid in the first 24 h, with a maximum reduction occurring within 2 weeks. The average effective dose of allopurinol is 300 mg/d. Allopurinol can be given once a day because of the long half-life (18 h) of its active metabolite oxypurinol. The drug is effective in patients with renal insufficiency, but the dose should be reduced. Allopurinol is also useful in reducing the recurrence of calcium oxalate stones in gouty patients and in nongouty individuals with hyperuricemia or hyperuricaciduria. Potassium citrate (30 to 80 mmol/d orally in divided doses) is an alternative therapy for patients with uric acid stones alone or mixed calcium/uric acid stones. Allopurinol is also indicated for the treatment of 2,8-dihydroxyadenine kidney stones.

Uric Acid Nephropathy Uric acid nephropathy is often preventable, and immediate, appropriate therapy has greatly reduced the mortality rate. Vigorous intravenous hydration and diuresis with furosemide dilute the uric acid in the tubules and promote urine flow to ^{3}100 mL/h. The administration of acetazolamide, 240 to 500 mg every 6 to

8 h, and sodium bicarbonate, 89 mmol/L, intravenously enhances urine alkalinity and thereby solubilizes more uric acid. It is important to ensure that the urine pH remains>7.0 and to watch for circulatory overload. In addition, antihyperuricemic therapy in the form of allopurinol in a single dose of 8 mg/kg is administered to reduce the amount of urate that reaches the kidney. If renal insufficiency persists, subsequent daily doses should be reduced to 100 to 200 mg because oxypurinol, the active metabolite of allopurinol, accumulates in renal failure. Despite these measures, hemodialysis may be required.

HYPOURICEMIA

Hypouricemia, defined as a serum urate concentration <120 umol/L (2.0 mg/dL) can result from decreased production of urate, increased excretion of uric acid, or a combination of both mechanisms. It occurs in<0.2% of the general population and<0.8% of hospitalized individuals. Hypouricemia causes no symptoms or pathology and therefore requires no therapy. It is, however, a sign of potential pathology, and its cause should be determined.

Most hypouricemia results from increased renal uric acid excretion. The finding of normal amounts of uric acid in a 24-h urine collection in an individual with hypouricemia is evidence for a renal cause. Medications with uricosuric properties (Table 347-3) include aspirin (at doses>2.0 g/d), x-ray contrast materials, and glycerylguaiacholate. Total parenteral hyperalimentation can also cause hypouricemia, possibly a result of the high glycine content of the infusion formula. Other causes of increased urate clearance include conditions such as neoplastic disease, hepatic cirrhosis, diabetes mellitus, and inappropriate secretion of vasopressin; defects in renal tubular transport such as primary Fanconi syndrome and Fanconi syndromes caused by Wilson's disease, cystinosis, multiple myeloma, and heavy metal toxicity; and isolated congenital defects in the bidirectional transport of uric acid.

Hypouricemia from decreased production of urate is accompanied by very low urinary uric acid levels. Accumulation of other purine nucleosides and bases may occur depending on the specific defect. Individuals treated with allopurinol and some patients with neoplastic disease or severe hepatic dysfunction are hypouricemic and excrete increased quantities of hypoxanthine and xanthine in the urine. Xanthine oxidase deficiency can be inherited or acquired. Inherited forms include isolated xanthine oxidase deficiency and combined xanthine oxidase and sulfite oxidase deficiencies. Both cause hypouricemia and xanthinuria. Affected individuals excrete essentially no uric acid and may develop xanthine nephrolithiasis. Individuals with purine nucleoside phosphorylase deficiency, an inborn error of metabolism causing T cell-deficient immune dysfunction, are hypouricemic and excrete increased quantities of guanosine, deoxyguanosine, inosine, and deoxyinosine in the urine.

INBORN ERRORS OF PURINE METABOLISM (See also Table 347-4, Fig. 347-3)

HPRTDEFICIENCY

A complete deficiency of HPRT, the Lesch-Nyhan syndrome, is characterized by hyperuricemia, self-mutilative behavior, choreoathetosis, spasticity, and mental

retardation. A partial deficiency of HPRT, the Kelley-Seegmiller syndrome, is associated with hyperuricemia but no central nervous system manifestations. In both disorders, the hyperuricemia results from urate overproduction and can cause uric acid crystalluria, nephrolithiasis, obstructive uropathy, and gouty arthritis. Early diagnosis and appropriate therapy with allopurinol can prevent or eliminate all the problems attributable to hyperuricemia but have no effect on the behavioral or neurologic abnormalities.

HPRTcatalyzes the reaction that combinesPRPP and the purine bases hypoxanthine and guanine to form the respective nucleoside monophosphateIMP orGMP and pyrophosphate. The enzyme is encoded by a single gene located on the X chromosome in region q26-q27. Consequently, affected males are hemizygous for the trait and inherit the mutant allele from their asymptomatic mother, who is a carrier, or are the result of spontaneous gene mutations. The deficiency state is generally the result of point mutations, small deletions or insertions, or endoduplication of exons rather than major gene alterations.

INCREASED PRPP SYNTHETASE ACTIVITY

Cells from individuals with increasedPRPPsynthetase activity contain elevated levels of PRPP. The high substrate content drives de novo purine synthesis, causing overproduction of uric acid. Like theHPRTdeficiency states, PRPP synthetase overactivity is X-linked and results in gouty arthritis and uric acid nephrolithiasis. Nerve deafness occurs in some families.

ADENINE PHOSPHORIBOSYLTRANSFERASE (APRT) DEFICIENCY

Individuals with a deficiency of APRT develop kidney stones composed of 2,8-dihydroxyadenine. APRT catalyzes the conversion of adenine to adenosine monophosphate (AMP). In the absence of APRT, adenine is converted by xanthine oxidase to 2,8-dihydroxyadenine, which is insolable in urine. Reports of 2,8-dihydroxyadenine stones are rare, most likely because of its chemical similarity to uric acid. Analysis by x-ray powder diffraction is necessary for correct identification. Because this technique is rarely employed, many 2,8-dihydroxyadenine stones are incorrectly called uric acid. The consequence of this misidentification is not deleterious, as allopurinol therapy is the correct treatment for each type of stone.

APRTdeficiency is inherited as an autosomal recessive trait. Caucasians with the disorder have a complete deficiency (type I), whereas Japanese subjects have some measurable enzyme activity (type II). Expression of the defect is similar in the two populations, as is the frequency of the heterozygous state (0.4 to 1.1 per 100).

HEREDITARY XANTHINURIA

A deficiency of xanthine oxidase causes all purine in the urine to occur in the form of hypoxanthine and xanthine. About two-thirds of deficient individuals are asymptomatic. The remainder develop kidney stones composed of xanthine. A very small number of symptomatic individuals also have myopathy or recurrent polyarteritis. Xanthinuria appears to be inherited in an autosomal recessive pattern.

In a second form of inherited xanthinuria, the deficiency of xanthine oxidase is associated with a deficiency of sulfite oxidase. Neurologic symptoms attributable to the sulfite oxidase deficiency predominate over those of xanthinuria in individuals with the combined deficiency.

MYOADENYLATE DEAMINASE DEFICIENCY

Adenylate deaminase (AMPdeaminase) catalyzes the conversion of AMP toIMP with the release of ammonia and is an integral component of the purine nucleotide cycle, which plays an important role in skeletal muscle energy metabolism. Both primary (inherited) and secondary (acquired) forms of myoadenylate deaminase deficiency have been described. Myoadenylate deaminase is the only activity affected in the inherited form, whereas other muscle enzymes (creatine kinase and myokinase) are also decreased in the acquired deficiencies. In contrast, mRNA abundance is low in muscle from patients with acquired deficiencies, suggesting a different molecular basis for this form.

The primary form is inherited as an autosomal recessive trait. Clinically, this form does not appear to cause disease, and most individuals with this defect may be asymptomatic. Another explanation for the myopathy should be sought in symptomatic patients with this deficiency. The acquired deficiency occurs in association with a wide variety of neuromuscular disease, including muscular dystrophies, neuropathies, inflammatory myopathies, and collagen vascular diseases.

ADENYLOSUCCINATE LYASE DEFICIENCY

Adenylosuccinate lyase participates in the synthesis of purine nucleotides in two ways. It catalyzes the conversion of succinylaminoimidazole carboxamide ribotide (SAICAR) to aminoimidazole carboxamide ribotide (AICAR) in the de novo pathway and in the conversion ofAMPsuccinate to AMP in the purine nucleotide cycle. Deficiency of this enzyme is due to an autosomal recessive trait and causes profound psychomotor retardation, seizures, and other movement disorders. All individuals with this deficiency are mentally retarded, and most are autistic.

ADENOSINE DEAMINASE DEFICIENCY AND PURINE NUCLEOSIDE PHOSPHORYLASE DEFICIENCY SeeChap. 308.

PYRIMIDINE DISORDERS

The pyrimidine, cytidine, is found in both DNA and RNA; it is a complementary base pair for guanine. Thymidine is found only in DNA where it is paired with adenine. Uridine is found only in RNA and can pair with either adenine or guanine in RNA secondary structures. Pyrimidines can be synthesized by a de novo pathway (Fig. 347-4) or reused in a salvage pathway. More than 25 different enzymes are involved in pyrimidine synthesis, salvage, and degradation pathways. Nonetheless, disorders of pyrimidine metabolism are rare. They are more difficult to recognize than purine disorders because of heterogeneous phenotypes and the absence of readily detected biochemical markers. Three disorders of pyrimidine metabolism are discussed below.

OROTIC ACIDURIA

Hereditary orotic aciduria is an autosomal recessive disorder caused by mutations in a bifunctional enzyme, uridine-5¢-monophosphate (UMP) synthase, which converts orotic acid to UMP in the de novo synthesis pathway (Fig. 347-4). The same protein encodes two distinct enzymatic activities. The disorder is characterized by hypochromic megaloblastic anemia that is unresponsive to vitamin B_{12} and folic acid, growth retardation, and neurologic abnormalities. Increased excretion of orotic acid causes crystalluria and obstructive uropathy. Replacement of uridine (100 to 200 mg/kg per day) corrects the anemia, reduces orotic acid excretion, and improves the other sequelae of the disorder.

PYRIMIDINE 5¢-NUCLEOTIDASE DEFICIENCY

Pyrimidine 5¢-nucleotidase catalyzes the removal of the phosphate group from pyrimidine ribonucleoside monophosphates (cytidine-5¢-monophosphate orUMP) (Fig. 347-4). Deficiency of this enzyme is transmitted as a recessive trait and causes hemolytic anemia with prominent basophilic stippling of erythrocytes. The accumulation of pyrimidines or cytidine diphosphate choline (CDPC) is thought to induce hemolysis. The enzyme deficiency alters nucleoside composition and thereby generates a characteristic ultraviolet spectrum in deproteinized erythrocytes. There is no specific treatment.

DIHYDROPYRIMIDINE DEHYDROGENASE DEFICIENCY

Dihydropyrimidine dehydrogenase (DPD) is the rate-limiting enzyme in the pathway of uracil and thymine degradation (Fig. 347-4). Deficiency of this enzyme causes excessive urinary excretion of uracil and thymine. DPD deficiency is transmitted in a recessive manner and causes nonspecific cerebral dysfunction with convulsive disorders, motor retardation, and mental retardation. A splice donor site mutation, which causes deletion of exon 14, accounts for 52% of mutant alleles. No specific treatment is available. DPD is also involved in the degradation of 5-fluorouracil (5-FU), a chemotherapeutic agent that inhibits thymidylate synthase. Consequently, deficiency of this enzyme is associated with 5-FU neurotoxicity.

MEDICATION EFFECTS ON PYRIMIDINE METABOLISM

In addition to the role ofDPD in5-FUdegradation (see above), other medications can influence pyrimidine metabolism. Leflunomide, which is used to treat rheumatoid arthritis, inhibits de novo pyrimidine synthesis by inhibiting dihydroorotate dehydrogenase, resulting in an antiproliferative effect on T cells. Allopurinol, an inhibitor of xanthine oxidase and purine synthesis, also inhibits orotidine-5¢-phosphate decarboxylase, a step inUMPsynthesis. Consequently, allopurinol use is associated with increased excretion of orotidine and orotic acid; there are no known clinical effects of this inhibition.

348. WILSON'S DISEASE - *I. Herbert Scheinberg*

Wilson's disease is an inherited disorder of copper metabolism in individuals with two mutant *ATP7B* genes. Impairment of the normal excretion of hepatic copper results in toxic accumulation of the metal in liver, brain, and other organs. The disease occurs in every ethnic and geographic population, with a worldwide prevalence of ~1 in 30,000, and a heterozygous carrier frequency of ~1 in 90.

NATURAL HISTORY

The average concentrations of ceruloplasmin and hepatic copper are indistinguishable in normal neonates and in patients with Wilson's disease. In normal infants, however, the ceruloplasmin concentration increases and the hepatic copper concentration falls to adult levels during the first 3 months of life. In infants with Wilson's disease, the neonatal deficiency of ceruloplasmin and excess of hepatic copper persist indefinitely. Clinical manifestations are rare before age 6, occur most frequently in mid-adolescence, and eventually develop in all untreated patients.

In about half of patients any of four types of hepatic disturbances may herald the clinical onset. *Acute hepatitis* is usually self-limited, is often mistaken for viral hepatitis or infectious mononucleosis, and may be forgotten later in life. *Parenchymal liver disease* may persist after acute hepatitis or may develop insidiously without prior acute disease into a histologic and clinical picture indistinguishable from chronic active hepatitis and cirrhosis. In other patients *cirrhosis* may develop insidiously after a lapse of decades with no prior sign or symptom of liver disease. *Fulminant hepatitis*, generally fatal, is characterized by progressive jaundice, ascites, encephalopathy, hypoalbuminemia, hypoprothrombinemia, moderately elevated plasma levels of liver enzymes, and Coombs-negative hemolytic anemia.

In most other patients neurologic or psychiatric disturbances are the first clinical signs and are always accompanied by Kayser-Fleischer rings (Plate III-16). These golden deposits of copper in Descemet's membrane of the cornea do not interfere with vision but indicate that copper has been released from the liver and has probably caused brain damage. If a patient with frank neurologic or psychiatric disease does not have Kayser-Fleischer rings when examined by a trained observer using a slit lamp, the diagnosis of Wilson's disease can be excluded. Rarely, Kayser-Fleischer rings may be accompanied by sunflower cataracts.

The neurologic manifestations include resting and intention tremors, spasticity, rigidity, chorea, drooling, dysphagia, and dysarthria. Babinski responses may be present, and abdominal reflexes are often absent. Inexplicably -- in view of the ubiquity of copper excess in the brain -- sensory changes never occur, except for headache.

Psychiatric disturbances are present in most patients with neurologic symptoms. Schizophrenia, manic-depressive psychoses, and classic neuroses may occur, but the commonest disturbances are bizarre behavioral patterns that defy classification. Improvement in the psychiatric state can occur with pharmacologic reduction of the copper excess, but psychotherapy and additional pharmacotherapy may be required.

In about 5% of patients the clinical onset reflects neither a hepatic nor a central nervous system disturbance. The first manifestation may be primary or secondary amenorrhea or repeated and unexplained spontaneous abortions, perhaps due to excess free copper in intrauterine secretions. Kayser-Fleischer rings may occasionally first be discovered during routine ophthalmologic examination.

PATHOGENESIS

The metabolic defect in Wilson's disease is an inability to maintain a near-zero balance of copper. Dietary copper is generally in excess of the small amount that is essential to life. Normally, any excess absorbed copper is excreted by the liver; in patients with Wilson's disease, copper accumulates in the liver, reaching a mean level of about 1000 ug/g dry weight -- 40 times normal.

Fatty infiltration of the hepatic parenchyma and nuclear glycogen deposits are the earliest findings by light microscopy (Fig. 348-1). With electron microscopy, characteristic mitochondrial abnormalities appear to be specific for Wilson's disease. Later, necrosis, inflammation, fibrosis, bile duct proliferation, and cirrhosis ensue. Abnormalities in liver chemistries, particularly elevations in aminotransferases, may be seen at any stage. The capacity of hepatocytes to store copper is eventually exceeded, and copper is released into blood and taken up into extrahepatic tissues with disastrous effects in the brain (Table 348-1).

With magnetic resonance imaging, the effects of copper toxicity in the brain are seen most frequently in the lenticular nuclei and less commonly in the pons, medulla, thalamus, cerebellum, and cerebral cortex. Opalski and Alzheimer type II cells are present early in the course, although neither is specific for Wilson's disease, and neuronal necrosis and cavitation develop later.

An increased copper concentration in the kidney produces little, if any, structural change and usually does not alter renal function. Microscopic hematuria and/or minimal proteinuria occur occasionally; and nephrocalcinosis, renal calculi, and renal tubular acidosis are rare. Pathologic effects in other organs and tissues are minor.

GENETIC CONSIDERATIONS

The autosomal recessive Wilson disease gene, *ATP7B*, and the X-linked Menkes disease gene, *ATP7A*, are membrane-bound, P-type, copper-transporting ATPases containing 6 copper-binding sites (Chap. 353). The amino acid sequences of these genes are 54% identical. In liver the Wilson protein incorporates copper ions into apoceruloplasmin to form ceruloplasmin whose catabolism is accompanied by biliary excretion of its copper ions. In fetal liver the Menkes protein incorporates copper ions into apoceruloplasmin to form fetal ceruloplasmin whose catabolism is accompanied by hepatic retention of its copper ions. In Wilson's disease, ceruloplasmin that is synthesized in the presence of the *ATP7B* mutant is catabolized like fetal ceruloplasmin, leading to hepatic retention of its copper ions.

DIAGNOSIS

The diagnosis is easy provided it is suspected. Wilson's disease should be considered in any patient younger than 40 years with an unexplained disorder of the central nervous system, signs or symptoms of hepatitis, chronic active hepatitis, unexplained persistent elevations of serum aminotransferase, hemolytic anemia in the presence of hepatitis, or unexplained cirrhosis and in any patient who has a relative with Wilson's disease.

The diagnosis is confirmed by the demonstration of either (1) a serum ceruloplasmin level<20 mg/dL *and* Kayser-Fleischer rings or (2) a serum ceruloplasmin level <20 mg/dL *and* a concentration of copper in a liver biopsy sample>250 ug/g dry weight. Most symptomatic patients excrete >100 ug copper per day in urine and have histologic abnormalities on liver biopsy.

TREATMENT

Treatment consists of removing and detoxifying the deposits of copper as rapidly as possible and must be instituted once the diagnosis is secure whether the patient is ill or asymptomatic. Penicillamine is administered orally in an initial dose of 1 g daily in a single or divided doses at least 30 min before and 2 h after eating. Because penicillamine has an antipyridoxine effect, 25 mg/d of pyridoxine is also given. In ~10% of patients sensitivity to penicillamine develops early, making it necessary to monitor the body temperature and skin daily. White blood cell and platelet counts should be assessed and urinalysis performed several times during the first month of treatment. Penicillamine should be discontinued and replaced by trientine, if rash, fever, leukopenia, thrombocytopenia, lymphadenopathy, or proteinuria develops, or if neurologic worsening accompanies the institution of penicillamine and persists for a week or more.

After therapy with penicillamine has been successfully instituted, the patient should be seen at 1- to 3-month intervals to assess the effectiveness of therapy and monitor for late drug toxicity. The history and the physical examination should focus on hepatic, neurologic, and psychiatric signs and symptoms. Slit-lamp examination of the corneas should be performed by an ophthalmologist if neurologic or psychiatric disturbances appear or worsen. White blood cell and platelet counts, transaminase levels, albumin, bilirubin, and free serum copper (total serum copper minus ceruloplasmin-bound copper) should be measured, the aim being a concentration of free copper less than ~0.2 umol/dL (10 ug/dL). A persistent concentration >0.4 umol/dL (20 ug/dL) indicates that the dose of penicillamine is too low or that the patient is noncompliant. For patients who are asymptomatic or who have improved maximally after several years on 1 g/d of penicillamine, the usual effective maintenance dose is 0.75 g/d taken 45 min before breakfast.

At any time, even after years of uneventful penicillamine administration, granulocytopenia, thrombocytopenia, the nephrotic syndrome, Goodpasture's syndrome, systemic lupus erythematosus, severe arthralgias, myasthenia, mammary gigantism, or elastosis perforans serpiginosa may supervene. Except for transient thrombocytopenia or granulocytopenia, these reactions mandate the replacement of penicillamine with trientine.

The dose of trientine is 1g/d on an empty stomach. Most patients find it convenient to take four 250-mg capsules, delaying breakfast for about an hour. Pyridoxine need not be given. Although the only reported toxic reaction to trientine is sideroblastic anemia, the same clinical procedures and laboratory determinations should be performed during its administration as are used during penicillamine therapy. Except for systemic lupus erythematosus and, occasionally, elastosis perforans serpiginosa, the other late penicillamine-induced toxic reactions disappear or improve with trientine therapy. Moreover, trientine is as effective therapeutically as penicillamine.

Zinc acetate or gluconate are effective as maintenance therapy, at doses of 150 mg/d of elemental zinc, for patients who are asymptomatic or have improved maximally on penicillamine or trientine. Zinc must *not*, however, be given together with penicillamine or trientine, both of which can chelate zinc and form complexes that are therapeutically ineffective.

Treatment must be continued for life. Inadequate treatment or interruption of therapy can be fatal or cause irreversible relapse. Indeed, of 11 patients who voluntarily discontinued penicillamine after years of successful treatment, 8 died after an average of 2.6 years of noncompliance. In contrast, of 13 patients in whom trientine was substituted because of an adverse reaction to penicillamine, 1 died accidentally, 5 were lost to follow-up, and 7 are alive and well 11 to 23 years later.

Prophylactic treatment of more than 100 asymptomatic patients with a documented diagnosis of Wilson's disease has shown that continual therapy with penicillamine or trientine can maintain the asymptomatic state indefinitely. Several such patients have been treated with penicillamine for >30 years.

Patients with severe neurologic disease who do not improve with penicillamine or trientine therapy that has reduced serum free copper to <0.3 umol/dL (15 ug/dL) may benefit significantly from treatment with dimercaprol. Intramuscular injections of 3 mL (containing 300 mg of dimercaprol) are given on five successive weekdays for 4 weeks. Treatment is interrupted for 1 week, and a second 4-week course is given. If there is neurologic improvement, additional courses are given as long as improvement continues. If no improvement is seen after two courses, it is unlikely that additional courses will be effective.

The simultaneous occurrence of fulminant hepatitis and Coombs-negative hemolytic anemia may be the initial clinical manifestation of Wilson's disease or may occur in a noncompliant patient. The syndrome is almost always fatal, usually within a week or two, unless liver transplantation is performed. Transplantation is also indicated if progressive hepatic insufficiency occurs despite adequate treatment with penicillamine or trientine.

More than 150 women with Wilson's disease treated with penicillamine and more than 20 women treated with trientine have had successful and uneventful pregnancies.

349. LYSOSOMAL STORAGE DISEASES - *Gregory A. Grabowski*

GENERAL FEATURES

Lysosomes are heterogeneous subcellular organelles containing specific hydrolyases that allow targeted processing or degradation of proteins, nucleic acids, carbohydrates, and lipids. There are >30 different lysosomal storage diseases, and they vary greatly in the types of metabolic abnormalities that occur as well as in their clinical manifestations. Nonetheless, these disorders are considered together because they share a related pathophysiology that involves the accumulation of specific macromolecules within cells that normally process large amounts of these substrates. The disorders are classified based on the nature of the stored material and include mucopolysaccharidoses (MPS), gangliosidoses, glycosphingolipidoses, glycoproteinoses, mucolipidoses, leukodystrophies, and lipid storage disorders (Table 349-1). The most prevalent lysosomal storage diseases in adults are Fabry disease, Gaucher disease, and Niemann Pick disease (NPD).

Lysosomal storage diseases should be considered in the differential diagnosis of patients with neurologic or muscular degeneration, unexplained hepatomegaly or splenomegaly, or skeletal dysplasias and deformations. Physical findings are disease-specific, and definitive diagnosis is made by enzyme assays.

PHYSIOLOGY OF LYSOSOMES

Lysosomal biogenesis is a continuous process that involves ongoing synthesis of lysosomal hydrolases, membrane constitutive proteins, and new membranes. Lysosomes originate from the fusion of *trans*-golgi network (TGN) vesicles with late endosomes. Progressive vesicular acidification accompanies the maturation of TGN vesicles, which contain various hydrolases, into lysosomes. Early endosomes have an internal pH of ~6.0 to 6.2; late endosomes and lysosomes have a pH of ~5.5 to 6.0 and £5, respectively. This gradient facilitates the pH-dependent dissociation of receptors and ligands [e.g., the mannose-6-phosphate (M6P) receptor and M6P-containing oligosaccharides] as well as activating lysosomal hydrolase function. This dynamic system, which has supplanted the static view of the lysosome, is consistent with the presence of heterogeneous populations of similar organelles whose contents differ significantly in time and location within the cell.

The accurate sorting, targeting, and activation of lysosomal enzymes is essential for maintaining normal cellular function. Abnormalities at several steps along the biosynthetic pathway can impair enzyme activation and lead to a lysosomal storage disorder. After cleavage of the hydrophobic signal peptide in the endoplasmic reticulum (ER) membrane, *N*-glycosylation occurs cotranslationally in the lumen of the ER. Complex oligosaccharide modifications occur during transit through the Golgi. TheM6Pmodification of high-mannose oligosaccharide chains of many soluble lysosomal hydrolases occurs early in this process. Defects of this modification result in inappropriate extracellular secretion of most soluble lysosomal hydrolases, leading to severe phenotypes (I-cell disease). Lysosomal integral or associated membrane proteins (LIMPS or LAMPS) are sorted to the membrane or interior of the lysosome by several different signals. Phosphorylation, sulfation, additional proteolytic processing,

and macromolecular assembly of heteromers occur concurrently and are critical to enzyme function. Defects in the latter can result in multiple enzyme/protein deficiencies.

PATHOGENESIS OF LYSOSOMAL STORAGE DISEASES

The final common pathway for lysosomal storage diseases is the accumulation of specific macromolecules within tissues and cells that normally have a high flux of these substrates. The majority of lysosomal enzyme deficiencies result from point mutations or genetic rearrangements at a locus that encodes a single lysosomal hydrolase. However, some mutations cause deficiencies of several different lysosomal hydrolases by altering the enzymes/proteins involved in targeting, active site modifications, or macromolecular association or trafficking. All are inherited as autosomal recessive disorders, except Hunter (MPS II) and Fabry diseases, which are X-linked. Lysosomal distortion, which is caused by substrate accumulation, probably has significant pathologic consequences. However, abnormal amounts of metabolites may also have pharmacologic effects important to disease pathophysiology.

For many lysosomal diseases, the accumulated substrates are endogenously synthesized within particular tissue sites of pathology. Other diseases have greater exogenous substrate supplies; that is, they are delivered by low-density lipoprotein receptor-mediated uptake in Fabry and cholesteryl ester storage diseases or by phagocytosis in Gaucher disease type 1.

The concept of the *threshold hypothesis* has important implications for disease classification, pathophysiology, and treatment. It implies a threshold of enzyme activity below which disease develops. Consequently, small changes in enzyme activity near the threshold can lead to or prevent disease. A critical element of this model is that enzymatic activity can be challenged by changes in substrate flux based on genetic background, cell turnover, recycling, or metabolic demands. Thus, a set level of residual enzyme may be adequate for substrate in some tissues or cells, but not in others. For some lysosomal storage diseases [e.g., metachromatic leukodystrophy (MLD), Tay-Sachs disease, Gaucher disease], genotype-phenotype correlations may help to predict the severity of clinical consequences associated with certain levels of enzyme activity. Defining enzyme activity thresholds may also be useful for predicting dose-response relationships for treatment and for the evaluation of exogenous enzyme replacement therapy.

SPECIFIC DISORDERS

MUCOPOLYSACCHARIDOSES (MPS)

The various forms ofMPSresult from deficiencies of lysosomal enzymes needed for glycosaminoglycan (GAG) catabolism. GAGs are long-chain, complex carbohydrates that are linked to proteins in connective tissue. They are components of proteoglycans and include: chondroitin-4-sulfate, chondroitin-6-sulfate, heparan sulfate, dermatan sulfate, keratan sulfate, and hyaluronic acid. The particular accumulated GAG is determined by the specific enzyme deficiency. GAG accumulation in various tissues produces a spectrum of clinical features that can include skeletal abnormalities, corneal clouding, organomegaly, joint stiffness, hernias, short stature, and, in some disorders,

mental retardation. Vacuolated lymphocytes in the peripheral smear and excessive urinary GAGs are typical findings. Clinical and laboratory features overlap among the MPS diseases and are not diagnostic. The MPS diseases occur with individual frequencies of about 1/50,000 to 1/100,000 in most populations.

The diagnosis is established by specific enzyme assays or, when known, DNA mutation analysis. Prenatal diagnosis is conducted most frequently with cultured amniotic cells. Mutation studies for carriers can be performed, if the mutation is known.

Treatment of theMPSdiseases requires comprehensive, multisystem evaluations. Symptomatic therapies currently include corneal transplantation, correction of nerve entrapment, and heart valve replacement. Physical therapy for joint contractures is needed in all but MPS IV. In MPS III variants, psychotropic drugs are used to control behavior. For patients with MPS IH and IV, cervical myelopathy can be prevented by prospective cervical spinal fusion. The efficacy of bone marrow transplantation and enzyme replacement is under investigation.

MPS IH (Hurler Disease) This a severe autosomal recessive disorder that results from numerous different mutations of a-L-iduronidase. Progressive mental retardation, hepatosplenomegaly, skeletal malformations, and cardiopulmonary compromise typically lead to death during the first decade. Affected individuals appear normal at birth but exhibit accelerated growth and mild coarsening of facial features in the first year. Subsequently, there is slowing of growth, leading to short stature. In the first 2 years, clinical diagnosis is suggested by hepatosplenomegaly, corneal clouding, coarse features, large tongue, joint stiffness, and characteristic dysostosis multiplex on skeletal x-rays. Instability of the cervical vertebral bodies can lead to paralysis, particularly with subluxation on hyperextension. Developmental delay is apparent by 12 to 28 months, with subsequent slow mental regression. Additional features of this multisystem disease include hearing loss, chronic respiratory infections, valvular heart disease, and brain ventricular enlargement. The latter occurs from involvement of the arachnoid granulations.

MPS (Scheie Disease) and MPS I H/S (Hurler-Scheie Disease) TheseMPSvariants are less severe than MPS IH (Hurler disease). They result from allelic mutations in the a-L-iduronidase gene, presumably with a less severe effect on enzyme function. Patients with MPS IS can survive into late adulthood with normal intelligence, though with severe progressive skeletal disease that resembles osteoarthritis. Bone marrow transplantation in MPS IH, if instituted before substantial central nervous system CNS involvement, has shown therapeutic promise. Preliminary intravenous enzyme administration has led to improvement in hepatosplenomegaly and connective tissue involvement.

MPS II (Hunter Syndrome) This is an X-linked recessive disorder that results from deletions and point mutations in the gene encoding iduronate sulfatase. Clinically,MPS IH and II are similar, though corneal clouding is absent in MPS II. Clinical manifestations range from severeCNS and visceral involvement with death in late childhood to milder forms with normal CNS function and survival into adulthood. Bone marrow transplantation has not been successful for treating the severe variants, and experience in the less severe variants is too limited to permit conclusions. Enzyme therapy trials are

imminent.

MPS IIIA, IIIB, IIIC, and IIID (the Sanfilippo Syndromes) These autosomal recessive disorders are caused by various enzymatic deficiencies as summarized inTable 349-1. Skeletal defects and hepatosplenomegaly are less pronounced in this group ofMPSvariants, though progressive behavioral problems, mental retardation, and seizures are present. Affected patients can survive into the third or fourth decade with progressiveCNSdisease.

MPS IV (Morquio Syndrome) TheseMPSvariants are autosomal recessive disorders characterized by severe skeletal diseases that resemble the spondyloepiphyseal dysplasias. There is extreme shortening of the trunk due to multiple vertebral collapses. The long bones are relatively spared. Joint laxity can lead to osteoarthritis-like destruction of the joints. Upper cervical spinal cord compression due to atlantoaxial instability predisposes to subluxation and paralysis. Many patients have mitral valve insufficiency that can be functionally significant. The A and B variants are distinguished clinically by more severe skeletal disease, *N*-acetylgalactosamine-6-sulfate sulfatase deficiency in A, than inb-galactosidase defects in B. Enzyme therapy trials will begin in the near future.

MPS VI (Maroteaux-Lamy Disease) Mutations in the arylsulfatase B gene cause this autosomal recessive disorder. Although clinically variable, the general phenotype resembles Hurler disease. Intelligence is normal, and the life span can extend beyond three decades. Cardiac valvular disease and progressive pulmonary hypertension are frequent causes of death. Bone marrow transplantation may be useful in diminishing these manifestations.

GM_2GANGLIOSIDOSES

The Tay-Sachs and Sandhoff disease variants are caused by defects inb-hexosaminidase (Hex) A and/or B. Hex A is a heteromeric protein with a andb chains, whereas Hex B contains onlyb chains. The a andb chains are encoded by different genes. Infantile, juvenile, and adult-onset variants are distinguished by age at onset and rate of progression.

In addition to other clinical manifestations described below, specific neurologic features, such as the retinal cherry red spot, suggest the diagnosis of Tay-Sachs and Sandhoff diseases. Diagnosis is confirmed byHex A and/or B levels in blood plasma or nucleated cells. Screening for Tay-Sachs disease carriers in the Ashkenazi Jewish population is recommended.

Tay-Sachs Disease About 1 in 30 Ashkenazi Jews is a carrier for Tay-Sachs disease, which is caused by totalHex A deficiency. The infantile form is a fatal neurodegenerative disease that is characterized by macrocephaly, loss of motor skills, increased startle reaction, and macular pallor with cherry red spot on retinal examination. The juvenile-onset form presents with ataxia and dementia, with death by age 10 to 15 years. The adult-onset disorder is characterized by clumsiness in childhood; progressive motor weakness in adolescence; and additional spinocerebellar, lower motor neuron symptoms, and dysarthria in adulthood. Intelligence declines slowly, and psychosis is

also common.

Sandhoff Disease Sandhoff disease is nearly identical to Tay-Sachs disease, though hepatosplenomegaly and bony dysplasias are present in the former. The later onset variants are characterized by progressive visceral and CNS disease. Treatment is supportive.

NEUTRAL GLYCOSPHINGOLIPID LIPID STORAGE DISORDERS

Fabry Disease This is an X-linked disorder that results from a variety of mutations in thea-galactosidase gene. This enzyme cleaves the terminala-galactosyl moiety from globotriaosylceramide (trihexosylceramide, THC), a key step in glycosphingolipid metabolism. Clinically, the disease manifests with angiokeratomas (telangiectatic skin lesions); hypohidrosis; corneal and lenticular opacities; acroparesthesia; and small-vessel disease of the kidney, heart, and brain. The estimated prevalence of hemizygous males with Fabry disease is 1/40,000.

The angiokeratomas and acroparesthesia may appear in childhood and lead to early diagnosis, if suspected. Angiokeratomas are punctate, dark red to blue-black, flat or slightly raised, usually symmetric, and do not blanch with pressure. They range from barely visible to several millimeters in diameter and have a tendency to increase in size and number with age. Characteristically, they are most dense between the umbilicus and knees -- "the bathing suit area" -- but may occur anywhere, including the mucosal surfaces. Corneal and lenticular lesions, detectable on slit-lamp examination, are present in affected men and ~70% of heterozygous women. Tortuosity of the conjunctival and retinal vessels is common. The acroparesthesia can be debilitating in childhood and adolescence, with a tendency to decrease after the third decade. Episodic agonizing, burning pain of the hands, feet, and proximal extremities can last from minutes to days and can be precipitated by exercise, fatigue, or fever. Abdominal pain can resemble that from appendicitis or renal colic.

Casts and microscopic hematuria can occur early, whereas proteinuria, isosthenuria, and progressive renal dysfunction occur in the second to fourth decades. Progressive renal failure occurs and requires transplantation. Hypertension, left ventricular hypertrophy, anginal chest pain with or without myocardial ischemia or infarction, and congestive heart failure can occur in the third to fourth decades. Leg lymphedema without hypoproteinemia and episodic diarrhea also occur. Death is due to renal failure or cardiovascular or cerebrovascular disease in untreated patients. Variants with residual a-galactosidase activity may have late-onset manifestations limited to the cardiovascular system that resemble hypertrophic myocardiopathies. Heterozygous females may exhibit some of these clinical manifestations but usually not the severe organ involvement.

Acroparesthesia, hypohidrosis or anhidrosis, angiokeratomas, and the typical corneal and lenticular lesions provide a presumptive diagnosis in males. Angiokeratomas are not diagnostic, however, and also occur in Fordyce scrotal angiokeratoma and several other lysosomal storage diseases.

Phenytoin and carbamazepine diminish the chronic and episodic acroparesthesia.

Chronic hemodialysis or kidney transplantation can be lifesaving in patients with renal failure. Initial enzyme therapy results are promising.

Gaucher Disease This is an autosomal recessive disorder that results from defective activity of acidb-glucosidase; >175 mutations have been described. This enzyme cleaves glucosylceramide, the parent compound of many glycosphingolipids and related glucolipids. Disease variants are classified based on the absence or presence and severity of neuronopathic involvement.

Type 2 Gaucher disease is a rare, severeCNSdisease that leads to death by 2 years of age; it will not be addressed here.

Type 3 Gaucher disease has highly variable manifestations in theCNS and viscera. It can present in early childhood with rapidly progressive, massive visceral disease and slowly progressive to static CNS involvement; in adolescence with dementia; or in early adulthood with rapidly progressive, uncontrollable myoclonic seizures and mild visceral disease. Variants that span this spectrum also occur. Visceral disease in type 3 is nearly identical to that in type 1 but is generally more severe (see below). Early CNS findings may be limited to defects in lateral gaze tracking, which may remain static for decades. Mental retardation can be slowly progressive or static. This variant is most frequent among individuals of Swedish descent.

Type 1 Gaucher disease is a highly variable nonneuronopathic disease that can present in childhood to adulthood with slowly to rapidly progressive visceral disease. There is marked variability in age at onset and degree and progression of visceral involvement. In general, earlier diagnoses are associated with worse prognosis. The average age at diagnosis is ~20 years in Caucasian populations and somewhat younger in other groups. This pattern of presentation is distinctly bimodal, however, with peaks at <10 to 15 years and at ~25 years. Younger patients tend to have a greater degree of hepatosplenomegaly and accompanying blood cytopenias. In contrast, the older group has a greater tendency for chronic bone disease. Hepatosplenomegaly occurs in virtually all symptomatic patients and can be minor or massive. Accompanying anemia and thrombocytopenia are variable and are not linearly related to liver or spleen volume. Severe liver dysfunction is unusual, though minor liver function abnormalities are common. Splenic infarctions can resemble an acute abdomen. Pulmonary hypertension and alveolar Gaucher cell accumulation are uncommon, but life-threatening, and can occur at any age.

Though it is more common in adult patients, clinically evident skeletal disease in children can be devastating, resulting in massive destruction of the axial and peripheral skeleton. All patients with Gaucher disease have nonuniform infiltration of bone marrow by lipid-laden macrophages, termed *Gaucher cells*. This can lead to marrow packing with subsequent infarction, ischemia, necrosis, and cortical bone destruction. Bone marrow involvement spreads from proximal to distal in the limbs and can involve the axial skeleton extensively, causing vertebral collapse. In addition to bone marrow involvement, bone remodeling is defective, with loss of total bone calcium leading to osteopenia, osteonecrosis, avascular infarction, and vertebral compression fractures and spinal cord involvement. Aseptic necrosis of the femoral head is common, as is fracture of the femoral neck. The mechanism by which diseased bone marrow

macrophages interact with osteoclasts and/or osteoblasts to lead to this complex bone disease is not well understood.

Affected patients experience chronic, ill-defined bone pain that can be debilitating and poorly correlated with radiographic findings. These are treated symptomatically. Some patients have one or more "bone crises" in their lifetimes that are associated with localized, excruciating pain, and, on occasion, local erythema, fever, and leukocytosis. Some patients have frequent crises, whereas other patients experience only one. Any bone can be involved, though the femurs and vertebral bodies are affected most often. These crises represent acute infarctions of bone, as evidenced in nuclear scans by localized absent uptake of pyrophosphate agents. X-rays are usually negative initially but may show lytic lesions 4 to 6 months after the acute phase. Osteomyelitis should be excluded by appropriate cultures. Bone cultures should be obtained only under sterile operating room conditions to minimize the chance of seeding an infection.

The diagnosis of Gaucher disease is established by demonstrating decreased acidb-glucosidase activity (0 to 20% of normal) in nucleated cells. The enzyme is not present in bodily fluids. The sensitivity of enzyme testing is poor for detecting heterozygous carriers; molecular testing is preferred when the mutations are known. The disease frequency varies from about 1 in 1000 in Ashkenazi Jews to <1 in 100,000 in some other populations. About 1 in 12 to 15 Ashkenazi Jews carries a Gaucher disease allele. Four common mutations account for ~90 to 95%of the mutations in affected patients: N370S (1226G), 84GG (a G insertion at cDNA position 84), L444P (1448C), and IVS-2 (an intron 2 splice junction mutation).

Genotype/phenotype studies indicate a significant correlation, though not absolute, between disease type and severity and the acid b-glucosidase genotype. For example, the most common mutation in the Ashkenazi Jewish population (N370S) shares a 100% association (to date) with nonneuronopathic, type 1 Gaucher disease, possibly because the N370S enzyme retains significant activity. The N370S/N370S and N370S/other mutant allele genotypes are associated with later onset/less severe and earlier onset/severe disease, respectively. The other alleles are L444P (very low activity), 84GG (null), or IVS-2 (null), and rare/private or uncharacterized alleles. As many as 50 to 60% of N370S/N370S patients are discovered as asymptomatic family members. The N370S/other mutant allele genotypes have disease onset about 2 decades earlier than those with N370S/N370S. The L444P/L444P patients almost always have life-threatening to very severe/early-onset disease, and many, though not all, developCNSinvolvement in the first 2 decades of life. Some patients with this genotype have lethal neuronopathic disease at <1 year (type 2). Thus, this genotype is prognostic of very severe disease, with or without obvious CNS involvement.

Symptomatic management of the blood cytopenias and joint replacement surgeries continue to have important roles in the treatment of affected patients. However, enzyme therapy is currently the treatment of choice in significantly affected patients. Cerezyme, a recombinantly produced mannose-terminated (macrophage-targeted) acidb-glucosidase, has proved highly efficacious and safe in diminishing the hepatosplenomegaly and improving bone marrow involvement and hematologic findings.

Niemann-Pick Disease NPD is an autosomal recessive trait that occurs as several variants. Types A and B result from defects in acid sphingomyelinase; various mutations have been detected at this locus. Other variants, including NPD C, result from defective transport of cholesterol across the lysosomal membrane. Only NPD variants A and B will be considered here.

NPDA and B are distinguished primarily by an early age of onset and progressiveCNSdisease in A. NPD A typically has onset in the first 6 months, with rapidly progressive CNS deterioration, spasticity, failure to thrive, and massive hepatosplenomegaly. In contrast, NPD B has a later, more variable onset and progression of hepatosplenomegaly, with eventual development of cirrhosis and hepatic replacement by foam cells. Affected patients develop progressive pulmonary disease with dyspnea, hypoxemia, and a reticular infiltrative pattern on chest x-ray. Foam cells are present in alveoli, lymphatic vessels, and pulmonary arteries. Progressive hepatic or lung disease with associated bronchopneumonia, pulmonary hypertension, cor pulmonale, and decreased diffusion capacities lead to demise in adolescence to early adulthood.

The diagnosis is established by markedly decreased (1 to 10% of normal) sphingomyelinase activity in nucleated cells. Enzyme assays to detectNPD A or B carriers are unreliable. In families with known mutations, the molecular defect in heterozygotes can be identified by DNA analysis.

There is no specific treatment forNPD. The efficacy of hepatic or bone marrow transplantation has not been proven. Clinical trials using enzyme therapy are anticipated to begin soon.

THE LEUKODYSTROPHIES

Globoid cell leukodystrophy and metachromatic leukodystrophy variants are autosomal recessive disorders that primarily involveCNSwhite matter and myelinated peripheral nervous system tracts.

Globoid Cell Leukodystrophy (GCL) The GCL variants are due to mutations in the galactosylceramidase gene. The term *globoid cell* is derived from the presence of characteristic multinucleated cells filled with galactosylceramide in the brains of affected patients. Infantile GCL (Krabbe disease) is a rapidly progressive, fatal disorder; patients succumb in the first 2 years. Juvenile and adult variants present with more slowly progressive dementia. For all variants, manifestations are confined to theCNS and peripheral nervous system. Diagnosis is confirmed by demonstrating defective galactosylceramidase activity in nucleated cells. Treatment is supportive, but bone marrow transplantation has shown some promise in the later onset variants.

Metachromatic Leukodystrophy MLD is due to defects in arylsulfatase A and accumulation of its substrate, galactosylceramide sulfate or sulfatide. The late-infantile form presents in the second year with progressive regression of developmental milestones and intellectual development. The disease is fatal in the first decade. The juvenile and adult forms have variable manifestations and present with gait disturbances, ataxia, mental regression, peripheral neuropathy, and/or seizures. In

adults, behavioral disturbances, psychosis, and dementia tend to predominate. These later onset diseases may respond to bone marrow transplantation.

The diagnosis is established by demonstrating a deficiency of arylsulfatase A in nucleated cells. Homozygosity for a null allele (splicing defect in intron 2) produces severe infantile disease, whereas P426L homozygotes develop adult-onset disease. Compound heterozygotes, such as null and P426L alleles, have juvenile-onset variants. The diagnosis ofMLD is complicated by the presence of a very frequent (10 to 15%) "pseudodeficiency allele" for arylsulfatase A. Although in vitro activity with synthetic substrates is deficient, cleavage of sulfatide is low-normal in vivo. Compound heterozygotes for the pseudodeficiency allele and true MLD alleles therefore appear to have deficient arylsulfatase A activity, diagnostic of MLD, but these individuals are not affected by the disease. MLD-causing mutations also occur on the background of the pseudodeficient allele, emphasizing the importance of careful genetic testing.

GLYCOGEN STORAGE DISEASE TYPE II (See also Chap. 350)

Glycogen storage disease type II is an autosomal recessive disorder due to defects in acid a-glucosidase that lead to lysosomal glycogen accumulation. Numerous mutations have been found at this locus in affected patients. Skeletal and cardiac muscles are primarily involved. The infantile form (Pompe disease) is a fatal disorder characterized by hypertrophic cardiomegaly, macroglossia, and hypotonia due to glycogen accumulation in muscle. The juvenile form has progressive proximal muscle weakness, including impairment of respiratory function. Adult patients have phenotypes resembling slowly progressive muscular dystrophies. Prenatal diagnosis can be performed. Treatment is supportive, and enzyme trials are underway.

MUCOLIPIDOSES

Mucolipidoses II (I-cell) and III (pseudo-Hurler polydystrophy) are rare autosomal recessive diseases. Both are caused by defective targeting of lysosomal hydrolases that require theM6Psignal for sorting to the lysosome. As a result,>20 enzymes are secreted out of the cell and their substrates accumulated in specific cell types. *N*-acetylglucosamine-1-phosphotransferase activity, which is necessary for developing the M6P signal, is defective in these diseases. I-cell disease has a phenotype similar toMPS IH, whereas mucolipidosis-III is more similar to MPS IH/S; mental retardation is a feature of both. Diagnosis is suspected based on the characteristic phenotype and is established by demonstrating greatly elevated serum levels of lysosomal enzymes, as well as their deficiency in cells. Specific enzyme assays can also be performed. Carrier detection is possible but is not straightforward. Prenatal diagnosis can be performed using amniotic fluid and cells in at-risk families. Treatment is supportive.

350. GLYCOGEN STORAGE DISEASES AND OTHER INHERITED DISORDERS OF CARBOHYDRATE METABOLISM - *Yuan-Tsong Chen*

Carbohydrate synthesis and degradation play a vital role in cellular function by providing the energy required for most metabolic processes. The carbohydrates to be discussed include three monosaccharides: glucose, galactose, and fructose, and a polysaccharide, glycogen; the relevant biochemical pathways involved in the metabolism of these carbohydrates are shown inFig. 350-1. Glucose is the principle substrate of energy metabolism in humans. Metabolism of glucose generates ATP via glycolysis and mitochondrial oxidative phosphorylation. A continuous source of glucose from dietary intake, gluconeogenesis, and degradation of glycogen maintain normal blood glucose levels. Sources of glucose in our diet are obtained by ingesting polysaccharides, primarily starch, and disaccharides including lactose, maltose, and sucrose. Galactose and fructose are two other monosaccharides that provide fuel for cellular metabolism; however, their role as fuel sources is much less significant than that of glucose. Galactose is derived from lactose (galactose+ glucose), which is found in milk and milk products. If necessary, galactose can be incorporated into glycogen and thus becomes a source of glucose. Galactose is also an important component for certain glycolipids, glycoproteins, and glycosaminoglycans. The two dietary sources of fructose are sucrose (fructose + glucose), a commonly used sweetener, and fructose itself, which is found in fruits, vegetables, and honey.

This chapter is devoted to the inherited disorders of carbohydrate metabolism caused by defects in enzymes or transport proteins involved in glycogen metabolism, gluconeogenesis, and glycolysis (Table 350-1). Defects in glycogen metabolism typically cause an accumulation of glycogen in the tissues; hence, the name *glycogen storage diseases*. The defects in gluconeogenesis or glycolytic pathways including galactose and fructose metabolism do not usually result in glycogen accumulation.

Clinical manifestations of the various disorders of carbohydrate metabolism differ markedly. The symptoms range from harmless to lethal. Unlike disorders of lipid metabolism, mucopolysaccharidoses, or other storage diseases, dietary therapy has been effective in many of the carbohydrate disorders. Almost all the genes responsible for the inherited defects of carbohydrate metabolism have been cloned, and mutations have been identified. Advances in our understanding of the molecular basis of these diseases are being used to improve diagnosis and management, and some of these disorders are candidates for early trials of gene therapy.

Glycogen, the storage form of glucose in animal cells, is composed of glucose residues joined in straight chains bya1-4 linkages and branched at intervals of 4 to 10 residues with a1-6 linkages. The treelike molecule can have a molecular weight of many millions and may aggregate to form structures recognizable by electron microscopy. In muscle, glycogen formsb particles, which are spherical and contain up to 60,000 glucose residues. Each b particle contains a covalently linked protein called *glycogenin*. Liver containsb particles and rosettes of glycogen calleda particles, which appear to be aggregatedb particles.

The primary function of glycogen varies in different tissues. In skeletal muscle, stored glycogen is a source of fuel that is used for short-term, high-energy consumption during

muscle activity; in the brain, the small amount of stored glycogen is used during brief periods of hypoglycemia or hypoxia as an emergency supply of energy. In contrast, the liver takes up glucose from the bloodstream after a meal and stores it as glycogen. When blood glucose levels start to fall, the liver converts glycogen back into glucose and releases it into the blood for use by tissues such as brain and erythrocytes that cannot store significant amounts of glycogen.

Glycogen storage diseases are inherited disorders that affect glycogen metabolism. Disorders in virtually every enzyme involved in the synthesis or degradation of glycogen and its regulation cause some type of glycogen storage disease (Fig. 350-1) in which glycogen is abnormal in quantity, quality, or both. Excluded from this chapter are those conditions in which tissue glycogen accumulation is secondary, such as overtreatment of diabetes mellitus with insulin or administration of pharmacologic amounts of glucocorticoids.

Historically, the glycogen storage diseases were categorized numerically in the order in which the enzymatic defects were identified. They can also be classified by the organs involved and clinical manifestations, the system followed in this chapter (Table 350-1).

Because liver and muscle have abundant glycogen, they are the most commonly and seriously affected tissues. The hepatic glycogen storage diseases can be divided into two groups, with some overlap. The first is characterized by hepatomegaly and hypoglycemia. Because carbohydrate metabolism in the liver controls plasma glucose levels, the disorders of hepatic glycogen degradation and glucose release cause fasting hypoglycemia. Diseases in this group include glucose-6-phosphatase deficiency (type I), debranching enzyme deficiency (type III), liver phosphorylase deficiency (type VI), phosphorylase kinase deficiency (type IX), glycogen synthase deficiency (type 0), and glucose transporter-2 defects (type XI). The second group, characterized by cirrhosis of the liver and hepatomegaly, is associated with accumulation of abnormal forms of glycogen, which may be the cause of the hepatocellular injury. This group is represented by branching enzyme deficiency (type IV).

The role of glycogen in muscle is to provide substrates for the generation of sufficient ATP for muscle contraction. The muscle glycogen storage diseases can also be divided into two groups. The first is a muscle-energy disorder characterized by muscle pain, exercise intolerance, myoglobinuria, and susceptibility to fatigue. This group includes type V (McArdle disease), a muscle phosphorylase deficiency, and deficiencies of phosphofructokinase (type VII), phosphoglycerate kinase, phosphoglycerate mutase, lactase dehydrogenase, fructose 1,6-biphosphate aldolase A, and pyruvate kinase. Some of these latter enzyme deficiencies are associated with a compensated hemolysis, suggesting a more generalized defect in glucose metabolism. The second group of muscle disorders is characterized by progressive skeletal muscle weakness and atrophy and/or cardiomyopathy; it includes a lysosomal enzyme deficiency (acida-glucosidase, type II) and deficiency of cardiac-specific phosphorylase kinase. Some glycogen storage diseases such as debranching enzyme deficiency (type IIIa) and branching enzyme deficiency (type IV) involve both muscle and liver.

The overall frequency of all forms of glycogen storage disease is approximately 1 in 20,000 live births; most are inherited as autosomal recessive traits, but

phosphoglycerate kinase deficiency and one form of phosphorylase kinase deficiency are X-linked disorders. The most common childhood disorders are glucose-6-phosphatase deficiency (type I), lysosomal acida-glucosidase deficiency (type II), debrancher deficiency (type III), and liver phosphorylase kinase deficiency (type IX). The most common adult disorder is myophosphorylase deficiency (type V, or McArdle disease). In the past, the prognosis for many glycogen storage diseases was guarded. However, early diagnosis and better management have improved the survival rates, and many affected children are now adults.

GLYCOGEN STORAGE DISEASES: LIVER GLYCOGENOSES

DISORDERS WITH HEPATOMEGALY AND HYPOGLYCEMIA

Type I Glycogen Storage Disease (Glucose-6-Phosphatase or Translocase Deficiency, von Gierke Disease) Type I glycogen storage disease is due to a defect in glucose-6-phosphatase in liver, kidney, and intestinal mucosa. It can be divided into two subtypes: type Ia, in which the glucose-6-phosphatase enzyme is defective, and type Ib, which is due to a defect in the translocase that transports glucose-6-phosphate across the microsomal membrane. The defects in both subtypes lead to inadequate conversion in the liver of glucose-6-phosphate to glucose and thus make affected individuals susceptible to fasting hypoglycemia.

GENETIC CONSIDERATIONS

Type I glycogen storage disease is an autosomal recessive disorder. Both types Ia and Ib disease have been reported in many ethnic groups, but type Ia is rarely seen in blacks. The structural gene for glucose-6-phosphatase is located on chromosome 17q21; three common mutations (R83C, 130X, Q347X) are responsible for 70% of the known disease alleles. The structural gene for glucose 6-phosphate translocase is located on chromosome 11q23; two mutations, G339C and 1211delCT, appear to be prevalent in Caucasian patients, while W118R appears to be most common in Japanese patients. Carrier detection and prenatal diagnosis are possible with the use of molecular techniques.

Clinical and laboratory findings Persons with type I disease may develop hypoglycemia and lactic acidosis during the neonatal period, but, more commonly, they present at 3 to 4 months of age with hepatomegaly and/or hypoglycemia. These children often have doll-like faces with fat cheeks, relatively thin extremities, short stature, and a protuberant abdomen that is due to massive hepatomegaly; the kidneys are enlarged, but the spleen and heart are of normal size.

The hallmarks of the disease are hypoglycemia, lactic acidosis, hyperuricemia, and hyperlipidemia. Hypoglycemia and lactic acidosis can develop after a short fast. Hyperuricemia is present in young children, but gout rarely develops before puberty. Despite hepatomegaly, liver enzymes are usually normal or near normal. Intermittent diarrhea may occur (the mechanism is not known). Easy bruising and epistaxis are associated with a prolonged bleeding time as a result of impaired platelet aggregation/adhesion.

Hypertriglyceridemia may cause the plasma to appear "milky," and cholesterol and phospholipids are also elevated. The lipid abnormality resembles type IV hyperlipidemia and is characterized by increased levels of very low-density lipoprotein (VLDL); low-density lipoprotein (LDL); increased levels of apoliproteins B, C, and E; and normal or reduced levels of apoliproteins A and D. The hepatocytes are distended by glycogen and fat with large and prominent lipid vacuoles. There is little associated fibrosis.

All these findings apply to both types Ia and Ib disease, but type Ib has the additional feature of recurrent bacterial infections due to neutropenia and impaired neutrophil function. Oral and intestinal mucosa ulcerations are common, and inflammatory bowel disease may occur.

Long-term complications Although type I glycogen storage disease mainly affects the liver, multiple organ systems are also involved. Gout usually becomes symptomatic around puberty as a result of the long-term hyperuricemia. Puberty is often delayed, but fertility appears to be normal. Hypertriglyceridemia causes an increased risk of pancreatitis, but premature atherosclerosis has not been documented. Impaired platelet aggregation may reduce the risk of atherosclerosis.

By the second or third decade of life, most patients with type I glycogen storage disease develop hepatic adenomas that can hemorrhage and, in rare cases, may become malignant. Other complications include pulmonary hypertension and osteoporosis.

Renal disease is a late complication, and almost all patients older than 20 years have proteinuria. Many have hypertension, kidney stones, nephrocalcinosis, and altered creatinine clearance. Glomerular hyperfiltration, increased renal plasma flow, and microalbuminuria can occur before the onset of gross proteinuria. In young patients, hyperfiltration and hyperperfusion may be the only signs of renal abnormalities. With advanced renal disease, focal segmental glomerulosclerosis and interstitial fibrosis are evident on biopsy. In some patients, renal function deteriorates and progresses to failure, requiring dialysis or transplantation. Other abnormalities in renal function include amyloidosis, Fanconi-like syndrome, and distal renal tubular acidification defect. The increases in renal perfusion and maternal blood volume that normally occur in pregnancy can exacerbate renal problems. In addition, hypoglycemia may also become more difficult to control.

Diagnosis The diagnosis of type I disease can be suspected on the basis of clinical presentation and abnormal plasma lactate and lipid values. In addition, administration of glucagon or epinephrine causes little or no rise in blood glucose but increases lactate levels significantly. Before the glucose 6-phosphatase and glucose 6-phosphate translocase genes were cloned, a definitive diagnosis required a liver biopsy to demonstrate a deficiency. Gene-based mutation analysis now provides a noninvasive way of diagnosis for most patients with types Ia and Ib disease.

TREATMENT

Treatment is designed to maintain normal blood glucose levels and is achieved by continuous nasogastric infusion of glucose or oral administration of uncooked cornstarch. Nasogastric drip feeding in early infancy may consist of an elemental enteral

formula or may contain only glucose to maintain normoglycemia during the night; frequent feedings with a high-carbohydrate content are given during the day.

Uncooked cornstarch acts as a slow-release form of glucose and can be given at a dose of 1.6 g/kg every 4 h for infants younger than 2 years. As the child grows older, the cornstarch regimen can be changed to every 6 h, and it can be given by mouth as a liquid (1:2, weight:volume) at a dose of 1.75 to 2.5 g/kg of body weight. Because fructose and galactose cannot be converted to free glucose, their dietary intake should be restricted, and dietary supplements of multivitamins and calcium are required. Allopurinol is given to lower the levels of uric acid. In patients with type Ib disease, granulocyte and granulocyte-macrophage colony stimulating factors have been used successfully to correct the neutropenia, decrease the severity of bacterial infection, and improve the chronic inflammatory bowel disease.

Before surgery, the bleeding status of the patient should be evaluated, and good metabolic control should be established. Prolonged bleeding time can be corrected by the administration of a constant intravenous glucose infusion for 24 to 48 h before surgery. Vasopressin can be given during surgery to reduce bleeding complications, and normal glucose levels should be maintained throughout surgery.

Prognosis In the past, many patients with type I glycogen storage disease died, and the prognosis was guarded for those who survived. The long-term complications discussed above occur mostly in adults whose disease was not adequately treated during childhood. Early diagnosis and initiation of effective treatment have improved the outcome, but it is not known if all long-term complications can be avoided through good metabolic control.

Type III Glycogen Storage Disease (Debrancher Deficiency, Limit Dextrinosis)
Type III glycogen storage disease is caused by a deficiency of glycogen debranching enzyme. Debranching enzyme and phosphorylase are responsible for complete degradation of glycogen; when debranching enzyme is defective, glycogen breakdown is incomplete, and an abnormal glycogen accumulates that has short outer chains and resembles limit dextrin.

GENETIC CONSIDERATIONS

The type III glycogenoses are inherited as autosomal recessive traits. The disease has been reported in many different ethnic groups, and the frequency is relatively high in non-Ashkenazi Jews of North African descent. The gene for debranching enzyme is located on chromosome 1p21. At least 20 different mutations that cause type III disease have been identified. Two mutations (17delAG and Q6X), both located in exon 3 at amino acid codon 6, are exclusively found in the subtype IIIb. Carrier detection and prenatal diagnosis are possible with DNA-based linkage or mutation analysis.

Clinical and laboratory findings Deficiency of glycogen debranching enzyme causes hepatomegaly, hypoglycemia, short stature, variable skeletal myopathy, and cardiomyopathy. The disorder usually involves both liver and muscle and is termed *type IIIa glycogen storage disease*. However, in about 15% of patients, the disease appears to involve only the liver and is classified as *type IIIb*.

During infancy and childhood, the disease may be almost indistinguishable from type I disease because hepatomegaly, hypoglycemia, hyperlipidemia, and growth retardation are common features of both. Splenomegaly may be present, but the kidneys are not enlarged in type III disease. Remarkably, hepatomegaly and hepatic symptoms in most patients with type III disease improve with age and usually disappear after puberty. However, progressive liver cirrhosis with failure may occur and seems especially common in Japanese patients.

In patients with muscle involvement (type IIIa), muscle weakness is usually minimal during childhood but can become severe during the third or fourth decade of life, as evidenced by slowly progressive weakness and muscle wasting. Electromyographic (EMG) changes are consistent with a widespread myopathy, and nerve conduction may be abnormal. Ventricular hypertrophy is frequent, but overt cardiac dysfunction is rare. Hepatic symptoms may be so mild that the diagnosis is not made until adulthood, when neuromuscular disease becomes manifest. Polycystic ovaries appear to be a common finding in female patients; fertility, however, does not seem to be affected.

Hypoglycemia, hyperlipidemia, and elevated liver transaminases occur in children. In contrast to type I disease, fasting ketosis is prominent, and blood lactate and uric acid concentrations are usually normal. The administration of glucagon 2 h after a carbohydrate meal causes a normal rise of blood glucose, but after an overnight fast glucagon may provoke no change in blood glucose. Serum creatine kinase levels can sometimes be used to identify patients with muscle involvement, but normal levels do not rule out muscle enzyme deficiency.

The histology of the liver is characterized by a universal distention of hepatocytes by glycogen and by the presence of fibrous septa. The fibrosis and the paucity of fat distinguish type III from type I glycogenosis. The fibrosis can range from minimal periportal fibrosis to micronodular cirrhosis.

Diagnosis In type IIIa glycogen storage disease, deficient debranching enzyme activity can be demonstrated in liver, skeletal muscle, and heart. In contrast, patients with type IIIb have debranching enzyme deficiency in the liver but not in muscle. In the past, definitive assignment of subtype required enzyme assays in both liver and muscle. DNA-based analyses now provide a noninvasive way of subtyping these disorders in most patients.

TREATMENT

Dietary management of type III disease is less demanding than that of type I. If hypoglycemia is present, frequent high-carbohydrate meals with cornstarch supplements or nocturnal gastric drip feedings are usually effective. A high-protein diet during the day plus overnight protein enteral infusion may be tried in patients with myopathy, but it is not established whether such a regimen is effective. Patients do not need to restrict dietary intake of fructose and galactose, as do those with type I disease.

Prognosis Liver symptoms improve with age and usually disappear after puberty. Cirrhosis of the liver may occur later in life. In type IIIa disease, muscle weakness and

atrophy worsen during adulthood.

Type VI Glycogen Storage Disease [Liver Phosphorylase Deficiency (Hers Disease)] The number of patients with enzymatically documented liver phosphorylase deficiency is small. It appears that patients with liver phosphorylase deficiency have a benign course. These patients present with hepatomegaly and growth retardation early in childhood. Hypoglycemia, hyperlipidemia, and hyperketosis are usually mild if present. Plasma lactic acid and uric acid levels are normal. The heart and skeletal muscles are not involved. The hepatomegaly and growth retardation improve with age and usually disappear at puberty. Treatment is symptomatic. A high-carbohydrate diet and frequent feeding are effective in preventing hypoglycemia, but most patients require no specific treatment. The liver phosphorylase gene is located on chromosome 14q21. A splicing site mutation in intron 13 has been identified in a large Mennonite kindred, and four other mutations have been found in patients with different ethnic backgrounds.

Type IX Glycogen Storage Disease (Liver Phosphorylase Kinase Deficiency) Defects of phosphorylase kinase cause a heterogeneous group of glycogenoses. The heterogeneity is due to the complexity of the phosphorylase kinase enzyme complex. It consists of four subunits (a, b,g, and d), each encoded by different genes (X chromosome as well as autosomes) that are differentially expressed in various tissues. Phosphorylase kinase deficiency can be divided into several subtypes on the basis of the gene/subunit involved, the tissues that are primarily affected, and the mode of inheritance.

Subtypes of Phosphorylase Kinase Deficiency

X-LINKED LIVER PHOSPHORYLASE KINASE DEFICIENCY X-linked liver phosphorylase kinase deficiency is one of the most common liver glycogenoses. Phosphorylase kinase activity may also be deficient in erythrocytes and leukocytes but is normal in muscle. Typically, a child between the ages of 1 and 5 years presents with growth retardation and hepatomegaly. Levels of cholesterol, triglycerides, and liver enzymes are mildly elevated. Ketosis may occur after fasting. Lactic and uric acid levels are normal. Hypoglycemia is mild, if present. The rise in the blood glucose level after the administration of glucagon is normal. Hepatomegaly and abnormal blood chemistries gradually return to normal with age. Most adults achieve a normal final height and are practically asymptomatic, despite a persistent phosphorylase kinase deficiency.

Liver histology shows glycogen-distended hepatocytes. The accumulated glycogen (a particles, rosette form) has a frayed or burst appearance and is less compact than in type I or type III disease. Fibrous septa and low-grade inflammatory changes may be present.

The structural gene for the liver isoform of the phosphorylase kinase a-subunit is located on chromosome Xp22, and mutations of this gene have been found in the disorder. Subtle mutations tend to retain the phosphorylase kinase activity in blood cells, whereas nonsense mutations cause enzyme deficiency in both liver and blood cells.

AUTOSOMAL LIVER AND MUSCLE PHOSPHORYLASE KINASE DEFICIENCY An autosomal recessive form of liver and muscle phosphorylase kinase deficiency has

been reported in several patients. As in the X-linked form of the disorder, hepatomegaly and growth retardation are the predominant symptoms in early childhood. Some patients also exhibit muscle hypotonia and have reduced activity of phosphorylase kinase in muscle. This form of the phosphorylase kinase deficiency is caused by mutations in theb-subunit of the gene located on chromosome 16q12-13.

AUTOSOMAL LIVER PHOSPHORYLASE KINASE DEFICIENCY In contrast to the benign course of X-linked phosphorylase kinase deficiency, patients with the autosomal recessive form of liver phosphorylase kinase deficiency have more severe phenotypes and often develop liver cirrhosis. This form of phosphorylase kinase deficiency is due to mutations in the testis/liver isoform of the g-subunit gene located on chromosome 16p.

MUSCLE-SPECIFIC PHOSPHORYLASE KINASE DEFICIENCY Muscle-specific phosphorylase kinase deficiency causes cramps and myoglobinuria on exercise or progressive muscle weakness and atrophy. The activity of the enzyme is decreased in muscle but normal (when determined) in liver and blood cells. There is no hepatomegaly or cardiomegaly. The disorder may be due to mutation in the muscle isoform of thea-subunit located on the X chromosome.

CARDIAC-SPECIFIC PHOSPHORYLASE KINASE DEFICIENCY Several sporadic cases of cardiac-specific phosphorylase kinase deficiency have been reported. All patients died during infancy from cardiac failure due to massive glycogen deposition in the myocardium. The molecular basis has not been defined.

Diagnosis Definitive diagnosis of phosphorylase kinase deficiency requires demonstration of the enzymatic defect in affected tissues. Although phosphorylase kinase can be measured in leukocytes and erythrocytes, the enzyme has many tissue-specific isozymes, and the diagnosis can be missed without studies of the liver, muscle, or heart.

TREATMENT

The treatment for liver phosphorylase or phosphorylase kinase deficiency is based on symptoms. A high-carbohydrate diet and frequent feedings are effective in preventing hypoglycemia, but most patients require no specific treatment. Prognosis is usually good; adult patients have normal stature and minimal hepatomegaly. There is no treatment for the fatal form of isolated cardiac phosphorylase kinase deficiency.

Type 0 Glycogen Storage Disease (Glycogen Synthase Deficiency) Strictly speaking, type 0 is not a glycogen storage disease, as the deficiency of the enzyme leads to decreased glycogen stores. The patients present in early infancy with morning drowsiness and fatigue and sometimes convulsions associated with hypoglycemia and hyperketonemia. There is no hepatomegaly or hyperlipidemia. Prolonged hyperglycemia and elevated lactate levels with normal insulin levels after administration of glucose suggest a possible diagnosis of glycogen synthase deficiency. Definitive diagnosis requires a liver biopsy to measure the enzyme activity. Treatment is symptomatic and involves frequent feedings rich in protein and nighttime supplements of uncooked cornstarch to alleviate hypoglycemia. Prognosis is good as patients survive to adulthood with a resolution of hypoglycemia except during pregnancy. Mutations in the liver

glycogen synthase gene (located on chromosome 12p12.2) that cause glycogen synthase deficiency have been identified.

Type XI Glycogen Storage Disease (Hepatic Glycogenosis with Renal Fanconi Syndrome, Fanconi-Bickel Syndrome) This rare autosomal recessive disease is caused by defects in the facilitative glucose transporter 2 (GLUT-2) which transports glucose in and out of hepatocytes, pancreatic cells, and the baso-lateral membranes of intestinal and renal epithelial cells. The disease is characterized by proximal renal tubular dysfunction, impaired glucose and galactose utilization, and accumulation of glycogen in liver and kidney.

GENETIC CONSIDERATIONS

The low prevalence of Fanconi-Beckel syndrome (fewer than 100 cases reported worldwide) is underscored by the fact that consanguinity is found in 70% of the patients with a detectableGLUT-2mutation. The gene for GLUT-2 is located on chromosome 3q26 and most mutations detected so far cause premature termination of translation.

Clinical and laboratory findings The affected child presents in the first year of life with failure to thrive, rickets, and a protuberant abdomen due to liver and kidney enlargement. Laboratory findings include glucosuria, phosphaturia, generalized aminoaciduria, bicarbonate wasting, hypophosphatemia, increased serum alkaline phosphatase levels, and radiologic findings of rickets. Mild fasting hypoglycemia and hyperlipidemia may be present. Liver transaminases, plasma lactate, and uric acid levels are usually normal. Oral galactose or glucose tolerance tests show intolerance to these sugars, which may be caused by the functional loss ofGLUT-2, which prevents liver uptake of these sugars. Tissue biopsies show marked accumulation of glycogen in hepatocytes and proximal renal tubular cells, presumably due to the altered transport of glucose out of these organs.

TREATMENT

There is no specific therapy. Growth retardation persists through adulthood. Symptomatic replacement of water, electrolytes, and vitamin D, restriction of galactose intake, and a diabetes mellitus-like diet, presented in frequent and small meals with a cornstarch supplement, may improve growth.

DISORDERS ASSOCIATED WITH LIVER CIRRHOSIS

Type IV Glycogen Storage Disease (Branching Enzyme Deficiency, Amylopectinosis, or Andersen Disease) Deficiency of branching enzyme activity results in accumulation of an abnormal glycogen with poor solubility. The disease is referred to as *type IV glycogen storage disease or amylopectinosis*, because the abnormal glycogen has fewer branch points, more 1-4 linked glucose units, and longer outer chains, resulting in a structure resembling amylopectin.

GENETIC CONSIDERATIONS

Type IV glycogen storage disease is a rare autosomal recessive disease. Prenatal

diagnosis is available with use of cultured amniocytes or chorionic villi to measure the level of enzymatic activity. The glycogen branching enzyme gene is located on chromosome 3p12. Both hepatic and neuromuscular forms of the disease are caused by mutations in the same branching enzyme gene; its characterization in individual patients may be useful in predicting the clinical course.

Clinical and laboratory findings This disorder is clinically variable. The most common form is characterized by progressive cirrhosis of the liver and is manifest in the first 18 months of life as hepatosplenomegaly and failure to thrive. The cirrhosis progresses to cause portal hypertension, ascites, esophageal varices, and liver failure that leads to death by age 5. Less frequently, patients survive without progression of liver disease.

Tissue deposition of amylopectin-like materials can be demonstrated in liver, heart, muscle, skin, intestine, brain, spinal cord, and peripheral nerve. The histologic findings in the liver are characterized by both micronodular cirrhosis and faintly stained basophilic inclusions in the hepatocytes. The inclusions consist of coarsely clumped, stored material that is periodic acid Schiff-positive and partially resistant to diastase digestion. Electron microscopy shows, in addition to the conventional c and bglycogen particles, an accumulation of fibrillar aggregations typical of amylopectin. Definitive diagnosis requires demonstration that branching enzyme activity is deficient in liver, muscle, cultured skin fibroblasts, or leukocytes.

A neuromuscular form of type IV glycogen storage disease has also been reported. Patients with this disease may present (1) at birth with severe hypotonia, muscle atrophy, and neuronal involvement and die during the neonatal period; (2) in late childhood with myopathy or cardiomyopathy; or (3) as adults with diffuse central and peripheral nervous system dysfunction accompanied by accumulation of polyglucosan bodies in the nervous system (so-called adult polyglucosan body disease). Definitive diagnosis of the adult disease requires assay of the branching enzyme in leukocytes or nerve biopsy, as the deficiency is limited to those tissues.

TREATMENT

There is no specific treatment for type IV glycogen storage disease. For progressive hepatic failure, liver transplantation has been performed. However, caution should be taken in selecting patients for liver transplantation because a nonprogressive hepatic form of the disease exists, and extra hepatic manifestations of the disease may occur after transplantation.

GLYCOGEN STORAGE DISEASES: MUSCLE GLYCOGENOSES

DISORDERS WITH MUSCLE-ENERGY IMPAIRMENT

Type V Glycogen Storage Disease (Muscle Phosphorylase Deficiency, McArdle Disease) Deficiency of muscle phosphorylase is the prototype muscle-energy disorder. Deficiency of this enzyme in muscle limits ATP generation by glycogenolysis and results in glycogen accumulation.

GENETIC CONSIDERATIONS

Type V glycogen storage disease is an autosomal recessive disorder that does not appear to have ethnic predilection. The gene for muscle phosphorylase is located on chromosome 11q13. The most common mutation in patients in the United States is a nonsense mutation that changes an arginine to a stop codon (R49X), and the most common mutation in the Japanese is deletion of a single codon (F708). These features allow DNA-based diagnosis and carrier detection in these two populations.

Clinical and laboratory findings Symptoms usually develop first in adulthood and are characterized by exercise intolerance with muscle cramps. Two types of activity tend to cause symptoms: (1) brief exercise of great intensity, such as sprinting or carrying heavy loads; and (2) less intense but sustained activity, such as climbing stairs or walking uphill. Moderate exercise, such as walking on level ground, can be performed by most patients for long periods. Many patients experience a characteristic "second wind" phenomenon; if they rest briefly at the first appearance of muscle pain, they can resume exercise with more ease. About half of patients report burgundy-colored urine after exercise, the consequence of myoglobinuria secondary to rhabdomyolysis. Intense myoglobinuria after vigorous exercise may cause renal failure. Although most patients are diagnosed in the second or third decade, many report weakness and lack of endurance since childhood. In rare cases, EMG findings may suggest an inflammatory myopathy, and the diagnosis can be confused with polymyositis.

The level of serum creatine kinase is usually elevated at rest and increases more after exercise. Exercise also increases the levels of blood ammonia, inosine, hypoxanthine, and uric acid. The latter abnormalities are attributed to accelerated recycling of muscle purine nucleotides in the face of insufficient ATP production.

Diagnosis Lack of an increase in blood lactate and exaggerated blood ammonia elevations after an ischemic exercise test are indicative of muscle glycogenosis and suggest a defect in the conversion of glycogen or glucose to lactate. The abnormal exercise response, however, is not limited to type V disease and can occur with other defects in glycogenolysis or glycolysis, such as deficiencies of muscle phosphofructokinase or debranching enzyme (when the test is done after fasting). Definitive diagnosis is made by enzymatic assay in muscle tissue or by mutation analysis of the myophosphorylase gene.

TREATMENT

In general, avoidance of strenuous exercise can prevent major episodes of rhabdomyolysis. Exercise tolerance can be augmented by aerobic training or by ingestion of glucose or fructose. A high-protein diet may increase exercise endurance in some patients. Longevity does not appear to be affected.

Type VII Glycogen Storage Disease (Muscle Phosphofructokinase Deficiency, Tarui Disease) Type VII disease is caused by a deficiency of muscle phosphofructokinase, which catalyzes the conversion of fructose-6-phosphate to fructose-1,6-diphosphate and is a key regulatory enzyme of glycolysis.

Phosphofructokinase is composed of three isozyme subunits (M, muscle; L, liver; and P,

platelet), which are encoded by different genes and are differentially expressed in tissues. Skeletal muscle contains only M isozyme, and red blood cells contain a hybrid of L and M forms. Type VII disease is due to defective M isoenzyme, which causes complete enzyme deficiency in muscle and partial deficiency in red blood cells.

GENETIC CONSIDERATIONS

Type VII glycogen storage disease is inherited as an autosomal recessive trait. The disease appears to be rare, and most reported patients are either Ashkenazi Jews or Japanese. The gene for the M isoenzyme is located on chromosome 12q13.3. In Ashkenazi Jews, 95% of mutant alleles are either a splicing defect or a nucleotide deletion.

Clinical and laboratory findings The features are similar to those in type V disease, namely, early onset of fatigue and pain with exercise. Vigorous exercise causes severe muscle cramps and myoglobinuria. However, several features of type VII disease are distinctive. (1) Exercise intolerance is usually evident in childhood, is more severe than in type V disease, and may be associated with nausea and vomiting. (2) A compensated hemolysis occurs as evidenced by an increased level of serum bilirubin and reticulocyte count. (3) Hyperuricemia is common and becomes more marked after exercise. (4) An abnormal glycogen resembling amylopectin is present in muscle fibers; it is periodic acid Schiff-positive and resistant to diastase digestion. (5) Exercise intolerance is particularly acute after meals rich in carbohydrate because glucose cannot be utilized in muscle and because the ingested glucose inhibits lipolysis and thus deprives muscle of fatty acid and ketone substrates. In contrast, patients with type V disease can metabolize glucose derived from either liver glycogenolysis or exogenous glucose. Indeed, glucose infusion improves exercise tolerance in patients with type V disease.

Two rare type VII variants have been reported. One begins in infancy with hypotonia and limb weakness, and a rapidly progressive myopathy leads to death by age 4. The other occurs in adults and is characterized by a slowly progressive, fixed muscle weakness rather than by cramps and myoglobinuria.

Diagnosis The M isoenzyme defect must be demonstrated in muscle, red blood cells, or cultured skin fibroblasts by biochemical or histochemical techniques.

TREATMENT

There is no specific treatment. Avoidance of strenuous exercise prevents acute attacks of muscle cramps and myoglobinuria.

Other Muscle Glycogenoses with Muscle-Energy Impairment Five additional enzyme defects produce muscle glycogenoses, namely, deficiencies in phosphoglycerate kinase, phosphoglycerate mutase, lactate dehydrogenase, fructose 1,6-bisphosphate aldolase A, and pyruvate kinase. All five enzymes affect terminal glycolysis, and deficiency causes muscle-energy impairment similar to that in type V and type VII disease. The failure of blood lactate to increase in response to exercise can be used to separate muscle glycogenoses from disorders of lipid metabolism, such as carnitine palmitoyl transferase II deficiency and very long chain acyl-coenzyme A

dehydrogenase deficiency, which also cause muscle cramps and myoglobinuria. Muscle glycogen levels may be normal in the disorders affecting terminal glycolysis, and definitive diagnosis is made by assaying the enzymatic activity in muscle.

DISORDERS WITH PROGRESSIVE SKELETAL MUSCLE MYOPATHY AND/OR CARDIOMYOPATHY

Type II Glycogen Storage Disease (Acid a-1,4 Glucosidase Deficiency, Pompe Disease) (See alsoChap. 349) Type II disease is caused by a deficiency of lysosomal acid a-1,4 glucosidase (acid maltase), an enzyme responsible for the degradation of glycogen in lysosomal vacuoles. It is characterized by the accumulation of glycogen in lysosomes as opposed to its accumulation in cytoplasm in the other glycogenoses.

GENETIC CONSIDERATIONS

Pompe disease is an autosomal recessive disorder and does not appear to have an ethnic predilection. The gene for acid a-glucosidase is on chromosome 17q25. A splice site mutation (IVS1-13TG) is common in patients with adult-onset disease. Prenatal diagnosis with amniocytes or chorionic villi is available.

Clinical and laboratory findings The disorder encompasses a range of phenotypes, each including myopathy but differing in age of onset, organ involvement, and clinical severity. The most severe is the infantile-onset disease with cardiomegaly, hypotonia, and death before 1 year of age. Infants appear normal at birth but soon develop generalized muscle weakness with feeding difficulties, macroglossia, hepatomegaly, and congestive heart failure due to a hypertrophic cardiomyopathy. Electrocardiographic findings include a high-voltage QRS complex and a shortened PR interval. Death usually occurs from cardiorespiratory failure.

The juvenile or late-childhood form is characterized by skeletal muscle manifestations, usually without cardiac involvement, and a slowly progressive course. The juvenile form typically presents as delayed motor milestones (if age of onset is early enough) and difficulty in walking; these manifestations are followed by swallowing difficulties, proximal muscle weakness, and respiratory muscle involvement. This form can cause death before the end of the second decade.

An adult form of type II disease presents as a slowly progressive myopathy without cardiac involvement and has its onset between the second and seventh decades. The clinical picture is dominated by slowly progressive proximal muscle weakness with truncal involvement. The pelvic girdle, paraspinal muscles, and the diaphragm are most seriously affected. The initial symptoms may be respiratory insufficiency manifested by somnolence, morning headache, orthopnea, and exertional dyspnea.

Laboratory findings include elevated levels of serum creatine kinase, aspartate transaminase, and lactate dehydrogenase, particularly in infants. Muscle biopsy shows the presence of vacuoles that stain positively for glycogen, and muscle acid phosphatase is increased, presumably from a compensatory increase of lysosomal enzymes. Electron microscopy reveals the glycogen accumulation. EMG reveals myopathic features with irritability of muscle fibers and pseudomyotonic discharges.

Serum creatine kinase is not always elevated in adults and, depending on the muscle biopsied or tested, muscle histology or EMG may not be abnormal. It is prudent to examine affected muscle.

Diagnosis Diagnosis can be established by demonstration of the absence or reduced levels of acid a-glucosidase activity in muscle or cultured skin fibroblasts. Deficiency is usually more severe in the infantile form than in the juvenile and adult disorders.

TREATMENT

No effective treatment for the infantile form is currently available. Enzyme replacement is a promising therapy for this fatal lysosomal storage disease, and clinical trials are ongoing to test its safety and efficacy. A high-protein diet may be useful for the juvenile and adult forms. Nocturnal ventilatory support can improve the quality of life.

DISORDERS OF GALACTOSE METABOLISM

GALACTOSE 1-PHOSPHATE URIDYL TRANSFERASE DEFICIENCY GALACTOSEMIA

"Classic" galactosemia is a serious disease with an early onset of symptoms; the incidence is 1 in 60,000. The newborn infant normally receives up to 20% of caloric intake as lactose, which consists of glucose and galactose. Without the transferase, the infant is unable to metabolize galactose 1-phosphate (Fig. 350-1), the accumulation of which results in injury to parenchymal cells of the kidney, liver, and brain.

GENETIC CONSIDERATIONS

Galactosemia caused by transferase deficiency is inherited as an autosomal recessive trait; there are several enzymatic variants. The Duarte variant exhibits diminished red cell enzyme activity that is usually of no clinical significance. Some African-American patients have milder symptoms despite the absence of measurable transferase activity in erythrocytes; these patients retain 10% of the enzyme activity in liver and intestinal mucosa. Most Caucasian patients have no detectable enzyme activity in any of these tissues. The gene for galactose-1 phosphate uridyl transferase is located on chromosome 9p13. In African Americans, 48% of the mutant alleles are represented by the S135L substitution, perhaps accounting for the milder phenotype. In the Caucasian population, 70% of mutant alleles are represented by the Q188R substitution. Carrier testing and prenatal diagnosis can be carried out by direct enzyme analysis of amniocytes or chorionic villi. DNA-based testing can also be performed.

Clinical and laboratory findings The clinical manifestations of uridyl transferase deficiency are myriad, necessitating a high index of suspicion if the diagnosis is to be made. Clinical features may include: jaundice, hepatomegaly, vomiting, hypoglycemia, convulsions, lethargy, irritability, feeding difficulties, poor weight gain, aminoaciduria, cataracts, vitreous hemorrhage, hepatic cirrhosis, ascites, splenomegaly, or mental retardation. Patients with galactosemia are at increased risk for *Escherichia coli* neonatal sepsis; the onset of sepsis often precedes the diagnosis of galactosemia. When the diagnosis is not made at birth, damage to the liver (cirrhosis) and brain

(mental retardation) becomes increasingly severe and irreversible. For this reason, routine neonatal screening tests for galactosemia have been instituted in many parts of the world.

Diagnosis The preliminary diagnosis of galactosemia is made by demonstrating a reducing substance (by Clinitest) in urine specimens collected while the patient is receiving human or cow's milk or another formula containing lactose. The reducing substance found in urine, which is negative in a glucose oxidase test, can be identified as galactose with chromatography or an enzymatic test specific for galactose. Definitive diagnosis requires the demonstration of deficient activity of galactose-1-phosphate uridyl transferase in erythrocytes or other tissues, which also exhibit increased concentrations of galactose-1-phosphate.

TREATMENT

Because of widespread newborn screening for galactosemia, patients are now being identified and treated early. Elimination of galactose from the diet reverses growth failure, renal, and hepatic dysfunction. Cataracts regress and most patients have no impairment of eyesight. Early diagnosis and treatment have improved the prognosis of galactosemia; on long-term follow-up, however, patients still have ovarian failure manifest as primary or secondary amenorrhea, as well as developmental delay and learning disabilities, which increase in severity with age. In addition, most patients have speech disorders and a smaller number demonstrate poor growth and impaired motor function and balance (with or without overt ataxia). The relative control of galactose-1-phosphate levels does not always correlate with long-term outcome, suggesting that other factors, such as uridine diphosphate (UDP)-galactose deficiency (a donor for galacto-lipids and proteins), may be responsible for some of the metabolic consequences of the disease.

GALACTOKINASE DEFICIENCY

In contrast to the multiple systems that are affected in uridyl transferase deficiency, cataracts are usually the sole manifestation of galactokinase deficiency. The affected infant is otherwise asymptomatic. This disorder is characterized by elevated blood galactose levels with normal uridyl transferase activity and an absence of galactokinase activity in erythrocytes. Treatment is dietary restriction of galactose intake. Mutations leading to galactokinase deficiency have been identified in the gene coding for galactokinase (located on chromosome 17q24).

URIDINE DIPHOSPHATE GALACTOSE 4-EPIMERASE (UDP GAL 4-EPIMERASE) DEFICIENCY

The abnormally accumulated metabolites in this disorder are very much like those seen in uridyl transferase deficiency; however, there is also an increase in cellular UDP galactose. There are two distinct forms of epimerase deficiency. A benign form was discovered incidentally as a result of the neonatal screening program. Affected persons in this case are healthy; the enzyme deficiency is limited to leukocytes and erythrocytes, without deranged metabolism in other tissues, and no treatment is required. The second form of epimerase deficiency is severe with clinical manifestations resembling uridyl

transferase deficiency. Additional features include hypotonia and nerve deafness. The enzyme deficiency is generalized, and clinical symptoms respond to restriction of dietary galactose. Although this form of galactosemia is very rare, it must be considered in a symptomatic patient who has normal transferase activity. The gene for epimerase is located on chromosome 1p35-36; mutations responsible for both forms of the epimerase deficiency have been identified.

DISORDERS OF FRUCTOSE METABOLISM

DEFICIENCY OF FRUCTOKINASE (BENIGN FRUCTOSURIA)

This condition is not associated with any clinical manifestations. It is an incidental finding, usually made through the detection of fructose as a reducing substance in the urine. No treatment is necessary.

DEFICIENCY OF FRUCTOSE 1,6-BISPHOSPHATE ALDOLASE (ALDOLASE B) (HEREDITARY FRUCTOSE INTOLERANCE)

This is a severe disease of infants that appears with the ingestion of fructose-containing food. It is caused by deficiency of fructose 1,6-bisphosphate aldolase B activity in the liver, kidney, and intestine. The enzyme catalyzes the hydrolysis of fructose 1-phosphate and fructose 1,6-bisphosphate into the 3-carbon sugars, dihydroxyacetone phosphate, glyceraldehyde-3-phosphate, and glyceraldehyde (Fig. 350-1). Deficiency of this enzyme activity causes rapid accumulation of fructose 1-phosphate and initiates severe toxic symptoms when exposed to fructose.

GENETIC CONSIDERATIONS

The true incidence of hereditary fructose intolerance is not known but may be as high as 1 in 23,000. The gene for aldolase B is on chromosome 9q22.3. Several mutations causing heredity fructose intolerance have been identified. A single missense mutation, which results in substitution of proline for alanine at position 149, is the most common mutation identified in northern Europeans. This mutation plus two other point mutations account for approximately 80 to 85% of hereditary fructose intolerance in Europe and the United States. The diagnosis of hereditary fructose intolerance can thus be made in most cases by direct DNA analysis. Prenatal diagnosis should be possible from either amniocentesis or chorionic villi with the use of DNA for mutational or linkage analysis.

Clinical and laboratory findings Patients with fructose intolerance are healthy and asymptomatic until fructose or sucrose (table sugar) is ingested (usually from fruit, fruit juice, or sweetened cereal). Clinical manifestations may resemble those of galactosemia and include jaundice, hepatomegaly, vomiting, lethargy, irritability, and convulsions. Laboratory findings include prolonged clotting time, hypoalbuminemia, elevation of bilirubin and transaminases, and proximal renal tubular dysfunction. If the disease is not diagnosed and intake of the noxious sugar persists, hypoglycemic episodes recur, and liver and kidney failure progress, eventually leading to death.

Diagnosis Suspicion of the enzyme deficiency is suggested by the presence of a reducing substance in the urine during an attack. The diagnosis is supported by an

intravenous fructose tolerance test, which will cause a rapid decline of serum phosphate, followed by blood glucose, and a subsequent rise of uric acid and magnesium. An oral tolerance test should not be performed as patients may become acutely ill. Definitive diagnosis is made by assay of fructaldoase B activity in the liver.

TREATMENT

Treatment consists of the complete elimination of all sources of sucrose, fructose and sorbitol from the diet. With this treatment, liver and kidney dysfunction improve, and catch-up growth is common. Intellectual development is usually unimpaired. As the patient matures, symptoms become milder, even after fructose ingestion, and the long-term prognosis is good. Owing to dietary avoidance of sucrose, affected patients have few dental caries.

FRUCTOSE 1,6-DIPHOSPHATASE DEFICIENCY

Fructose 1,6-diphosphatase deficiency is a defect in gluconeogenesis. The disease is characterized by life-threatening episodes of acidosis, hypoglycemia, hyperventilation, convulsions, and coma. These episodes are triggered by febrile infections and gastroenteritis when oral food intake decreases. Laboratory findings include low blood glucose, high lactate and uric acid levels, and a blood gas picture of metabolic acidosis. In contrast to hereditary fructose intolerance, there is usually no aversion to sweets, and renal tubular and liver functions are normal. Treatment of acute attacks consists of correction of hypoglycemia and acidosis by intravenous infusion; the response is usually rapid. Later, avoidance of fasting and elimination of fructose and sucrose from the diet prevent further episodes. For long-term prevention of hypoglycemia, a slowly released carbohydrate such as cornstarch is useful. Patients who survive childhood seem to develop normally.

Diagnosis The diagnosis is established by demonstrating enzyme deficiency in either the liver or an intestinal biopsy specimen. The enzyme defect may also be demonstrated in leukocytes in some cases. The gene coding for fructose 1,6-diphosphatase is located on chromosome 9q22. In patients with known mutations, carrier detection and prenatal diagnosis are possible by DNA-based testing.

351. INHERITED DISORDERS OF CONNECTIVE TISSUE - *Darwin J. Prockop*, *Helena Kuivaniemi*, *Gerard Tromp*, *Leena Ala-Kokko*

Heritable disorders that involve the major connective tissues of the body such as bone, skin, cartilage, blood vessels, and basement membranes are among the most common genetic diseases in human beings. Here we will focus primarily on those disorders that can have severe manifestations, are relatively common, and are sufficiently understood at the molecular level to provide useful paradigms: osteogenesis imperfecta (OI), the Ehlers-Danlos syndrome (EDS), chondrodysplasias (CDs), the Marfan syndrome (MFS), epidermolysis bullosa (EB), and the Alport syndrome (AS).

THE CHALLENGE OF CLASSIFYING THE DISEASES

The original classification of connective tissue diseases was based on the pattern of inheritance, the cluster of signs and symptoms, the histologic changes in tissues, and limited information about the molecular defects involved. This classification included about a dozen types and subtypes forOI, about the same number for theEDS, and over 150 for theCDs. Several limitations in these original classifications are now apparent. One is that the same mutation does not always produce the same disease phenotype in terms of severity of the condition or its clinical course. Such phenotypic variation occurs in many genetic diseases, including the connective tissue disorders, in which some members of a family are severely affected, whereas others with the same mutation have a mild disorder.

Most patients with classic features of a severe connective tissue disease have a mutation in a gene or genes coding for a single protein. For example, the majority of patients withOI have a mutation in one of the two genes coding for type I procollagen. Similarly, most patients withMFS have mutations in a gene for fibrillin. For other disease categories, the situation is more complex. InEDS, for example, the type IV variant is usually caused by mutations in the gene for type III procollagen, the type VI variant by defects in the gene for lysyl hydroxylase, and the type VII variant by defects that impair the processing of type I procollagen to type I collagen.

Classifications of these disorders also tend to overemphasize the etiologic differences between severe genetic diseases that are apparent in infants and the more common diseases that appear much later in life. Single-gene defects can cause subsets of late-onset diseases such as osteoporosis, aneurysms, and osteoarthritis. For example, a small subset of patients with postmenopausal osteoporosis have mutations in the genes for procollagen I similar to the mutations in the same genes that produce lethal variants ofOI. Likewise, a subset of patients with familial aortic aneurysms have mutations in the gene for procollagen III similar to the mutations in the same gene that cause lethal variants of type IVEDS, and occasional patients with osteoarthritis have mutations in the gene for procollagen II similar to the mutations in the same gene that cause lethalCDs. There is disagreement as to the best diagnosis for such patients in that some investigators feel that after a mutation similar to those seen in the early-onset diseases is identified, the patients should be reclassified as having mild forms of OI, EDS, or CD, even though they do not have definitive evidence of the early-onset diseases or seek medical attention until adulthood. Therefore, the category of diseases referred to as *inherited disorders of connective tissue* may have to be expanded as we

obtain additional information about more common diseases.

DEFINITION AND COMPOSITION OF CONNECTIVE TISSUES

Connective tissues are composed of specific macromolecules, many of which are also constituents of the lung, the kidney, the walls of blood vessels, the vitreous gel of the eye, and the synovial fluid. Indeed, most organs and tissues contain small amounts of the same macromolecules assembled into membranes and septa. Therefore, virtually all structures contain some connective tissue.

The distinguishing feature of connective tissues is that the component macromolecules are assembled into an insoluble extracellular matrix (Table 351-1). The macromolecules include at least 19 different types of collagens, the related fibrous proteins known as *elastin* and *fibrillin*, a series of proteoglycans, and components whose structure and function are only partially defined.

Differences in the connective tissues of bone, skin, and cartilage are in part explained by differences in the content of specific components (Table 351-1). For example, tendons and ligaments consist primarily of type I collagen fibrils and small amounts of other components that help organize the type I fibrils into fibers and fiber bundles. Cartilage consists primarily of fibrils of type II collagen in the form of arcades that are distended by highly charged proteoglycans. The extracellular matrix of the aorta contains collagens that provide tensile strength and elastin that provides elasticity. Differences among the connective tissues also depend on the three-dimensional organization of the molecular components. The type I collagen fibrils in tendon are packed into thick, parallel bundles of fibers, whereas type I collagen fibrils in skin are randomly oriented. In cortical bone, helical arrays of type I collagen fibrils are deposited around haversian canals.

BIOSYNTHESIS OF CONNECTIVE TISSUE

Connective tissues form primarily by a process of self-assembly, in which a molecule of the correct size, shape, and surface properties binds to other molecules with the same or similar structure in a spontaneous but ordered manner. The molecular mechanisms and driving forces are similar to those involved in crystal formation.

Collagen Synthesis The self-assembly of connective tissue is illustrated by the assembly of collagen into fibrils. The collagen molecule that forms fibrils is a long, thin rod consisting of three polypeptide a chains wrapped into a rigid, ropelike triple helix (Fig. 351-1). The molecule has a triple-helical conformation, because each of the three a chains has a simple, repetitive amino acid sequence of about 1000 amino acids in which glycine (Gly) appears as every third amino acid. Therefore, the sequence of eacha chain can be designated as $(\text{-Gly-X-Y-})_{333}$, where X and Y represent amino acids other than glycine. To fold into a triple helix, every third amino acid in an a chain must be glycine, the smallest amino acid, since this residue must fit in a sterically restricted space where the three chains of the triple helix come together. Many of the X- and Y-position amino acids are proline and hydroxyproline, which provide rigidity to the triple helix. The remaining amino acids form clusters of hydrophobic and charged regions on the surface of the molecule that direct how one molecule spontaneously binds to other

collagen molecules and thereby self-assembles into the large collagen fibrils in tissues (seeFig. 351-1).

More than 19 different collagens have been identified. Most are minor constituents that probably have highly specialized functions. The fibrillar collagens are found in tissues as long, highly ordered fibrils with a characteristic banding pattern by electron microscopy. Type I collagen, the most abundant, is found as cross-striated fibrils in a large number of tissues (Table 351-1). It is composed of two identicala chains called a1(I) and a third called a2(I). Type II collagen, another fibrillar collagen of cartilage, is composed of three identicala chains called a1(II). Type III collagen is found in small amounts in many tissues that contain type I collagen and in large amounts in large blood vessels; it is composed of three identical chains called a1(III). The nonfibrillar collagens are similar to the fibrillar collagens in that they contain -Gly-X-Y- sequences of amino acids that form triple-helical domains, but they also contain large globular domains. Self-assembly of most of the nonfibrillar collagens usually involves binding between the globular domains to form networks. For example, the type IV collagen in basement membranes self-assembles into a complex three-dimensional network that provides a diffusion barrier in the renal glomerulus and pulmonary alveolus. The network also provides support for epithelial and endothelial cells in these tissues and in skin, the gastrointestinal tract, and blood vessels. Some nonfibrillar collagens bind to the surface of fibrils formed by the more abundant collagens and alter the lateral growth of the fibrillar collagens or prevent the fibrils from coalescing into fiber bundles.

Because the molecules or monomers fibrillar collagens spontaneously self-assemble into fibrils, they are first synthesized as larger and more soluble precursors called *procollagens* and composed of proa chains. As the proa chains of procollagen are synthesized on ribosomes, the free ends move into the cisternae of the rough endoplasmic reticulum (Fig. 351-1). Hydrophobic signal peptides at the N termini are cleaved, and additional posttranslational reactions begin. Proline residues in the Y position of the repeating -Gly-X-Y- sequences are converted to hydroxyproline by prolyl hydroxylase in a reaction requiring ascorbic acid. Lysine residues in the Y position are similarly hydroxylated to hydroxylysine by lysyl hydroxylase. Many of the hydroxylysine residues are glycosylated with galactose or with galactose and glucose. A large mannose-rich oligosaccharide is assembled on the C-terminal propeptide of each chain. The association of the proa chains is directed by the structure and the surface properties of the globular C-propeptides. After the C-propeptides assemble correctly, the structure is locked in place by the formation of interchain disulfide bonds. Posttranslational modifications of the proa chains continue until each chain acquires about 100 hydroxyproline residues. Then a few of the hydroxyproline-rich -Gly-X-Y- sequences at the C terminus of the protein fold into a triple helix. The short region of triple helix becomes a nucleus for self-assembly of the triple helix of the whole protein, much like a nucleus for crystallization, in that the triple-helical conformation in one -Gly-X-Y- sequence induces the next -Gly-X-Y- sequence to fold into the same conformation. As a result, the conformation is propagated in a zipper-like fashion from the C terminus to the N terminus of the molecule, and the entire a-chain domain becomes a continuous triple helix. The protein then passes from the rough endoplasmic reticulum to other compartments and is secreted. The requirement for ascorbic acid in the hydroxylation of prolyl residues explains why wounds fail to heal in scurvy (Chap. 75). If sufficient proline residues are not converted to hydroxyproline, collagen cannot

fold into a triple helix that is stable at body temperature. The abnormal protein accumulates in the cisternae of the rough endoplasmic reticulum and is slowly degraded.

After secretion, procollagen is processed to collagen by cleavage of the N-propeptides by procollagen N-proteinase and of the C-propeptides by procollagen C-proteinase. The processing of type I procollagen by the two proteinases converts the precursor to type I collagen and thereby decreases the solubility of the protein about 1000-fold. The 1000-fold decrease in solubility provides the entropic energy that drives the spontaneous self-assembly of the collagen into fibrils. Collagen monomers first assemble into a nucleus that grows by addition of monomers as determined by the structure of the nucleus. The nucleus and the final fibril can be assembled spontaneously from a single kind of collagen such as type I or type II. Fibrils can also be assembled as copolymers in which two or more collagens are incorporated into the same fibril simultaneously. Alternatively, a second collagen or a proteoglycan can bind to the surface of a growing fibril or to a fully formed fibril and thereby influence the final structure and the functional properties of the fibrils. The final structure of the fibrils in tissues is also influenced by the pressure and tensions on the fibrils, particularly after their tips are inserted into muscle and bone. The tension on tendons, for example, probably makes the initial thin fibrils coalesce into large fiber bundles.

Self-assembled collagen fibers have considerable tensile strength, which is increased by cross-linking reactions that form covalent bonds between a chains in one molecule and a chains in adjacent molecules. The first step in cross-linking is oxidation by lysyl oxidase of amino groups on a few lysine or hydroxylysine residues to form aldehydes that interact to form stable covalent bonds.

During growth and development, the collagen fibrils in all tissues undergo repeated synthesis, degradation, and resynthesis. The degradation of collagen fibers in tissues is initiated by specific collagenases found in leukocytes, fibroblasts, synovial cells, or related cell types. The collagenases cleave the collagen molecule at a point about three-quarters of the distance from its N terminus. The cleavage apparently triggers unfolding of the molecules on the surface of a fibril and further degradation by other proteinases.

Collagen fibers in most tissues of normal adults undergo very little metabolic turnover. One exception to this is the collagen fibrils that are degraded and resynthesized as part of the continual remodeling of bone. Although the collagen in many adult tissues is metabolically stable, the rate of turnover changes under some circumstances. In starvation, a large fraction of the collagen in skin and other connective tissues is degraded, thus providing amino acids for gluconeogenesis. Large losses of collagen also occur in most connective tissues during immobilization or prolonged periods of low-gravitational stress. In rheumatoid arthritis, pannus invasion causes a rapid degradation of collagen in the articular cartilage. Glucocorticoids decrease the collagen content of most connective tissues, including bone, by decreasing the rate of collagen synthesis. Decreases in collagen weaken tissues. In many pathologic states, however, collagen is deposited in excess. With injury to tissue, inflammation is usually followed by increased deposition primarily of type I collagen fibrils in the form of fibrotic tissue and scars. The deposition of collagen fibrils during the repair process is largely irreversible

and is a major feature of the pathologic changes in hepatic cirrhosis, pulmonary fibrosis, atherosclerosis, and nephrosclerosis and in the scarring in skin and ligaments after surgery or trauma.

Elastin Synthesis Elastin assembly appears to be closely related to that of collagen, since a few of the prolines in the protein are hydroxylated to hydroxyproline by prolyl hydroxylase. The elastin monomer, however, is a single polypeptide that does not fold into a defined three-dimensional structure and is not synthesized as a larger precursor molecule. Instead, it is slowly secreted from cells into extracellular compartments, where it forms amorphous deposits around previously deposited microfibrils. The elastin deposits then become covalently cross-linked through oxidation of lysine residues to aldehydes by the same lysyl oxidase that initiates the cross-linking of collagen. The microfibrils in elastin deposits are largely composed of fibrillin, a large protein that forms beadlike strands.

Proteoglycan Synthesis The synthesis of proteoglycans begins in the cisternae of the rough endoplasmic reticulum with assembly of a core protein that then undergoes modification by sugar and sulfate transferases that generate large side chains of glycosaminoglycans. At least 30 proteoglycans have been identified by differences in the structures of their core proteins. The major proteoglycan of cartilage, called *aggrecan*, has a core protein of about 2000 amino acids to which are bound multiple side chains of chondroitin sulfate and keratin sulfate, polysaccharides consisting of highly charged and repetitive disaccharide sequences. After secretion from cells, the aggrecan monomer binds to a smaller protein called a *link protein*. The complex of core protein and link protein then spontaneously binds to a long chain of hyaluronic acid to form a huge copolymer called a *proteoglycan aggregate*. The highly charged proteoglycan aggregate binds water and small ions and thereby provides a large swelling pressure and resiliency to cartilage. Smaller proteoglycans such as decorin, biglycan, and fibromodulin have smaller core proteins with fewer and different polysaccharide side chains. They do not form large aggregates with hyaluronate but bind to fibrils of collagen or fibronectin and may thereby help regulate the assembly or spatial orientation of fibrils. One group of small proteoglycans known as *syndecans* binds to the plasma membranes of cells and may have a role in cell migration along fibrils or in signal transduction.

The assembly of bone follows much the same principles as the assembly of other connective tissues (Chap. 340). The first step is deposition of osteoid tissue that consists largely of type I collagen fibrils. Mineralization of osteoid occurs by steps that are still incompletely defined; proteins such as osteopontin and osteocalcin probably bind to the collagen fibrils and chelate calcium to initiate mineralization. Small proteoglycans such as decorin or fibromodulin may also play a role.

MUTATIONS THAT PRODUCE DISEASES OF CONNECTIVE TISSUES

Because of the large number of tissue-specific macromolecules present in connective tissues, a large number of gene-protein systems are candidates for mutations that might cause disease of the tissues.

The most complete data on mutations causing heritable disorders of connective tissue

are available onOI. Most patients with severe OI (types II and III) have mutations in either the gene for the proa1(I) chain or the gene for the proa2(I) chain of type I procollagen (the COL1A1 and COL1A2 genes). In patients with mild disease, many of the mutations decrease expression of protein from one allele of the genes. Most of the mutations in patients with severe OI cause synthesis of a structurally abnormal but partially functional proa chain. Mutations that cause synthesis of structurally abnormal proa chains include partial gene deletions, partial gene duplications, and RNA splicing mutations. The most common mutations, however, cause the substitution of single amino acids with bulky side chains for the glycine residues that appear as every third amino acid in the triple helix of a proa chain (Fig. 351-2). The structurally abnormal proa chains exert their effects primarily through one of three mechanisms (Fig. 351-1). First, the presence of an abnormal proa chain in a procollagen molecule containing two normal proa chains can prevent folding of the protein into a triple-helical conformation and lead to degradation of the whole molecule in a process called *procollagen suicide*. Similar dominant negative mutations are seen with other multisubunit proteins. The net result of procollagen suicide is accumulation of the unfolded protein in the rough endoplasmic reticulum of cells and a reduction in the amount of collagen available for fibril assembly. Second, the presence of one abnormal proa chain in a procollagen molecule can interfere with cleavage of the N-propeptide from the protein. The persistence of the N-propeptide on a fraction of the molecules interferes with the self-assembly of normal collagen so that thin and irregular collagen fibrils are formed. Third, the substitution of a bulkier amino acid for glycine can produce a change in the conformation of the molecule and result in the assembly of collagen fibrils that are abnormally branched or abnormally thick and short. Also, copolymerization of the mutated collagen with normal collagen can slow fibril assembly and decrease the total amount of collagen incorporated into fibrils.

Over 300 mutations in the two genes for type I procollagen have been found in patients withOI(Fig. 351-2). Initially, there was concern that many of the mutations might be neutral variations in the structure of the genes and not the cause of the disease phenotypes. However, the causal relationship between most of the mutations and the disease has been established by several kinds of evidence: (1) DNA linkage studies in families with mild variants of OI showed that specific mutated alleles were coinherited with the disease phenotypes. (2) Probands with lethal variants of OI were shown to have new mutations not found in the normal parents or in only a few cells from a mosaic parent (see below). (3) Studies with cultured skin fibroblasts from patients demonstrated that the mutations either produced specific disruptions in the biosynthesis of type I procollagen or caused synthesis of a type I procollagen that formed abnormal collagen fibrils (Fig. 351-1). (4) The mutations in probands with OI were not found in normal alleles for the genes. (5) Expression of several of the mutated genes for type I procollagen in transgenic mice generated disease phenotypes similar to those seen in patients who inherited the mutated genes (Fig. 351-3).

The data on mutations in type I procollagen that causeOI have been used as a paradigm for defining other mutations in other collagen and procollagen genes that cause other disorders of connective tissue. For example, similar mutations in the gene for type III procollagen occur in patients with the type IV variant ofEDS, which causes early death because of rupture of the aorta or other hollow organs (Fig. 351-4). Also, similar mutations in the gene for type II procollagen (COL2A1) are found in a number of

patients withCDs(Fig. 351-5). In addition, transgenic mice expressing mutated genes for type II procollagen develop phenotypes resembling the CDs. Similar mutations in the gene for type VII collagen (COL7A1) are found in patients with the dystrophic form ofEB, and mutations in the genes for type IV collagen are found in many patients withAS. As discussed below, the paradigm for defining the consequences of mutations in procollagen genes also helps explain findings on mutations in a fibrillin gene that causeMFS and mutations in keratin genes that cause the simplex variant of EB.

Several generalizations can be made about mutations in collagen genes. One is that unrelated patients rarely have the same mutation in the same gene. Another is that mutations that cause the most severe disease are usually new mutations in one allele that occur either during the generation of the germline in one of the parents or during meiosis in the fertilized egg (Chap. 65). Still another generalization is that most mild variants are caused by mutations that are specific or "private" to a given family. Indeed, the number of recurrent mutations in structural genes are so infrequent that there are, in effect, no common mutations responsible for the disorders in unrelated patients and no "hot spots" that contain most of the mutations.

Another general trend is that similar mutations in the same gene can produce different disease syndromes in terms of both severity and the major tissues involved. One reason for heterogeneity in pathologic manifestations is that different regions of a large molecule may be more important for its function in some connective tissues than in others. For example, some regions of the type I collagen molecule may be essential for the binding of mineralizing proteins in bone so that mutations in these regions cause fragile bones but do not impair function in skin and other nonmineralizing tissues. It is more difficult, however, to explain how the same mutation can produce a severe phenotype in some and a mild phenotype in other members of the same family. Such phenotypic variation appears to be characteristic ofOI, where some subjects are short and have multiple fractures from minor trauma, whereas others in the same family can be of normal stature and free of fractures. In the past, such phenotypic variation was explained by undefined variations in the genetic background of different family members. Studies in transgenic mice, however, demonstrated similar phenotypic variation with expression of a mutated collagen gene in an inbred strain of mice in whom the genetic background is uniform. Therefore, the phenotypic variation is probably caused by undefined stochastic or chance events during embryonic and fetal development. Although dramatic phenotypic variations are relatively rare in OI and related disorders, it is important to consider in counseling families about the consequences of inherited mutations.

OSTEOGENESIS IMPERFECTA

OIis an inherited disorder that causes a generalized decrease in bone mass (osteopenia) and makes the bones brittle. The disorder is frequently associated with blue sclerae, dental abnormalities (dentinogenesis imperfecta), progressive hearing loss, and a positive family history. The most severe forms cause death in utero, at birth, or shortly thereafter. The course of mild and moderate forms is more variable. Some patients appear normal at birth and become progressively worse. Some have multiple fractures in infancy and childhood, improve after puberty, and fracture more frequently later in life. Women are particularly prone to fracture during pregnancy and after

menopause. A few women from families with mild variants of OI do not develop fractures until after menopause, and their disease may be difficult to distinguish from postmenopausal osteoporosis.

Classification The most common classification forOI was developed by Sillence (Table 351-2). Type I, the mildest form, is inherited as an autosomal dominant trait. Most patients have distinctly blue sclerae. Type I is subdivided into types IA and IB depending on whether or not dentinogenesis imperfecta is present. Type II is lethal in utero or shortly after birth. Radiographic criteria can be used to subdivide type II into five groups, with subgroup 1 showing the most severe changes and subgroup 5 the least. Types III and IV OI are intermediate in severity between types I and II. They differ from type I because of lesser severity and because the sclerae are only slightly bluish in infancy and white in adulthood. Type III differs from type IV in that it tends to become more severe with age. Also, type III can be inherited either as an autosomal recessive or autosomal dominant trait, whereas type IV is always dominant. The clinical courses are variable, and the mode of inheritance in types III and IV may be difficult to ascertain because many patients have sporadic mutations and because many couples with one child severely affected by OI do not have additional children. For these and related reasons, the distinction between type IV OI and other severe variants of OI may not be helpful. Therefore, it may be sufficient to classify patients simply as mild (type I), lethal (type II), and moderately severe (type III).

Incidence Type IOI has a frequency of about 1 in 30,000. Type II OI has a reported incidence at birth of about 1 in 60,000, but the incidence of the three severe forms recognizable at birth (types II, III, and IV) may be as high as 1 in 20,000.

Skeletal Changes In type IOI, the fragility of bones may be severe enough to limit physical activity or so mild that individuals are unaware of any disability. Radiographs of the skull of patients with mild disease may show a mottled appearance because of small islands of irregular ossification. In type II OI, bones and other connective tissues are so fragile that massive injuries can occur in utero or during delivery (Fig. 351-3). Ossification of many bones is frequently incomplete. Continuously beaded or broken ribs and crumpled long bones (accordina femora) may be present. For unclear reasons, the long bones may be either thick or thin. In types III and IV, multiple fractures from minor physical stress can produce severe deformities. Kyphoscoliosis can impair respiration, cause cor pulmonale, and predispose to pulmonary infections. The appearance on radiographs of "popcorn-like" deposits of mineral on the ends of long bones is an ominous sign. Progressive neurologic symptoms may result from basilar compression and communicating hydrocephalus.

In all forms ofOI, bone mineral density in unfractured bone is decreased. However, the degree of osteopenia may be difficult to evaluate because recurrent fractures limit exercise and thereby worsen the decrease in bone mass. Surprisingly, fractures appear to heal normally.

Ocular Changes The sclerae can be normal, slightly bluish, or bright blue. The color is probably caused by a thinness of the collagen layers of the sclerae that allows the choroid layers to be seen. Blue sclerae, however, are an inherited trait in some families who do not have increased bone fragility.

Dentinogenesis Imperfecta The teeth may be normal, moderately discolored, or grossly abnormal. The enamel generally appears normal, but the teeth may have a characteristic amber, yellowish brown, or translucent bluish gray color because of improper deposition or deficiency of dentin. The deciduous teeth are usually smaller than normal, whereas permanent teeth are frequently bell-shaped and restricted at the base. In some patients, the teeth readily fracture and need to be extracted. The defect in dentin is directly attributable to the fact that normal dentin is rich in type I collagen. Similar tooth defects, however, can be inherited without any evidence ofOI.

Hearing Loss Hearing loss usually begins during the second decade of life and occurs in over 50% of subjects over age 30. The loss can be conductive, sensorineural, or mixed and varies in severity. The middle ear usually exhibits maldevelopment, deficient ossification, persistence of cartilage in areas that are normally ossified, and abnormal calcium deposits.

Associated Features Other connective tissue involvement can include thin skin that scars extensively, joint laxity with permanent dislocations indistinguishable from those ofEDS, and, occasionally, cardiovascular manifestations such as aortic regurgitation, floppy mitral valves, mitral incompetence, and fragility of large blood vessels. For unknown reasons, some patients develop a hypermetabolic state with elevated serum thyroxine levels, hyperthermia, and excessive sweating.

Molecular Defects Most patients withOI have mutations in one of the two genes that encode type I procollagen. Over 90% of patients with type I OI and blue sclerae have mutations in the proa1(I) gene that decrease the steady-state levels of the mRNA for proa1(I) chains and decrease the rates of synthesis of proa1(I) chains relative to those for proa2(I) chains. In more severe forms (types II, III, and IV), the effects of mutations that cause synthesis of abnormal proa chains are amplified by the three mechanisms discussed above (Fig. 351-1). Mutations that change the structure of the protein near the N-proteinase cleavage site cause accumulation of a partially processed procollagen and produce lax joints similar to those in type VIIEDS that is caused by mutations in the gene for the N-proteinase. Mutations that change the structure in the middle or near the C terminus of the molecule tend to cause severe or lethal variants of OI. It is difficult, however, to correlate the site or nature of the mutation and the clinical phenotype (Fig. 351-2). Most patients are heterozygotes with mutations in a single allelle, but rare patients are homozygotes with two mutated alleles for proa1(I) or proa2(I) chains.

Mosaicism in Germ-Line Cells and in Somatic Cells Most lethalOI is the result of new autosomal dominant mutations. The frequency of a second child with lethal OI in the same family, however, is about 7% because of germ-line mosaicism in one of the parents. The presence of germ-line mosaicism has been demonstrated in several fathers of patients with type II OI by demonstrating the mutated gene in a fraction of their sperm. Apparently normal parents of children with severe OI may also have somatic cell mosaicism in which the mutated allele is present in a fraction of somatic cells such as fibroblasts, leukocytes, and hair root cells. Because of the possibility of germ-line mosaicism, asymptomatic parents of a child with severe OI should be counseled that recurrence can occur.

Diagnosis The diagnosis is usually made on the basis of clinical criteria. The presence of fractures together with blue sclerae, dentinogenesis imperfecta, or family history of the disease is usually sufficient to make the diagnosis. Other causes of pathologic fractures must be excluded, including the battered child syndrome, nutritional deficiencies, malignancies, and other inherited disorders such asCDs and hypophosphatasia (Table 351-3). X-rays usually reveal a decrease in bone density that can be verified by photon or x-ray absorptiometry. There is no consensus, however, as to whether the diagnosis can be made by microscopy of bone. A molecular defect in type I procollagen can be demonstrated in half or more of patients by incubating skin fibroblasts with radioactive amino acids and then analyzing the proa chains by polyacrylamide gel electrophoresis. The analysis detects decreases in the rate of synthesis of proa1(I) chains relative to proa2(I) chains, abnormally long proa chains, abnormally short proa chains, and proa chains with abnormal posttranslational modification because of an amino acid substitution that impairs folding of the triple helix. The mutations themselves can be defined in most patients by sequencing of genomic DNA. Because each proband and family usually has a "private" mutation, extensive analysis of about 10,000 bases in each of the two genes is required to identify the exact mutation. After a mutation in a type I procollagen gene is identified, a test based on the polymerase chain reaction can be used to screen family members at risk and for prenatal diagnosis.

TREATMENT

Many patients withOI have successful careers despite severe deformities. Those with mild disorder may need little treatment when fractures decrease after puberty, but women require special attention during pregnancy and after menopause, when fractures again increase. More severely affected children require a comprehensive program of physical therapy, surgical management of fractures and skeletal deformities, and vocational education.

Many of the fractures are only slightly displaced and have little soft tissue swelling. Therefore, they can be treated with minimal support or traction for a week or two followed by a light cast. If fractures are relatively painless, physical therapy can be initiated early. A judicious amount of exercise prevents loss of bone mass secondary to physical inactivity. Some physicians advocate insertion of steel rods into long bones to correct limb deformities; the risk/benefits and cost/benefits of such procedures are difficult to evaluate. Aggressive conventional intervention is usually warranted for pneumonia and cor pulmonale. For severe hearing loss, stapedectomy or replacement of the stapes with a prosthesis may be successful. Moderately to severely affected patients should be evaluated periodically to anticipate possible neurologic problems. About half of children have a substantial increase in growth when given growth hormone. Treatment with bisphosphonates to decrease bone loss has been introduced on an experimental basis. Initial results are promising, but the long-term effects of decreasing bone resorption are unknown. Also, a clinical trial has been initiated to use stromal cells from bone marrow that can differentiate into osteoblasts after systemic infusion. In the first phase of the trial, three children with severeOI (type III) showed clinical improvement after marrow ablation and transplantation of whole bone marrow from an HLA-compatible sibling.

A program for careful orthotic management developed by Bleck and a program for compressive management developed by Marini are useful. Counseling and emotional support are important for patients and parents, and lay organizations in some countries provide help in these areas. Prenatal ultrasonography will detect severely affected fetuses at about 16 weeks of pregnancy. Diagnosis by demonstrating synthesis of abnormal proa chains or by DNA sequencing can be carried out in chorionic villa biopsies at 8 to 12 weeks of pregnancy.

EHLERS-DANLOS SYNDROME

EDSis characterized by hyperelasticity of the skin and hypermobile joints.

Classification Five types ofEDS were initially defined based primarily on the extent to which the skin, joints, and other tissues are involved, but the classification has now been extended (Table 351-4). Type I is the classic, severe form of the disease, with both severe joint hypermobility and skin that is velvety in texture, hyperextensible, and easily scarred. Type II is similar to type I but milder. In type III joint hypermobility is more prominent than skin changes. In type IV the skin changes are more prominent than joint changes. However, type IV patients are predisposed to sudden death from rupture of large blood vessels or other hollow organs. Type V is similar to type II but is inherited as an X-linked trait. Type VI is characterized by scoliosis, ocular fragility, and a cone-shaped deformity of the cornea (keratoconus). Type VII is characterized by marked joint hypermobility that is difficult to distinguish from type III except by the specific molecular defects in the processing of type I procollagen to collagen. Type VIII is distinguished by periodontal changes. Types IX, X, and XI were defined on the basis of preliminary biochemical and clinical data, but these classifications have not proven useful. Because of overlapping signs and symptoms, many patients and families with some of the features of EDS cannot be assigned to any of the defined types.

Incidence The incidence ofEDS is difficult to establish, largely because patients with mild skin or joint symptoms rarely seek medical attention. It is also difficult to define the normal range of variation for joint mobility or skin elasticity. The incidence may be about 1 in 5000 births, although a higher value has been reported for blacks. Types I, II, and III account for most diagnoses.

Skin The changes vary from thin and velvety skin to skin that is either dramatically hyperextensible ("rubber man" syndrome) or easily torn or scarred. Type I patients develop characteristic "cigarette-paper" scars. In type IV extensive scars and hyperpigmentation develop over bony prominences, and the skin may be so thin that subcutaneous blood vessels are visible. In type VIII the skin is more fragile than hyperextensible, and it heals with atrophic, pigmented scars. Easy bruisability occurs in several types ofEDS.

Ligament and Joint Changes Laxity and hypermobility of joints vary from mild to unreducible dislocations of hips and other large joints. In mild forms patients learn to reduce dislocations themselves and to avoid them by limiting physical activity. In more severe forms, surgical repair may be required. Some patients have progressive difficulty with age, but severe joint laxity is compatible with a normal life span.

Associated Changes Mitral valve prolapse and hernias occur, particularly in type I. Pes planus and mild to moderate scoliosis are common. Extreme joint laxity and repeated dislocations may lead to degenerative arthritis. In type VI the eye may rupture with minimal trauma, and kyphoscoliosis can cause respiratory impairment. Sclerae may be blue in type VI.

Molecular Defects Mutations in two of the three genes for type V collagen have been found in patients with types I and IIEDS. The mutations include glycine substitutions in the triple-helical domain, RNA splicing mutations, exon skipping mutations, a small deletion of 7 bp, and a substitution of serine for cysteine in the C-propeptide. Mutations in both thea1(V) and a2(V) chain are found in patients with type I EDS, but to date only mutations in thea1(V) chain have been found in patients with type II EDS. Electron microscopy of skin from some patients with types I, II, or III EDS are consistent with mutations in a low-abundance collagen such as types III or V that either copolymerize with or bind to the surface of type I fibrils. However, irregular fibrils are not seen in all patients, and similar irregular fibrils can be seen in normal skin.

Most patients with type IVEDS have a defect either in the synthesis or structure of type III procollagen, a finding consistent with the fact that these patients are prone to spontaneous rupture of the aorta and intestines, tissues rich in type III collagen. The thinness and scarring of skin are more difficult to explain, since type III constitutes a small fraction of the collagen in skin (Table 351-1). The >50 mutations identified in the type III procollagen gene include partial gene deletions, RNA splicing mutations, and single-base mutations that cause substitution of glycine by amino acids with bulkier side chains (Fig. 351-4). In effect, most of the mutations lead to synthesis of abnormal but partially functional proa1(III) chains that produce procollagen suicide or alter fibril formation by the same mechanisms that amplify the effects of mutations in the genes for type I procollagen. Similar mutations in type III procollagen can cause aortic aneurysms in some individuals without other evidence of EDS type IV,MFS, or other inherited disorders of connective tissue.

Type VIEDS is caused by mutations in the gene that encodes lysyl hydrolase. In one series, all the patients were homozygous or compound heterozygotes for the mutated genes, and all the mutations caused profound deficiency of lysyl hydroxylase, a decrease in the hydroxylysine content of collagen, and a decrease in the cross-links in collagen fibers. The decrease in cross-links is explained by the observation that some cross-links are less stable if formed from lysine instead of hydroxylysine.

Type VIIEDS is due to a defect in the conversion of procollagen to collagen caused either by mutations that make type I procollagen resistant to cleavage by procollagen N-proteinase or by mutations that decrease the activity of the enzyme. The type VIIA mutations alter the cleavage site in the proa1(I) chain, and the type VIIB mutations alter the cleavage site in the proa2(I) chain. Both types are dominantly inherited. Type VIIC is caused by mutations that decrease the activity of procollagen N-proteinase and is inherited as an autosomal recessive trait. In all three forms of type VII EDS, the persistence of the N-propeptide causes the formation of collagen fibrils that are thin and irregular. Since most patients do not have clinical osteopenia, the thin and irregular fibrils apparently suffice for the mineralization of bone but do not provide the necessary tensile strength for ligaments and joint capsules. However, some patients fracture easily

and are difficult to distinguish from variants of OI.

The cause of type VIIIEDS is unknown. Type IX is a disorder of copper transport. The syndrome, also referred to as *Menkes' syndrome*, is due to an X-linked defect and is associated with cutis laxa, hypopigmentation, unusual hair ("kinky"), vascular aneurysms, neurologic degeneration, and mental retardation. Mutations in a gene coding for a copper-transporting ATPase cause the disease (Chaps. 348 and353). Type X EDS may be caused by defects in fibronectin, but no specific mutations have been defined.

Diagnosis The diagnosis is based on clinical criteria. Biochemical assays and gene analyses for known molecular defects inEDS are difficult and time-consuming, but specific diagnostic tests should be available in the future for families in which the genes at fault have been defined.

TREATMENT

There is no specific therapy. Surgical repair and tightening of joint ligaments require careful evaluation of individual patients, as the ligaments frequently do not hold sutures. Patients with easy bruisability should be evaluated for other bleeding disorders. Patients with type IVEDS and members of their families should probably be evaluated at regular intervals by sonography and related techniques for early detection of aneurysms. Surgical repair of aneurysms may be difficult because of increased friability of tissues, and there is limited experience with elective surgery in such patients. Also, women with type IV EDS should be counseled about the increased risk of uterine rupture, bleeding, and other complications of pregnancy.

CHONDRODYSPLASIAS (See alsoChap. 343)

TheCDs are inherited skeletal disorders that cause dwarfism and abnormal body proportions. The category also includes some individuals with normal stature and body proportions who have features such as ocular changes or cleft palate that are common in more severe CDs. Many patients develop degenerative joint changes, and mild CD in adults may be difficult to differentiate from primary generalized osteoarthritis. Some authors refer to the disorders as "skeletal dysplasias," but CD is a more widely used term.

Classification Over 150 distinct types and subtypes have been defined (Table 351-5) based on criteria such as "bringing death" (thanatophoric), causing "twisted" bones (diastrophic), affecting metaphyses (metaphyseal), affecting epiphyses (epiphyseal), and producing histologic changes such as an apparent increase in the fibrous material in the epiphyses (fibrochondrogenesis). Also, a number of eponyms are based on the first or most comprehensive case reports. Severe forms of the diseases produce gross distortions of most cartilaginous structures and of the eye. Mild forms are more difficult to classify. Among the features are cataracts, degeneration of the vitreous and retinal detachment, high forehead, hypoplastic facies, cleft palate, short extremities, and gross distortions of the epiphyses, metaphyses, and joint surfaces.

Incidence Data on the frequency of mostCDs are not available, but the incidence of the

Stickler syndrome may be as high as 1 in 10,000. Therefore, the diseases are probably among the more common heritable disorders of connective tissue.

Molecular Defects The first mutations shown to cause CDs were in the COL2A1 gene for type II collagen, the most abundant protein in cartilage. A number of mutations in this gene have now been reported in variants of CD ranging from mild to lethal (Fig. 351-5). A large fraction of patients with lethal CDs, a smaller number of patients with moderately severe CDs, and about 2% of families with early-onset generalized osteoarthritis have mutations in the same gene. However, similar phenotypes can also be caused by mutations in other genes, including genes for three other collagens, additional components of the cartilage matrix, growth factors, growth factor receptors, and transcription factors (see Table 351-6 for selected examples). The number of mutated genes reported does not necessarily reflect the incidence of such mutations in the diseases themselves but rather the complexity of the genes and the technical difficulties in searching the complete gene for mutations. Also, it reflects the availability of large families for DNA linkage analysis and the vigor with which investigators have pursued their interest in a given gene. It is likely that mutations in additional genes will be found.

Mutations in the COL2A1 gene were first found in patients with severe CDs characterized by gross deformities of bones and cartilage such as spondyloepiphyseal dysplasia congenita, hypochondrogenesis/achondrogenesis II, and the Kniest syndrome. However, mutations in the COL2A1 gene have been found in a few families in which few if any symptoms are present in childhood but in which joint stiffness, joint pain, and degenerative changes of osteoarthritis develop in midlife. The mutations in the COL2A1 gene are similar to the mutations in the genes for types I and III procollagens (Fig. 351-5), and the correlations between genotype and the severity of the phenotype are equally difficult. In addition, mutations that change a codon for a Y-position amino acid in the -Gly-X-Y- repeat sequence from an arginine to cystine were found in families with early-onset osteoarthritis and minimal evidence of CDs. Stickler syndrome and related syndromes are caused by mutations in three different genes: the COL2AI gene for type II collagen and the COL11A1 and COL11A2 genes for type XI collagen. A series of mutations that introduce premature terminal signals in the COL2A1 gene lead to classic Stickler syndrome. However, some patients with classic Stickler syndrome have glycine substitutions in COL11A1. RNA splicing mutations in the COL11A1 gene are found in patients with the Marshall syndrome, which is similar to classic Stickler syndrome but with milder eye changes and more severe hearing loss. Patients classified as having nonocular Stickler syndrome have RNA splicing mutations in the COL11A2 gene.

Many individuals with the Schmid metaphyseal CD, characterized by short stature, *coxa vara*, flaring metaphyses, and waddling gait, have mutations in the gene for the type X collagen, a short, network-forming collagen found primarily in the hypertrophic zone of endochondral cartilage.

Mutations in the receptor for fibroblast growth factor 3 (FGFR-3) are present in most patients with achondroplasia, the most common cause of short-limbed dwarfism accompanied by macrocephaly and dysplasias of the metaphyses of long bones (Table 351-6). The same single-base mutation in the gene that converts glycine to arginine at position 380 is present in>90% of patients. Most patients represent sporadic new mutations, and this nucleotide change must be one of the most common recurring

mutations in the human genome. The mutation causes unregulated signal transduction through the receptor and inappropriate development of cartilage. Mutations that alter other domains of FGFR-3 have been found in patients with the more severe disorders hypochondroplasia and thanatophoric dysplasia and in a few families with a variant of craniosynostosis. However, most patients with craniosynostosis appear to have mutations in the related gene FGFR-2 gene.

Mutations in the gene for the cartilage oligomeric matrix protein (COMP) have been found in patients with multiple epiphyseal dysplasia or pseudoachondroplasia, and in related syndromes characterized by short limbs and degenerative arthritis. However, some families with multiple epiphyseal dysplasia had a mutation in the gene for thea2(IX) or a3(IX) chain of type IX collagen (COL9A2 and COL9A3). All the known mutations in these two type IX collagen genes in patients with multiple epiphyseal dysplasia cause splicing out of the codons of exon 3. A mutation in the COL9A2 gene was also found in patients with the common condition of sciatica and herniations of vertebral discs. About 4% of Finnish probands with the phenotype had a single base substitution that converted a codon for glutamate to tryptophan in thea2(IX) chain of type IX collagen.

Diagnosis The diagnosis of severe forms ofCD is made on the basis of the physical appearance, x-ray findings, histologic changes, and clinical course (Table 351-5).

TREATMENT

No definitive therapy is available. Symptomatic treatment is directed to secondary features such as degenerative arthritis. Many patients require joint replacement surgery and corrective surgery for cleft palate. The eyes should be monitored carefully for the development of cataracts and for the need for laser therapy to prevent retinal detachment. Patients should probably be advised to avoid obesity and contact sports. Counseling for the psychological problems of short stature is critical, and support groups have formed in many countries. Ultrasonography is sometimes successful for prenatal diagnosis but less frequently than withOI. Specific DNA tests are available for theCDscaused by mutations in the genes for types II, X, and XI collagens.

MARFAN SYNDROME

SevereMFS is characterized by a triad of features: (1) long, thin extremities frequently associated with other skeletal changes, such as loose joints and arachnodactyly; (2) reduced vision as the result of dislocations of the lenses (ectopia lentis); and (3) aortic aneurysms that typically begin at the base of the aorta.

Classification The clinical diagnosis is frequently problematic because some affected members of families with MFSpresent with only one or two features of the typical clinical trial. Also, many patients present with one or two of the features of MFS without a family history, apparently because they represent sporadic mutations. Therefore, it is frequently difficult to determine on the basis of clinical data alone whether a patient with ectopia lentis or the characteristic body habitus of MFS is at risk for developing a life-threatening aortic aneurysm. The new DNA diagnostic tests for mutations in the fibrillin-1 and fibrillin-2 genes can probably resolve most, but not all, of these problems.

Most patients who are prone to develop an aortic aneurysm as a component of MFS can be identified by detection of mutations in the fibrillin-1 gene. Some of these patients develop aortic aneurysms because of a mutation in the fibrillin-1 gene without the skeletal or ocular changes characteristic of MFS. Patients with the rarer form of MFS that is characterized by contractural arachnodactyly instead of loose joints can usually be identified by detection of a mutation in the fibrillin-2 gene that is similar in structure to the gene for fibrillin-1. Preliminary data suggest that patients with mutations in the fibrillin-2 gene are not prone to develop aneurysms. However, affected members of some rare families with a mutation in the fibrillin-1 gene also do not develop aortic aneurysms, even though they may show the skeletal or ocular changes. Therefore, the DNA tests are most helpful if: (1) a mutation is detected in either of the two genes, and (2) informative data are available on the clinical symptoms that the same mutation produces in the patient's family or in other families with similar clinical features.

Incidence and Inheritance MFS has an incidence of about 1 in 10,000 in most racial and ethnic groups. The disorder is inherited as an autosomal dominant trait; at least one-fourth of patients do not have an affected parent, and their cases are probably due to new mutations.

Skeletal Changes Patients are usually tall compared with other members of the same family and have long limbs. The ratio of the upper segment (top of the head to top of the pubic ramus) to the lower segment (top of the pubic ramus to the floor) is usually 2 SDs below mean for age, race, and sex. The fingers and hands are long and slender and have a spider-like appearance (arachnodactyly). Many patients have severe chest deformities, including depression (pectus excavatum), protrusion (pectus carinatum), or asymmetry. Scoliosis is frequent and usually accompanied by kyphosis. High-arched palate and high pedal arches or pes planus are common. A few patients have severe joint hypermobility similar toEDS.

Cardiovascular Changes Cardiovascular abnormalities are the major source of morbidity and mortality (Chap. 247). Mitral valve prolapse develops early in life and in about one-quarter progresses to mitral valve regurgitation of increasing severity because of redundancy of the leaflets, stretching of the chordae tendineae, and dilatation of the valvulae annulus. Dilatation of the root of the aorta and the sinuses of Valsalva are characteristic and ominous features of the disease that can develop at any age and in rare instances may be detected by echocardiography in utero. The rate of dilatation is unpredictable, but it can lead to aortic regurgitation, dissection of the aorta, and rupture. Dilatation is probably accelerated by physical and emotional stress, as well as by pregnancy.

Ocular Changes Dislocations of the lens may be readily apparent, but diagnosis usually requires pupillary dilatation and slit-lamp examination. The displacement is usually not progressive but may contribute to the formation of cataracts. The ocular globe is frequently elongated, most patients are myopic, and some develop retinal detachment. A few patients have lattice degeneration and retinal tears; most have adequate vision.

Associated Changes Striae may occur over the shoulders and buttocks. Otherwise the skin is normal. A number of patients develop spontaneous pneumothorax. Inguinal and

incisional hernias are common. Marked dilatation of the dural sac is seen frequently in computed tomography scans, but the condition is usually asymptomatic. Patients are typically thin with little subcutaneous fat, but adults may develop centripetal obesity.

Molecular Defects Most patients with the classic features ofMFS are heterozygotes for mutations in a gene on chromosome 15 that encodes fibrillin-1, a glycoprotein of 350 kDa that is a major component of elastin-associated microfibrils. These microfibrils are abundant in large blood vessels and the suspensory ligaments of the lens. Mutations in the fibrillin-1 gene include missense, nonsense, in-frame deletions, and RNA splicing mutations. Many of the mutations are single amino acid substitutions in the epidemal growth factor-like domains of the molecule that may be involved with calcium binding. Mutations in the fibrillin-2 gene that cause the MFS variant characterized by contractures appear to follow a similar pattern. As with most genetic diseases, the nature and location of mutations in the genes are only an approximate guide to the severity of the phenotype unless the same mutation has been seen in other members of the same family or in similar unrelated patients. However, there is a clustering of mutations in the middle portion of the molecule of fibrillin-1 encoded by exons 23 to 32 that causes the most severe phenotype, referred to as *neonatal lethal MFS*. The function of fibrillin has not been defined, but the data suggest that fibrillin self-assembles into a fibrillar structure and that the conformation and surface properties of the entire molecule are critical for normal assembly. Therefore, the functional consequences of mutations that change the amino acid sequence of fibrillin may be similar to the effects of mutations that change the conformation of a fibrillar collagen.

Diagnosis The diagnosis is easily established if the patient and other members of the family have dislocated lenses, aortic dilatation, and long and thin extremities together with kyphoscoliosis or other chest deformities. The diagnosis is frequently made if ectopia lentis and an aneurysm of the ascending aorta occur in the absence of a Marfan habitus or a positive family history. All patients in whom the diagnosis is suspected should have a slit-lamp examination and an echocardiogram. Also, homocystinuria (Table 351-3) should be ruled out by a negative cyanide-nitroprusside test for disulfides in the urine (Chap. 352). A few patients with types I, II, and IIIEDS have ectopia lentis but lack the Marfan habitus and instead have characteristic skin changes not present inMFS. Patients with familial aortic aneurysms tend to develop aneurysms at the base of the abdominal aorta. The location of the aneurysms, however, is somewhat variable, and the high incidence of aortic aneurysms in the general population (1 in 100) makes the differential diagnosis difficult unless other features of MFS are clearly present. A few families with familial aortic aneurysms have mutations in the gene for type III procollagen (Fig. 351-4).

TREATMENT

There is no established treatment, but several investigators have recommended use of propranolol or other b-adrenergic blocking agents to lower blood pressure and thereby delay or prevent aortic dilatation. Surgical replacement of the aorta, aortic valve, and mitral valve has been successful in some patients, and all patients should be followed carefully with echocardiography and other techniques for evaluation of cardiovascular changes (Chap. 247). Patients should probably be advised of the risks of severe physical and emotional stress and of pregnancy.

The scoliosis tends to be progressive and should be treated by mechanical bracing and physical therapy if>20° or by surgery if it progresses to>45°. Estrogen has been tried in girls with scoliosis, but the results are inconclusive. Dislocated lenses rarely require surgical removal, but patients should be followed closely for retinal detachment.

Diagnostic tests based on detection of fibrillin defects in cultured skin fibroblasts or DNA analysis of the gene are now available from several laboratories.

DISEASES RELATED TO ELASTIN

As may be expected from the role of elastin in maintaining the elasticity of skin, mutations in the elastin gene cause *cutis laxa*, a rare and heterogeneous group of disorders characterized by skin that is both lax and inelastic. Three different frame-shift mutations were found in three unrelated families with dominant forms of the disease. Surprisingly, other mutations in the elastin gene produce phenotypes that primarily involve the aorta, whose elasticity also depends on the presence of elastin. A large deletion that includes the elastin gene and probably several adjacent genes causes the *Williams syndrome*, characterized by supravalvular aortic stenosis, growth retardation, characteristic facies, and an unusual mental phenotype of low intelligence quotient together with a high degree of sociability.

EPIDERMOLYSIS BULLOSA

EBconsists of a group of similar disorders in which the skin and related epithelial tissues break and blister as the result of minor trauma. As with most heritable disorders of connective tissues, the clinical manifestations range from lethal to mild.

Classification Four types of EB are defined on the basis of the level at which blistering occurs:EBsimplex for blistering in the epidermis, EB hemidesmosomal for fissures between kerotinocytes and between kerotinocytes and the basal lamina, EB junctional for blistering in the dermal-epidermal junction, and EB dystrophica for blistering in the dermis (Table 351-7).

Incidence The incidence ofEB in the United States is estimated to be 1 in 50,000.

Molecular Defects The molecular basis of several specific variants ofEB has been defined. A series of patients with EB simplex were found to have mutations in either keratin 14 or keratin 5, two of the major keratins in basal epithelial cells. Patients with the related syndrome, epidermolytic icthyosis, have mutations in keratin 1 and keratin 10. The new disease phenotype of hemidesmosomal EB has three clinical variants that are caused by mutations in one of four genes (Table 351-7): (1) A generalized atrophic and benign form of EB is caused by mutations in the COL17A1 gene for type XVII collagen; (2) a variant with EB associated with pyloric atresia and other intestinal abnormalities is caused by mutations in either the gene for thea6 integrin (ITG A6) or the gene for theb4 integrin (ITG B4); and (3) another variant characterized by relatively mild blistering at birth but associated with late-onset muscular dystrophy is caused by mutations in the gene for plectin (PLEC-1). Junctional EB is caused by mutations in any one of three genes for laminin (LAMA-3, LAMB-3, LAMC-2). The most severe dystrophic

form of EB is caused by mutations in the gene for type VII collagen (COL7A1).

Diagnosis The diagnosis is based on skin that readily breaks and forms blisters.EBsimplex and EB hemidesmosomal are generally milder than EB junctional or EB dystrophica. EB dystrophica variants usually cause large and prominent scars. Precise classification within subtypes usually requires electron microscopy. The treatment is symptomatic.

ALPORT SYNDROME (See also Chap. 275)

ASis an inherited disorder characterized by hematuria. Four forms of the disease are now recognized: (1) classic AS, which is inherited as an X-linked disorder with hematuria, sensorineural deafness, and conical deformation of the anterior surface of the lens (lenticonus); (2) a subtype of the X-linked form associated with diffuse leiomyomatosis; (3) an autosomal recessive form; and (4) an autosomal dominant form. The two autosomal forms can cause renal disease without deafness or lenticonus.

Incidence The incidence ofAS is about 1 in 10,000 in the general population and as high as 1 in 5000 in some ethnic groups. About 80% of AS patients have the X-linked variant.

Molecular Defects Electron microscopy of kidneys from patients with classicASdemonstrates that the glomerular basement membrane is up to five times thicker than normal and that the lamina densa is distorted and split. The X-linked and autosomal recessive forms are caused primarily by mutations in genes for thea3(IV), a4(IV),a5(IV), or a6(IV) chains of type IV collagen, a major component of basement membranes. The type IV collagen in most membranes consists primarily of a1(IV) anda2(IV) chains folded into a large, rodlike molecule with globular ends and a long triple-helical domain that is interrupted by short sequences that do not form triple helices. The molecules self-assemble through both the globular ends and the long triple-helical domain to form a complex three-dimensional network. The four additional achains of type IV collagen are minor components of basement membranes, similar in structure, and are probably incorporated into the same or similar molecules. The six genes for the proteins are arranged in tandem pairs on different chromosomes in a head-to-head orientation and with overlapping promoters, i.e., the a1(IV) and a2(IV) genes are head-to-head on chromosome 13q34, the a3(IV) anda4(IV) genes are on chromosome 2q35-37, and thea5(IV) and a6(IV) genes are on chromosome Xq22. An X-linked variant is caused by mutations in the COL4A5 gene, and the X-linked variant associated with leiomyomatosis is caused by deletions that involve both the COL4A5 gene and the nearby COL4A6 gene. The autosomal recessive variants are caused by mutations in either the COL4A3 or COL4A4 genes. The mutations responsible for the autosomal dominant variants are still unknown, but they have been mapped to the same locus as the COL4A3 and COL4A4 genes.

Diagnosis The diagnosis of classicAS is based on X-linked inheritance of hematuria, sensorineural deafness, and lenticonus. Because of the X-linked transmission, women are usually less severely affected than men and are generally underdiagnosed. The hematuria progresses to nephritis and may cause renal failure in late adolescence in affected males and at older ages in some women. The sensorineural deafness is

primarily in the high-tone range. It can frequently be detected only by an audiogram and is usually not progressive. The lenticonus can occur without nephritis but is generally considered to be pathognomonic of classic AS.

TREATMENT

There is no known treatment, but renal transplantation is usually successful.

352. INHERITED DISORDERS OF AMINO ACID METABOLISM AND STORAGE - *Nicola Longo*

All polypeptides and proteins are polymers of amino acids. Eight amino acids, referred to as *essential*, cannot be synthesized by humans and must be obtained from dietary sources. The others are formed endogenously. Although most of the body's amino acids are "tied up" in proteins, small intracellular pools of *free* amino acids are in equilibrium with extracellular reservoirs in plasma, cerebrospinal fluid, and the lumina of the gut and kidney. Physiologically, amino acids are more than mere "building blocks" of proteins. Some (glycine, glutamate,g-aminobutyric acid) are neurotransmitters. Others (phenylalanine, tyrosine, tryptophan, glycine) are precursors of hormones, coenzymes, pigments, purines, or pyrimidines. Each has a unique degradative pathway by which its nitrogen and carbon components are used for the synthesis of other amino acids, carbohydrates, and lipids.

More than 70 disorders of amino acid metabolism are now known. The catabolic and storage defects (approximately 60) discussed in this chapter far outnumber the transport abnormalities (approximately 10) considered in Chap. 353. Each of these disorders is rare -- the incidences range from 1 in 10,000 for cystinuria or phenylketonuria to 1 in 200,000 for homocystinuria or alkaptonuria. Collectively, however, they occur in perhaps 1 in 500 to 1 in 1000 live births. Almost all are transmitted as autosomal recessive traits.

The features of inherited disorders of amino acid catabolism are summarized inTable 352-1. In general, these disorders are named for the compound that accumulates to highest concentration in blood (*-emias*) or urine (*-urias*). For many conditions (often called *aminoacidopathies*), the parent amino acid is found in excess; for others, generally referred to as *organic acidemias*, products in the catabolic pathway accumulate. Which compound(s) accumulates depends, of course, on the site of the enzymatic block, the reversibility of the reactions proximal to the lesion, and the availability of alternative pathways of metabolic "runoff." For some amino acids, such as the sulfur-containing or branched-chain molecules, defects have been described at nearly each step in the catabolic pathway. For others, only small numbers of defective reactions have been described. Biochemical and genetic heterogeneity is common. Four distinct forms of hyperphenylalaninemia, seven forms of homocystinuria, and seven types of methylmalonic acidemia are recognized. Such heterogeneity reflects the presence of an even larger array of molecular defects.

The manifestations of these conditions differ widely (Table 352-1). Some, such as sarcosinemia or hyperprolinemia, produce no clinical consequences. At the other extreme, complete deficiency of ornithine transcarbamylase or of branched-chain keto acid dehydrogenase is lethal in the untreated neonate. Central nervous system (CNS) dysfunction, in the form of developmental retardation, seizures, alterations in sensorium, or behavioral disturbances, is present in more than half the disorders. Protein-induced vomiting, neurologic dysfunction, and hyperammonemia occur in many disorders of urea cycle intermediates. Metabolic ketoacidosis, often accompanied by hyperammonemia, is a frequent presenting finding in the disorders of branched-chain amino acid metabolism. Occasional disorders produce focal tissue or organ involvement such as liver disease, renal failure, cutaneous abnormalities, or ocular lesions.

The clinical manifestations in many of these conditions can be prevented or mitigated if diagnosis is achieved early and appropriate treatment (i.e., dietary protein or amino acid restriction or vitamin supplementation) is instituted promptly. For this reason, several aminoacidopathies and organic acidemias are routinely screened in newborns using an array of chemical and microbiologic techniques. Once a presumptive diagnosis is made, confirmation can be provided by direct enzyme assay on extracts of leukocytes, erythrocytes, or cultured fibroblasts. DNA-based testing is possible for several disorders including phenylketonuria, ornithine transcarbamylase deficiency, citrullinemia, gyrate atrophy of the retina, propionic acidemia, and methylmalonic acidemia. As additional mutations are defined, DNA-based analysis may allow better predictions of outcome and improved therapeutic plans.

Several of these disorders (including branched-chain ketoaciduria, isovaleric acidemia, propionic acidemia, methylmalonic acidemia, homocystinuria, cystinosis, phenylketonuria, ornithine transcarbamylase deficiency, citrullinemia, argininosuccinic aciduria) can be diagnosed prenatally by chemical analysis of amniotic fluid or by chemical, enzymatic, or DNA-based studies of fresh or cultured amniotic fluid cells. In addition to predicting genotype and alleviating parental anxiety, prenatal diagnosis has led to improved treatment of affected newborns.

The focus of this chapter is on selected disorders that illustrate the principles, properties, and problems presented by the disorders of amino acid metabolism.

THE HYPERPHENYLALANINEMIAS

DEFINITION

The hyperphenylalaninemias (Table 352-1) result from impaired conversion of phenylalanine to tyrosine. The most common and clinically important is *phenylketonuria*, which is characterized by an increased concentration of phenylalanine in blood, increased concentrations of phenylalanine and its by-products (notably phenylpyruvate, phenylacetate, phenyllactate, and phenylacetylglutamine) in urine, and severe mental retardation if untreated in infancy.

GENETIC CONSIDERATIONS

Each of the hyperphenylalaninemias results from reduced activity of phenylalanine hydroxylase. In humans, this complete enzyme system is expressed only in liver. Phenylalanine and molecular oxygen are substrates, and a reduced pteridine, tetrahydrobiopterin, is a cofactor (Fig. 352-1). Tyrosine and dihydrobiopterin are the products of this catalytic system, the latter being reconverted to tetrahydrobiopterin by two enzymes, pterin-4a-carbinolamine dehydratase and dihydropteridine reductase.

Abnormalities in phenylalanine metabolism are autosomal recessive traits that occur in about 1 in 10,000 births. Phenylketonuria type I is widely distributed among whites and Orientals. It is rare in blacks. Phenylalanine hydroxylase activity in obligate heterozygotes is low but higher than in affected homozygotes. Adult heterozygous carriers are clinically well but can be identified by an increased ratio of phenylalanine/tyrosine in plasma in the semifasting state. They may have transient

cognitive impairment after phenylalanine loads. Hyperphenylalaninemias are caused by mutations in the gene encoding phenylalanine hydroxylase (*PAH*) or in genes encoding enzymes involved in tetrahydrobiopterin synthesis or recycling. In the vast majority of patients, mutations occur in the *PAH* gene (causing phenylketonuria type I), and>300 mutations have been identified. Mutations causing a complete impairment of enzyme activity, such as the R408W, are associated with a more severe outcome requiring stringent dietary restriction of phenylalanine. Mutations causing a less complete deficiency of the enzyme, such as the I65T, are associated with milder forms of phenylketonuria.

In fewer than 2% of patients with phenylketonuria, mutations occur in other genes, including dihydrobiopterin reductase (*DHPR*) (30%), 6-pyruvoyl-tetrahydropterin synthase (*6-PTS*) (60%), GTP cyclohydrolase I (*GTP-CH*) (5%), and pterin-4a-carbinolamine dehydratase (*PCD*) (5%). In these cases, the impairment in phenylalanine hydroxylation results from tetrahydrobiopterin deficiency due to blocks in the pathway by which tetrahydrobiopterin is synthesized from GTP (phenylketonuria type III and malignant hyperphenylalaninemia) or deficiency of dihydropterine reductase (phenylketonuria type II), the enzyme that regenerates tetrahydrobiopterin from dihydrobiopterin (Fig. 352-1). Tyrosine hydroxylase and tryptophan hydroxylase also require tetrahydrobiopterin. Their products (L-dopa and 5-hydroxytryptophan) are essential for the synthesis of neurotransmitters. Heterozygotes for these conditions do not have hyperphenylalaninemia, but carriers of mutations in GTP cyclohydrolase have a peculiar form of dystonia, transmitted as a dominant trait with variable expressivity and higher penetrance in females; it is exquisitely responsive to levodopa. Neurotransmitter levels are not altered in transient hyperphenylalaninemia (sometimes called *transient phenylketonuria*), which has been described in some patients with pterin-4a-carbinolamine dehydratase deficiency.

Etiology and Pathogenesis Phenylalanine accumulation in blood and urine and reduced tyrosine formation are direct consequences of the impaired hydroxylation. In untreated phenylketonuria and in its tetrahydrobiopterin-deficient variants, plasma concentrations of phenylalanine become sufficiently high [1 mmol/L (16 mg/dL)] to activate alternative pathways of metabolism and lead to formation of phenylpyruvate, phenylacetate, phenyllactate, and other derivatives that are rapidly cleared by the kidney and excreted in urine. The severe brain damage is due to several consequences of phenylalanine accumulation: competitive inhibition of transport of other amino acids required for protein synthesis, impaired polyribosome formation or stabilization, reduced synthesis and increased degradation of myelin, and inadequate formation of norepinephrine and serotonin. Phenylalanine is a competitive inhibitor of tyrosinase, a key enzyme in the pathway of melanin synthesis. This block, plus reduced availability of the melanin precursor tyrosine, accounts for the hypopigmentation of hair and skin.

Clinical Manifestations No abnormalities are apparent at birth, but untreated children with classic phenylketonuria fail to attain early developmental milestones, develop microcephaly, and demonstrate progressive impairment of cerebral function. Hyperactivity, seizures, and severe mental retardation are major clinical problems later in life. Electroencephalographic abnormalities; "mousy" odor of skin, hair, and urine (due to phenylacetate accumulation); and a tendency to hypopigmentation and eczema complete the devastating clinical picture. In contrast, affected children who are detected

at birth and treated promptly show none of these abnormalities. Children with tetrahydrobiopterin deficiency, however, suffer a worse clinical course. Seizures appear early, followed by progressive cerebral and basal ganglia dysfunction (rigidity, chorea, spasms, hypotonia). Most succumb to secondary infection within a few years despite early diagnosis and vigorous treatment.

A number of women with phenylketonuria who have been treated since infancy have reached adulthood and become pregnant. If maternal phenylalanine levels are not strictly controlled before and during pregnancy, their offspring are at risk, even if they are heterozygous, for *maternal phenylketonuria*. Affected children have microcephaly and an increased risk of congenital defects. After birth, these children have severe neurodevelopmental delay and growth retardation.

Diagnosis Plasma phenylalanine concentrations are usually normal at birth in the hyperphenylalaninemias but rise rapidly after institution of protein feedings. To prevent mental retardation, diagnosis and initiation of dietary treatment of classic phenylketonuria must occur before the child is 3 weeks of age. For this reason, most newborns in North America and Europe are screened by determinations of blood phenylalanine concentration using the Guthrie bacterial inhibition assay. Abnormal values are confirmed using quantitative analysis of plasma amino acids. Prenatal diagnosis of type I phenylketonuria is now feasible using DNA-based tests that detect specific mutations or polymorphic markers that are linked to the *PAH* gene.

In newborns with type I phenylketonuria, plasma levels depend on the amount of phenylalanine in the diet and the degree of impairment of phenylalanine hydroxylase. Dietary phenylalanine restriction is usually instituted if blood phenylalanine levels are >250 umol/L (4 mg/dL). Careful monitoring of these infants reveals the degree of phenylalanine hydroxylase impairment and dictates the degree of dietary phenylalanine restriction.

Deficiency of tetrahydrobiopterin, which occurs in 1 to 2% of newborns with increased blood phenylalanine, is excluded by screening the urinary pteridine profile and by assay of dihydropteridine reductase activity on dried blood specimens. Dihydropteridine reductase deficiency and the blocks in tetrahydrobiopterin synthesis can be detected in utero using assays on cultured amniocytes. Tetrahydrobiopterin deficiency manifests with hyperphenylalaninemia and progressive neurologic impairment despite prompt dietary restriction of phenylalanine.

TREATMENT

Phenylketonuria is the first inherited metabolic disease in which a strategy of reducing the accumulation of the offending metabolite prevented the dire clinical consequences. This was accomplished by a special diet low in phenylalanine and supplemented with tyrosine. Tyrosine becomes an essential amino acid in phenylalanine hydroxylase deficiency. Sufficient phenylalanine is provided for new protein synthesis and normal growth. This amount varies with age and requires frequent adjustments, especially early in life. Ordinarily, plasma phenylalanine concentrations are maintained between 120 and 360 umol/L (2 and 6 mg/dL). Such diet therapy must be instituted during the first 3 weeks of life. Even then, modestCNSdysfunction may occur with more deleterious

mutations or after excess protein intake. Because uncontrolled hyperphenylalaninemia results in brain damage, dietary restriction should be continued and monitored indefinitely, recognizing that transient phenylketonuria may not require lifelong therapy. An enteric-coated formulation of phenylalanine ammonia lyase, which degrades phenylalanine in the gut, is under investigation for its potential to reduce the strain imposed by the special diet.

Children with tetrahydrobiopterin deficiency deteriorate despite dietary phenylalanine restriction. Such patients may be helped, however, by a regimen in which dietary phenylalanine restriction is combined with tetrahydrobiopterin supplements, levodopa, 5-hydroxytryptophan, and carbidopa. Finally, the deleterious consequences of maternal phenylketonuria can be minimized by continuing lifelong phenylalanine-restricted diets in females with phenylketonuria and assuring strict phenylalanine restriction prior to conception and throughout gestation.

THE HOMOCYSTINURIAS (HYPERHOMOCYSTEINEMIAS)

The homocystinurias are seven biochemically and clinically distinct disorders (Table 352-1), each characterized by increased concentration of the sulfur-containing amino acid homocystine in blood and urine. The most common form results from reduced activity of cystathionineb-synthase (CBS), an enzyme in the transsulfuration pathway that converts methionine to cysteine (Fig. 352-2). The other forms are the result of impaired conversion of homocysteine to methionine, a reaction catalyzed by homocysteine:methyltetrahydrofolate methyltransferase (also known as *methionine synthase*) and two essential cofactors, methyltetrahydrofolate and methylcobalamin (methyl-vitamin B_{12}). Depending on the underlying disorder, some patients show chemical and, in some instances, clinical improvement following administration of specific vitamin supplements (pyridoxine, folate, or cobalamin) (Chap. 75). In classic homocystinuria, the levels of free homocystine in plasma increase and result in homocystinuria. *Hyperhomocysteinemia* refers to increased total plasma concentration of homocysteine in the sulfhydryl and disulfide form, free and protein-bound. Hyperhomocysteinemia, in the absence of significant homocystinuria, is found in individuals who are heterozygous or homozygous for certain genetic defects that impair folate or vitamin B_{12}metabolism or cause cystathionine synthase deficiency. Changes of homocysteine levels are also observed with increasing age; in postmenopausal women; in patients with renal failure, hypothyroidism, leukemias, or psoriasis; and during therapy with drugs such as methotrexate, nitrous oxide, isoniazid, and some antiepileptic agents.

Homocysteine acts as an atherogenic and thrombophilic agent. An increase in total plasma homocysteine represents an independent risk factor for coronary, cerebrovascular, and peripheral arterial disease as well as for deep-vein thrombosis (Chap. 241). Homocysteine is synergistic with hypertension and smoking, and it is additive with other risk factors that predispose to peripheral arterial disease. In addition, hyperhomocysteinemia and folate and vitamin B_{12}deficiency have been associated with an increased risk of neural tube defects in pregnant women.

CYSTATHIONINEb-SYNTHASE DEFICIENCY

Definition Deficiency of this enzyme leads to increased concentrations of methionine and homocystine in body fluids and to decreased concentrations of cysteine and cystine. Clinical hallmarks include dislocation of optic lenses (usually downward and medially), mental retardation, marfanoid habitus, osteoporosis, and thrombotic vascular disease.

GENETIC CONSIDERATIONS

The sulfur atom of the essential amino acid methionine is transferred to cysteine by the transsulfuration pathway (Fig. 352-2). In one of these steps, homocysteine condenses with serine to form cystathionine. This reaction is catalyzed by the pyridoxal phosphate-dependent enzymeCBS. Heterogenous mutations in the *CBS* gene are present in different families. The G307S mutation is associated with lack of response to pyridoxine, whereas the I278T mutation correlates with pyridoxine-responsiveness and a milder clinical phenotype. Homocystinuria is common in Ireland (1 in 60,000 births) but rare elsewhere (<1 in 200,000 births).

Etiology and Pathogenesis Homocysteine and methionine accumulate in cells and body fluids; cysteine synthesis is impaired, resulting in reduced concentrations of this amino acid and its disulfide form, cystine. In approximately half of patients, synthase activity in liver, brain, leukocytes, and cultured fibroblasts is undetectable. In the remaining patients, tissues retain 1 to 5% of normal activity, and this residual activity can often be stimulated by pyridoxine supplementation.

Homocysteine interferes with the normal cross-linking of collagen, an effect that likely plays an important role in the ocular, skeletal, and vascular complications. Altered collagen in the suspensory ligament of the optic lens and in bone matrix may account for the dislocated lenses and osteoporosis. Similarly, interference with normal ground substance metabolism in vascular walls may predispose to the arterial and venous thrombotic diathesis. Increased platelet adhesiveness may result from homocysteine accumulation, thereby contributing to the thrombotic occlusive disease so often observed. Recurrent cerebrovascular accidents secondary to thrombotic disease may account for the mental retardation, but direct chemical effects on cerebral cell metabolism have not been excluded.

Clinical Manifestations More than 80% of homozygotes for completeCBSdeficiency develop dislocated optic lenses. This abnormality usually appears by 3 to 4 years of age and often results in glaucoma and impaired visual acuity. Mental retardation occurs in about half of such patients, often accompanied by ill-defined behavioral disturbances. Osteoporosis is a common radiologic finding (seen in two-thirds of patients by age 15) but rarely causes clinical disease. Life-threatening vascular complications, probably initiated by damage to vascular endothelium, are the major cause of morbidity and mortality. Occlusion of coronary, renal, and cerebral arteries with attendant tissue infarction can occur during the first decade of life. Nearly a fourth of patients die of vascular disease before age 30. These vascular complications seem to be exacerbated by angiographic procedures. Importantly, pyridoxine-responsive patients have milder clinical manifestations in all regards and may escape newborn screening and present with ectopia lentis or premature vascular occlusion. Heterozygous carriers for *CBS* deficiency (about 1 in 70 in the population) may have hyperhomocysteinemia, with an

increased risk for premature coronary, peripheral, and cerebral occlusive vascular disease.

Diagnosis The cyanide-nitroprusside test is a simple way of demonstrating increased excretion of sulfhydryl-containing compounds in urine. This is confirmed by measurement of free plasma methionine and homocystine. Plasma methionine tends to be increased in synthase-deficient patients and normal or low in those with other causes of homocystinuria and impaired methionine formation (see below). Diagnostic confirmation depends on measurements ofCBSactivity in tissue extracts or cells cultured from patients. Heterozygotes can be identified by measurement of peak serum homocystine after an oral methionine load (100 mg/kg) and by measurement of tissue synthase activity.

TREATMENT

As with classic phenylketonuria, effective treatment depends on early diagnosis. A number of infants diagnosed in the newborn period have been treated successfully with methionine-restricted, cystine-supplemented diets. In approximately half of patients, oral pyridoxine (25 to 500 mg/d) produces a fall in plasma and urinary methionine and homocystine and an increase in cystine concentration in body fluids. This effect probably reflects a modest increase inCBSactivity in cells of patients in whom the defect is characterized either by reduced affinity for cofactor or by accelerated degradation of mutant enzyme. Vitamin supplementation at these doses is apparently harmless and should be tried in all patients. Folate deficiency should be prevented by adequate supplementation. Betaine has also been effective in reducing homocystine levels in pyridoxine-unresponsive patients.

5,10-METHYLENETETRAHYDROFOLATE REDUCTASE (MTFR) DEFICIENCY

Definition Hyperhomocysteinemia with normal or decreased methionine levels is caused by deficiency of MTFR, the enzyme involved in the synthesis of 5-methyltetrahydrofolate, a cofactor in the enzymatic formation of methionine from homocysteine (Fig. 352-2).CNSdysfunction and premature vascular occlusion may occur.

Genetic Basis and Pathogenesis 5-Methyltetrahydrofolate:homocysteine methyltransferase (methionine synthase) catalyzes the conversion of homocysteine to methionine. A primary defect inMTFRactivity results, secondarily, in deficient methyltransferase activity and impaired conversion of homocysteine to methionine. This series of reactions is critical to normal DNA and RNA synthesis. Methionine deficiency and impaired nucleic acid synthesis may contribute toCNSdysfunction, while homocystine accumulation may predispose to thrombosis.

Hyperhomocysteinemia is inherited as an autosomal recessive trait and is caused by mutations in theMTFR(*MTHFR*) gene, which is located on chromosome 1p36.3. A thermolabile variant form of this enzyme, which has reduced activity, may be a common cause of hyperhomocysteinemia associated with increased risk of vascular disease in young adults.

Clinical Manifestations More than 30 patients with homocystinuria due toMTFRdeficiency have been reported. The most severely affected have developmental retardation and cerebral atrophy early in life. Others have behavioral disturbances (catatonia) during the second decade or mild retardation. The severity of the clinical manifestations reflects the severity of the reductase deficiency.

Diagnosis Increased concentrations of free homocystine in body fluids with normal or decreased concentrations of methionine suggest severeMTFRdeficiency. Total plasma homocysteine levels slightly above the normal range suggest milder dysfunction of this enzyme. Serum folate concentration is low in some patients. Confirmation requires direct MTFR assays in cultured fibroblasts.

TREATMENT

Therapeutic experience is limited. Folate, vitamin B_{12}, methionine, or betaine supplementation decrease homocystine urinary excretion and improve the clinical manifestations in some patients.

DEFICIENCY OF COBALAMIN (VITAMIN B_{12}) COENZYME SYNTHESIS

Definition Five other forms of homocystinuria also reflect impaired conversion of homocysteine to methionine. The primary defects in these entities, however, are in the synthesis of methylcobalamin, a cobalamin (vitamin B_{12}) coenzyme required by methionine synthase (MS) (Fig. 352-2). In some, methylmalonic acid accumulates in body fluids because of impaired synthesis of a second coenzyme, adenosylcobalamin, required for isomerization of methylmalonyl coenzyme A (CoA) to succinyl CoA. These disorders are designated cblC, -D, -E, -F, and -G.

Etiology and Pathogenesis As withMTFRdeficiency, each disorder impairs remethylation of homocysteine. Since methylcobalamin is required for methyl-group transfer from methyltetrahydrofolate to homocysteine, impaired cobalamin metabolism leads to deficient methyltransferase activity. The defects responsible for impaired synthesis of methylcobalamin involve one of several steps in lysosomal or cytosolic activation of the vitamin precursor (Fig. 352-2). Somatic cell genetic studies indicate that each of the five abnormalities (cblC to -G) is distinct and imply that all are inherited as autosomal recessive traits.

Clinical Manifestations More than 45 patients -- mostly children -- with these defects in cobalamin metabolism have been described. Although clinical manifestations vary, abnormalities include developmental delay, dementia, spasticity, megaloblastic anemia, and pancytopenia. It is not possible to define a specific clinical syndrome for each of the defects in cobalamin metabolism.

Diagnosis Homocystinuria, homocysteinemia, and hypomethioninemia are the chemical hallmarks. Methylmalonic acidemia, too, has been noted in those defects resulting from defective synthesis of both cobalamin coenzymes. These findings may also be present in juvenile- or adult-onset pernicious anemia in which intestinal cobalamin absorption is impaired. Measurement of serum cobalamin concentrations, low in pernicious anemia and normal in patients with defective conversion of cobalamin vitamin to coenzymes,

helps in the differential diagnosis. Definitive diagnosis depends on demonstrating impaired coenzyme synthesis in cultured cells.

TREATMENT

Treatment of affected children with hydroxycobalamin injections (1 to 2 mg/QD) and betaine supplements decreases homocystine and methylmalonate excretion; the hematologic and neurologic deficits have also been diminished to variable degrees in some patients. Intervention early in life seems to offer the best long-term prognosis.

ALKAPTONURIA

Definition Alkaptonuria is a rare disorder of tyrosine catabolism in which deficiency of homogentisate 1,2-dioxygenase (also known as *homogentisic acid oxidase*) leads to excretion of large amounts of homogentisic acid in urine and accumulation of oxidized homogentisic acid pigment in connective tissues (*ochronosis*). After many years, ochronosis produces a distinctive form of degenerative arthritis.

Genetic Basis and Pathogenesis Alkaptonuria was the first human disease shown to be inherited as an autosomal recessive trait. Affected homozygotes occur with a frequency of about 1 in 200,000. Heterozygous carriers are clinically well and excrete no homogentisic acid in urine, even after loading doses of tyrosine. The gene for homogentisate 1,2-dioxygenase (*HGD*) maps to chromosome 3q21-q23 and encodes a 445 amino acid protein expressed not only in liver and kidney but also in small intestine, colon, and prostate. Expression in this latter organ is consistent with accumulation of black calculi of homogentisic acid in the prostate of patients with alkaptonuria, sometimes requiring prostatectomy.

Patients have minimally increased concentrations of homogentisic acid in blood because it is rapidly cleared by the kidney. However, homogentisic acid accumulates in cells and body fluids. Its oxidized polymers bind to collagen, leading to the progressive deposition of a gray to bluish-black pigment. The mechanism(s) by which this deposition causes degenerative changes in cartilage, intervertebral disk, and other connective tissues is unknown but may involve direct chemical irritation, impaired collagen cross-linking, disturbed articular chondrocyte metabolism, or some combination of factors.

Clinical Manifestations Alkaptonuria may go unrecognized until middle life when degenerative joint disease develops. Prior to this time, the tendency of the patient's urine to darken on standing may go unnoticed, as may slight pigmentation of the sclerae and ears. The latter manifestations are generally the earliest external evidence of the disorder and develop after age 20 to 30. Foci of gray-brown scleral pigment and generalized darkening of the concha, anthelix, and finally, helix of the ear are typical. Ear cartilages may be irregular and thickened. *Ochronotic arthritis* is heralded by pain, stiffness, and some limitation of motion of the hips, knees, and shoulders. Acute arthritis may resemble rheumatoid arthritis, but small joints are usually spared. Limitation of motion and ankylosis of the lumbosacral spine are common late manifestations. Pigmentation of heart valves, larynx, tympanic membranes, and skin occurs, and occasional patients develop pigmented renal or prostatic calculi. Degenerative

cardiovascular disease may be increased in older patients.

Diagnosis A patient whose urine darkens to blackness on standing must be suspected of having alkaptonuria, but this may not be observed with the use of modern plumbing conditions. The diagnosis is usually made from the triad of degenerative arthritis, ochronotic pigmentation, and urine that turns black upon alkalinization. Homogentisic acid in urine may be identified presumptively by other tests: after addition of ferric chloride, a purple-black color is observed; treatment with Benedict's reagent yields a brown color; addition of a saturated silver nitrate solution produces an intermediate black color. These screening tests can be confirmed by chromatographic, enzymatic, or spectrophotometric determinations of homogentisic acid. X-rays of the lumbar spine show degeneration and dense calcification of the intervertebral disks and narrowing of the intervertebral spaces (bamboo-like appearance).

TREATMENT

There is no specific treatment for ochronotic arthritis. Joint manifestations might be mitigated if homogentisic acid accumulation and deposition could be curbed by dietary restriction of phenylalanine and tyrosine, but the long-term nature of the disease discourages such therapeutic attempts. Ascorbic acid impedes oxidation and polymerization of homogentisic acid in vitro, but the efficacy of this form of treatment has not been established. Symptomatic treatment is similar to that for osteoarthritis (Chap. 321).

CYSTINOSIS

Definition Cystinosis is a rare disorder characterized by the intralysosomal accumulation of free cystine in body tissues. This results in the appearance of cystine crystals in the cornea, conjunctiva, bone marrow, lymph nodes, leukocytes, and internal organs. Three variants have been identified: an infantile (nephropathic) form leading to the Fanconi syndrome and renal insufficiency in the first decade, a juvenile (intermediate) form in which renal disease is manifest during the second decade, and an adult (benign) form characterized by deposition of cystine in the cornea but not in the kidney.

GENETIC CONSIDERATIONS

All types are inherited as autosomal recessive traits. The gene for the infantile form of nephropathic cystinosis encodes an integral membrane protein, which is a putative lysosomal cystine transporter. The gene is located on chromosome 17p13 and is designated *CTNS*. It is highly expressed in the pancreas, kidney, skeletal muscle, placenta, and heart. A common 65-kb deletion accounts for the majority of patients of European ancestry with infantile cystinosis. The juvenile- and adult-onset forms of nephropathic cystinosis are allelic with the infantile form. Obligate heterozygotes have intracellular cystine concentrations intermediate between those of normal persons and affected patients, but they are free of clinical abnormalities.

The basic defect involves impaired efflux of cystine from lysosomes rather than an abnormality in cystine catabolism. Lysosomal cystine efflux is an active, ATP-dependent

process. The cystine content of tissues may be more than 100 times normal in the infantile form and more than 30 times normal in the adult form. Intracellular cystine in lysosomes does not exchange with other intra- or extracellular pools of this amino acid. Neither plasma nor urinary concentrations of cystine are particularly elevated. Cystine accumulation in the kidney causes renal insufficiency in the infantile and juvenile forms. Patchy depigmentation and degeneration of the peripheral retina occur in the infantile and juvenile forms. Cystine crystals may also be deposited in the cornea, ocular conjunctiva, or uvea.

Clinical Manifestations In the infantile form, abnormalities are usually apparent by 6 to 10 months of age. Growth retardation, vomiting, fever, vitamin D-resistant rickets, polyuria, dehydration, and metabolic acidosis are prominent. Generalized proximal tubular dysfunction (the Fanconi syndrome) leads to hyperphosphaturia and hypophosphatemia, renal glycosuria, generalized amino aciduria, low plasma carnitine, hypouricemia, and often hypokalemia. Death due to uremia or intercurrent infection usually occurs before age 10. Ocular manifestations are prominent. Photophobia is usually demonstrable within the first years of life due to cystine deposits in the cornea, and retinal degeneration may appear even earlier. Hypothyroidism, insulin-dependent diabetes mellitus, and delayed puberty are often observed in older patients.

In contrast, patients with the adult form have only ocular abnormalities. Photophobia, headache, and burning or itching of the eyes are major complaints. Glomerular and tubular function and the integrity of the retina are preserved. The findings in the juvenile variant fall between these extremes. Ocular and renal manifestations do not become significant until the second decade. The renal lesion, albeit milder than that in the infantile form, eventually leads to renal insufficiency.

Diagnosis Cystinosis must be considered in any child with vitamin D-resistant rickets, the Fanconi syndrome, or glomerular insufficiency. Hexagonal or rectangular cystine crystals can be detected in the cornea (by slit-lamp examination), in leukocytes from peripheral blood or bone marrow, or in biopsies of rectal mucosa. Diagnosis is confirmed by measurement of cystine in leukocytes. The infantile form has been diagnosed prenatally by the demonstration of increased cystine content in cultured amniotic fluid cells.

TREATMENT

The adult form is benign and requires no treatment. Symptomatic treatment of renal disease in the infantile or juvenile form includes maintenance of adequate fluid intake to prevent dehydration; correction of the metabolic acidosis; administration of supplementary calcium, phosphate, and vitamin D to heal the rickets; and carnitine supplements (100 mg/kg per day) to correct the increased urinary losses. Specific therapy with the free thiol cysteamine slows the progression of renal dysfunction and improves growth. This compound acts in lysosomes by forming a mixed disulfide with cysteine, allowing it to be transported out of the organelle by an unrelated transporter not affected by the disease. Treatment is more effective if initiated before the patient is 2 years of age. Eye drops containing cysteamine can remove corneal crystals but requires frequent applications (10 to 14 times a day).

Children with nephropathic cystinosis and end-stage renal disease benefit from kidney transplantation. Patients who tolerate the procedure and do not develop immunologic problems have return of kidney function toward normal. The transplanted kidneys have not developed the functional abnormalities typical of cystinosis (i.e., the Fanconi syndrome or glomerular insufficiency). Patients may, however, continue to accumulate cystine in the cornea and other organs (thyroid, brain, and muscle).

PRIMARY HYPEROXALURIA

Definition Primary hyperoxaluria is the designation for two rare autosomal recessive disorders characterized by chronic excessive urinary excretion of oxalic acid and by calcium oxalate nephrolithiasis and nephrocalcinosis. Typically, patients with both forms develop renal insufficiency early in life and die of uremia. Calcium oxalate deposits are widespread in renal and extrarenal tissues, causing a condition referred to as *oxalosis*.

GENETIC CONSIDERATIONS

The metabolic basis for the primary hyperoxalurias involves pathways of glyoxylate metabolism. In type I hyperoxaluria, urinary excretion of oxalate and of the oxidized and reduced forms of glyoxylate is increased. The excessive synthesis of these substances results from a block in glyoxylate metabolism. The primary defect in most patients is deficiency of the hepatic peroxisomal enzyme alanine:glyoxylate amino transferase. The gene (*AGXT*) for this enzyme maps to 2q36-37, and several distinct mutations have been defined in patients with type I hyperoxaluria. Some of these mutations misdirect the enzyme to mitochondria and render it nonfunctional.

In type II hyperoxaluria, L-glyceric acid is excreted in excess along with oxalate. In this condition, activity of D-glyceric acid dehydrogenase, which catalyzes the reduction of hydroxypyruvate to D-glyceric acid in the catabolic pathway of serine metabolism, is absent in leukocytes (and presumably other tissues). The accumulated hydroxypyruvate is instead reduced by lactic dehydrogenase to the L-isomer of glycerate, which is excreted in the urine. The same enzyme possesses glyoxylate reductase activity, and its deficiency promotes the oxidation of glyoxylate to oxalate, thus causing the formation of increased oxalate.

Stone formation, nephrocalcinosis, and oxalosis are due to insolubility of calcium oxalate. Extrarenal deposits of oxalate are prominent in the heart, walls of arteries and veins, male urogenital tract, and bone, particularly in type I hyperoxaluria.

Clinical Manifestations Nephrolithiasis and oxalosis may be manifest during the first year of life. Most patients experience renal colic or hematuria between ages 2 and 10 and succumb to uremia before age 20. With the onset of uremia, patients may develop severe peripheral arterial spasm and necrosis with resulting vascular insufficiency. Oxalate excretion falls as renal failure worsens. In patients with delayed onset of symptoms, survival to age 50 or 60 has been reported, despite recurrent nephrolithiasis. Type II hyperoxaluria is a milder disease with less involvement of extrarenal organs and delayed impairment of kidney function.

Diagnosis Oxalate excretion in normal children or adults is <0.5 mmol (60 mg) per 1.73

m^2surface area per day. Patients with type I or type II hyperoxaluria excrete two to four times this amount. Distinction between the two types depends on the identification of the other organic acids that identify them: glycolic acid in type I and L-glyceric acid in type II. Since patients with pyridoxine deficiency or chronic ileal disease may excrete excessive amounts of oxalate, these conditions must be excluded.

TREATMENT

There is no satisfactory treatment. Increasing the volume of urine can transiently reduce urinary oxalate concentration. Large doses of pyridoxine (100 mg/d) may reduce urinary oxalate in some patients, but long-term effects are not dramatic. A diet high in phosphate content seems to reduce the frequency of attacks of renal colic, but oxalate excretion is unaffected. Combined liver-kidney transplantation can correct the enzyme deficiency and replace the damaged organs. Liver transplantation seems promising in patients diagnosed before the onset of kidney failure.

353. INHERITED DEFECTS OF MEMBRANE TRANSPORT - *Nicola Longo*

Specific membrane transporters mediate the passage of a wide variety of substances across plasma cell membranes. Classes of substrates represented include amino acids, sugars, cations, anions, vitamins, and water. The disorders considered in this chapter have three features in common: each is characterized by a specific defect in the transport of one or more compounds; each is inherited as a dominant or recessive trait, implying that variation in a single genetic locus is involved; and each is presumed to reflect a primary alteration in a specific membrane protein. Many of these defects have been well characterized physiologically and genetically. Inherited defects impairing the transport of amino acids, hexoses, and chloride are discussed here as examples of the abnormalities encountered; others are considered elsewhere in this text.

The number of inherited disorders of membrane transport continues to increase with the identification of new transporters and the clarification of the molecular basis of diseases with previously unknown pathophysiology. The first transport disorders identified affected the gut or the kidney, but transport processes are now proving essential for the normal function of every organ. Mutations in transporter molecules have been demonstrated in disorders of the heart, muscle, brain, and endocrine and sensory organs (see examples inTable 353-1). In some cases, the same phenotype can be caused by mutations in different genes (*nonallelic heterogeneity*), often because they encode interacting proteins. In other cases, distinct mutations in the same gene (*allelic heterogeneity*) can cause different diseases depending on the degree of functional inactivation caused by the mutation, the presence of dominant-negative effects, or paradoxical activation of function.

DISORDERS OF AMINO ACID TRANSPORT

As listed inTable 353-1, 10 disorders of amino acid transport have been described. Five (cystinuria, dibasic aminoaciduria, Hartnup disease, iminoglycinuria, and dicarboxylic aminoaciduria) show transport abnormalities for structurally related amino acids, thereby implying the existence of group-specific membrane receptors or carriers. With the exception of iminoglycinuria and dicarboxylic aminoaciduria, the defects have important clinical consequences. The remaining five disorders affect the transport of only one amino acid, implying the existence of substrate-specific transport systems. Each of these conditions affects transport in the kidney, gut, or both; none has been shown to alter transport in other tissues.

CYSTINURIA

Definition Cystinuria, the most common inborn error of amino acid transport, is characterized by impaired renal tubular reabsorption and excessive urinary excretion of the dibasic amino acids lysine, arginine, ornithine, and cystine. A similar transport defect exists in the intestinal mucosa. Because cystine is the least soluble of the naturally occurring amino acids, its overexcretion predisposes to the formation of renal, ureteral, and bladder stones. Such stones are responsible for the signs and symptoms of the disorder.

GENETIC CONSIDERATIONS

Cystinuria is among the most common inborn errors, with a frequency of 1 in 10,000 to 1 in 15,000 in many ethnic groups. The disorder is transmitted as an autosomal recessive trait and results from impaired function of membrane carrier proteins in the apical brush border of proximal renal tubule and small intestinal cells.

There are three genetic variants of cystinuria. The urinary excretion patterns and renal clearance abnormalities in each type are similar in homozygotes, but the three variants are distinguished by studies of intestinal transport in homozygotes and urinary excretion patterns in heterozygotes. Type I homozygotes lack mediated intestinal transport of cystine, lysine, arginine, and ornithine; heterozygotes have normal urinary amino acid excretion patterns. Type II homozygotes lack mediated lysine transport in the gut but retain some capacity for cystine transport; heterozygotes have moderately increased urinary excretion of each of the four amino acids. Type III homozygotes retain some capacity for mediated intestinal transport of the four involved substrates; heterozygotes have modestly increased urinary lysine and cystine. The gene for type I cystinuria (*SLC3A1*) encodes solute carrier family 3 and maps to chromosome 2p16.3. The other two types of cystinuria (types II and III) are caused by mutations in *SLC7A9*, which maps to chromosome 19q13 and encodes the light subunit needed for the correct processing of SLC3A1.

Clinical Manifestations Massive excretion of cystine and the other disbasic amino acids occurs in homozygotes with classic cystinuria. Cystine stones account for 1 to 2% of all urinary tract calculi but are the most common cause of stones in children. The maximum solubility of cystine in the physiologic urinary pH range of 4.5 to 7.0 is about 1200 umol/L (300 mg/L). Since affected homozygotes regularly excrete 2400 to 7200 umol (600 to 1800 mg) daily, crystalluria and stone formation are a constant threat. Stone formation usually becomes manifest in the second or third decade but may occur in the first year of life or as bladder calculi at birth. Symptoms and signs are those typical of urolithiasis: hematuria, flank pain, renal colic, obstructive uropathy, and infection (Chap. 279). Recurrent urolithiasis may lead to progressive renal insufficiency.

Diagnosis The presence of cystine in a urinary tract stone is pathognomonic of cystinuria. However, because half the stones in cystinuric individuals are of mixed composition, and because the cystine core in as many as 10% may not be detected, a urinary nitroprusside test should be performed on all patients with urolithiasis to exclude this diagnosis. The nitroprusside test is also positive (appearance of a cherry red color) in some heterozygotes for cystinuria and in patients with hypercystinuria, homocystinuria, and mercaptolactate-cysteine disulfiduria. When cystine content exceeds 1000 umol/L (250 mg/L), cystine crystals may be seen in the sediment of acidified, concentrated, chilled urine. These hexagonal crystals are pathognomonic of cystine overexcretion in patients not taking sulfonamides.

Diagnostic confirmation of cystinuria depends on demonstration of the characteristic amino acid excretion pattern in the urine. Selective overexcretion of cystine, lysine, arginine, and ornithine can be demonstrated by qualitative and quantitative chromatography. Quantitation is important for differentiating heterozygotes from homozygotes and for following free cystine excretion during therapy.

TREATMENT

Management is aimed at preventing cystine crystal formation by reducing the concentration of cystine in urine. This aim is accomplished by increasing urinary volume and by maintaining an alkaline urine pH. Fluid ingestion in excess of 4 L/d is essential, and 5 to 7 L/d is optimal. Urinary cystine concentration should be<1000 to 1200 umol/L (250 to 300 mg/L). The daily fluid ingestion necessary to maintain this dilution of excreted cystine should be spaced over 24 h, with one-third of the total volume ingested between bedtime and 2 to 3 A.M. Stones can be prevented and even dissolved by such hydration. It must be made clear to individuals with cystinuria that water is a necessary drug for them. Solubility of cystine in urine rises sharply above pH 7.5, and urinary alkalinization can be therapeutic in some situations. Vigorous administration of sodium bicarbonate, acetazolamide, and polycitrates is required to maintain a persistently alkaline pH, but this measure introduces the danger of inducing formation of calcium oxalate, calcium phosphate, and magnesium ammonium phosphate stones and of producing nephrocalcinosis.

Another treatment involves administration of penicillamine, which undergoes sulfhydryl-disulfide exchange with cystine to form the mixed disulfide of penicillamine and cysteine. Since this disulfide is more than 50 times as soluble as cystine, penicillamine (1 to 3 g/d) reduces free cystine excretion markedly, thereby preventing new stone formation and promoting dissolution of existing calculi. Unfortunately, side effects include acute serum sickness, agranulocytosis, pancytopenia, immune glomerulitis, and the Goodpasture syndrome. Thus its use should be reserved for patients who fail to respond to hydration alone or who are in a high-risk category (one remaining kidney, renal insufficiency). Tiopronin (a-mercaptopropionylglycine, 800 to 1200 mg/d in four divided doses) has a mechanism of action similar to that of penicillamine, has lower toxicity, and is a suitable alternative. Captopril, a sulfhydryl-containing antihypertensive agent, has limited efficacy to reduce cystine excretion. When medical management fails, urologic surgery is required, but it should be a last resort as cystine stones reform more easily in scarred epithelium. Small (<1.5 cm) cystine stones can be treated with extracorporeal shock wave lithotripsy. Ureteroscopic removal is effective for ureteral stones, while larger or branched cystine stones require percutaneous nephrostolithotomy, sometimes associated with other procedures. All these procedures may produce smaller fragments, which can cause severe renal colic. Occasional patients progress to renal failure and require kidney transplantation.

DIBASIC AMINOACIDURIA

This disorder is characterized by a defect in renal tubular reabsorption of the three dibasic amino acids lysine, arginine, and ornithine but *not* cystine. There are two variants, transmitted as autosomal recessive traits. In the common form of dibasic aminoaciduria (type II), also known as *lysinuric protein intolerance*, homozygotes show defective intestinal transport of dibasic amino acids as well as exaggerated renal losses. It is most common in Finland (1 in 60,000) and is rare elsewhere. The transport defect affects basolateral rather than luminal membrane transport and is associated with impairment of the urea cycle. The defective gene (*SLC7A7*) in this condition maps to chromosome 14q11.2 and encodes a unique membrane transporter, y^+LAT, that

associates with the cell-surface glycoprotein 4F2 heavy chain to form the complete sodium-independent transporter y^+L. The requirement for multiple gene products in the formation of this dimeric transporter probably explains part of the intrafamilial variability observed in lysinuric protein intolerance.

Manifestations are related to the losses of ornithine, arginine, and lysine. Affected patients present in childhood with hepatosplenomegaly, protein intolerance, and episodic ammonia intoxication. Older patients may present with severe osteoporosis, impairment of kidney function, or interstitial changes in the lungs. Plasma concentrations of lysine, arginine, and ornithine are reduced, whereas urinary excretion of lysine and orotic acid are increased. Hyperammonemia may develop after the ingestion of protein loads or with infections, probably due to insufficient amounts of arginine and ornithine to maintain proper function of the urea cycle. The clinical features have been attributed to the hyperammonemia and to insufficient amounts of lysine to support protein synthesis during growth.

Type I dibasic aminoaciduria has been described in a large French-Canadian kindred. Type I patients have profound mental retardation without hyperammonemia and protein intolerance. The condition also differs from type II by the presence of a modest excess of dibasic amino acids in the urine of asymptomatic heterozygotes. Type I disease may involve the same transport system as that impaired in the more common type II dibasic aminoaciduria.

TREATMENT

Dietary protein should be restricted in conjunction with supplementation of citrulline (2 to 8 g/d), a neutral amino acid that fuels the urea cycle when metabolized to arginine and ornithine. Carnitine supplements may improve growth by sparing lysine and by enhancing fatty acid oxidation. Pulmonary disease responds to glycocorticoids in some patients.

HARTNUP DISEASE

Pellagra-like skin lesions, variable neurologic manifestations, and neutral or aromatic aminoaciduria characterize this disease. Alanine, serine, threonine, valine, leucine, isoleucine, phenylalanine, tyrosine, tryptophan, glutamine, asparagine, and histidine are excreted in urine in quantities 5 to 10 times normal, and intestinal transport of these same amino acids is defective. The clinical manifestations result from nutritional deficiency of the essential amino acid tryptophan, caused by its intestinal and renal malabsorption. Manifestations are episodic, related in part to metabolic demands for tryptophan. Only a small fraction of patients with the chemical findings of this disorder develop a pellagra-like syndrome, implying that manifestations depend on other factors in addition to the transport defect.

Hartnup disease is inherited as an autosomal recessive trait, and the gene has been mapped to chromosome 11q13. Homozygotes occur with a frequency of about 1 in 24,000 births. Heterozygotes exhibit no clinical or chemical abnormalities. In patients with Hartnup disease, the renal and intestinal transport defect for tryptophan leads to niacin deficiency. Tryptophan metabolism leads to the synthesis of niacin and

nicotinamide-adenine dinucleotide and supplies about half the daily niacin needs. The transport defect likely reflects abnormalities of a group-specific system for neutral amino acids. Some residual reabsorptive capacity persists for each involved amino acid. This suggests that they are transported by other carrier systems as well, a conclusion supported by the identification of patients with substrate-specific transport defects for tryptophan, methionine, and histidine.

The diagnosis of Hartnup disease should be suspected in any patient with clinical features of pellagra without a history of dietary niacin deficiency (Chap. 75). The neurologic and psychiatric manifestations range from attacks of cerebellar ataxia to mild emotional lability to frank delirium and are usually accompanied by exacerbations of the erythematous, eczematoid skin rash. Fever, sunlight, stress, and sulfonamide therapy provoke clinical relapses. Diagnosis is made by detection of the neutral aminoaciduria, which does not occur in dietary niacin deficiency. Treatment is directed at niacin repletion and includes a high-protein diet and daily nicotinamide supplementation (50 to 250 mg). Tryptophan ethyl esters can also bypass the absorption defect.

IMINOGLYCINURIA

This benign autosomal recessive trait is characterized by excessive urinary excretion of glycine and the imino acids proline and hydroxyproline. Homozygotes occur with a frequency of about 1 in 16,000. The enhanced excretion of glycine, proline, and hydroxyproline reflects a defect in the tubular transport system shared by these three compounds. An intestinal transport defect may also be present. This suggests that more than one mutation may lead to iminoglycinuria, a thesis corroborated by the demonstration that obligate heterozygotes from some, but not all, families have glycinuria. No consistent clinical abnormalities have been reported in homozygotes that are usually detected by urinary amino acid screening programs.

DICARBOXYLIC AMINOACIDURIA

Selective urinary loss and exaggerated endogenous renal clearance of glutamic and aspartic acids have been described in two unrelated children. Intestinal absorption of these dicarboxylic amino acids was impaired in one. This patient suffered from recurrent hypoglycemia; the other was asymptomatic.

SUBSTRATE-SPECIFIC DEFECTS IN AMINO ACID TRANSPORT

Rare pedigrees exist in which individuals have defective renal tubular reabsorption and/or impaired intestinal absorption of a single free amino acid (Table 353-1). These disorders, each apparently inherited as an autosomal recessive trait, suggest that transport of amino acids is catalyzed by substrate-specific as well as group-specific transport mechanisms. Examples include hypercystinuria, lysinuria, histidinuria, and selective malabsorption of methionine or tryptophan.

DISORDERS OF HEXOSE TRANSPORT

D-Glucose is the major carbohydrate used by the cell for energy production and many other anabolic purposes. A number of transporter proteins work together to maintain

glucose homeostasis in the intact organism by coordinating absorption and utilization of D-glucose by all cells in the body. Two main classes of glucose transporters have been identified in humans: active Na^+-glucose cotransporters (SGLT) and the facilitative glucose transporters (GLUT). Na^+-glucose cotransporters actively concentrate glucose inside intestinal and renal cells using the electrochemical potential of Na^+ as their energy source. Defects in this class of transporters cause renal glycosuria (SGLT2) and intestinal glucose-galactose malabsorption (SGLT1). Facilitative glucose transporters allow glucose to enter cells using its own concentration gradient. This process is essential for the delivery of glucose to the cell for energy production. Defects in facilitative transporters cause the glucose-transporter protein syndrome (GLUT1) and the Fanconi-Bickel syndrome (GLUT2) and may be involved in one subtype of glycogen storage disorder (GLUT7).

DISORDERS OF CONCENTRATIVE GLUCOSE TRANSPORTERS

Renal glycosuria is characterized by the urinary excretion of glucose at normal concentrations of blood glucose. The renal tubular malabsorption is specific for glucose. Unlike generalized tubular dysfunction, other compounds such as phosphate and amino acids are transported normally. The genetic basis for this condition is not known at present. The condition is benign, but occasionally glycosuria may be severe enough to cause polyuria and polydipsia. Even more rarely, dehydration or ketosis may develop under conditions of stress such as pregnancy or starvation.

In normal persons, glucose is present in the glomerular filtrate at a concentration equal to that in plasma water and is reabsorbed throughout the proximal renal tubule by a sodium-dependent, phlorizin-inhibitable transport process. Reabsorptive capacity exceeds normal plasma glucose concentration. The plasma concentration at which filtered glucose begins to escape proximal tubular reabsorption is usually around 10 mmol/L (200 mg/dL). Maximal renal absorptive capacity is exceeded at a filtered load of around 2 mmol (325 mg)/min per 1.73 m_2 body surface area, and this value is defined as the tubular maximum for glucose (TmG).

Two patterns of glycosuria are recognized: type A, characterized by a reduced tubular maximum reabsorptive capacity, and type B, showing a reduced threshold for glycosuria, an increased "splay" in the titration curve, and a normalTmG. Renal glycosuria occurs in homozygotes with either of these recessively inherited mutations and in compound heterozygotes with these presumably allelic mutations. Modest reduction in renal threshold or TmG is present in heterozygotes in some families; modest glycosuria occurs in such family members when plasma glucose is elevated. In the few patients studied, renal glycosuria was not associated with impaired intestinal transport.

Glucose-galactose malabsorption is characterized by profuse, watery diarrhea in infants fed milk or foods containing lactose, sucrose, glucose, or galactose. The primary defect involves the sodium-hexose cotransporter in the intestinal and renal brush border. A specific defect in intestinal absorption of glucose and galactose can be demonstrated by oral tolerance tests that produce little or no increase in plasma glucose or galactose. Active D-glucose and D-galactose transport is absent in affected children, and intermediate transport capacity is present in their parents. Fructose-containing or

carbohydrate-free formulas are well tolerated. Treatment with a glucose- and galactose-free diet leads to resolution of symptoms in childhood. Although the basic transport defect is present throughout life, most patients show an improved tolerance for glucose and galactose with age.

A number of these patients have renal glycosuria at normal plasma glucose concentrations. Renal titration studies generally demonstrate a reduced threshold for glucose reabsorption (type B renal glycosuria) and a normalTmG. Urinary glucose loss is not as severe as in isolated renal glycosuria. This finding suggests the presence of multiple glucose transport proteins in the kidney. One, whose gene remains to be identified, is responsible for the bulk of glucose reabsorption in the proximal convoluted tubule and is believed to be abnormal in renal glycosuria. Another transporter, SGLT1, is shared by glucose and galactose and is responsible for the reabsorption of the least traces of glucose in the late proximal straight tubule. Its function is abnormal in glucose-galactose malabsorption, and heterogeneous mutations have been found in the *SGLT1* gene on chromosome 22q. In glucose-galactose malabsorption, as in renal glycosuria, transport of sugars in other tissues is normal, reflecting the multiplicity and tissue specificity of hexose transporters.

DISORDERS OF FACILITATIVE GLUCOSE TRANSPORTERS

At least five different facilitative glucose transporters (GLUT1, -2, -3, -4, and -7) mediate the influx and efflux of glucose in mammalian cells. Disease-causing mutations have been identified in two of these transporters (GLUT1 and GLUT2). The tissue specificity and redundancy of facilitative glucose transporters in different tissues helps to explain the clinical manifestations that result from their defective function. De novo mutations in the gene encoding the ubiquitous GLUT1 transporter cause the glucose-transporter protein syndrome. Patients present with seizures, developmental delay, and acquired microcephaly. These patients have normal blood glucose concentration but markedly decreased concentration of glucose in their cerebrospinal fluid. GLUT1 is the predominant glucose transporter in the blood-brain barrier. Haploinsufficiency reduces the transfer of glucose through the blood-brain barrier, restricting the energy supply to the brain. This defect is expressed in other cells, such as erythrocytes and fibroblasts, that have less stringent energy requirements or express additional glucose transporters, preventing cellular damage and clinical sequelae. Therapy in the glucose-transporter protein syndrome consists of using a ketogenic diet to deliver alternative fuels to the brain.

The GLUT2 transporter is expressed mainly in liver, pancreaticb cells, and in the basolateral membrane of gut and renal tubular cells. Truncating mutations in the *GLUT2* transporter gene have been identified in the autosomal recessive disorder Fanconi-Bickel syndrome. Patients present early in life with failure to thrive and polydipsia, with prominent glycosuria and aminoaciduria, rickets, fasting hypoglycemia with ketonuria, and prolonged postprandial hyperglycemia. Glycogen is accumulated in the liver and kidney, reflecting the inability to release glucose through the GLUT2 transporter. This results in fasting hypoglycemia and ketonuria and in generalized renal tubular dysfunction. The prolonged postprandial hyperglycemia is due to decreased sugar uptake by the liver and by the pancreaticb cell, the latter resulting in defective insulin synthesis and release. Affected patients do not develop diabetes because

human pancreatic b cells have alternative glucose transporters (GLUT1 and GLUT3) that can partially compensate for the absence of GLUT2 transporters. Therapy consists of symptomatic replacement of the renal losses of water and electrolytes, vitamin D replacement, and a diet plan consisting of frequent meals rich in complex carbohydrates to prevent hypoglycemia, analogous to the treatment of patients with glycogen storage diseases (Chap. 350).

DEFECTIVE ANION TRANSPORT: CHLORIDORRHEA

This rare, autosomal recessive disease results from impairment of active transport of chloride in the ileum and colon. Absence of chloride-bicarbonate ion exchange causes profound symptoms even before birth (polyhydramnios and absence of meconium). Massive watery diarrhea is apparent from the first days of life. This fluid loss, with its attendant impairment of electrolyte homeostasis, is life-threatening. A hypokalemic, hypochloremic, hyponatremic metabolic alkalosis develops with dehydration and secondary hyperaldosteronism. Fecal fluid contains an excess of chloride ion over the sum of the accompanying cations sodium and potassium. Fecal chloride concentration always exceeds 90 mmol/L when volume and serum electrolyte disturbances are corrected, and this chloridorrhea is diagnostic. Renal chloride transport is normal. Decreased urine chloride results from the kidney's attempts to conserve salt and water. The defective gene in this condition, called *DRA* (for downregulated in adenoma), maps to chromosome 7q and encodes an anion transporter, which is expressed only in the gastrointestinal tract. A deletion of the Val 317 codon in the *DRA* gene is responsible for the Finnish form of congenital chloride diarrhea.

Treatment requires adequate, lifelong repletion of electrolyte and fluid losses. Exact replacement of water, sodium chloride, and potassium chloride can prevent the growth and psychomotor retardation and the development of progressive renal damage. The renal lesion, with hyalinized glomeruli, juxtaglomerular hyperplasia, calcifications, and arteriolar changes, is probably a result of chronic volume depletion. Treatment of hyperreninemia and hypokalemia with prostaglandin inhibitors may reduce renal damage but does not alter intestinal symptoms or the need for chronic sodium chloride repletion. Omeprazole, while not decreasing the need for adequate oral replacement of electrolytes, may decrease stool output and improve the social life of patients.

354. THE LIPODYSTROPHIES AND OTHER PRIMARY DISORDERS OF ADIPOSE TISSUE - *Abhimanyu Garg*

The distribution and quantity of adipose tissue are controlled by multiple factors, including genetic background, diet, hormones, and exercise. The lipodystrophies are a heterogeneous group of adipose tissue disorders characterized by a selective loss of body fat (Tables 354-1 and354-2). Patients with lipodystrophies have a propensity to develop insulin resistance, hypertriglyceridemia, diabetes mellitus, and fatty liver.

FAMILIAL OR GENETIC LIPODYSTROPHIES

CONGENITAL GENERALIZED LIPODYSTROPHY (BERARDINELLI-SEIP SYNDROME)

Clinical Features The primary diagnostic features of congenital generalized lipodystrophy (CGL) include a near-total lack of body fat and a marked muscular appearance from birth (Fig. 354-1*A*). On careful physical examination, however, fat can be detected in the palms and soles; with magnetic resonance imaging (MRI), normal amounts of fat can also be visualized in the orbits, scalp, perineum, and juxtaarticular and epidural regions (where the cushioning or protective functions of adipose tissue are critical). MRI studies also reveal a near-complete absence of metabolically active adipose tissue from most subcutaneous areas, intraabdominal and intrathoracic regions, and bone marrow.

Children exhibit accelerated linear growth and advanced bone age, but plasma levels of growth hormone or insulin-like growth factor I (IGF-I) are normal. Their basal metabolic rate is relatively high. It is unclear, however, whether hypermetabolism results from a primary increase in sympathetic nervous system activity or whether it is a compensatory response to protect against excessive heat loss due to extreme lack of body fat. Other features include acanthosis nigricans, prominent umbilicus or hernia, and an acromegalic appearance with coarse facial features and large hands and feet. Occasionally, excess body hair and hyperhidrosis have been noted. Fatty liver has been noted during infancy and can lead to cirrhosis and its complications. Liver, spleen, and kidney enlargement can cause abdominal protuberance. A few patients develop hypertrophic cardiomyopathy, but it rarely leads to heart failure.

Postpubertal women may have clitoromegaly, mild hirsutism, polycystic ovaries, and oligomenorrhea. Successful pregnancy in affected women is rare, whereas affected males have normal reproductive potential. Penile enlargement may be noted in childhood. After puberty, the skeleton appears sclerotic and focal lytic lesions develop in the appendicular bones. Some patients develop goiter.

Metabolic Abnormalities Patients withCGL have markedly elevated fasting serum insulin and C-peptide concentrations, as well as extreme insulin resistance. Diabetes mellitus appears during the pubertal years, and pancreatic pathology reveals severe amyloidosis of the pancreatic islets with loss of b cells. Plasma leptin concentrations are low, as expected in view of the reduced adipose tissue. Fasting plasma free fatty acid concentrations are normal. Hypertriglyceridemia may be observed during childhood, and patients can develop chylomicronemia, eruptive xanthomas, and acute pancreatitis. Low

concentrations of high-density lipoprotein (HDL) cholesterol are also common.

Course Patients withCGL are at risk of early mortality from cirrhosis and its complications, acute pancreatitis, or diabetic nephropathy. They also may develop diabetic retinopathy. Despite long-standing hypertriglyceridemia and hyperglycemia, atherosclerotic vascular complications are rare.

GENETIC CONSIDERATIONS

Approximately 120 patients of various ethnic backgrounds have been reported with this autosomal recessive form of lipodystrophy. The absence of fat could result from agenesis, failure of differentiation of preadipocytes, or an inability of mature adipocytes to synthesize and/or store triglycerides. Numerous candidate genes have been excluded, including the insulin receptor,b_3-adrenergic receptor, fatty acid binding protein 2,IGF-Ireceptor, insulin receptor substrate-1, hormone-sensitive lipase, leptin, and peroxisome proliferator-activated receptor g. Genome-wide linkage analysis of 17 families revealed genetic heterogeneity, but a candidate *CGL1* gene was localized to chromosome 9q34; the defective *CGL* gene(s) have yet to be identified.

FAMILIAL PARTIAL LIPODYSTROPHY

Dunnigan Variety

Clinical Features Patients with familial partial lipodystrophy, Dunnigan variety (FPLD) appear normal during childhood. During puberty, however, these patients begin to lose subcutaneous fat from the limbs and trunk, while exhibiting "increased muscularity" (Fig. 354-1*B*). Many patients accumulate excess fat in the face and neck, often resulting in a double chin, supraclavicular humps, and round face. Occasionally, fat accumulates in the axillae. Labia majora appear prominent in women.MRIdemonstrates excess fat inside the abdomen and in the intermuscular fasciae. Bone marrow and fat in certain mechanical locations, such as the orbits and joints, are normal. Acanthosis nigricans, hirsutism, menstrual abnormalities, and polycystic ovaries are infrequent. Hepatomegaly due to fatty liver is common, but progression to cirrhosis has not been reported.

Metabolic Abnormalities Patients withFPLDhave mild to moderate insulin resistance, and diabetes mellitus develops, usually after the second decade. Patients have low serumHDLcholesterol and can develop severe hypertriglyceridemia. Fasting plasma free fatty acid concentrations may be elevated.

Course Major causes of morbidity and mortality in patients withFPLDinclude coronary heart disease, other atherosclerotic vascular complications, and acute pancreatitis.

GENETIC CONSIDERATIONS

This rare autosomal dominant disorder has been reported in 35 Caucasian families and one Indian family comprising approximately 200 affected individuals. The *FPLD* locus has been mapped to chromosome 1q21-22. Recently, several missense mutations in the gene encoding the nuclear envelope protein lamin A/C (*LMNA*) have been found to be responsible forFPLD. Alternative splicing of *LMNA* produces Lamins A and C,

members of the intermediate filament multigene family. All mutations causing typical FPLD cluster in exon 8 of *LMNA*, affecting the globular C-terminal tail of the Lamin A/C protein except one in exon 11 that only affects Lamin A and causes an atypical mild FPLD. The loss of subcutaneous adipose tissue in the limbs and trunk in FPLD may be due to adipocyte apoptosis and degeneration. Fat accumulation in the face and neck may be a secondary phenomenon, since it is not always present.

Kobberling Variety Characteristic features include loss of fat from the limbs with preservation of facial fat; truncal subcutaneous fat may be excessive. Most patients have hypertriglyceridemia and diabetes mellitus. Still unknown are the pattern of inheritance, age of onset, and whether this disorder is a distinct entity or a variant of the Dunnigan variety. Only a few women from two small pedigrees and four sporadic cases have been reported; it is not yet clear whether men can also be affected.

Mandibuloacral Dysplasia Variety This autosomal recessive disorder is characterized by short stature, high-pitched voice, mandibular and clavicular hypoplasia, dental abnormalities, acroosteolysis, stiff joints, and ectodermal defects. A few patients have also exhibited loss of limb fat. Insulin resistance and diabetes mellitus are rare.

OTHER TYPES

An autosomal dominant type of generalized lipodystrophy with acromegaloid features has been reported in a pedigree from Brazil. The onset of lipodystrophy occurred after 18 years of age. In another form of lipodystrophy, marked loss of subcutaneous fat from the limbs, face, palms, and soles, but excess subcutaneous fat in the neck and trunk has been noted.

ACQUIRED LIPODYSTROPHIES

ACQUIRED GENERALIZED LIPODYSTROPHY (LAWRENCE SYNDROME)

This form of lipodystrophy has been reported in approximately 50 patients and is characterized by a generalized disappearance of fat, mostly during childhood or adolescence. It is three times more common in females than males.

Clinical Features Fat loss affects the face, neck, trunk, and extremities and usually occurs over several months or years; superficial veins and muscles become prominent (Fig. 354-1*C*). Fat loss can include the palms and soles. In some, the onset of the disorder was reported after infections such as varicella, measles, pertussis, diphtheria, pneumonia, osteomyelitis, parotitis, infectious mononucleosis, or hepatitis. In others, lipodystrophy starts with painful, purple-brown subcutaneous nodules that leave depressed areas with loss of subcutaneous fat. Adipose tissue may show infiltration with lymphocytes, mononuclear macrophages, fat-cell necrosis, and fat-filled macrophages; this infiltration is consistent with a type of acute panniculitis. Almost one-third of these patients develop acanthosis nigricans, and some have mild hirsutism. Hepatomegaly due to fatty infiltration is a consistent finding and can lead to cirrhosis. Splenomegaly has also been reported.

Metabolic Abnormalities Ketosis-resistant diabetes mellitus usually occurs after the

onset of lipodystrophy, and metabolic abnormalities are similar to those inCGL. Severely hyperglycemic patients may have elevated plasma free fatty acids.

Pathogenesis It is not yet known whether preceding infections play a causal role in this disorder. Some patients reportedly develop autoimmune diseases, including childhood dermatomyositis, juvenile rheumatoid arthritis, Hashimoto's thyroiditis, vitiligo, hemolytic anemia, or chronic active hepatitis. Autoantibodies against adipocyte membranes have been reported; it seems likely that antibody- and/or cell-mediated adipocyte lysis causes fat loss in these patients.

ACQUIRED PARTIAL LIPODYSTROPHY (BARRAQUER-SIMONS SYNDROME)

This form of lipodystrophy affects females three times more often than males and has been reported in about 200 patients. The onset usually occurs during childhood or adolescence. Fat loss typically affects the face, neck, upper limbs, thorax, and upper abdomen, and there is increased fat deposition in the hips and lower extremities (Fig. 354-1*D*).

Clinical Features Fat loss occurs gradually over 1 to 2 years and initially affects the face; other areas are affected later. In most cases, the lower abdomen, hips, and lower extremities are spared. In general, patients do not develop insulin resistance and other metabolic abnormalities, acanthosis nigricans, hirsutism, or menstrual problems. Approximately one-third of patients develop mesangiocapillary glomerulonephritis, usually 10 years after disease onset. Systemic lupus erythematosus and other autoimmune diseases have also been reported, including childhood dermatomyositis, thyroiditis, pernicious anemia, celiac disease, dermatitis herpetiformis, rheumatoid arthritis, Sjogren's syndrome, temporal arteritis, and leukocytoclastic vasculitis. In addition, many patients have serum antinuclear and anti-double-stranded DNA antibodies.

Pathogenesis C3 nephritic factor (C3NeF), a polyclonal IgG immunoglobulin, can be detected in the serum of up to 90% of these patients. Serum C3 is universally low, but C1q, C4, C5, C6, factor B, and properdin concentrations are usually normal (which suggests activation of the alternative complement pathway). Loss of fat may be due to C3NeF-induced lysis of adipocytes that express factor D. C3NeF also binds and inactivates factor H, which can induce glomerulonephritis by mechanisms similar to those seen in genetic factor H deficiency.

HIV-1 PROTEASE INHIBITOR-INDUCED LIPODYSTROPHY

Highly active antiretroviral therapy (HAART) therapy for HIV, a combination which includes HIV-1 protease inhibitors, is associated with the development of lipodystrophy in the majority of patients after 18 months to 2 years of treatment (Chap. 309). It is characterized by marked reduction in subcutaneous fat from the face, trunk, and limbs, resulting in an appearance of "increased muscularity." Excess fat may also accumulate around the neck (double chin and buffalo hump) and inside the abdomen. Patients are prone to develop insulin resistance, diabetes mellitus, and hypertriglyceridemia. It is unclear whether this disorder is caused by a side effect of one or more of the drugs (most likely a protease inhibitor) or by a metabolic response to dramatic reduction of

viral load. Hormonal causes, such as hypercortisolism, have been excluded.

LOCALIZED LIPODYSTROPHIES

These disorders are characterized by a loss of subcutaneous adipose tissue from small areas or parts of a limb. Fat loss may occur secondary to injections of insulin, glucocorticoids, antibiotics, iron dextrans, or diphtheria/pertussis/tetanus vaccine. Repeated pressure against any body part, such as the thigh or chin, can cause lipodystrophy. In some patients, acute panniculitis causes localized lipodystrophy without progressing further. *Centrifugal lipodystrophy* begins in the abdomen, groin, and axillae of children under the age of 3, and eventually spreads to involve the entire abdomen. The surrounding areas show slightly erythematous and scaly changes with an accumulation of lymphocytes and histiocytes on histology. Complete or partial improvement occurs spontaneously after 8 to 10 years.

TREATMENT

Patients with lipodystrophies have cosmetic problems that warrant judicious treatment. Facial reconstruction can be accomplished with free flaps, transposition of facial muscle, and silicone or other implants. In acquired partial lipodystrophy, adipose tissue transplantation from the thigh to face lasts for only 2 to 5 years. InFPLD, excess fat in the face and neck may require liposuction or lipectomy. Etretinate and fish oil have improved acanthosis nigricans in some patients with generalized lipodystrophy.

Dietary fat should be restricted for patients with severe hypertriglyceridemia. Reduced energy intake and increased physical activity can mitigate insulin resistance. In children, however, enough energy should be provided to allow for normal growth and development. Medium chain triglycerides have been reported to benefit some patients with acquired generalized lipodystrophy.

In patients withCGL, diabetes control may require extremely high doses of insulin. Oral hypoglycemic agents may also be used (Chap. 333). Glycemic control can mitigate dyslipidemia and prevent diabetic complications. Severe hypertriglyceridemia should be treated with fibrates and/or omega-3 polyunsaturated fatty acids. Niacin worsens glycemic control and should not be used. Estrogens should be avoided because they may accentuate hypertriglyceridemia and can cause acute pancreatitis.

LIPOMATOSIS

MULTIPLE SYMMETRIC LIPOMATOSIS (MADELUNG DISEASE)

This type of lipomatosis affects men 4 to 15 times more frequently than women. It is characterized by a symmetric, progressive growth of nonencapsulated subcutaneous adipose tissue, primarily in the neck (bull neck with buffalo hump and double chin) and supraclavicular and shoulder regions. Fat may also accumulate in the trunk and proximal limbs, though the distal arms and legs are spared. Rarely, laryngeal, tracheal, or vena caval compression may occur from deep lipomatous infiltration in the neck and mediastinum. Many patients also have peripheral neuropathy; hypertriglyceridemia and hyperuricemia are uncommon. SerumHDLcholesterol levels are usually elevated, and

diabetes mellitus has not been reported.

Most of these patients have a preceding history of heavy ethanol intake. The underlying mechanisms and predisposing factors for the disorder, however, remain unknown. The lipomatous tissue contains small adipocytes (but not brown fat) with increased lipoprotein lipase activity and reduced catecholamine-stimulated lipolysis. In several families and in some sporadic cases, mitochondrial DNA mutations A-to-G and G-to-A transitions at nucleotides 8344 and 8363, respectively, or deletions in the $tRNA_{Lys}$ gene have been reported. Most of these patients had multiple, discrete, and encapsulated lipomas in the neck and trunk, which is distinct from the features of typical patients with multiple symmetric lipomatosis. These patients also have associated peripheral neuropathy, myopathy, cerebellar ataxia, myoclonus, or hearing loss. Mitochondrial DNA mutations have not been found in many patients with typical multiple symmetric lipomatosis.

Surgical resection may be required to relieve compression or for cosmetic reasons. Cessation of alcohol intake does not result in regression but may slow growth rate.

OTHER FORMS OF LIPOMATOSIS

Mediastinal lipomatosis is characterized by local overgrowth of adipose tissue in the mediastinum. It occurs in patients with Cushing's syndrome and can occasionally cause tracheal compression.

Pelvic lipomatosis is characterized by overgrowth of pelvic fat, causing bladder dysfunction (frequency, dysuria, and nocturia), constipation, and lower abdominal pain. Bilateral ureteral obstruction may also occur. The male:female ratio is 18:1. The etiology is not known, but the condition may result from a localized manifestation of obesity. Surgery may be needed to relieve urinary tract obstruction.

Epidural lipomatosis occurs in obese patients or in those receiving exogenous steroid therapy. Fat deposition most often occurs in the thoracic or lumbar spine, causing back pain, radicular pain, or spinal cord compression. Laminectomy may be indicated for cord compression. Weight loss or discontinuation of steroid therapy may also be helpful.

ADIPOSIS DOLOROSA (DERCUM DISEASE)

This is a rare disease of unknown etiology that mainly affects obese postmenopausal women (female:male ratio, 30:1). It is characterized by the presence of multiple circumscribed or diffuse painful subcutaneous fat deposits on the trunk and limbs, particularly near the knees. Patients also report weakness, fatigue, and emotional lability. Relief of pain is difficult; intravenous lidocaine, glucocorticoids, surgical excision, and liposuction are sometimes helpful.

ACUTE PANNICULITIS

A variety of systemic diseases including collagen vascular diseases such as systemic lupus erythematosus and scleroderma are associated with *acute panniculitis*, or *nodular fat necrosis* (Chap. 311). Panniculitis may also occur as a manifestation of

lymphoproliferative disorders (Chap. 112).

Disseminated fat necrosis is usually associated with acute pancreatitis or pancreatic carcinoma. It may be caused by the release of pancreatic enzymes into the circulation (Chap. 304).

HORMONAL EFFECTS ON ADIPOSE DISTRIBUTION

A variety of hormones influence the distribution of adipose tissue. Growth hormone, for example, reduces truncal fat but can increase fat in the palms and soles. Insulin enhances lipogenesis and fat storage. Thyroid hormones increase metabolic rate, including energy expenditure by fat tissue. Estrogens induce fat accumulation in the hips, legs, breasts and other subcutaneous regions. Glucocorticoids redistribute adipose tissue from peripheral to central locations. In Cushing's syndrome, characteristic features include buffalo hump, increased supraclavicular and truncal fat.

PART FOURTEEN -NEUROLOGIC DISORDERS

SECTION 1 -DIAGNOSIS OF NEUROLOGIC DISORDERS

355. NEUROBIOLOGY OF DISEASE - *Stephen L. Hauser, M. Flint Beal*

The human nervous system is the organ of consciousness, cognition, ethics, and behavior; as such, it is the most intricate structure known to exist. One-third of the 100,000 genes encoded in the human genome is expressed in the nervous system. Each mature brain is composed of 100 billion neurons, several million miles of axons and dendrites, and more than 10_{15}synapses. Neurons exist within a dense parenchyma of multifunctional glial cells that synthesize myelin, preserve homeostasis, and regulate immune responses. Measured against this background of complexity, the achievements of molecular neuroscience have been extraordinary. Advances in cell biology and genetics have provided new tools to explore the pathophysiology of nervous system diseases, clarifying their underlying causes, revealing new unanticipated groupings, and raising realistic hope that novel therapies and prevention strategies will be possible. This chapter reviews selected themes in neurobiology that provide a context for understanding fundamental mechanisms underlying neurologic disorders.**The reader is also referred to related discussions of neurogenetic disorders (Chap. 359) and the neurobiology of addiction (Chap. 386), and to the individual chapters on specific disorders.*

ION CHANNELS AND CHANNELOPATHIES

The resting potential of neurons and the action potentials responsible for impulse conduction are generated by ion currents and ion channels. Most ion channels are gated, meaning that they can transition between conformations that are open or closed to ion conductance. Individual ion channels are distinguished by the specific ions they conduct; by their kinetics; and by whether they directly sense voltage, are linked to receptors for neurotransmitters or other ligands such as neurotrophins, or are activated by second messengers. The diverse characteristics of different ion channels provide a means by which neuronal excitability can be exquisitely modulated at both the cellular and the subcellular levels. Mutations in ion channels -- channelopathies -- are responsible for a growing list of human neurologic disorders (Table 355-1). One example is epilepsy, a syndrome of diverse causes characterized by repetitive, synchronous firing of neuronal action potentials. Action potentials are normally generated by the opening of sodium channels and the inward movement of sodium ions down the intracellular concentration gradient. Depolarization of the neuronal membrane opens potassium channels, resulting in outward movement of potassium ions, repolarization, closure of the sodium channel, and hyperpolarization. Sodium or potassium channel subunit genes have long been considered candidate disease genes in inherited epilepsy syndromes, and recently such mutations have been identified (Chap. 360). These mutations appear to alter the normal gating function of these channels, increasing the inherent excitability of neuronal membranes in regions where the abnormal channels are expressed.

Whereas the specific clinical manifestations of channelopathies are quite variable, one common feature is that manifestations tend to be intermittent or paroxysmal, such as

occurs in epilepsy, migraine, ataxia, myotonia, or periodic paralysis. Exceptions are clinically progressive channel disorders such as spinocerebellar ataxia type 6 (SCA6) and autosomal dominant hearing impairment. The neurologic channelopathies identified to date are all uncommon disorders caused by obvious mutations in channel genes. As the full repertoire of human ion channels and related proteins are identified, it is likely that additional channelopathies will be discovered. In addition to rare disorders that result from obvious mutations, it is possible that subtle allelic variations in channel genes or in their pattern of expression might underlie susceptibility to some common forms of epilepsy, migraine, or other disorders.

NEUROTRANSMITTERS AND NEUROTRANSMITTER RECEPTORS

Synaptic neurotransmission is the predominant means by which neurons communicate with each other. Classic neurotransmitters are synthesized in the presynaptic region of the nerve terminal; stored in vesicles; and released into the synaptic cleft, where they bind to receptors on the postsynaptic cell. Secreted neurotransmitters are eliminated by reuptake into the presynaptic neuron (or glia), by diffusion away from the synaptic cleft, and/or by specific inactivation. In addition to the classic neurotransmitters, many neuropeptides have been identified as definite or probable neurotransmitters; these include substance P, neurotensin, enkephalins, b-endorphin, histamine, vasoactive intestinal polypeptide, cholecystokinin, neuropeptide Y, and somatostatin. Peptide neurotransmitters are synthesized in the cell body rather than the nerve terminal and may colocalize with classic neurotransmitters in single neurons. Nitric oxide and carbon monoxide are gases that appear also to function as neurotransmitters, in part by signaling in a retrograde fashion from the postsynaptic to the presynaptic cell.

Neurotransmitters modulate the function of postsynaptic cells by binding to specific neurotransmitter receptors, of which there are two major types. *Ionotropic receptors* are direct ion channels that open after engagement by the neurotransmitter. *Metabotropic receptors* interact with G proteins, stimulating production of second messengers and activating protein kinases, which modulate a variety of cellular events. Ionotropic receptors are multiple subunit structures, whereas metabotropic receptors are composed of single subunits only. One important difference between ionotropic and metabotropic receptors is that the kinetics of ionotropic receptor effects are fast (generally less than a millisecond) because neurotransmitter binding directly alters the electrical properties of the postsynaptic cell, whereas metabotropic receptors function over longer time periods. These different properties contribute to the potential for selective and finely modulated signaling by neurotransmitters.

Individual neurotransmitter systems are perturbed in a large number of clinical disorders, examples of which are highlighted in Table 355-2. One example is the involvement of dopaminergic neurons originating in the substantia nigra of the midbrain and projecting to the striatum (nigrostriatal pathway) in Parkinson's disease and in heroin addicts after the ingestion of the toxin MPTP (1-methyl-4-phenyl-1,2,5,6-tetrahydropyridine) (Chap. 363). A second important dopaminergic system arising in the subtantia nigra is the mesolimbic pathway, which influences behavior and appears to be important in the pathogenesis of addiction. Addictive drugs share the property of increasing dopamine release, and blockade of dopamine in the nucleus accumbens (a part of the mesolimbic pathway) terminates the

rewarding effects of addictive drugs (Chap. 386).

CELL TO CELL COMMUNICATION THROUGH GAP JUNCTIONS

Not all cell-to-cell communication in the nervous system occurs via neurotransmission. Gap junctions provide for direct neuron-neuron electrical conduction and also create openings for the diffusion of ions and metabolites between cells. In addition to neurons, gap junctions are also widespread in glia, creating a syncytium that protects neurons by removing glutamate and potassium from the extracellular environment. Gap junctions consist of membrane-spanning proteins termed connexins that pair across adjacent cells. Mechanisms that involve gap junctions have been related to a variety of neurologic disorders. Mutations in connexin 32, a gap junction protein expressed by Schwann cells, are responsible for the X-linked form of Charcot-Marie-Tooth disease (Chap. 379). Mutations in either of two gap junction proteins expressed in the inner ear -- connexin 26 and connexin 31 -- result in autosomal dominant progressive hearing loss (Chap. 29). Glial calcium waves mediated through gap junctions also appear to explain the phenomenon of spreading depression associated with migraine auras and the march of epileptic discharges. Spreading depression is a neural response that follows a variety of different stimuli and is characterized by a circumferentially expanding negative potential that propagates at a characteristic speed of 20 um/s and is associated with an increase in extracellular potassium.

SIGNALING PATHWAYS AND GENE TRANSCRIPTION

The fundamental issue of how memory, learning, and thinking are encoded in the nervous system is likely to be clarified by identifying the signaling pathways involved in neuronal differentiation, axon guidance, and synapse formation, and by understanding how these pathways are modulated by experience. Many families of transcription factors, each comprising multiple individual components, are expressed in the nervous system. Elucidation of these signaling pathways has already begun to provide insights into the cause of a variety of neurologic disorders, including inherited disorders of cognition such as X-linked mental retardation. This syndrome affects approximately 1 in 500 males, and linkage studies in different families suggest that as many as 60 different X-chromosome encoded genes may be responsible. A number of disease genes have now been identified. Three encode proteins that regulate members of the ras family of GTP-binding proteins thought to have roles in regulation of the actin cytoskeleton and in neurite outgrowth (*OPHN1*, *PAK3*) or synaptic vesicle transport and neurotransmitter release (*GDI1*); one (*IL1RAPL*) has homology to an interleukin (IL)1 receptor accessory protein involved in IL-1 signaling; and one (*FMR2*) functions as a nuclear transcriptional regulatory protein. Rett syndrome, a common cause of (dominant) X-linked progressive mental retardation in females, is also due to a mutation in a gene (*MECP2*) encoding a DNA-binding protein involved in transcriptional repression. As the X chromosome comprises only approximately 3% of germline DNA, then by extrapolation the number of genes that potentially contribute to clinical disorders affecting intelligence in humans must be potentially very large.

MYELIN

Myelin is the multilayered insulating substance that surrounds axons and speeds

impulse conduction by permitting action potentials to jump between naked regions of axons (nodes of Ranvier) and across myelinated segments. A single oligodendrocyte usually ensheaths multiple axons in the central nervous system (CNS), whereas in the peripheral nervous system (PNS) each Schwann cell typically myelinates a single axon. Myelin is a lipid-rich material formed by a spiraling process of the membrane of the myelinating cell around the axon, creating multiple membrane bilayers that are tightly apposed (compact myelin) by charged protein interactions. A number of clinically important neurologic disorders are caused by inherited mutations in myelin proteins of the CNS or PNS. Constituents of myelin also have a propensity to be targeted as autoantigens in autoimmune demyelinating disorders (Fig. 355-1).

NEUROTROPHIC FACTORS

Neurotrophic factors (Table 355-3) are secreted proteins that modulate neuronal growth, differentiation, repair, and survival; some have additional functions, including roles in neurotransmission and in the synaptic reorganization involved in learning and memory. Because of their survival promoting and anti-apoptotic effects, neurotrophic factors are in theory outstanding candidates for therapy of disorders characterized by premature death of neurons such as occurs in amyotrophic lateral sclerosis (ALS) and other degenerative motor neuron disorders. Knockout mice lacking receptors for ciliary neurotrophic factor (CNTF) receptor or brain-derived neurotrophic factor (BDNF) show loss of motor neurons, and experimental motor neuron death can be rescued by treatment with various neurotrophic factors including CNTF and BDNF. However, in phase 3 clinical trials both CNTF and BDNF were ineffective in human ALS, and two other trials of insulin-like growth factor 1 yielded conflicting results with little evidence of clinically significant efficacy. Current understanding of the redundancy and diversity of neurotrophic factor activities at different stages in the life and health of individual neurons is extremely limited, and data obtained in rodent systems are not always applicable to humans. For example, CNTF knockout mice show a partial loss of motoneurons, yet humans who have homozygous mutations that inactivate the gene for CNTF gene are asymptomatic.

STEM CELLS AND TRANSPLANTATION

The nervous system is traditionally considered to be a nonmitotic organ, in particular with respect to neurons. These concepts have been challenged by the finding that neural progenitor or stem cells exist in the adultCNS that are capable of differentiation, migration over long distances, and extensive axonal arborization and synapse formation with appropriate targets. These capabilities also indicate that the repertoire of factors required for growth, survival, differentiation, and migration of these cells exist in the mature nervous system. The poor outcome associated with many neurologic disorders, however, clearly indicates that any potential for functional neuronal reconstitution after injury must be extremely limited in most clinical contexts. In rodents, neural stem cells, defined as progenitor cells capable of differentiating into mature cells of neural or glial lineage, have been experimentally propagated from fetal CNS and neuroectodermal tissues, and also from adult germinal matrix and ependyma regions. Human fetal CNS tissue is also capable of differentiation into cells with neuronal, astrocyte, and oligodendrocyte morphology when cultured in the presence of particular growth factors. Impressively, such cells could be stably engrafted into mouse CNS tissue, creating

neural chimeras. Once the repertoire of signals required for cell type specification are better understood, differentiation into specific neural or glial subpopulations can be directed in vitro; such cells could also be engineered to express therapeutic molecules.

Experimental transplantation of human fetal dopaminergic neurons in patients with Parkinson's disease has shown that these transplanted cells can survive within the host striatum. Studies of transplantation for patients with Huntington's disease have also reported encouraging, although very preliminary, results. Oligodendrocyte precurser cells transplanted into mice with a dysmyelinating disorder effectively migrated in the new environment, interacted with axons, and mediated myelination; such experiments raise hope that similar transplantation strategies may be feasible in human disorders of myelin such as multiple sclerosis. Enthusiasm for transplantation therapy must be tempered by unresolved concerns over safety (including the theoretical risk of malignant transformation of transplanted cells), ethics (particularly with respect to use of fetal tissue), and efficacy.

CELL DEATH -- EXCITOTOXICITY AND APOPTOSIS

Excitotoxicity refers to neuronal cell death caused by activation of excitatory amino acid receptors (Fig. 355-2). Compelling evidence for a role of excitotoxicity, especially in ischemic neuronal injury, is derived from experiments in animal models. Experimental models of stroke are associated with increased extracellular concentrations of the excitatory amino acid neurotransmitter glutamate, and neuronal damage is attenuated by denervation of glutamine-containing neurons or the administration of glutamate receptor antagonists. The distribution of cells sensitive to ischemia corresponds closely with that of *N*-methyl-D-aspartate (NMDA) receptors (except for cerebellar Purkinje cells, which are vulnerable to hypoxia-ischemia but lack NMDA receptors); and competitive and noncompetitive NMDA antagonists are effective in preventing focal ischemia. In global cerebral ischemia, non-NMDA receptors (kainic acid and AMPA) are activated, and antagonists to these receptors are protective. Experimental brain damage induced by hypoglycemia is also attenuated by NMDA antagonists.

Excitotoxicity is not a single event but rather a cascade of cell injury. Excitotoxicity causes influx of calcium into cells and much of the calcium is sequestered in mitochondria rather than in the cytoplasm. Increased mitochondrial calcium causes metabolic dysfunction and free radical generation; activates protein kinases, phospholipases, nitric oxide synthase, proteases, and endonucleases; and inhibits protein synthesis. Activation of nitric oxide synthase generates nitric oxide ($NO^{\times}$), which can react with superoxide ($O^{\times}_2$) to generate peroxynitrite ($ONOO^-$), which may play a direct role in neuronal injury. Another critical pathway is activation of poly-ADP-ribose polymerase, which occurs in response to free radical-mediated DNA damage. Experimentally, mice with knockout mutations of neuronal nitric oxide synthase or poly-ADP-ribose polymerase, or those that overexpress superoxide dismutase, are resistant to focal ischemia.

Apoptosis, or programmed cell death, plays an important role in both physiologic and pathologic conditions. During embryogenesis, apoptotic pathways operate to destroy neurons that fail to differentiate appropriately or reach their intended targets. There is mounting evidence for an increased rate of apoptotic cell death in a variety of acute and

chronic neurologic diseases. Apoptosis is characterized by neuronal shrinkage, chromatin condensation, and DNA fragmentation, whereas necrotic cell death is associated with cytoplasmic and mitochondrial swelling followed by dissolution of the cell membrane. Apoptotic and necrotic cell death can coexist or be sequential events depending on the severity of the initiating insult. Cellular energy reserves appear to have an important role in these two forms of cell death, with apoptosis favored under conditions in which ATP levels are preserved. Evidence of DNA fragmentation has been found in a number of degenerative neurologic disorders, including Alzheimer's disease, Huntington's disease, andALS. The best characterized genetic neurologic disorder related to apoptosis is infantile spinal muscular atrophy (Werdnig-Hoffmann disease), in which two genes thought to be involved in the apoptosis pathways are causative.

Mitochondria are essential in controlling specific apoptosis pathways. The redistribution of cytochrome c from mitochondria during apoptosis leads to the activation of a cascade of intracellular proteases known as caspases. Redistribution of cytochrome c is prevented by overproduction of the apoptotic protein BCL2 and is promoted by the proapoptotic protein BAX. These pathways may be triggered by activation of a large pore in the mitochondrial inner membrane known as the permeability transition pore. Recent studies suggest that blocking this pore reduces both hypoglycemic and ischemic cell death.

PROTEIN AGGREGATION AND NEURODEGENERATION

The possibility that protein aggregation plays a role in the pathogenesis of neurodegenerative diseases is a major focus of current research. Protein aggregation is a major histopathologic hallmark of neurodegenerative diseases. Deposition ofb-amyloid is strongly implicated in the pathogenesis of Alzheimer's disease. Genetic mutations in familial Alzheimer's disease produce increased amounts of b-amyloid with 42 amino acids, which has an increased propensity to aggregate, as compared tob-amyloid with 40 amino acids. Mutations in genes encoding the microtubule associated protein tau lead to altered splicing of tau and the production of neurofibrillary tangles in frontotemporal dementia and progressive supranuclear palsy. Familial Parkinson's disease is associated with mutations in a-synuclein and the ubiquitin carboxy-terminal hydrolase. The characteristic histopathologic feature of Parkinson's disease is the Lewy body, an eosinophilic cytoplasmic inclusion that contains both neurofilaments and a-synuclein. Huntington's disease and cerebellar degenerations are associated with expansions of polyglutamine repeats in proteins, which aggregate to produce neuronal intranuclear inclusions. FamilialALS is associated with superoxide dismutase mutations and cytoplasmic inclusions containing superoxide dismutase. In autosomal dominant neurohypophyseal diabetes insipidus, mutations in vasopressin result in abnormal protein processing, accumulation in the endoplasmic reticulum, and cell death (Chap. 329).

The major scientific question presently is whether protein aggregates contribute to neuronal death or whether they are merely a secondary bystander. Protein aggregates are usually ubiquinated, which targets them for degradation by the 26S component of the proteosome. An inability to degrade protein aggregates could lead to cellular dysfunction, impaired axonal transport, and cell death by apoptotic mechanisms.

In experimental models of Huntington's disease and cerebellar degeneration, protein aggregates are not well correlated with neuronal death. A number of compounds have been developed to block b-amyloid production and/or aggregation, and these agents are being studied in early clinical trials in humans.

NEUROIMMUNOLOGY

The nervous system is traditionally considered to be an immunologically privileged organ, a concept originally derived from observations that tissue grafts implanted in the brain were not rejected efficiently. In this context, immune privilege of the CNS may be maintained by a variety of mechanisms including: the lack of an efficient surveillance function by T cells; the absence of a traditional lymphoid system; limited expression of major histocompatibility complex (MHC) molecules required for T cell recognition of antigen; effects of regulatory cytokines secreted spontaneously or in response to mediators such as nerve growth factor (NGF), creating an immunosuppressive milieu; and also from expression of fas ligand that can induce apoptosis of fas-expressing immune cells that enter the brain. The blood-brain barrier (BBB) partially isolates the brain from the peripheral environment and contributes to immune privilege. Anatomically, the barrier is created by the presence of impermeable tight junctions between endothelial cells, and by a relative absence of transendothelial conduits for the passive diffusion of soluble molecules. The BBB serves to preserveCNShomeostasis by excluding neuroactive substances present in the serum, such as neurotransmitters and neurotrophic factors. Because of the BBB, lipid insoluble molecules must utilize either ion channels or specific transport systems (for glucose or various amino acids) to gain entry to the CNS. Astrocyte foot processes that encircle the subendothelial basal surface of small blood vessels in the brain contribute to development and maintenance of the BBB.

The concept of immune privilege is at odds with clinical experience that vigorous immune reactions readily occur in the nervous system in response to infections and that autoimmune diseases of the nervous system are relatively common. Although primary (sensitizing) immune responses are not easily generated in theCNS for the reasons outlined above, this is not the case for secondary immune responses. When sensitization to nervous system antigens occurs *outside* the nervous system (e.g., in a regional lymph node), activated autoreactive T lymphocytes are easily generated, and these cells readily cross theBBB and induce immune mediated injury. The paradigm for this mechanism of T cell-mediated CNS disease is experimental allergic encephalomyelitis (EAE), a laboratory model for the human autoimmune demyelinating disorders multiple sclerosis (MS) and acute disseminated encephalomyelitis; the sequence of events in EAE is illustrated in Fig. 355-3.

Under normal circumstances theBBB is impermeable to antibodies. For autoantibodies to reach theCNS, the BBB must first be disrupted. In inflammatory conditions it is thought that this disruption most often occurs via actions of proinflammatory cytokines elaborated within the brain consequent to interactions between pathogenic T cells and antigen-presenting cells (APCs). In contrast to the BBB, in thePNS the blood-nerve barrier is incomplete. Endothelial tight junctions are lacking, and the capacity of charged molecules, including antibodies, to cross the barrier appears to be greatest in two regions of the PNS: proximally in the spinal roots and distally at neuromuscular

junctions. This anatomic feature is likely to contribute to the propensity of antibody-mediated autoimmune disorders of the PNS to target proximal nerves (Guillain-Barre syndrome) or the neuromuscular junction (myasthenia gravis, Eaton-Lambert syndrome).

The majorAPCs in the CNSare microglial cells and macrophages; both cell types expressMHCclass 2 molecules as well as costimulatory molecules required for antigen presentation. Neurons do not express MHC class 2 molecules; however, some neurons express MHC class 1 proteins, which may be further increased in response to neuronal activity. Neuronal MHC class 1 molecules may function as retrograde postsynaptic signaling molecules that interact with presynaptic CD3z molecules to stabilize active synapses and transynaptically modulate neuronal function. Studies in mice also indicate that MHC class 1 molecules influence the mating behavior of females; a hierarchichal pattern of preference is determined by the specific class 1 alleles expressed by potential male suitors. This behavior appears to be mediated by distinctive odors imparted either by the class 1 molecules themselves or by other families of molecules controlled by class 1 alleles. Thus, it appears likely that MHC molecules subserve a variety of signaling and adhesion functions that influence nervous system function far beyond their well-established roles as mediators of APC-T lymphocyte interactions.

356. APPROACH TO THE PATIENT WITH NEUROLOGIC DISEASE- *Joseph B. Martin*, *Stephen L. Hauser*

Neurologic disorders are common and costly. According to one recent estimate, 180 million Americans suffer from a nervous system disorder, resulting in annual cost of 634 billion dollars (Table 356-1). Most patients with neurologic symptoms seek care from internists and other generalists rather than from neurologists, and this situation is likely to continue as primary care-based health care systems become increasingly prevalent and access to specialists is reduced. Because useful therapies now exist for many neurologic disorders, a skillfull approach to their diagnosis is important. Many errors result from an over-reliance on neuroimaging and other laboratory tests at the expense of a primary focus on the history and examination. These errors can be avoided by adherence to an approach in which the patient's illness is defined first in *anatomic* and then in *pathophysiologic* terms; only then should a specific diagnosis be entertained. Arrival at a diagnosis permits the physician to institute therapy and to inform and counsel patients and their families about the expected disease course.

THE NEUROLOGIC METHOD OF CLINICAL EVALUATION

LOCATE THE LESION(S)

The first priority is to define the anatomic substrate responsible for the patient's illness by seeking to determine what part of the neural axis is likely to be involved in causing the neurologic symptoms. Can the disorder be mapped to one specific site in the nervous system, is it multifocal, or is there evidence of a more diffuse neurologic disease? Is the disorder restricted to the nervous system, or does it arise in the context of a systemic illness? Is it in the central nervous system (CNS), the peripheral nervous system (PNS), or both? If in the CNS, is the process restricted to the cerebral cortex, or is there evidence of basal ganglia, brainstem, cerebellum, and/or spinal cord involvement? Are the pain-sensitive meninges involved? If in the PNS, could the disorder be located in peripheral nerves and, if so, are motor or sensory nerves primarily affected, or is a lesion in the neuromuscular junction or muscle more likely?

The first clues to defining the anatomic area of involvement appear in the history, and the examination is then directed to confirm or rule out these impressions and to clarify uncertainties suggested by the history. A more detailed examination of a particular region of the CNSor PNSis often indicated. For example, the examination of a patient who presents with a history of ascending paresthesias and weakness should be directed toward deciding, among other things, if the location of the lesion is in the spinal cord or peripheral nerves. Focal back pain, a spinal cord sensory level, and incontinence suggest a spinal cord origin, whereas a stocking-glove pattern of sensory loss suggests peripheral nerve disease; areflexia usually indicates peripheral neuropathy but may also be present with spinal shock in acute spinal cord disorders.

Deciding "where the lesion is" accomplishes the task of limiting the possible etiologies to a manageable, finite number. In addition, this strategy safeguards against making tragic errors. Symptoms of recurrent vertigo, diplopia, and nystagmus should not trigger "multiple sclerosis" as an answer (etiology) but "brainstem" or "pons" (location); then a diagnosis of brainstem arteriovenous malformation will not be missed for lack of

consideration. Similarly, the combination of optic neuritis and spastic ataxic paraparesis should initially suggest optic nerve and spinal cord disease; multiple sclerosis,CNSsyphilis, and vitamin B_{12}deficiency are treatable disorders that can produce this syndrome. Once the question, "Where is the lesion?" is answered, then the question, "What is the lesion?" can be addressed.

DEFINE THE PATHOPHYSIOLOGY

Clues to the pathophysiology of the disease process may also be present in the history. Primary neuronal (gray matter) disorders may present as early cognitive disturbances, movement disorders, or seizures, whereas white matter involvement produces predominantly "long tract" disorders of motor, sensory, visual and cerebellar pathways. Progressive and symmetric symptoms often have a metabolic or degenerative origin; in such cases lesions are usually not sharply circumscribed. Thus, a patient with paraparesis and a clear spinal cord sensory level is unlikely to have vitamin B_{12}deficiency as the explanation. A Lhermitte symptom (electric shock-like sensations evoked by neck flexion) is due to ectopic impulse generation in white matter pathways and occurs with demyelination in the cervical spinal cord. Symptoms that worsen after exposure to heat or exercise may indicate conduction block in demyelinated axons and suggest a diagnosis of multiple sclerosis. Slowly advancing visual scotoma with luminous edges, termed fortification spectra, are diagnostic of spreading cortical depression, such as occurs in migraine.

ESTABLISH AN ETIOLOGIC DIAGNOSIS

The clinical data obtained from the history and the examination are assembled into one of the known syndromes and are interpreted and translated in terms of neuroanatomy and neurophysiology (Table 356-2). From the syndrome the physician should be able to determine the anatomic localization(s) that best explains the clinical findings. The proper selection of laboratory tests is important to arrive at an anatomic, but more particularly an etiologic, diagnosis. The laboratory assessment of a patient with positive neurologic findings may include (1) serum electrolytes, complete blood count, and renal, liver, and endocrine studies; (2) cerebrospinal fluid (CSF) examination (see below); (3) neuroimaging studies (Chap. 358); or (4) electrophysiologic studies (Chap. 357). The anatomic localization, mode of onset and course of illness, other medical data, and laboratory findings are then integrated to establish an etiologic diagnosis.

THE NEUROLOGIC HISTORY

Attention to the description of the symptoms as experienced by the patient and substantiated by family members or friends often permits an accurate localization and determination of the probable cause of the complaints even before the neurologic examination is undertaken. Two principles should be followed. First, each complaint should be pursued as far as possible in an effort to delineate where the lesion might be or, more importantly, to formulate a set of questions to be answered by the examination. A patient complains of weakness of the right arm. What are the associated features? Is this weakness for brushing the hair (proximal) or opening a twist-top bottle (distal)? Second, negative associations may also be crucial. A patient with a right hemiparesis without a language deficit likely has a lesion (and likely an etiology) different from that of

a patient with a right hemiparesis and aphasia. Additional features of the history include the following:

1. *Temporal course of the illness*. It is important to ascertain the precise time of appearance and rate of progression of the symptoms experienced by the patient. The rapid onset of a neurologic complaint, occurring within seconds or minutes, usually indicates a cerebrovascular event, a seizure, or rarely migraine. The onset of sensory symptoms located in one extremity that spread over a few seconds to adjacent portions of that extremity and then to the other limb or to the face suggests a seizure. A more gradual onset and less well localized sensory symptoms point to the possibility of a transient ischemic attack (TIA). A similar but slower temporal march of a sensory change occurring with headache, nausea, or visual disturbance suggests migraine. In general, the march of migraine is slower than that of seizure, and a TIA tends to be more generalized in location on the side of the body or extremities. The presence of "positive" sensory symptoms (e.g., tingling) or involuntary motor movements suggests a seizure; in contrast, transient loss of function (negative symptoms) suggests a TIA. A stuttering onset where symptoms appear, stabilize, and then progress over hours or days also suggests cerebrovascular disease; an additional history of transient remission or regression indicates that the process is due to ischemia and not hemorrhage. On occasion, a demyelinating process may also produce new symptoms that evolve rapidly over the course of a few hours. Progressing symptoms associated with the systemic manifestations of fever, stiff neck, and altered level of consciousness raise the possibility of an infectious process. Relapsing and remitting symptoms involving different levels of the neuraxis suggest multiple sclerosis. Slowly progressive symptoms without remissions are characteristic of neurodegenerative disorders.

2. *Subjective descriptions of the complaint*. The same words often mean different things to different patients. "Dizziness" may imply impending syncope, a sense of giddiness, or true spinning vertigo. "Numbness" may mean a complete loss of feeling, a positive sensation of tingling, or paralysis. "Blurred vision" may be used to describe unilateral visual loss, as in transient monocular blindness, or diplopia. It is important to define the contextual meaning of the patient's complaint to understand its true significance.

3. *Corroboration of the history by others*. It is often useful to obtain additional information from family, friends, or observers to corroborate or expand the patient's description. Memory loss, aphasia, loss of insight, drug or alcohol abuse, and other factors may impair the patient's capacity to communicate normally with the examiner or prevent openness about factors that have contributed to the illness. Episodes of loss of consciousness that may be due to syncope or seizures necessitate that details be sought from observers to ascertain the exact circumstances.

4. *Family history*. Many neurologic disorders have an underlying genetic component. The presence of a Mendelian disorder, such as Huntington's disease or Charcot-Marie-Tooth neuropathy, is often obvious if appropriate family data are available. In polygenic disorders such as multiple sclerosis or migraine, a positive family history, when present, may be helpful. It is important to elicit family history about all illnesses, in addition to neurologic and psychiatric disorders. A familial propensity to hypertension or heart disease may be relevant to a patient who presents with a stroke. Many inherited neurologic illnesses are associated with multisystem manifestations that

may provide clues to the correct diagnosis (e.g., the phakomatoses, hepatocerebral disorders, neuro-ophthalmic syndromes).

5. *Medical illnesses*. Many neurologic illnesses occur in the context of systemic disorders. Disorders such as diabetes mellitus, hypertension, and abnormalities of blood lipids predispose to cerebrovascular disease. Marfan's syndrome and related collagen disorders predispose to dissection of the cranial arteries and also to aneurysmal subarachnoid hemorrhage; the latter may also occur with polycystic kidney disease. A recent onset of asthma suggests the possibility of polyarteritis nodosa. Various neurologic disorders occur with dysthyroid states. A solitary mass lesion may be a brain abscess in a patient with valvular heart disease, a primary hemorrhage in a patient with a coagulopathy, a metastasis in a patient with underlying cancer, or a lymphoma or toxoplasmosis in a patient with AIDS. The presence of systemic diseases that are associated with peripheral neuropathy should be explored. Most patients with coma in a hospital setting can be shown to have a metabolic, toxic, or infectious process.

6. *The patient's perception of the disease*. It is frequently helpful to ask patients what they perceive to be wrong. Patients who complain of failing memory are often concerned that they have early symptoms of Alzheimer's disease; more often they are found to suffer from depression. Patients with headaches may fear that a tumor or an impending stroke is a possibility. Patients with sensory symptoms frequently are concerned about the possibility of multiple sclerosis. The patient may seek medical attention because a relative or friend has been diagnosed with a serious neurologic illness.

7. *Drug use and abuse and toxin exposure*. It is essential to inquire about the history of drug use, both prescribed and illicit. Digitalis use may provoke complaints of yellow vision. Excessive vitamin ingestion may lead to disease; for example, vitamin A and pseudotumor cerebri, or pyridoxine and peripheral neuropathy. Aminoglycoside antibiotics may exacerbate symptoms of weakness in patients with disorders of neuromuscular transmission, such as myasthenia gravis. Dizziness may be secondary to ototoxicity caused by aminoglycosides. Many patients are unaware that over-the-counter sleeping pills, cold preparations, and diet pills are actually drugs. Alcohol, the most prevalent neurotoxin, is often not recognized as such by patients. A history of environmental or industrial exposure to neurotoxins may provide an essential clue; consultation with the patient's family or employer may be required.

8. *History of malignancy*. Patients with malignancy may present with nervous system metastases, a paraneoplastic syndrome (Chap. 101), or complications from chemotherapy or radiotherapy.

9. *Formulating an impression of the patient*. Use the opportunity while taking the history to form an impression of the patient. Is there evidence of anxiety, depression, hypochondriasis? Are there any clues to defects of language, memory, inappropriate behavior, or secondary gain? The neurologic assessment begins as soon as the patient walks into the room and the first introduction is made.

THE NEUROLOGIC EXAMINATION

A systematic neurologic examination should encompass a survey of all functions from the cerebrum to the peripheral nerve and muscle, i.e., from the mental status examination to the simplest reflexes. Physicians should acquire skills that come only from the repeated use of the same techniques and instruments on a large number of individuals with and without neurologic disease. Errors and serious omissions are avoided if the examination procedure is orderly and systematic, beginning with mental (cerebral) functions and continuing with cranial nerves; then with motor, reflex, and sensory functions of the arms, trunk, and legs; and finishing with an analysis of posture and gait (Table 356-3).

This detailed examination is undertaken only if there are symptoms of disturbed nervous system functioning. If none are present, it suffices to do an abbreviated examination that includes evaluation only of pupils, ocular movements, optic fundi, facial movements, speech, strength of arm and leg muscles, tendon and plantar reflexes, pain and vibratory sensation in hands and feet, and gait. All this can be completed in 3 to 5 min.

Several additional points about the examination are worth noting. First, in recording observations, it is important to describe what is found rather than to apply a poorly defined medical term (i.e., "patient groans to sternal rub" rather than "obtunded"). Second, if the patient's complaint is brought out by some activity, reproduce the activity in the office. If the complaint is of dizziness when raising the right arm and turning the head to the left, have the patient do it. If pain occurs after walking two blocks, have the patient demonstrate it, and repeat the examination. Finally, the use of tests that are individually tailored to the patient's problem can be of value in assessing changes over time. Tests of walking a 25-ft distance (normal, 5 to 6 s; note assistance, if any), repetitive finger or toe tapping (normal, 20 to 25 taps in 5 s), or handwriting are examples.

The neurologic examination may be normal even in patients with a serious neurologic disease, such as one that causes seizures or syncope. A comatose patient may arrive with no available history; the examination proceeds along the lines described in Chap. 24. An inadequate history may be compensated for to some extent by a succession of examinations from which the course of the illness may be plotted.

LUMBAR PUNCTURE

The clinical indications for lumbar puncture (LP) are listed in Table 356-4. In experienced hands, LP is a safe procedure. The patient is asked to lie on his or her side facing away from the examiner. The back is positioned at the edge of the bed or table near the examiner. The patient is asked to "roll up into a ball" -- the neck is gently flexed and the knees drawn up to the abdomen. Proper positioning is essential for success; the examiner should ensure that the shoulders and pelvis are vertically aligned without forward or backward tilt. A pillow is placed under the neck for comfort and a blanket offered for warmth. Because the spinal cord terminates at approximately the L1 vertebral level, the LP is performed below this level; i.e., at or below the L2-L3 interspace. A useful anatomic guidepost is the iliac crest which corresponds to the L3-L4 interspace. The interspace is chosen after gentle palpation to identify the spinous processes at each lumbar level. The skin is cleansed with an antibacterial liquid and alcohol, and the area is draped with sterile cloths. Local anesthetic, typically 1%

lidocaine, is injected into the subcutaneous tissue; a topical anesthetic cream (lidocaine 2.5%/prilocaine 2.5%) applied 90 min before the procedure can eliminate pain associated with injection. Approximately 5 min after the lidocaine injection, the LP needle (typically 22 gauge) is inserted in the midline between two spinous processes and slowly advanced at a slightly cephalic angle aiming at the umbilicus. The bevel of the needle should be maintained in a horizontal position, parallel to the direction of the dural fibers; this minimizes injury to the fibers as the dura is penetrated. In most adults, the needle is advanced 4 to 5 cm (1$_{1}$/$_{2}$to 2 in.) before the subarachnoid space is reached, and the examiner usually recognizes entry as a sudden release of resistance. Some examiners prefer to remove the stylet periodically as the needle is advanced to look forCSFflow. If the needle cannot be advanced because bone is hit, if the patient experiences sharp radiating pain down one leg, or if the tap is "dry," the needle is removed completely and repositioned.

Once the subarachnoid space is reached, a manometer is attached to the needle and theCSFpressure is measured. The examiner should look for normal oscillations in CSF pressure associated with pulse and respirations. Depending on the clinical indication, fluid is then obtained for studies that include the following: (1) cell count, differential, and presence of microorganisms -- it is often useful to repeat the cell count in the first and last tube; (2) protein, glucose, and other chemical measurements; (3) cytology; (4) bacteriologic cultures and virus isolation; (5) VDRL, cryptococcal antigen, and serologic and genetic tests for other microorganisms as appropriate; (6) immunoelectrophoresis for determination of gamma globulin level (paired serum sample essential), oligoclonal banding, and other special biochemical tests (NH_3, pH, CO_2, enzymes). Normal values of CSF constituents are shown inAppendix A. Under most conditions, the physician should not be concerned about removing too large a quantity of CSF. A sufficient volume to obtain all the data required is essential. In particular, adequate volumes for cytology, when indicated, should be removed.

Failure to enter the lumbar subarachnoid space after two or three trials can usually be corrected by repositioning the patient in the sitting position and then assisting them to lie on their side. The "dry tap" is more often due to an improperly placed needle than to a pathologic obliteration of subarachnoid space by a compressive lesion of the spinal cord or by chronic adhesive arachnoiditis. A bloody tap due to penetration of a meningeal vessel may be confused with subarachnoid hemorrhage. In these situations a specimen ofCSFshould be centrifuged immediately after it is obtained; clear supernatant CSF after centrifugation supports the diagnosis of a bloody tap, whereas xanthochromic supernatant suggests subarachnoid hemorrhage. In general, bloody CSF due to a meningeal vessel puncture clears gradually in successive tubes, whereas blood due to a subarachnoid hemorrhage does not. In addition to subarachnoid hemorrage, xanthochromic CSF may also be present in patients with liver disease or when the level of CSF protein is elevated [>1.5 to 2.0 g/L (150 to 200 mg/dL)].

There are several absolute or relative contraindications toLP. The procedure should be undertaken with particular care in patients with thrombocytopenia or disorders of blood coagulation because serious hemorrhage into the extradural or intradural space may occur. In these situations, it is prudent whenever possible to transfuse platelets, administer fresh frozen plasma, or reverse therapeutic anticoagulation before the procedure. Patients receiving low-molecular-weight heparin may be at risk of

hemorrhage unless doses are held for 24 h. An LP through areas of cutaneous or soft tissue infection may spread infection to the meninges; thus LP at these sites should be avoided.

In patients with elevatedCSFpressure, potentially fatal cerebellar or tentorial herniation may followLP. This possibility should be considered in all patients with focal neurologic findings, altered mental status, or papilledema. If CSF examination is required in such cases, it is wise to first obtain a neuroimaging scan to exclude a mass lesion. An exception to this rule is suspected meningitis, where immediate CSF examination is indicated. In this situation, the LP may be performed with a fine-bore (24-gauge) needle. If the pressure is>400 mmHg, the minimum required sample of fluid should be obtained, the needle removed, and, according to the suspected clinical disease and the patient's condition, intravenous mannitol administered in a dose of 0.75 to 1.0 mg/kg; unless contraindicated, dexamethasone may also be started in a dose of 4 to 6 mg every 6 h.

AfterLP, the patient is normally positioned in a comfortable, recumbant position for 1 h before rising. The principal complication of LP is headache, occurring in 10 to 30% of patients, caused by a drop inCSFpressure related to persistent leakage of CSF. Such headaches typically begin 12 to 48 h after the procedure and may last from several days to 2 weeks, rarely longer. These headaches are strikingly positional in character; they are worsened by an upright posture and are relieved by lying flat.**Therapy is discussed in Chap. 15.*

357. ELECTROPHYSIOLOGIC STUDIES OF THE CENTRAL AND PERIPHERAL NERVOUS SYSTEMS - *Michael J. Aminoff*

ELECTROENCEPHALOGRAPHY

The electrical activity of the brain [the *electroencephalogram* (EEG)] is easily recorded from electrodes placed on the scalp. The potential difference between pairs of electrodes on the scalp (bipolar derivation) or between individual scalp electrodes and a relatively inactive common reference point (referential derivation) is amplified and displayed on paper or the screen of an oscilloscope. The findings depend on the patient's age and level of arousal. The rhythmic activity normally recorded represents the postsynaptic potentials of vertically oriented pyramidal cells of the cerebral cortex and is characterized by its frequency. In normal awake adults lying quietly with the eyes closed, an 8- to 13-Hz alpha rhythm is seen posteriorly in the EEG, intermixed with a variable amount of generalized faster (beta) activity, and it is attenuated when the eyes are opened (Fig. 357-1). During drowsiness, the alpha rhythm is also attenuated; with light sleep, slower activity in the theta (4 to 7 Hz) and delta (<4 Hz) ranges becomes more conspicuous.

TheEEG is best recorded from several different electrode arrangements (montages) in turn, and activating procedures are generally undertaken in an attempt to provoke abnormalities. Such procedures commonly include hyperventilation (for 3 or 4 min), photic stimulation, sleep, and the deprivation of sleep on the night prior to the recording.

Electroencephalography is relatively inexpensive and may aid clinical management in several different contexts.

THEEEGAND EPILEPSY

The EEG is most useful in evaluating patients with suspected epilepsy. The presence of *electrographic seizure activity*, i.e., of abnormal, repetitive, rhythmic activity having an abrupt onset and termination, clearly establishes the diagnosis. The absence of such electrocerebral accompaniment does not exclude a seizure disorder, however, because there may be no change in the scalp-recorded EEG during simple or complex partial seizures. With generalized tonic-clonic seizures, however, the EEG is always abnormal during the episode. It is often not possible to obtain an EEG during clinical events that may represent seizures, especially when such events occur unpredictably or infrequently. The development of portable equipment to record the EEG continuously on cassettes for 24 h or longer in ambulatory patients has made it easier to capture the electrocerebral accompaniments of such clinical episodes, and monitoring by this means is sometimes helpful in confirming that seizures are occurring, characterizing the nature of clinically equivocal episodes, and determining the frequency of epileptic events.

TheEEGfindings may also be helpful in the interictal period by showing certain abnormalities that are strongly supportive of a diagnosis of epilepsy. Such *epileptiform activity* consists of bursts of abnormal discharges containing spikes or sharp waves. The presence of epileptiform activity is not specific for epilepsy, but it has a much greater prevalence in epileptic patients than in normal individuals. When epileptiform

activity is found in the EEG of a patient with episodic behavioral disturbances that clinically might be epileptic in nature, the likelihood that epilepsy is the correct diagnosis is markedly increased.

TheEEGfindings have also been used in classifying seizure disorders and selecting appropriate anticonvulsant medication for individual patients (Fig. 357-2). The episodic generalized spike-wave activity that occurs during and between seizures in patients with typical absences (petit mal epilepsy) contrasts with the normal findings, focal interictal epileptiform discharges, or ictal patterns found in patients with complex partial seizures. These latter seizures may have no correlates in the scalp-recorded EEG or may be associated with abnormal rhythmic activity of variable frequency, a localized or generalized distribution, and a stereotyped pattern that varies with the patient. Focal or lateralized epileptogenic lesions are important to recognize, especially if surgical treatment is contemplated. Intensive long-term monitoring of clinical behavior and the EEG is required for operative candidates, however, and this generally also involves recording from intracranially placed electrodes (which may be subdural, extradural, or intracerebral in location).

The findings in the routine scalp-recordedEEG may indicate the prognosis of seizure disorders: in general, a normal EEG implies a better prognosis than otherwise, whereas an abnormal background or profuse epileptiform activity suggests a poor outlook. The EEG findings are not helpful in determining which patients with head injuries, stroke, or brain tumors will go on to develop seizures, because in such circumstances epileptiform activity is commonly encountered regardless of whether seizures occur. The EEG findings are sometimes used to determine whether anticonvulsant medication can be discontinued in epileptic patients who have been seizure-free for several years, but the findings provide only a general guide to prognosis: further seizures may occur after withdrawal of anticonvulsant medication despite a normal EEG or, conversely, may not occur despite a continuing EEG abnormality. The decision to discontinue anticonvulsant medication is made on clinical grounds, and the EEG does not have a useful role in this context except for providing guidance when there is clinical ambiguity or the patient requires reassurance about a particular course of action.

TheEEG has no role in the management of tonic-clonic status epilepticus except when there is clinical uncertainty whether seizures are continuing in a comatose patient. In patients treated by pentobarbital-induced coma for refractory status epilepticus, the EEG findings are useful in indicating the level of anesthesia and whether seizures are occurring. During status epilepticus, the EEG shows repeated electrographic seizures or continuous spike-wave discharges. In nonconvulsive status epilepticus, a disorder that may not be recognized unless an EEG is performed, the EEG may also show continuous spike-wave activity ("spike-wave stupor") or, less commonly, repetitive electrographic seizures (complex partial status epilepticus).

THE EEG AND COMA

In patients with an altered mental state or some degree of obtundation, the EEG tends to become slower as consciousness is depressed, regardless of the underlying cause (Fig. 357-1). Other findings may also be present and may suggest diagnostic possibilities, as when electrographic seizures are found or there is a focal abnormality

indicating a structural lesion. The EEG generally slows in metabolic encephalopathies, and triphasic waves may be present. The findings do not permit differentiation of the underlying metabolic disturbance but help to exclude other encephalopathic processes by indicating the diffuse extent of cerebral dysfunction. The response of the EEG to external stimulation is helpful prognostically because electrocerebral responsiveness implies a lighter level of coma than a nonreactive EEG. Serial records provide a better guide to prognosis than a single record and supplement the clinical examination in following the course of events. As the depth of coma increases, the EEG becomes nonreactive and may show a burst-suppression pattern, with bursts of mixed-frequency activity separated by intervals of relative cerebral inactivity. In other instances there is a reduction in amplitude of the EEG until eventually electrocerebral activity cannot be detected. Such electrocerebral silence does not necessarily reflect irreversible brain damage, because it may occur in hypothermic patients or with drug overdose. The prognosis of electrocerebral silence, when recorded using an adequate technique, depends upon the clinical context in which it is found. In patients with severe cerebral anoxia, for example, electrocerebral silence in a technically satisfactory record implies that useful cognitive recovery will not occur.

In patients with clinically suspected brain death, anEEG, when recorded using appropriate technical standards, may be confirmatory by showing electrocerebral silence. However, complicating disorders that may produce a similar but reversible EEG appearance (e.g., hypothermia or drug intoxication) must be excluded. The presence of residual EEG activity in suspected brain death fails to confirm the diagnosis but does not exclude it. The EEG is usually normal in patients with locked-in syndrome and helps in distinguishing this disorder from the comatose state with which it is sometimes confused clinically.

THE EEG IN OTHER NEUROLOGIC DISORDERS

In the developed countries, computed tomography (CT) scanning and magnetic resonance imaging (MRI) have taken the place of EEG as a noninvasive means of screening for focal structural abnormalities of the brain, such as tumors, infarcts, or hematomas (Fig. 357-1). Nonetheless, the EEG is still used for this purpose in many parts of the world, although infratentorial or slowly expanding lesions may fail to cause any abnormalities. Focal slow-wave disturbances, a localized loss of electrocerebral activity, or more generalized electrocerebral disturbances are common findings but provide no reliable indication about the nature of the underlying pathology.

In patients with an acute encephalopathy, focal or lateralized periodic slow-wave complexes, sometimes with a sharpened outline, suggest a diagnosis of herpes simplex encephalitis, and periodic lateralized epileptiform discharges (PLEDs) are commonly found with acute hemispheric pathology such as a hematoma, abscess, or rapidly expanding tumor. TheEEGfindings in dementia are usually nonspecific and do not distinguish between the different causes of cognitive decline except in rare instances when the presence of complexes occurring with a regular repetition rate (so-called periodic complexes) in dementing disorders, for example, supports a diagnosis of Creutzfeldt-Jakob disease (Fig. 357-1) or subacute sclerosing panencephalitis. In most patients with dementias, the EEG is normal or diffusely slowed, and the EEG findings alone cannot indicate whether a patient is demented or distinguish between dementia

and pseudodementia.

EVOKED POTENTIALS

SENSORY EVOKED POTENTIALS

The noninvasive recording of spinal or cerebral potentials elicited by stimulation of specific afferent pathways is an important means of monitoring the functional integrity of these pathways but does not indicate the pathologic basis of lesions involving them. Such evoked potentials (EPs) are so small compared to the backgroundEEGactivity that the responses to a number of stimuli have to be recorded and averaged with a computer in order to permit their recognition and definition. The background EEG activity, which has no fixed temporal relationship to the stimulus, is averaged out by this procedure.

Visual evoked potentials (VEPs) are elicited by monocular stimulation with a reversing checkerboard pattern and are recorded from the occipital region in the midline and on either side of the scalp. The component of major clinical importance is the so-called P100 response, a positive peak having a latency of approximately 100 ms. Its presence, latency, and symmetry over the two sides of the scalp are noted. Amplitude may also be measured, but changes in size are much less helpful for the recognition of pathology. VEPs are most useful in detecting dysfunction of the visual pathways anterior to the optic chiasm. In patients with acute severe optic neuritis, the P100 is frequently lost or grossly attenuated; as clinical recovery occurs and visual acuity improves, the P100 is restored but with an increased latency that generally remains abnormally prolonged indefinitely. The VEP findings are therefore helpful in indicating previous or subclinical optic neuritis. They may also be abnormal with ocular abnormalities and with other causes of optic nerve disease, such as ischemia or compression by a tumor. Normal VEPs may be elicited by flash stimuli in patients with cortical blindness.

Brainstem auditory evoked potentials (BAEPs) are elicited by monaural stimulation with repetitive clicks and are recorded between the vertex of the scalp and the mastoid process or earlobe. A series of potentials, designated by roman numerals, occurs in the first 10 ms after the stimulus and represents in part the sequential activation of different structures in the pathway between the auditory nerve (wave I) and the inferior colliculus (wave V) in the midbrain. The presence, latency, and interpeak latency of the first five positive potentials recorded at the vertex are evaluated. The findings are helpful in screening for acoustic neuromas, detecting brainstem pathology, and evaluating comatose patients. The BAEPs are normal in coma due to metabolic/toxic disorders or bihemispheric disease but abnormal in the presence of brainstem pathology.

Somatosensory evoked potentials (SEPs) are recorded over the scalp and spine in response to electrical stimulation of a peripheral (mixed or cutaneous) nerve. The configuration, polarity, and latency of the responses depend on the nerve that is stimulated and on the recording arrangements. SEPs are used to evaluate proximal (otherwise inaccessible) portions of the peripheral nervous system and the integrity of the central somatosensory pathways.

Clinical Utility of Sensory Evoked Potentials EPstudies may detect and localize lesions in afferent pathways in the central nervous system (CNS). They have been used

particularly to investigate patients with suspected multiple sclerosis (MS), the diagnosis of which requires the recognition of lesions involving several different regions of the central white matter. In patients with clinical evidence of only one lesion, the electrophysiologic recognition of abnormalities in other sites helps to suggest or support the diagnosis but does not establish it unequivocally. Multimodality EP abnormalities are not specific for MS; they may occur in AIDS, Lyme disease, systemic lupus erythematosus, neurosyphilis, spinocerebellar degenerations, familial spastic paraplegia, and deficiency of vitamin E or B_{12}, among other disorders. The diagnostic utility of the electrophysiologic findings therefore depends upon the circumstances in which they are found. Abnormalities may aid in the localization of lesions to broad areas of the CNS, but attempts at precise localization on electrophysiologic grounds are misleading because the generators of many components of the EP are unknown.

TheEPfindings are sometimes of prognostic relevance. Bilateral loss ofSEPcomponents that are generated in the cerebral cortex implies that cognition may not be regained in posttraumatic or postanoxic coma, and EP studies may also be useful in evaluating patients with suspected brain death. In patients who are comatose for uncertain reasons, preservedBAEPssuggest either a metabolic-toxic etiology or bihemispheric disease. In patients with spinal cord injuries, SEPs have been used to indicate the completeness of the lesion -- the presence or early return of a cortically generated response to stimulation of a nerve below the injured segment of the cord indicates an incomplete lesion and thus a better prognosis for functional recovery than otherwise. In surgery, intraoperative EP monitoring of neural structures placed at risk by the procedure may permit the early recognition of dysfunction and thereby permit a neurologic complication to be averted or minimized.

Visual and auditory acuity may be determined usingEPtechniques in patients whose age or mental state precludes traditional ophthalmologic or audiologic examinations.

COGNITIVE EVOKED POTENTIALS

CertainEPcomponents depend upon the mental attention of the subject and the setting in which the stimulus occurs, rather than simply on the physical characteristics of the stimulus. Such "event-related" potentials (ERPs) or "endogenous" potentials are related in some manner to the cognitive aspects of distinguishing an infrequently occurring target stimulus from other stimuli occurring more frequently. For clinical purposes, attention has been directed particularly at the so-called P3 component of the ERP, which is also designated the P300 component because of its positive polarity and latency of approximately 300 to 400 ms after onset of an auditory target stimulus. The P3 component is prolonged in latency in many patients with dementia, whereas it is generally normal in patients with depression or other psychiatric disorders that might be mistaken for dementia. ERPs are therefore sometimes helpful in making this distinction when there is clinical uncertainty, although a response of normal latency does not exclude a dementing disorder.

MOTOR EVOKED POTENTIALS

The electrical potentials recorded from muscle or the spinal cord following stimulation of the motor cortex or central motor pathways are referred to as *motor evoked potentials*.

For clinical purposes such responses are recorded most often as the compound muscle action potentials elicited by transcutaneous magnetic stimulation of the motor cortex. A strong but brief magnetic field is produced by passing a current through a coil, and this induces stimulating currents in the subjacent neural tissue. The procedure is painless and apparently safe. Abnormalities have been described in several neurologic disorders with clinical or subclinical involvement of central motor pathways, includingMS and motor neuron disease. In addition to a possible role in the diagnosis of neurologic disorders or in evaluating the extent of pathologic involvement, the technique provides information of prognostic relevance (e.g., in suggesting the likelihood of recovery of motor function after stroke) and is useful as a means of monitoring intraoperatively the functional integrity of central motor tracts.

ELECTROPHYSIOLOGIC STUDIES OF MUSCLE AND NERVE

The motor unit is the basic element subserving motor function. It is defined as an anterior horn cell, its axon and neuromuscular junctions, and all the muscle fibers innervated by the axon. The number of motor units in a muscle ranges from approximately 10 in the extraocular muscles to several thousand in the large muscles of the legs. There is considerable variation in the average number of muscle fibers within the motor units of an individual muscle, i.e., in the innervation ratio of different muscles. Thus the innervation ratio is less than 25 in the human external rectus or platysma muscle and between 1600 and 1700 in the medial head of the gastrocnemius muscle. The muscle fibers of individual motor units are divided into two general types by distinctive contractile properties, histochemical stains, and characteristic responses to fatigue. Within each motor unit, all of the muscle fibers are of the same type.

ELECTROMYOGRAPHY

The pattern of electrical activity in muscle [i.e., the *electromyogram* (EMG)], both at rest and during activity, may be recorded from a needle electrode inserted into the muscle. The nature and pattern of abnormalities relate to disorders at different levels of the motor unit.

Relaxed muscle normally is electrically silent except in the endplate region, but abnormal spontaneous activity (Fig. 357-3) occurs in various neuromuscular disorders, especially those associated with denervation or inflammatory changes in affected muscle. Fibrillation potentials and positive sharp waves (which reflect muscle fiber irritability) and complex repetitive discharges are most often -- but not always -- found in denervated muscle and may also occur after muscle injury and in certain myopathic disorders, especially inflammatory disorders such as polymyositis. After an acute neuropathic lesion they are found earlier in proximal rather than distal muscles and sometimes do not develop distally in the extremities for 4 to 6 weeks; once present, they may persist indefinitely unless reinnervation occurs or the muscle degenerates so completely that no viable tissue remains. Fasciculation potentials (which reflect the spontaneous activity of individual motor units) are characteristic of slowly progressive neuropathic disorders, especially those with degeneration of anterior horn cells (such as amyotrophic lateral sclerosis). Myotonic discharges -- high-frequency discharges of potentials derived from single muscle fibers that wax and wane in amplitude and frequency -- are the signature of myotonic disorders such as myotonic dystrophy or

myotonia congenita but occur occasionally in polymyositis or other, rarer, disorders.

Slight voluntary contraction of a muscle leads to activation of a small number of motor units. The potentials generated by any muscle fibers of these units that are within the pick-up range of the needle electrode will be recorded (Fig. 357-3). The parameters of normal motor unit action potentials depend on the muscle under study and age of the patient, but their duration is normally between 5 and 15 ms, amplitude is between 200 uV and 2 mV, and most are bi- or triphasic. The number of units activated depends on the degree of voluntary activity. An increase in muscle contraction is associated with an increase in the number of motor units that are activated (recruited) and in the frequency with which they discharge. With a full contraction, so many motor units are normally activated that individual motor unit action potentials can no longer be distinguished, and a complete interference pattern is said to have been produced.

The incidence of small, short-duration, polyphasic motor unit action potentials (i.e., having more than four phases) is usually increased in myopathic muscle, and an excessive number of units is activated for a specified degree of voluntary activity. By contrast, the loss of motor units that occurs in neuropathic disorders leads to a reduction in number of units activated during a maximal contraction and an increase in their firing rate, i.e., there is an incomplete or reduced interference pattern; the configuration and dimensions of the potentials may also be abnormal, depending on the duration of the neuropathic process and on whether reinnervation has occurred. The surviving motor units are initially normal in configuration but, as reinnervation occurs, they increase in amplitude and duration and become polyphasic (Fig. 357-3).

Action potentials from the same motor unit sometimes fire with a consistent temporal relationship to each other, so that double, triple, or multiple discharges are recorded, especially in tetany, hemifacial spasm, or myokymia.

Electrical silence characterizes the involuntary, sustained muscle contraction that occurs in phosphorylase deficiency, which is designated a *contracture*.

EMGenables disorders of the motor units to be detected and characterized as either neurogenic or myopathic. In neurogenic disorders, the pattern of affected muscles may localize the lesion to the anterior horn cells or to a specific site as the axons traverse a nerve root, limb plexus, and peripheral nerve to their terminal arborizations. The findings do not enable a specific etiologic diagnosis to be made, however, except in conjunction with the clinical findings and results of other laboratory studies.

The findings may provide a guide to the severity of an acute disorder of a peripheral or cranial nerve (by indicating whether denervation has occurred and the completeness of the lesion), and whether the pathologic process is active or progressive in chronic or degenerative disorders such as amyotrophic lateral sclerosis. Such information is important for prognostic purposes.

Various quantitativeEMGapproaches have been developed. The most common is to determine the mean duration and amplitude of 20 motor unit action potentials using a standardized technique. The technique of macro-EMG provides information about the number and size of muscle fibers in a larger volume of the motor unit territory and has

also been used to estimate the number of motor units in a muscle. Scanning EMG is a computer-based technique that has been used to study the topography of motor unit action potentials and, in particular, the spatial and temporal distribution of activity in individual units. The technique of single-fiber EMG is discussed separately below.

NERVE CONDUCTION STUDIES

Recording of the electrical response of a muscle to stimulation of its motor nerve at two or more points along its course (Fig. 357-4) permits conduction velocity to be determined in the fastest-conducting motor fibers between the points of stimulation. The latency and amplitude of the electrical response of muscle (i.e., of the compound muscle action potential) to stimulation of its motor nerve at a distal site are also compared with values defined in normal subjects. Sensory nerve conduction studies are performed by determining the conduction velocity and amplitude of action potentials in sensory fibers when these fibers are stimulated at one point and the responses are recorded at another point along the course of the nerve. In adults, conduction velocity in the arms is normally between 50 and 70 m/s, and in the legs is between 40 and 60 m/s.

Nerve conduction studies complement theEMGexamination, enabling the presence and extent of peripheral nerve pathology to be determined. They are particularly helpful in determining whether sensory symptoms are arising from pathology proximal or distal to the dorsal root ganglia (in the former instance, peripheral sensory conduction studies will be normal) and whether neuromuscular dysfunction relates to peripheral nerve disease. In patients with a mononeuropathy, they are invaluable as a means of localizing a focal lesion, determining the extent and severity of the underlying pathology, providing a guide to prognosis, and detecting subclinical involvement of other peripheral nerves. They enable a polyneuropathy to be distinguished from a mononeuropathy multiplex when this is not possible clinically, an important distinction because of the etiologic implications. Nerve conduction studies provide a means of following the progression and therapeutic response of peripheral nerve disorders and are being used increasingly for this purpose in clinical trials. They may suggest the underlying pathologic basis in individual cases. Conduction velocity is often markedly slowed, terminal motor latencies are prolonged, and compound motor and sensory nerve action potentials may be dispersed in the demyelinative neuropathies (such as in Guillain-Barre syndrome, chronic inflammatory polyneuropathy, metachromatic leukodystrophy, or certain hereditary neuropathies); conduction block is frequent in acquired varieties of these neuropathies. By contrast, conduction velocity is normal or slowed only mildly, sensory nerve action potentials are small or absent, and there is EMG evidence of denervation in axonal neuropathies such as occur in association with metabolic or toxic disorders.

The utility and complementary role ofEMG and nerve conduction studies are best illustrated by reference to a common clinical problem. Numbness and paresthesia of the little finger, and associated wasting of the intrinsic muscles of the hand may result from a spinal cord lesion, C8/T1 radiculopathy, brachial plexopathy (lower trunk or medial cord), or a lesion of the ulnar nerve. If sensory nerve action potentials can be recorded normally at the wrist following stimulation of the digital fibers in the affected finger, the pathology is probably proximal to the dorsal root ganglia, i.e., there is a radiculopathy or more central lesion; absence of the sensory potentials, by contrast, suggests distal

pathology. EMG examination will indicate whether the pattern of affected muscles conforms to radicular or ulnar nerve territory, or is more extensive (thereby favoring a plexopathy); ulnar motor conduction studies will generally also distinguish between a radiculopathy (normal findings) and ulnar neuropathy (abnormal findings) and will often identify the site of an ulnar nerve lesion -- the nerve is stimulated at several points along its course to determine whether the compound action potential recorded from a distal muscle that it supplies shows a marked alteration in size or area, or a disproportionate change in latency, with stimulation at a particular site. The electrophysiologic findings thus permit a definitive diagnosis to be made and specific treatment instituted in circumstances where there is clinical ambiguity.

F WAVE STUDIES

Stimulation of a motor nerve causes impulses to travel antidromically (i.e., toward the spinal cord) as well as orthodromically (to the nerve terminals). Such antidromic impulses cause a few of the anterior horn cells to discharge, producing a small motor response that occurs considerably later than the direct response elicited by nerve stimulation. The F wave so elicited is sometimes abnormal (absent or delayed) with proximal pathology of the peripheral nervous system, such as a radiculopathy, and may therefore be helpful in detecting abnormalities when conventional nerve conduction studies are normal. In general, however, the clinical utility of F wave studies has been disappointing, except perhaps in Guillain-Barre syndrome, where they are often absent or delayed.

H REFLEX STUDIES

The H reflex is easily recorded only from the soleus muscle (S1) in normal adults. It is elicited by low-intensity stimulation of the tibial nerve and represents a monosynaptic reflex in which spindle (Ia) afferent fibers constitute the afferent arc and alpha motor axons the efferent pathway. The H reflexes are often absent bilaterally in elderly patients or with polyneuropathies and may be lost unilaterally in S1 radiculopathies.

MUSCLE RESPONSE TO REPETITIVE NERVE STIMULATION

The size of the electrical response of a muscle to supramaximal electrical stimulation of its motor nerve relates to the number of muscle fibers that are activated. Neuromuscular transmission can be tested by several different protocols, but the most helpful is to record with surface electrodes the electrical response of a muscle to supramaximal stimulation of its motor nerve by repetitive (2 to 3 Hz) shocks delivered before and at selected intervals after a maximal voluntary contraction.

There is normally little or no change in size of the compound muscle action potential following repetitive stimulation of a motor nerve at 2 to 3 Hz with stimuli delivered at intervals after voluntary contraction of the muscle for about 20 to 30 s, even though preceding activity in the junctional region influences the release of acetylcholine and thus the size of the endplate potentials elicited by a test stimulus. This is because more acetylcholine is normally released than is required to bring the motor endplate potentials to the threshold for generating muscle fiber action potentials. In disorders of neuromuscular transmission this safety factor is reduced. Thus, in myasthenia gravis

repetitive stimulation, particularly at a rate of between 2 and 5 Hz, may lead to a depression of neuromuscular transmission, with a decrement in size of the response recorded from affected muscles. Similarly, immediately after a period of maximal voluntary activity, single or repetitive stimuli of the motor nerve may elicit larger muscle responses than before, indicating that more muscle fibers are responding. This postactivation facilitation of neuromuscular transmission is followed by a longer-lasting period of depression, maximal between 2 and 4 min after the conditioning period and lasting for as long as 10 min or so, during which responses are reduced in size.

Decrementing responses to repetitive stimulation at 2 to 5 Hz are common in myasthenia gravis but may also occur in the congenital myasthenic syndromes. In Lambert-Eaton myasthenic syndrome, in which there is defective release of acetylcholine at the neuromuscular junction, the compound muscle action potential elicited by a single stimulus is generally very small. With repetitive stimulation at rates of up to 10 Hz, the first few responses may decline in size, but subsequent responses increase. If faster rates of stimulation are used (20 to 50 Hz), the increment may be dramatic so that the amplitude of compound muscle action potentials eventually reaches a size that is several times larger than the initial response. In patients with botulism, the response to repetitive stimulation is similar to that in Lambert-Eaton syndrome, although the findings are somewhat more variable and not all muscles are affected.

SINGLE-FIBER ELECTROMYOGRAPHY

The technique is particularly helpful in detecting disorders of neuromuscular transmission. A special needle electrode is placed within a muscle and positioned to record action potentials from two muscle fibers belonging to the same motor unit. The time interval between the two potentials will vary in consecutive discharges, and this is called the *neuromuscular jitter*. The jitter can be quantified as the mean difference between consecutive interpotential intervals and is normally between 10 and 50 us. This value is increased when neuromuscular transmission is disturbed for any reason, and in some instances impulses in individual muscle fibers may fail to occur because of impulse blocking at the neuromuscular junction. Single-fiberEMG is more sensitive than repetitive nerve stimulation or determination of acetylcholine receptor antibody levels in diagnosing myasthenia gravis.

Single-fiberEMG can also be used to determine the mean fiber density of motor units (i.e., mean number of muscle fibers per motor unit within the recording area) and to estimate the number of motor units in a muscle, but this is of less immediate clinical relevance.

BLINK REFLEXES

Electrical or mechanical stimulation of the supraorbital nerve on one side leads to two separate reflex responses of the orbicularis oculi -- an ipsilateral R1 response having a latency of approximately 10 ms and a bilateral R2 response with a latency in the order of 30 ms. The trigeminal and facial nerves constitute the afferent and efferent arcs of the reflex, respectively. Abnormalities of either nerve or intrinsic lesions of the medulla or pons may lead to uni- or bilateral loss of the response, and the findings may therefore be helpful in identifying or localizing such pathology.

358. NEUROIMAGING IN NEUROLOGIC DISORDERS - *William P. Dillon*

A dramatic increase in the role of imaging in diagnosis of neurologic diseases occurred with the development of computed tomography (CT) in the early 1970s and of magnetic resonance imaging (MRI) in the 1980s. MRI has gradually replaced CT for many indications and has also reduced the indications for invasive neuroimaging techniques, such as myelography and angiography. In general, MRI is more sensitive than CT for the evaluation of most lesions affecting the central nervous system, particularly those in the spinal cord, cranial nerves, and posterior fossa. CT is more sensitive than MRI for visualizing fine osseous detail, such as temporal bone anatomy and fractures. Recent developments, such as helical CT, CT angiography (CTA), MR angiography (MRA), positron emission tomography (PET), Doppler ultrasound, and interventional angiography have continued to advance diagnosis and guide therapy. Conventional angiography is reserved for cases in which small-vessel detail is essential for diagnosis (Table 358-1).

COMPUTED TOMOGRAPHY

Technique TheCT image is a computer-generated cross-sectional representation of anatomy created by an analysis of the attenuation of x-ray beams passed through various points around a section of the body. As the x-ray source, collimated to the desired slice thickness, rotates around the patient, sensitive x-ray detectors aligned 180° from the source detect x-rays attenuated by the patient's anatomy. A computer calculates a "back projection" image from the 360° x-ray attenuation profile. Greater x-ray attenuation, as caused by bone, results in areas of high "density," while soft tissue structures, which attenuate x-rays less, are lower in density. The resolution of an image depends on the radiation dose, the collimation (slice thickness), the field of view, and the matrix size of the display. A typical modern CT scanner is capable of obtaining sections 1 to 2, 5, and 10 mm thick at a speed of 1 to 3 s per section; complete studies of the brain can be completed in <2 to 3 min.

Intravenous contrast is often administered prior to or during aCT study to identify vascular structures and to detect defects in the blood-brain barrier (BBB) associated with disorders such as tumors, infarcts, and infections. An intact BBB prevents contrast molecules, which are large, from exiting the intravascular compartment. In the normal central nervous system, only vessels and those structures not having a BBB (e.g., the pituitary gland, choroid plexus, and dura) enhance. The use of contrast agents carries a risk of allergic reaction, increases the dose of radiation when both noncontrast and contrast CT scans are to be obtained, adds expense, and may mask hemorrhage; thus, before contrast is administered, the indication for its use should always be considered carefully.

HelicalCT is a new technique in which continuous three-dimensional CT information is obtained. In the helical scan mode, the table moves continuously through the rotating x-ray beam, generating a "helix" of information that can be reformatted into various slice thicknesses. Advantages include shorter scan times, reduced patient and organ motion, and the ability to acquire images during the infusion of intravenous contrast. The contrast images can be used to construct CT angiograms of vascular structures.CTAimages require a workstation to threshold and segment CT images for

display (Fig. 358-1). CTA has proven useful in assessing the carotid bifurcation and intracranial arterial anatomy in selected instances in which a contraindication toMRAexists. Newer "multidetector" scanners allow multiple sections to be obtained with each revolution of the gantry. These scanners have further decreased the time per examination and permit rapid assessment of vascular anatomy (Fig. 358-2).

Indications The indications forCT have decreased since the development ofMRI. While MRI gives greater soft tissue contrast and is more sensitive than CT in detecting early brain damage, CT is useful in imaging osseous structures of the spine, skull base, and temporal bones. CT is also more sensitive and specific than MRI for acute subarachnoid hemorrhage. In the spine, CT is useful in evaluating patients with osseous spinal stenosis and spondylosis, but MRI is often preferred in those with neurologic deficits. CT can also be obtained following intrathecal contrast injection to evaluate the intracranial cisterns for cerebrospinal fluid (CSF) fistula, as well as the spinal subarachnoid space.

Complications CT is safe and reliable. Radiation exposure is between 3 and 5 cGy per examination. The most frequent complications are associated with use of intravenous contrast agents. Two broad categories of contrast media, ionic and nonionic, are in use. Ionic agents are relatively safe and inexpensive but cause a higher incidence of toxicity reactions than nonionic agents.

Nephrotoxicity caused by contrast administration (*contrast nephropathy*) may result from hemodynamic changes, tubular obstruction and cell damage, or immunologic reactions to contrast agents. A rise in serum creatinine of at least 85 umol/L (1 mg/dL) within 48 h of contrast administration is often used as a definition of contrast nephropathy, although other causes of acute renal failure must be excluded. The prognosis is usually favorable, with serum creatinine levels returning to baseline within 1 to 2 weeks. Risk factors for contrast nephropathy include advanced age, preexisting renal disease, diabetes, dehydration, and high contrast dose. Patients with diabetes and those with mild renal failure should be well hydrated prior to the administration of nonionic agents. Nonionic, low-osmolar media produce fewer abnormalities in renal blood flow and less endothelial cell damage than ionic agents (seeGuidelines).

A sensation of heat, *pain*, *nausea*, and *vomiting* are well-known side effects following intravenous administration of ionic contrast media, and they become more important as studies require longer imaging times and repeated contrast injections. Pain and the sensation of heat are probably due to the osmolality of the agent and vasodilation. These side effects are less intense or nonexistent with nonionic contrast media.

Anaphylactoid reactions to intravenous contrast media range from mild hives to bronchospasm to acute anaphylaxis and death. The pathogenesis of these allergic reactions is not fully understood, but it is thought to include the release of mediators such as histamine, antibody-antigen reactions, and complement activation. Severe allergic reactions occur in approximately 0.04% of patients receiving nonionic media, sixfold fewer than with ionic media. Risk factors include a history of prior contrast reaction, allergy (asthma and hay fever), and cardiac disease. In these patients, a noncontrastCT orMRIprocedure should be considered as an alternative to contrast administration. If contrast is absolutely required, a nonionic agent should be used in conjunction with pretreatment with glucocorticoids and antihistamines (Table 358-2

andGuidelines). Patients with allergic reactions to iodinated contrast material do not usually react against gadolinium-based magnetic resonance (MR) contrast material, although it would be wise to pretreat in a similar fashion prior to MR contrast administration.

MAGNETIC RESONANCE IMAGING

Technique The phenomenon of magnetic resonance is a complex interaction between protons in biologic tissues, a static and alternating magnetic field (the magnet), and energy in the form of radiofrequency waves of a specific frequency (Rf), introduced by coils placed next to the body part of interest. The energy state of the hydrogen protons is transiently excited. The subsequent return to equilibrium (*relaxation*) of the protons results in a release of Rf energy (the *echo*), which can be measured by the same surface coils that delivered the Rf pulses. The complex Rf signal, or echo, is transformed by Fourier analysis into the information used to form anMRimage.

T1 and T2 Relaxation Times The rate of return to equilibrium of perturbed protons is called the *relaxation rate*. The relaxation rate is different for different normal and pathologic tissues. The relaxation rate of a hydrogen proton in a tissue is influenced by surrounding molecular environment and atomic neighbors. Two relaxation rates, the T1 and T2 relaxation times, are measurable. The T1 relaxation rate is the time for 63% of the protons to return to their normal equilibrium state, while the T2 relaxation rate is the time for 63% of the protons to become dephased owing to interactions among adjacent protons. The intensity of the signal, and thus the image contrast, can be modulated by altering certain parameters, such as the interval between Rf pulses (TR) and the time between the Rf pulse and the signal reception (TE). So-called T1-weighted (T1W) images are produced by keeping the TR and TE relatively short. Under these conditions, contrast between structures is based primarily on their T1 relaxation differences. T2-weighted (T2W) images are produced by using longer TR and TE times. Fat and subacute hemorrhage have short T1 relaxation rates and a high signal intensity on T1W images. Watery media, such asCSF and edematous tissue, have long T1 and T2 relaxation rates, a low signal intensity on T1W images, and a high signal intensity on T2W images. As white matter contains more lipid (due to myelin), it contains 10 to 15% less water than gray matter. These two chemical differences account for much of the contrast difference between gray and white matter onMRI(Fig. 358-3). T2W images are more sensitive than T1W images to edema or myelin destruction (Fig. 371-2).

MRimages can be generated in sagittal, coronal, axial, and oblique planes without changing the patient's position. Each plane obtained requires a separate sequence lasting 5 to 10 min. UnlikeCT, movement of the patient during a sequence will distort *all* the images; therefore, patient cooperation is important. Approximately 5% of the population experience claustrophobia in the MR environment. This can be reduced by mild sedation. Three-dimensional volumetric imaging is also possible with MR, resulting in data that can be reformatted in any plane and manipulated in a real-time fashion to highlight certain disease processes. Fluid-attenuated inversion recovery, or FLAIR, is a pulse sequence that producesT2Wimages in which theCSFsignal is suppressed. FLAIR images are more sensitive than standard spine echo images for cortical lesions and meningeal processes (Fig. 358-2*D*).

Contrast Material The heavy-metal element *gadolinium* forms the basis of all current intravenousMRcontrast agents. Gadolinium is a paramagnetic substance, which means that it reduces the T1 and T2 relaxation times of nearby water protons, resulting in a high signal onT1Wimages. The metal is chelated to an agent such as DTPA, which allows renal excretion without toxicity. Approximately 0.2 mL/kg body weight is administered intravenously (10 to 15 mL for the average-sized adult); the cost is approximately $60 per 20 mL. Gadolinium contrast does not cross a normalBBB, and thus it causes enhancement of brain tissue only at sites of abnormalities in the BBB (Fig. 371-2*D*) and in areas of the brain that normally have no BBB, such as the pituitary gland. Allergic reactions are extremely rare; renal failure does not occur. These agents can be administered safely to children as well as adults.

MAGNETIC RESONANCE ANGIOGRAPHY

Flowing blood exhibits complexMRsignals that range from bright to dark relative to background stationary tissue (Fig. 358-3). Fast-flowing blood, such as arterial blood, shows no signal on routine MR images. Slower flow, as in veins or distal to arterial stenoses, may appear high in signal. It is possible, by varying the MR image parameters, to assess blood flow either qualitatively or quantitatively. This is the basis ofMRA, which capitalizes on the differences in signal between moving blood and stationary tissue on gradient echo images (Fig. 358-4). *Gradient echo images* differ from standard spin echo images in being more sensitive to blood products, calcification, and other susceptibility artifacts. The suppression of background signal achieved in short-flip-angle gradient echo images provides the contrast needed for flowing blood to appear bright in signal on MRA images.

It is important to understand thatMRAprovides a *vascular flow map* rather than the anatomic map given by conventional angiography. Two MRA techniques, time-of-flight (TOF) and phase-contrast, are used. TOF, currently the technique used most frequently, relies on the suppression of nonmoving tissue to provide a background for the high signal intensity of flowing blood. A typical TOF angiography sequence results in a series of contiguous thinMRsections (0.9 mm thick), which can be viewed as a stack to create an angiographic image data set that can be reformatted or viewed in various planes and angles to reveal the vascular relationships (Fig. 358-4). Either arterial (MRA) or venous (MRV) structures may be highlighted.

Phase-contrastMRA has a longer acquisition time thanTOF MRA but reveals the velocity and direction of blood flow in addition to providing anatomic information similar to that of TOF imaging. Through the selection of different imaging parameters, differing blood velocities can be highlighted; selective venous and arterial MRA images thus can be obtained. One advantage of phase-contrast MRA is the excellent suppression of background signal.

MRAhas lower resolution than conventional angiography and therefore cannot detect small-vessel detail, such as is needed in the workup of vasculitis. It is also less sensitive to slow flow and thus may not differentiate occlusive disease from near-occlusive disease. Motion, either by the patient or by anatomic structures, may distort the images, creating artifacts that may be misinterpreted as stenoses or occlusions. These limitations notwithstanding, MRA has proved useful in evaluation of the cervical carotid

artery and larger-caliber intracranial arterial and venous structures. It has also proved useful in the noninvasive detection of intracranial aneurysms (Fig. 361-13) and vascular malformations.

ECHO-PLANARMRIMAGING

Recent improvements in gradients, software, and high-speed computer processors now permit MR imaging of the brain on the order of milliseconds. With echo-planar MRI (EPI), fast gradients are switched on and off at high speeds to create the information used to form an image. In routine spin echo imaging, images of the brain can be obtained in 5 to 10 min. With EPI, all of the information required for processing an image is accumulated in 50 to 150 ms, and the information for the entire brain is obtained in 5 to 10 s. EPI allows motion-free imaging, as well as perfusion imaging, diffusion imaging (Fig. 358-4*A*), functionalMRI, and kinematic motion studies.

EPItechniques are making their way into clinical practice. The hope for these techniques is that they will provide useful functional data in addition to exquisite anatomic images. EPI *perfusion imaging* and *diffusion imaging* are useful in early detection of ischemic injury of the brain, and may be useful in demonstrating "tissue at risk" of further infarction (Fig. 358-4*A*). Diffusion imaging may also be useful in the characterization of white matter tracts. *FunctionalMRI*of the brain is a technique that localizes regions of activity in the brain following task activation. Tasks alter the balance of oxyhemoglobin and deoxyhemoglobin within specific regions of the activated cortex. Repetitive actions such as finger tapping elicit an increase in the amount of blood flow delivered to a specific region of the brain, resulting in a slight increase in oxyhemoglobin and a 2 to 3% change in signal intensity (Fig. 358-5). Further work will determine whether these techniques are cost-effective or clinically useful, but currently somatosensory and auditory cortex localization are possible.

Complications of MRI and Patient Safety MRI is considered safe for patients, even at very high field strengths. Serious injuries have been caused, however, by the high magnetic fields used. Ferromagnetic (metal) objects are attracted to the magnet and may act as missiles if brought too close to the magnet. Likewise, ferromagnetic aneurysm clips may torque within the magnet, causing hemorrhage and even death. Metallic foreign bodies in the eye have moved and caused hemorrhage, so screening for ocular metallic fragments is indicated in those with a history of ocular metallic foreign bodies. Implanted cardiac pacemakers are a contraindication to MRI owing to the risk of induced arrhythmias. All personnel and patients must be screened and educated thoroughly to prevent such disasters.Table 358-3 lists several of the more common contraindications for MRI.

POSITRON EMISSION TOMOGRAPHY

PETrelies on the detection of positrons emitted during the decay of a radionuclide that has been injected into a patient. The most frequently used moiety is 2-[$_{18}$F]fluoro-2-deoxy-D-glucose (FDG), which is an analogue of glucose and is taken up by cells competitively with 2-deoxyglucose. Multiple images of glucose uptake activity are formed after 45 to 60 min. Images reveal differences in regional glucose activity among normal and pathologic brain structures. FDG PET scanning has been used to

assist in differentiating radiation necrosis from active neoplasm following therapy, in localizing temporal lobe epileptic foci, and in detecting metastatic disease and determining cardiac viability. A lower activity of FDG in the parietal lobes has been associated with Alzheimer's disease (Fig. 362-1).

MYELOGRAPHY

Technique Myelography involves the intrathecal instillation of 8 to 15 mL of water-soluble iodinated contrast medium (180 to 300 mg/mL) into the lumbar or cervical subarachnoid space via a percutaneously placed spinal needle (22 gauge or smaller). Contrast is maneuvered into the area of interest by fluoroscopic guidance and patient rotation. *Conventional myelography* involves a relatively high concentration and volume of contrast material and visualization by x-ray "spot films" and formal "overhead" plain films. The radiation exposure during conventional myelography is 4 to 8 cGy, making it one of the more radiation-intense procedures. The gonads should be shielded if possible, although doing so is sometimes difficult.CTscanning is often performed after myelography (*CT myelography*), to better demonstrate the spinal cord and roots as filling defects in the opacified subarachnoid space. CT myelography alone, in which CT is performed after the subarachnoid injection of a small amount of relatively dilute contrast material, has replaced conventional myelography for many indications, thereby reducing exposure to radiation and contrast media. CT slices 3 mm thick are routinely obtained through the area of interest.

Indications For diagnosis of diseases of the spinal canal and cord, myelography has been largely replaced byCT, CT myelography, andMRI(Table 358-1). The remaining indications for conventional plain film myelography include the evaluation of suspected meningeal or arachnoid cysts and the localization of spinal dural arteriovenous fistulas andCSFfistulas. Conventional myelography and CT myelography provide the most precise information in patients with prior spinal fusion and spinal fixation hardware.

Contraindications Myelography is relatively safe. However, it should be performed with caution in any patient with suspected herniation, elevated intracranial pressure, or a history of allergic reaction to intrathecal contrast media. In patients with a suspected spinal block, only a small amount of contrast medium should be instilled below the level of the block to minimize the risk of deterioration. Lumbar puncture is to be avoided in patients with bleeding disorders, including patients receiving anticoagulant therapy (Chap. 356).

Complications Complications resulting from myelography are related to the needle puncture and to reactions to intrathecal contrast material.

Vasovagal syncope may occur during lumbar puncture; it is accentuated by the upright position used during lumbar myelography. Adequate hydration before and after myelography will reduce the incidence of this complication.

Headache, *nausea*, and *vomiting* are the most frequent complications of dural puncture and myelography, occurring in up to 38% of patients. These symptoms are thought to result from neurotoxic effects of the contrast agent, persistent leakage ofCSF at the puncture site, or psychological reactions to the procedure. The incidence of headache

has been reduced with the use of smaller-gauge spinal needles and nonionic, water-soluble contrast agents.

Postural headache (post-lumbar puncture headache) is generally due to prolonged leakage ofCSF from the puncture site, resulting in CSF hypotension. Intravenous hydration may be helpful, and an autologous epidural blood patch is indicated in patients with persistent headache 48 h after myelography (Chap. 15).

Hearing loss is a rare complication. It may result from a direct toxic effect of the contrast medium or from an alteration of the pressure equilibrium betweenCSF and perilymph in the inner ear.

Puncture of the spinal cord is a rare but serious complication of cervical (C1-2) and high lumbar puncture. The cervical approach requires proper alignment of the patient and is best performed in the prone position using fluoroscopic guidance. Direct puncture of the spinal cord, laceration of epidural and vertebral venous and arterial structures, and hyperextension of the neck are reported complications. Injection of contrast material into the spinal cord can precipitate acute neurologic decline or subacute hemorrhagic necrosis of the gray matter. The risk of cord puncture is greatest in patients with spinal stenosis or conditions that reduceCSFvolume. In these settings, a low-dose lumbar injection followed by thin-sectionCT is a safer alternative to cervical puncture.

Intrathecal contrast reactions are rare, but aseptic meningitis and encephalopathy may occur. The latter is usually dose-related and associated with contrast entering the intracranial subarachnoid space. *Seizures* occur following myelography in 0.1 to 0.3% of patients. Risk factors include a preexisting seizure disorder and the use of a total iodine dose of >4500 mg. Other reported symptoms include headache, hyperthermia, hallucinations, depression, and anxiety states. These neurotoxic side effects have been reduced by the development of nonionic, water-soluble contrast agents, as well as by head elevation and generous hydration following myelography.

Arachnoiditis, or inflammation of the leptomeninges, has also been ascribed to the use of contrast agents for myelography. Pantopaque, an oil-soluble contrast agent no longer used, was first noted to cause arachnoiditis, especially in cases where myelography resulted in subarachnoid bleeding (i.e., traumatic tap). The incidence of arachnoiditis with new water-soluble, nonionic contrast agents is much lower than with Pantopaque and with ionic, water-soluble agents (metrizamide). Other variables that increase the likelihood of arachnoiditis include trauma, infection, and subarachnoid hemorrhage.

ANGIOGRAPHY

Technique Angiography is essential in the diagnostic evaluation of many patients with vascular pathology. However, it carries the greatest risk of morbidity of all diagnostic imaging procedures, owing to the necessity of inserting a catheter into a blood vessel, directing the catheter to the required location, injecting contrast material to visualize the vessel, and removing the catheter while maintaining hemostasis. Therapeutic transcatheter procedures (see below) have become important options for the treatment of some cerebrovascular diseases. The decision to undertake a diagnostic or therapeutic angiographic procedure requires careful assessment of the goals of the

investigation and its attendant risks.

Patients undergoing angiography should be well hydrated before and after the procedure to better tolerate the contrast agents. Since the femoral route is used most commonly, the femoral artery must be compressed after the procedure to prevent a hematoma from developing. The puncture site and distal pulses should be evaluated carefully after the procedure; complications can include thigh hematoma or distal emboli.

Indications Table 358-1 lists some of the indications for conventional angiography. Over the past 20 years, angiography has been replaced for many indications by CT or MRI. However, it is still used today for evaluating intracranial small-vessel pathology (such as vasculitis), for assessing vascular malformations and aneurysms, and in intravascular therapeutic procedures.

Complications The vast majority of aortic arch, carotid, and vertebral arteriograms are carried out via transfemoral arterial access. A common femoral arterial puncture provides retrograde access via the aorta to the aortic arch and great vessels. The most feared complication of cerebral angiography is stroke. Thrombus can form on or inside the tip of the catheter, and atherosclerotic thrombus or plaque can be dislodged by the catheter or guidewire or by the force of injection and can embolize distally in the cerebral circulation. The duration and extent of the resulting ischemic neurologic deficit depends on the size and length of the embolus, its composition (fresh thrombus is thought to fragment more readily), its location, and the available collateral circulation. Risk factors for ischemic complications include limited experience on the part of the angiographer, atherosclerosis, vasospasm, low cardiac output, decreased oxygen-carrying capacity, advanced age, and possibly migraine. The risk of a neurologic complication varies but is approximately 4% for transient ischemic attack and stroke, 1% for permanent deficit, and<0.1% for death.

Ionic contrast material injected into the cerebral vasculature can be neurotoxic if the BBB is breached, either by an underlying disease or by the injection of hyperosmolar contrast agent. Ionic contrast media are less well tolerated than nonionic media, probably because they can induce changes in cell membrane electrical potentials. Patients with dolichoectasia of the basilar artery can suffer reversible brainstem dysfunction and acute short-term memory loss during angiography owing to the slow percolation of the contrast material and the consequent prolonged exposure of the brain. Rarely, an intracranial aneurysm ruptures during an angiographic contrast injection, causing subarachnoid hemorrhage, perhaps as a result of injection under high pressure.

Spinal Angiography Spinal angiography may be indicated to evaluate vascular malformations and tumors and to identify the artery of Adamkiewicz prior to aortic aneurysm repair. The procedure is lengthy and requires the use of relatively large volumes of contrast; the incidence of serious complications, including paraparesis, subjective visual blurring, and altered speech, is approximately 2%.

Interventional Neuroradiology This rapidly developing field is providing new therapeutic options for patients with difficult neurovascular problems. Available

procedures include detachable coil therapy for aneurysms, particulate or liquid adhesive embolization of arteriovenous malformations, balloon angioplasty and stenting of stenosis or vasospasm, transarterial or transvenous embolization of dural arteriovenous fistulas, balloon occlusion of carotid-cavernous and vertebral fistulas, endovascular treatment of vein-of-Galen malformations, preoperative embolization of tumors, and thrombolysis of acute arterial or venous thrombosis. Many of these disorders place the patient at high risk of cerebral hemorrhage, stroke, or death. The therapeutic risks are comparable to those of neurosurgery rather than routine diagnostic radiographic procedures.

The highest complication rates are found with the therapies designed to treat the highest-risk diseases. In a large series of surgically difficult intracranial aneurysms treated with detachable balloons, Higashida and colleagues reported a 7.4% incidence of stroke and a 9.8% death rate. These figures must be considered in light of the high morbidity and mortality associated with untreated and surgically unapproachable aneurysms (Chap. 361). The advent of the electrolytically detachable coil has reduced these rates and ushered in a new era in the treatment of cerebral aneurysms. It remains to be determined what the role of coils will be relative to surgical options, but in many centers, coiling of aneurysms has become standard therapy for many aneurysms.

359. MOLECULAR DIAGNOSIS OF NEUROLOGIC DISORDERS - *Joseph B. Martin*, *Frank M. Longo*

Completion of the Human Genome Project, along with evolving strategies for linking disease phenotypes with gene loci, will increase the rate at which genes responsible for neurologic disorders are discovered. The widespread availability of DNA testing has already changed traditional diagnostic approaches and raised novel ethical issues. For example, the discovery of "susceptibility" genes that do not directly cause disease but modify the age of disease onset or rate of disease progression creates complexity in the application of molecular diagnosis, particularly in guiding the use of preventative therapies. In this chapter we review molecular diagnostic approaches relevant to neurologic disease and illustrate how they contribute to patient care.

DNA-BASED DIAGNOSIS OF NEUROLOGIC DISORDERS

Appropriate use of DNA testing in the clinical setting requires that the clinician have a general understanding of the available molecular diagnostic approaches and the limitations in their application and interpretation. For many of the disorders listed inTable 359-1, the identification of specific disease-causing mutations has made direct DNA diagnosis possible. Most disease-causing mutations consist of single base substitutions leading to amino acid substitutions (missense mutations), premature translation stop signals (nonsense mutations), or abnormal RNA transcript splicing. Other mutations result from DNA deletions, DNA duplications, or instability of trinucleotide repeats. The ability to detect a mutation eliminates the need for additional diagnostic studies. For disorders that have been linked to specific gene loci but for which specific mutations have not been identified, DNA diagnosis may be possible by family linkage analysis. Linkage analysis requires that family relationships (such as paternity) are correctly established, that informative markers are available, and that an adequate number of family members are genotyped and clinically evaluated. For many patients, lack of this information makes DNA diagnosis impossible.

Approaches for Detection of DNA Mutations

Direct sequencing of patient DNA These methods generally require amplification of DNA by the polymerase chain reaction (PCR). With most current sequencing methods, only 300 to 400 DNA bases are determined in each sequencing reaction; therefore, sequencing-based strategies are best applied when a limited region contains the majority of potential mutation sites. Direct DNA sequencing allows novel mutations to be detected and decreases the chances of a false-negative result. In some cases, the significance of previously uncharacterized missense mutations will be difficult to interpret. While they may code for harmless amino acid polymorphisms, in other cases they may be the cause of the disease. The segregation of the same mutation with the disease phenotype within a family or the substitution of nonconserved amino acids, especially in critical protein regions, suggests the latter.

Allele-Specific Oligonucleotide Hybridization This technique, in which sequence-specific oligonucleotides differentially recognize DNA segments with normal or mutated sequence, is best suited for detecting known mutations and can be applied to a large number of samples.

Differential restriction endonuclease patterns of PCR-amplified DNA DNA is digested with restriction enzymes that recognize either normal or mutated DNA sequence; the size pattern of resulting DNA fragments indicates whether the DNA sample contains normal or variant sequence (Chap. 65). This method is directed toward detecting known mutations.

Analysis of Unstable Repeats The number of trinucleotide (or other sized) repeats at a specific DNA locus can be counted by amplifying the DNA segment using PCR and then applying electrophoresis to determine the repeat number present in the amplified DNA. Large repeat expansions such as occur in myotonic dystrophy often prevent reliable application of PCR and require Southern blot analysis for detection.

Analysis of Single-Stranded Conformation Polymorphisms Gene segments of several hundred bases are PCR-amplified and electrophoresed under denaturing conditions. Mutation-induced alterations of DNA structure lead to altered electrophoretic patterns. This approach can detect novel mutations directly. Large numbers of samples, either covering many exons of a large gene or from many patients, can be analyzed using this method.

Detection of DNA deletions by fluorescence in situ hybridization DNA deletions are detected by hybridizing chromosomes with a fluorescent probe corresponding to the gene of interest. Fluorescence in situ hybridization (FISH) can detect deletions smaller than the 2000- to 3000-kb minimum detected by banding techniques.

Detection of DNA deletions or duplications by pulsed-field electrophoresis with Southern blot analysis DNA deletions and duplications can also be detected using an electrophoresis technique (pulsed-field) optimized for separation of large DNA segments. This method is used for the detection of chromosome 17p11.2-12 duplications or deletions in the diagnosis of Charcot-Marie-Tooth disease type 1A (CMT1A) and hereditary neuropathy with liability to pressure palsies (HNPP), respectively.

Cytogenetic Testing Chromosomes isolated from peripheral blood lymphocytes or tissue are stained, allowing identification of insertions, deletions, other chromosome imbalances, and assessment of chromosomal number (Chap. 66).

Some disorders such as Duchenne muscular dystrophy (DMD), Becker muscular dystrophy (BMD), neurofibromatosis (type 1 and 2), and familial amyotrophic lateral sclerosis (ALS) can be caused by dozens of different mutations within one gene. Heterogeneity over a wide region of a given gene is common for many genes involved in metabolic diseases. Many methods of DNA analysis focus on recurring point mutations or relatively short segments of DNA. Using such focused DNA analysis, mutations are found in only about two-thirds of DMD, BMD, and neurofibromatosis type 2 patients and in fewer than half of those with neurofibromatosis type 1. Advances in multiplex PCR and single-strand chain polymorphism analysis have increased this yield, but the clinician should be aware of the sensitivity of each DNA analysis.

Detection of Protein Abnormalities For some applications, diagnostic methods based

on protein properties or function are more effective and efficient than DNA-based tests. Traditional enzyme activity-based assays continue to be useful for diagnosis of many metabolic diseases, and additional protein functions can be used to detect other disorders. For example, immunostaining or western blot analysis using dystrophin antibodies may reveal decreased protein levels or aberrant distribution of dystrophin in a muscle biopsy of a patient in whom no DNA mutations are detected.

COMPLICATIONS AND LIMITATIONS OF GENETIC TESTING

The limitations of DNA testing must be considered. If the presumed diagnosis is in error or if the phenotype overlaps with other disorders, the failure to detect a given mutation does not rule out other phenotype-causing mutations in the same gene or other genes. Different mutations in the same gene can result in different phenotypes (*allelic heterogeneity*), and mutations in different genes can result in the same phenotype (*nonallelic genetic heterogeneity*). Other phenomena such as phenocopies, incomplete penetrance, age-dependent onset of phenotype, polygenic inheritance, imprinting, mitochondrial inheritance, and dynamic mutations (trinucleotide repeats) may also make interpretation of genetic testing difficult.

Nonallelic Genetic Heterogeneity Nonallelic genetic heterogeneity (also known simply as genetic heterogeneity) exists when individuals or families have similar pathologic and/or clinical syndromes caused by mutations in different genes, as in the multiple demyelinating forms ofCMTdisease (Table 359-1). For CMT type 1A the locus is 17p11.2, and mutations are present in the *PMP-22* gene encoding the peripheral myelin protein. CMT type 1B, which is clinically similar to CMT 1A but less common, is caused by a mutation on chromosome 1q22 in the *PMZ* gene encoding the P_0protein, a component of compact myelin. Familial Alzheimer's disease (AD) is caused by mutations in genes located on chromosome 14 (*presenilin 1*, causing 70 to 80% of early-onset AD), 1 (*presenilin 2*), and 21 (*amyloid precursor protein*). Type I autosomal dominant spinocerebellar ataxias (SCAs) are caused by mutations in at least 10 different genes. The phenotypically similar limb-girdle muscular dystrophies (LGMD) are also caused by mutations in a large number of distinct genes, several of which encode products in distinct protein families. As disease-causing mutations continue to be identified, genetic heterogeneity is emerging as a common theme.

An intriguing basis of genetic heterogeneity consists of mutations in distinct genes encoding proteins that function via direct interaction in common mechanistic pathways. The phenotypically similar X-linked and autosomal dominant Emery-Dreifuss muscular dystrophies are caused by mutations in genes encoding emerin and lamin A/C, respectively. Emerin and lamin A/C interaction is likely to be important for targeting emerin to the nuclear envelope. Tuberous sclerosis types 1 and 2 are caused by mutations in the genes encoding tuberin and hamartin, respectively. Evidence suggests that tuberin binds to hamartin, possibly acting as a chaperon.

Allelic Heterogeneity Different mutations in the same gene (allelic mutations) can cause markedly distinct clinical phenotypes. Mutations in the a1A voltage-gated calcium channel subunit can cause either familial hemiplegic migraine,SCA type 6, or episodic ataxia type 2 (EA-2). Familial Creutzfeldt-Jakob disease, fatal familial insomnia, and Gerstmann-Straussler-Scheinker disease are all caused by allelic mutations in the prion

protein gene (20pter-p12), each of which results in distinct aberrant protein isoforms or alterations in expression. Mutations in the gene encoding the L1 cell adhesion molecule (L1CAM) can cause either isolated hydrocephalus or MASA syndrome (mental retardation, aphasia, shuffling gait, and adducted thumbs). Mutations in the sodium channela subunit (SCN4A) can cause either hyperkalemic periodic paralysis (HYPP) or paramyotonia congenita (PC). In cases of allelic heterogeneity, different mutations cause distinct alterations in protein structure and function, resulting in separate phenotypes.

Phenocopies Patients may have a clinical presentation that resembles the phenotype of a genetic disorder but that has a nongenetic cause. Examples include vascular dementia appearing as familialAD, toxin- or drug-induced chorea mimicking Huntington's disease (HD), and vitamin E deficiency resembling Friedreich's ataxia (FA).

Variable Expressivity Variable expressivity occurs when the severity of a trait resulting from a mutant allele varies from mild to severe. Expression of the disease phenotype can be modified by other factors such as predisposing alleles of other genes, environmental agents, sex, and age. Variation in expression can also occur following somatic variations in trinucleotide repeats, as occurs in myotonic dystrophy (dystrophia myotonica, or DM).

Incomplete Penetrance Penetrance refers to the all-or-none expression of a mutant genotype. If a disease is expressed in <100% of individuals carrying the abnormal allele, it is said to have incomplete penetrance.

Polygenic Inheritance and Complex Traits The majority of diseases listed inTable 359-1 are caused by mutations in single genes. In disorders such as "sporadic"AD, Parkinson's disease, and multiple sclerosis, it is likely that disease onset is determined by concomitant mutations or polymorphisms in large numbers of genes. Genetic testing for susceptibility or diagnosis will require assessment of multigene "panels."

INFLUENCE OF GENETIC BACKGROUND

Machado-Joseph disease (MJD) andSCA type 3 are autosomal dominant ataxias originally described in different ethnic backgrounds with distinct features. MJD occurs in families, often of Portuguese-Azorean origin, and is manifest as hereditary ataxia with dystonia, rigidity, faciolingual fasciculation, and bulging eyes. In French families with a syndrome of progressive ataxia and dysarthria recognizably distinct from that found in Portuguese-Azorean families, the SCA3 gene was mapped to a site on chromosome 14q near the MJD locus. It is now clear that MJD and SCA3 are both caused by expansion of the same tract of CAG repeats in the same gene (*MJD1*) at 14q32.1. Although expansions in *MJD1* are the most common mutations in German SCA patients, the diagnosis of MJD had not previously been considered in this population. The extent to which different genetic background causes phenotypic heterogeneity will require further studies.

SUSCEPTIBILITY GENES

Allelic variations or mutations can cause increased susceptibility to specific diseases.

Detection of such DNA polymorphisms can influence differential diagnosis, as in the genotyping of *APOE* alleles in the diagnosis ofAD. Apolipoprotein E (apoE) is a 299-amino-acid protein involved in mobilization and reutilization of lipoprotein cholesterol. ApoE secreted by astrocytes appears to be internalized by neurons via low-density lipoprotein-related receptors where it contributes to neuronal function. The three isoforms of apoE (apoE2, apoE3, and apoE4) are derived from three corresponding alleles of the *APOE* gene located at 19q13.2; the apoE4 allele is overrepresented in sporadic and familial AD and is a significant risk factor for the disease. In contrast, the apoE2 allele is underrepresented and thus may have a "protective" effect (Chap. 362).

The increased incidence of the *APOE4/4* genotype inADpatients has raised the possibility that ascertainment of *APOE* genotype might be useful in the diagnostic assessment of patients with dementia. For example, since AD accounts for some two-thirds of late-onset dementia, the prior probability of an elderly patient with dementia having AD is approximately 0.66. In many populations the probability of a demented patient with the *APOE4/4* genotype having AD increases to>0.90. However, since the relationship between *APOE4* genotype and probability of AD changes with age, gender, and ethnic background, application of population-based probabilities to specific individuals is limited. If a 25-year-old presents with dementia and has the *APOE4/4* genotype, it is very unlikely that this patient has AD. Since individuals with all *APOE* genotypes can have AD, genotypes cannot absolutely rule in or rule out this diagnosis. Even if genotyping increases the odds that a given patient has AD, it does not rule out the possibility that a treatable cause of dementia is present. Current diagnostic studies for demented patients are focused on detecting reversible causes of dementia (Chap. 26) *APOE* genotype results would not change the diagnostic evaluation and should not be ordered on a routine basis. Nevertheless, *APOE* genotyping might eventually be combined with yet-to-be developed diagnostic tests to form a "panel" of data with acceptable sensitivity and specificity for diagnosis (Chap. 362).

The availability of *APOE* genotyping raises questions about the use of predictive testing in asymptomatic individuals. Until preventive therapy is available, many clinicians would consider such predictive testing unethical. Moreover, useful predictions of age of onset based solely on *APOE* genotyping are not possible. For the 2% of the population with the high-risk *E4/E4* genotype, the period of risk extends from the fifties to beyond the nineties.

APPROACHES TO GENETIC TESTING

One indication for DNA analysis is to confirm the diagnosis of a specific disease already suggested by clinical assessment. DNA testing can also be used to narrow the differential diagnosis in cases with multiple diagnostic possibilities. DNA testing forHDallows patients to avoid neuroimaging and other diagnostic studies. When a patient presents with a well-established and relatively specific clinical phenotype, such as that of HD, initial genetic testing can focus on a single gene. In other disorders, such as theSCAs, the high degree of phenotypic overlap calls for concomitant testing of a panel of genes (*SCA1*, *SCA2*, *SCA3*, *SCA6*, and *SCA7*). Another application of genetic analysis is presymptomatic testing in members of families known or suspected to have a specific disorder. In these cases the most common reasons for testing are life

management issues, reproductive planning decisions, and eliminating the stress of unknown carrier status. Development of new therapies that delay onset or progression of neurodegenerative diseases will provide additional indications for presymptomatic testing.

Genetic testing should be conducted only in the context of comprehensive genetic counseling, in which the implications of potential test results are fully explained and adequate support services are available. Clinicians ordering genetic studies should be familiar with issues regarding informed consent, suicide risk, ongoing patient support, insurance, employment discrimination, testing of minors, and testing of fetal tissue.

A directory of diseases for which DNA diagnostic testing is available, along with a listing of testing sites, on thehttp://www.genetests.org, web site. This site was developed at the University of Washington, Seattle, and is supported by the U.S. National Library of Medicine and Maternal and Child Health Bureau.

CLINICAL AND GENETIC CLASSIFICATION OF GENE DISORDERS

Neurogenetic disorders have traditionally been classified and subtyped on the basis of clinical and pathophysiologic concepts. Their complexity, phenotypic variability, and overlapping features limit the resolution of phenotype-based classification and confound nosology. Identification of tightly linked disease markers and discovery of disease-causing mutations have provided a basis for refining such classifications. For example, the clinical distinction between neurofibromatosis type 1 and type 2 has been upheld by the discovery that they are caused by mutations in different genes, encoding the GTPase-activating protein and the merlin (schwannomin) cytoskeletal protein, respectively. In contrast, the finding thatDMD andBMD are caused by mutations in the same gene points to shared pathophysiologic mechanisms and blurs the distinctions between these disorders. Mutations in different genes can lead to overlapping clinical syndromes as in the inherited ataxias. In other instances, phenotypically dissimilar disorders are caused by mutations in the same gene, as described above for thea1A voltage-gated calcium channel subunit gene.

Neurogenetic disorders with known chromosomal gene localization are organized primarily by clinical phenotype inTable 359-1. As in any clinical classification, there is frequent overlap in specific phenotypic features. Reference numbers from the Online Mendelian Inheritance in Man (OMIM) database (described below) are included to facilitate access to continuously updated disease information.

Different modes of inheritance occur in each of these categories. Neurologic genetic disorders inherited in Mendelian autosomal dominant mutations includeHD, familialAD,ALS,DM,CMT, familialHYPP,SCA, and tuberous sclerosis. Autosomal recessive disorders includeFA, Wilson's disease, and ataxia telangiectasia. X-linked recessive traits includeDMD, spinobulbar muscular atrophy (Kennedy syndrome), and fragile X syndrome. Non-Mendelian patterns of transmission such as maternal inheritance can result from mitochondrial mutations (Chap. 383) and unstable trinucleotide repeats (see below).

The types of mutations causing neurologic genetic disorders include gene deletions (the

most common finding inDMD), insertions (e.g., Fukuyama-type congenital muscular dystrophy), duplications (e.g.,CMT1A), translocations that interrupt the gene (neurofibromatosis type 1), and point mutations (e.g., in the superoxide dismutase gene inALS). Point mutations, either missense or nonsense, are considered "static" mutations because they generally remain stable during meiosis and provide the basis for classic Mendelian inheritance. Unstable trinucleotide repeats cause "dynamic" mutations and account for the clinical phenomenon of anticipation.

GENETICALLY INDUCED MECHANISMS OF CELL DEATH

Three general mechanisms of cell death in genetic disorders have been proposed: loss of function, dominant-negative effects, and gain of function.

In *loss-of-function disorders*, the mutation causes a deficiency in an enzyme or protein resulting in cellular dysfunction. The best defined examples are the lysosomal storage disorders in which enzymatic deficiencies in complex lipid metabolism lead to accumulation of normal or abnormal cellular constituents. The mode of inheritance in these disorders is most often autosomal recessive, but it can also be X-linked or the combined result of an inherited germline mutation and an acquired somatic mutation ("second hit") that knocks out both alleles (such as the loss of a growth-suppressor gene in tumors such as retinoblastoma). It is less common for loss-of-function disorders to result from autosomal dominant mutations.

In the case of a *dominant-negative effect*, the abnormal mutation competes with or abolishes the normal allelic function at either the DNA, RNA, or protein level. A dominant-negative mechanism inDM has been suggested by observations that RNA transcripts with expanded CTG repeats precipitate normal RNA transcripts. In myotonia congenita, abnormal protein isoforms combined with normal isoforms of the CLC-1 chloride channel disrupt overall homomultimeric channel function.

In *gain-of-function effects*, the abnormal cellular function exerted by the mutation at one allele in some way renders the cell susceptible to toxic effects, whether or not the normal allele is expressed.

True dominant disorders such asHD andSCA1, in which the heterozygote genotype elicits the full disease phenotype, could be the result of (1) dominant-negative effects, in which proteins with expanded polyglutamine tracts would form oligomers with normal protein isoforms and thereby interfere with their function; or (2) toxic gain-of-function effects.

DISORDERS ASSOCIATED WITH TRINUCLEOTIDE REPEATS

An important group of neurologic disorders is caused by abnormal expansions of trinucleotide repeats (Table 359-2). A useful way of organizing repeat diseases and understanding their mechanisms is based on the location of the repeat expansions within the gene. Expansions can occur in the 5¢ untranslated region (UTR), within the open reading frame (translated portion of the gene), within the 3¢ UTR, or within introns.

The first category of trinucleotide repeat disorders in which repeats are located in the

5¢UTRincludes fragile X syndrome andSCA12. Expansions in this region lead to impaired transcription with subsequent loss of protein expression.

The second category of trinucleotide diseases consists of neurodegenerative disorders in which expansion of a CAG repeat in the open reading frame encodes an aberrant protein with an expanded polyglutamine tract. The stretches of CAG repeats, which vary between 5 and 37 in the normal alleles of each gene, are increased two- to fourfold in the mutation. There is a striking correlation between larger numbers of repeats and both increased severity of the neurologic disorder and earlier age of onset.HDpatients homozygous for the disease allele have phenotypes similar to heterozygous patients.

These observations suggest a model in which a gain of function is toxic to neurons. One possibility is that expanded polyglutamine tracts provide a substrate for aberrant protein-protein interactions. Such interactions might lead to a loss of function of a critical protein or toxic accumulations of protein aggregates. Several lines of evidence support such a protein-based hypothesis. Open reading frame CAG repeats are indeed translated into protein. Transgenic mice expressing a human *SCA1* gene with an expanded CAG repeat develop the characteristic phenotype only when the transgene is expressed. One study has suggested that polyglutamine tracts of the proteins that causeHD and dentatorubral-pallidoluysian atrophy (DRPLA) interact with glyceraldehyde-3-phosphate dehydrogenase and thereby might have a deleterious effect on neuronal energy metabolism.

Gain-of-function models of polyglutamine tract diseases must also reconcile the observations that each neurodegenerative disease affects only regionally specific populations of neurons, yet proteins associated with these disorders are widely expressed. One possibility is that each of these polyglutamine tract proteins interacts with yet-to-be discovered proteins that are indeed cell-type specific. The huntingtin-associated protein (HAP1) is one such candidate. HAP1 is selectively expressed in brain tissue and demonstrates enhanced association with forms of huntingtin protein with increased lengths of glutamine repeats. Another potential mechanism of cell-type specificity is that somatic instability of CAG repeats leads to greater expansions in specific cell populations. However, the relatively small variations of three to five in the number of triplet repeats in the HDgene in different regions of the brain makes this explanation less likely.

In the third category of trinucleotide repeat disorders, repeat expansion occurs in the 3¢UTR. InDM, a GTC (CAG in the antisense) repeat in the 3¢ UTR of the DM kinase gene expands manyfold, from 5 to 40 repeats in normal alleles to up to 2700 in severe cases. The repeat expansion is variable in different tissues, indicating that errors in DNA replication can occur during meiosis and during somatic cell mitosis. Since DNA sequence motifs in the 3¢ UTR of RNA transcripts regulate transcript stability and processing, expansions in this region might affect transcript levels and alter DM kinase protein levels. Quantitative analysis of messenger RNA in muscle biopsies has demonstrated marked disease-specific decreases in DM kinase mRNA in adult-onset DM patients. Levels of normal as well as mutant DM transcripts were decreased, suggesting a novel mechanism of a dominant-negative mutation occurring at the RNA level.

A second potential mechanism inDM is that expansion of the GTC repeat could inhibit expression of the adjacent *DMR-N9* (telomeric) and *DMAHP* (centromeric) genes. Disruption of adjacent chromatin structure by repeat expansion is one mechanism by which expression of adjacent genes could be inhibited. Alternatively, repeat expansions at one locus might affect expression of more than one gene by a *cis*-acting effect, and expansion-containing transcripts may alter levels of transcripts derived from a separate allele by a *trans*-acting effect.

A fourth category of trinucleotide repeat disease occurs with repeat expansion in an intron.FA is caused by the expansion of a GAA triplet in intron 1 of the *X25* gene. Repeat expansions with associated alterations in DNA structure are likely to impair *X25* transcription. Consistent with an autosomal recessive pattern of inheritance and a loss-of-function disease mechanism, the majority of FA patients tested to date demonstrate homozygosity for expanded alleles, while a smaller number are heterozygous with a combination of one expanded allele and point mutations in the other allele. FA is not associated with anticipation (see below) and manifests more often during adolescence rather than middle age, distinguishing it from other trinucleotide repeat diseases.

The discovery of triplet repeats has given molecular precision to old concepts such as *anticipation* (earlier onset of the disease in successive generations, which is associated with further expansion of the abnormal repeats in more severely affected individuals) and has helped to account for variations in gene expression. Variations in trinucleotide repeats inHD, and particularly inDM have given a molecular explanation for *variable expression*, where variations in repeats occurring among individual members of the family can lead to earlier onset or more severe symptoms and signs, as occurs in juvenile HD. Studies suggesting that other neurologic and psychiatric disorders involve anticipation raise the possibility that additional trinucleotide repeat diseases will be discovered.

ONLINE MENDELIAN INHERITANCE IN MAN

TheOMIMcatalogue contains a frequently updated listing of all known genetic traits. For each disease it includes information on clinical manifestations, mapping studies and identity (if available) of the relevant gene, and status of genetic testing. OMIM is administered by the National Center for Biotechnologic Information and is on the Internet at

www3.ncbi.nlm.nih.gov/omim/.

SECTION 2 -DISEASES OF THE CENTRAL NERVOUS SYSTEM

360. SEIZURES AND EPILEPSY - *Daniel H. Lowenstein*

A *seizure* (from the Latin *sacire*, "to take possession of") is a paroxysmal event due to abnormal, excessive, hypersynchronous discharges from an aggregate of central nervous system (CNS) neurons. Depending on the distribution of discharges, this abnormal CNS activity can have various manifestations, ranging from dramatic convulsive activity to experiential phenomena not readily discernible by an observer. Although a variety of factors influence the incidence and prevalence of seizures, approximately 5 to 10% of the population will have at least one seizure during their lifetime, with the highest incidence occurring in early childhood and late adulthood. Because seizures are common, this clinical problem is encountered frequently during medical practice in a variety of settings.

The meaning of the term seizure needs to be carefully distinguished from that of epilepsy. *Epilepsy* describes a condition in which a person has *recurrent* seizures due to a chronic, underlying process. This definition implies that a person with a single seizure, or recurrent seizures due to correctable or avoidable circumstances, does not necessarily have epilepsy. Epilepsy refers to a clinical phenomenon rather than a single disease entity, since there are many forms and causes of epilepsy. However, among the many causes of epilepsy there are various *epilepsy syndromes* in which the clinical and pathologic characteristics are distinctive and suggest a specific underlying etiology.

Using the definition of epilepsy as two or more unprovoked seizures, the incidence of epilepsy is approximately 0.3 to 0.5% in different populations throughout the world, and the prevalence of epilepsy has been estimated at 5 to 10 persons per 1000.

CLASSIFICATION OF SEIZURES

An essential step in the evaluation and management of a patient with a seizure is to determine the type of seizure that has occurred. The importance of this cannot be overemphasized -- classifying the seizure is essential for focusing the diagnostic approach on particular etiologies, selecting the appropriate therapy, and providing potentially vital information regarding prognosis. In 1981, the International League Against Epilepsy (ILAE) published a modified version of the International Classification of Epileptic Seizures that has continued to be a useful classification system (Table 360-1). This system is based on the clinical features of seizures and associated electroencephalographic findings. Other potentially distinctive features such as etiology or cellular substrate are not considered in this classification system, although this will undoubtedly change in the future as more is learned about the pathophysiologic mechanisms that underlie specific seizure types.

The main characteristic that distinguishes the different categories of seizures is whether the seizure activity is partial (synonymous with focal) or generalized. *Partial seizures* are those in which the seizure activity is restricted to discrete areas of the cerebral cortex. *Generalized seizures* involve diffuse regions of the brain simultaneously in a bilaterally symmetric fashion. Partial seizures are often associated with structural abnormalities of the brain. In contrast, generalized seizures may result from cellular, biochemical, or

structural abnormalities that have a more widespread distribution.

PARTIAL SEIZURES

Partial seizures occur within discrete regions of the brain. If consciousness is fully preserved during the seizure, the clinical manifestations are considered relatively simple and the seizure is termed a *simple partial seizure*. If consciousness is impaired, the symptomatology is more complex and the seizure is termed a *complex partial seizure*. An important additional subgroup comprises those seizures that begin as partial seizures and then spread diffusely throughout the cortex, i.e., *partial seizures with secondary generalization*.

Simple Partial Seizures Simple partial seizures cause motor, sensory, autonomic, or psychic symptoms without an obvious alteration in consciousness. For example, a patient having a partial motor seizure arising from the right primary motor cortex in the vicinity controlling hand movement will note the onset of involuntary movements of the contralateral, left hand. These movements are typically clonic (i.e., repetitive, flexion/extension movements) at a frequency of approximately 2 to 3 Hz; pure tonic posturing may be seen as well. Since the cortical region controlling hand movement is immediately adjacent to the region for facial expression, the seizure may also cause abnormal movements of the face synchronous with the movements of the hand. The electroencephalogram (EEG) recorded with scalp electrodes during the seizure (i.e., an ictal EEG) may show abnormal discharges in a very limited region over the appropriate area of cerebral cortex if the seizure focus involves the cerebral convexity (Chap. 357). Seizure activity occurring within deeper brain structures is often not recorded by the standard EEG, however, and may require intracranial electrodes for its detection.

Three additional features of partial motor seizures are worth noting. First, in some patients the abnormal motor movements may begin in a very restricted region such as the fingers and gradually progress (over seconds to minutes) to include a larger portion of the extremity. This phenomenon was originally described by Hughlings Jackson and is known as a "Jacksonian march," representing the spread of seizure activity over a progressively larger region of motor cortex. Second, patients may experience a localized paresis (Todd's paralysis) for minutes to many hours in the involved region following the seizure. Third, in rare instances the seizure may continue for hours or days. This condition, termed *epilepsia partialis continua*, is often quite refractory to medical therapy.

Other forms of simple partial seizures include those that cause changes in somatic sensation (e.g., paresthesias), vision (flashing lights or formed hallucinations), equilibrium (sensation of falling or vertigo), or autonomic function (flushing, sweating, piloerection). Simple partial seizures arising from the temporal or frontal cortex may also cause alterations in hearing, olfaction, or higher cortical function (psychic symptoms). This includes the sensation of unusual, intense odors (e.g., burning rubber or kerosene) or sounds (crude or highly complex sounds), or an epigastric sensation that rises from the stomach or chest to the head. Some patients describe odd, internal feelings such as fear, a sense of impending change, detachment, depersonalization, deja vu, or illusions that objects are growing smaller (micropsia) or larger (macropsia). When such symptoms precede a complex partial or secondarily generalized seizure, these simple

partial seizures serve as a warning, or *aura*.

Complex Partial Seizures Complex partial seizures are characterized by focal seizure activity accompanied by a transient impairment of the patient's ability to maintain normal contact with the environment. Operationally this means that the patient is unable to respond appropriately to visual or verbal commands during the seizure and has impaired recollection or awareness of the ictal phase. The seizures frequently begin with an aura (i.e., a simple partial seizure) that is stereotypic for the patient. The start of the ictal phase is often a sudden behavioral arrest or motionless stare, and this marks the onset of the event for which the patient will be amnestic. The behavioral arrest is usually accompanied by automatisms, which are involuntary, automatic behaviors that have a wide range of manifestations. Automatisms may consist of very basic behaviors such as chewing, lip smacking, swallowing, or "picking" movements of the hands, or more elaborate behaviors such as a display of emotion or running. The patient is typically confused following the seizure, and the transition to full recovery of consciousness may range from seconds up to an hour. Careful examination of the patient immediately following the seizure may show an anterograde amnesia or, in cases involving the dominant hemisphere, a postictal aphasia.

The routine, interictal (i.e., between seizures)EEG in patients with complex partial seizures is often normal, or may show brief discharges termed *epileptiform spikes*, or *sharp waves*. Since complex partial seizures can arise from the medial temporal lobe or inferior frontal lobe, i.e., regions distant from the scalp, the EEG recorded during the seizure may be nonlocalizing. However, the seizure focus is often detected using special electrodes such as sphenoidal or surgically placed intracranial electrodes.

The range of potential clinical behaviors linked to complex partial seizures is so broad that extreme caution is advised before concluding that stereotypic episodes of bizarre or atypical behavior are not due to seizure activity. In such cases it is imperative to consider more detailedEEGstudies to determine whether the behaviors are caused by a seizure disorder.

Partial Seizures with Secondary Generalization Partial seizures can spread to involve both cerebral hemispheres and produce a generalized seizure, usually of the tonic-clonic variety (discussed below). Secondary generalization is observed frequently following simple partial seizures, especially those with a focus in the frontal lobe, but may also be associated with partial seizures occurring elsewhere in the brain. A partial seizure with secondary generalization is often difficult to distinguish from a primarily generalized tonic-clonic seizure, since bystanders tend to emphasize the more dramatic, generalized convulsive phase of the seizure and overlook the more subtle, focal symptoms present at onset. In some cases, the focal onset of the seizure becomes apparent only when a careful history identifies a preceding aura (i.e., simple partial seizure). Often, however, the focal onset is not clinically evident and may be established only through carefulEEGanalysis. Nonetheless, distinguishing between these two entities is extremely important, as there may be substantial differences in the evaluation and treatment of partial versus generalized seizure disorders.

GENERALIZED SEIZURES

By definition, generalized seizures arise from both cerebral hemispheres simultaneously. However, it is currently impossible to exclude entirely the existence of a focal region of abnormal activity that initiates the seizure prior to rapid secondary generalization. For this reason, generalized seizures may be practically defined as bilateral clinical and electrographic events without any detectable focal onset. Fortunately, a number of the subtypes of generalized seizures have distinctive features that facilitate clinical diagnosis.

Absence Seizures (Petit Mal) Absence seizures are characterized by sudden, brief lapses of consciousness without loss of postural control. The seizure typically lasts for only seconds, consciousness returns as suddenly as it was lost, and there is no postictal confusion. Although the brief loss of consciousness may be clinically inapparent or the sole manifestation of the seizure discharge, absence seizures are usually accompanied by subtle, bilateral motor signs such as rapid blinking of the eyelids, chewing movements, or small-amplitude, clonic movements of the hands.

Absence seizures usually begin in childhood (ages 4 to 8) or early adolescence and are the main seizure type in 15 to 20% of children with epilepsy. The seizures can occur hundreds of times per day, but the child may be unaware of or unable to convey their existence. This can lead to a situation in which the patient is constantly struggling to piece together experiences that have been interrupted by the seizures. Since the clinical signs of the seizures are subtle, especially to new parents, it is not surprising that the first clue to absence epilepsy is often unexplained "daydreaming" and a decline in school performance recognized by a teacher.

The electrophysiologic hallmark of typical absence seizures is a generalized, symmetric, 3-Hz spike-and-wave discharge that begins and ends suddenly on a normalEEGbackground (Chap. 357). Periods of spike-and-wave discharges lasting more than a few seconds usually correlate with the clinical signs, but the EEG often shows many more periods of abnormal cortical activity than were suspected clinically. Hyperventilation tends to provoke these electrographic discharges and even the seizures themselves and is routinely used when recording the EEG.

Typical absence seizures are often associated with generalized, tonic-clonic seizures, but patients usually have no other neurologic problems and respond well to treatment with specific anticonvulsants. Although estimates vary, approximately 60 to 70% of such patients will have a spontaneous remission during adolescence.

Atypical Absence Seizures Atypical absence seizures have features that deviate from both the clinical andEEGfeatures of typical absence seizures. For example, the lapse of consciousness is usually of longer duration and less abrupt in onset and cessation, and the seizure is accompanied by more obvious motor signs that may include focal or lateralizing features. The EEG shows a generalized, slow spike-and-wave pattern with a frequency of £2.5/s, as well as other abnormal activity. Atypical absence seizures are usually associated with diffuse or multifocal structural abnormalities of the brain and therefore may accompany other signs of neurologic dysfunction such as mental retardation. Furthermore, the seizures are less responsive to anticonvulsants compared to typical absence seizures.

Generalized, Tonic-Clonic Seizures (Grand Mal) Primarily generalized, tonic-clonic seizures are the main seizure type in approximately 10% of all persons with epilepsy. They are also the most common seizure type resulting from metabolic derangements and are therefore frequently encountered in many different clinical settings. The seizure usually begins abruptly without warning, although some patients describe vague premonitory symptoms in the hours leading up to the seizure. This prodrome should be distinguished from the stereotypic auras associated with focal seizures that secondarily generalize. The initial phase of the seizure is usually tonic contraction of muscles throughout the body, accounting for a number of the classic features of the event. Tonic contraction of the muscles of expiration and the larynx at the onset will produce a loud moan or cry. Respirations are impaired, secretions pool in the oropharynx, and the patient becomes cyanotic. Contraction of the jaw muscles may cause biting of the tongue. A marked enhancement of sympathetic tone leads to increases in heart rate, blood pressure, and pupillary size. After 10 to 20 s, the tonic phase of the seizure typically evolves into the clonic phase, produced by the superimposition of periods of muscle relaxation on the tonic muscle contraction. The periods of relaxation progressively increase until the end of the ictal phase, which usually lasts no more than 1 min. The postictal phase is characterized by unresponsiveness, muscular flaccidity, and excessive salivation that can cause stridorous breathing and partial airway obstruction. Bladder or bowel incontinence may occur at this point as well. Patients gradually regain consciousness over minutes to hours, and during this transition there is typically a period of postictal confusion. Patients will subsequently complain of headache, fatigue, and muscle ache that can last for many hours. The duration of impaired consciousness in the postictal phase can be extremely long, i.e., many hours, in patients with prolonged seizures or underlyingCNSdiseases such as alcoholic cerebral atrophy.

TheEEGduring the tonic phase of the seizure shows a progressive increase in generalized low-voltage fast activity, followed by generalized high-amplitude, polyspike discharges. In the clonic phase, the high-amplitude activity is typically interrupted by slow waves to create a spike-and-wave pattern. The postictal EEG shows diffuse slowing that gradually recovers as the patient awakens.

There are many variants of the generalized tonic-clonic seizure, including pure tonic and pure clonic seizures. Brief tonic seizures lasting only a few seconds are especially noteworthy since they are usually associated with known epileptic syndromes having mixed seizure phenotypes, such as the Lennox-Gastaut syndrome (discussed below).

Atonic Seizures Atonic seizures are characterized by sudden loss of postural muscle tone lasting 1 to 2 s. Consciousness is briefly impaired, but there is usually no postictal confusion. A very brief seizure may cause only a quick head drop or nodding movement, while a longer seizure will cause the patient to collapse. This can be quite dramatic and extremely dangerous, since there is a substantial risk of direct head injury with the fall. TheEEGshows brief, generalized spike-and-wave discharges followed immediately by diffuse slow waves that correlate with the loss of muscle tone. Similar to pure tonic seizures, atonic seizures are usually seen in association with known epileptic syndromes.

Myoclonic Seizures Myoclonus is a sudden and brief muscle contraction that may

involve one part of the body or the entire body. A normal, common physiologic form of myoclonus is the sudden jerking movement observed while falling asleep. Pathologic myoclonus is most commonly seen in association with metabolic disorders, degenerativeCNSdiseases, or anoxic brain injury (Chap. 22). Although the distinction from other forms of myoclonus is imprecise, myoclonic seizures are considered to be true epileptic events since they are caused by cortical (versus subcortical or spinal) dysfunction. TheEEGshows bilaterally synchronous spike-and-wave discharges. Myoclonic seizures usually coexist with other forms of generalized seizure disorders but are the predominant feature of juvenile myoclonic epilepsy (discussed below).

UNCLASSIFIED SEIZURES

Not all seizure types can be classified as partial or generalized. This appears to be especially true of seizures that occur in neonates and infants. The distinctive phenotypes of seizures at these early ages likely result, in part, from differences in neuronal function and connectivity in the immature versus matureCNS.

EPILEPSY SYNDROMES

In addition to recognizing the patterns of different types of seizures, it is also useful to be familiar with some of the more common epilepsy syndromes, since this often helps in the determination of therapy and prognosis. Epilepsy syndromes are disorders in which epilepsy is a predominant feature, and there is sufficient evidence (e.g., through clinical,EEG, radiologic, or genetic observations) to suggest a common underlying mechanism. Three important epilepsy syndromes are listed below; additional examples with a known genetic basis are shown in Table 360-2.

JUVENILE MYOCLONIC EPILEPSY

Juvenile myoclonic epilepsy (JME) is a generalized seizure disorder of unknown cause that appears in early adolescence and is usually characterized by bilateral myoclonic jerks that may be single or repetitive. The myoclonic seizures are most frequent in the morning after awakening and can be provoked by sleep deprivation. Consciousness is preserved unless the myoclonus is especially severe. Many patients also experience generalized tonic-clonic seizures, and up to one-third have absence seizures. The condition is otherwise benign, and although complete remission is uncommon, the seizures respond well to appropriate anticonvulsant medication. There is often a family history of epilepsy, and genetic linkage studies suggest a polygenic cause.

LENNOX-GASTAUT SYNDROME

Lennox-Gastaut syndrome occurs in children and is defined by the following triad: (1) multiple seizure types (usually including generalized tonic-clonic, atonic, and atypical absence seizures); (2) anEEGshowing slow (<3 Hz) spike-and-wave discharges and a variety of other abnormalities; and (3) impaired cognitive function in most but not all cases. Lennox-Gastaut syndrome is associated withCNSdisease or dysfunction from a variety of causes, including developmental abnormalities, perinatal hypoxia/ischemia, trauma, infection, and other acquired lesions. The multifactorial nature of this syndrome suggests that it is a nonspecific response of the brain to diffuse neural injury.

Unfortunately, many patients have a poor prognosis due to the underlying CNS disease and the physical and psychosocial consequences of severe, poorly controlled epilepsy.

MESIAL TEMPORAL LOBE EPILEPSY SYNDROME

Mesial temporal lobe epilepsy (MTLE) is the most common syndrome associated with complex partial seizures and is an example of a symptomatic, partial epilepsy. Distinctive clinical, electroencephalographic, and pathologic features define this syndrome (Table 360-3). High-resolution magnetic resonance imaging (MRI) can detect the characteristic hippocampal sclerosis that appears to be an essential element in the pathophysiology of MTLE for many patients (Fig. 360-1). Recognition of this syndrome is especially important because it tends to be refractory to treatment with anticonvulsants but responds extremely well to surgical intervention. Major advances in the understanding of basic mechanisms of epilepsy have come through studies of experimental models of MTLE, discussed below.

THE CAUSES OF SEIZURES AND EPILEPSY

Seizures are a result of a shift in the normal balance of excitation and inhibition within theCNS. Given the numerous properties that control neuronal excitability, it is not surprising that there are many different ways to perturb this normal balance, and therefore many different causes of both seizures and epilepsy. Our understanding of the basic mechanisms involved remains very limited, and consequently there is not a rigorous, mechanistic-based framework for organizing all the etiologies. Conceptually, however, three important clinical observations emphasize how a variety of factors determine why certain conditions may cause seizures or epilepsy in a given patient.

1. *The normal brain is capable of having a seizure under the appropriate circumstances, and there are differences between individuals in the susceptibility or threshold for seizures*. For example, seizures may be induced by high fevers in children who are otherwise normal and who never develop other neurologic problems, including epilepsy. However, febrile seizures occur only in a relatively small proportion of children. This implies there are various underlying, *endogenous factors* that influence the threshold for having a seizure. Some of these factors are clearly genetic, as it has been shown that a family history of epilepsy will influence the likelihood of seizures occurring in otherwise normal individuals. Normal development also plays an important role, since the brain appears to have different seizure thresholds at different maturational stages.

2. *There are a variety of conditions that have an extremely high likelihood of resulting in a chronic seizure disorder*. One of the best examples of this is severe, penetrating head trauma, which is associated with up to a 50% risk of subsequent epilepsy. The high propensity for severe traumatic brain injury to lead to epilepsy suggests that the injury results in a long-lasting, pathologic change in theCNS that transforms a presumably normal neural network into one that is abnormally hyperexcitable. This process is known as *epileptogenesis*, and the specific changes that result in a lowered seizure threshold can be considered *epileptogenic factors*. Other processes associated with epileptogenesis include stroke, infections, and abnormalities of CNS development. Likewise, the genetic abnormalities associated with epilepsy likely involve processes that trigger the appearance of specific sets of epileptogenic factors.

3. *Seizures are episodic*. Patients with epilepsy have seizures intermittently and, depending on the underlying cause, many patients are completely normal for months or even years between seizures. This implies there are important provocative or *precipitating factors* that induce seizures in patients with epilepsy. Similarly, precipitating factors are responsible for causing the single seizure in someone without epilepsy. Precipitants include those due to intrinsic physiologic processes, such as psychological or physical stress, sleep deprivation, or hormonal changes associated with the menstrual cycle. They also include exogenous factors such as exposure to toxic substances and certain medications.

These observations emphasize the concept that the many causes of seizures and epilepsy result from a dynamic interplay between endogenous factors, epileptogenic factors, and precipitating factors. The potential role of each needs to be carefully considered when determining the appropriate management of a patient with seizures. For example, the identification of predisposing factors (e.g., family history of epilepsy) in a patient with febrile seizures may increase the necessity for closer follow-up and a more aggressive diagnostic evaluation. Finding an epileptogenic lesion may help in the estimation of seizure recurrence and duration of therapy. Finally, removal or modification of a precipitating factor may be an effective and safer method for preventing further seizures than the prophylactic use of anticonvulsant drugs.

CAUSES ACCORDING TO AGE

In practice, it is useful to consider the etiologies of seizures based on the age of the patient, as age is one of the most important factors determining both the incidence and likely causes of seizures or epilepsy (Table 360-4). During the *neonatal period and early infancy*, potential causes include hypoxic-ischemic encephalopathy, trauma,CNSinfection, congenital CNS abnormalities, and metabolic disorders. Babies born to mothers using neurotoxic drugs such as cocaine, heroin, or ethanol are susceptible to drug-withdrawal seizures in the first few days after delivery. Hypoglycemia and hypocalcemia, which can occur as secondary complications of perinatal injury, are also causes of seizures early after delivery. Seizures due to inborn errors of metabolism usually present once regular feeding begins, typically 2 to 3 days after birth. Pyridoxine (vitamin B_6) deficiency, an important cause of neonatal seizures, can be effectively treated with pyridoxine replacement. The idiopathic or inherited forms of benign neonatal convulsions are also seen during this time period.

The most common seizures arising in *late infancy and early childhood* are febrile seizures, which are seizures associated with fevers but without evidence ofCNSinfection or other defined causes. The overall prevalence is 3 to 5% and even higher in some parts of the world, such as Asia. Patients often have a family history of febrile seizures or epilepsy. Febrile seizures usually occur between 3 months and 5 years of age and have a peak incidence between 18 and 24 months. The typical scenario is a child who has a generalized, tonic-clonic seizure during a febrile illness in the setting of a common childhood infection such as otitis media, respiratory infection, or gastroenteritis. The seizure is likely to occur during the rising phase of the temperature curve (i.e., during the first day) rather than well into the course of the illness. A *simple* febrile seizure is a single, isolated event, brief, and symmetric in appearance. *Complex* febrile seizures

have repeated seizure activity, last>15 min, or have focal features. Approximately one-third of patients with febrile seizures will have a recurrence, but<10% have three or more episodes. Recurrences are much more likely when the febrile seizure occurs in the first year of life. Simple febrile seizures are not associated with an increase in the risk of developing epilepsy, while complex febrile seizures have a risk of 2 to 5%; other risk factors include the presence of preexisting neurologic deficits and a family history of nonfebrile seizures.

Childhood marks the age at which many of the well-defined epilepsy syndromes present. Some children who are otherwise normal develop idiopathic, generalized tonic-clonic seizures without other features that fit into specific syndromes. Temporal lobe epilepsy usually presents in childhood and may be related to mesial temporal lobe sclerosis (as part of theMTLEsyndrome) or other focal abnormalities such as cortical dysgenesis. Other types of partial seizures, including those with secondary generalization, may be the relatively late manifestation of a developmental disorder, an acquired lesion such as head trauma,CNSinfection (especially viral encephalitis), or very rarely a CNS tumor.

The period of *adolescence and early adulthood* is one of transition during which the idiopathic or genetically based epilepsy syndromes, includingJME and juvenile absence epilepsy, become less common, while epilepsies secondary to acquiredCNSlesions begin to predominate. Seizures that begin in patients in this age range may be associated with head trauma, CNS infections (including parasitic infections such as cysticercosis), brain tumors, congenital CNS abnormalities, illicit drug use, or alcohol withdrawal.

Head trauma is a common cause of epilepsy in adolescents and adults. The head injury can be caused by a variety of mechanisms, and the likelihood of developing epilepsy is strongly correlated with the severity of the injury. A patient with a penetrating head wound, depressed skull fracture, intracranial hemorrhage, or prolonged posttraumatic coma or amnesia has a 40 to 50% risk of developing epilepsy, while a patient with a closed head injury and cerebral contusion has a 5 to 25% risk. Recurrent seizures usually develop within 1 year after head trauma, although intervals of 10 years or longer are well known. In controlled studies, mild head injury, defined as a concussion with amnesia or loss of consciousness of <30 min, was not found to be associated with an increased likelihood of epilepsy. Nonetheless, most epileptologists know of patients who have partial seizures within hours or days of a mild head injury and subsequently develop chronic seizures of the same type; such cases may represent rare examples of chronic epilepsy resulting from mild head injury.

The causes of seizures in *older adults* include cerebrovascular disease, trauma (including subdural hematoma),CNStumors, and degenerative diseases. Cerebrovascular disease may account for approximately 50% of new cases of epilepsy in patients older than 65. Acute seizures (i.e., occurring at the time of the stroke) are seen more often with embolic rather than hemorrhagic or thrombotic stroke. Chronic seizures typically appear months to years after the initial event and are associated with all forms of stroke.

Metabolic disturbances such as electrolyte imbalance, hypo- or hyperglycemia, renal

failure, and hepatic failure may cause seizures at any age. Similarly, endocrine disorders, hematologic disorders, vasculitides, and many other systemic diseases may cause seizures over a broad age range. A wide variety of medications and abused substances are known to precipitate seizures as well (Table 360-5).

BASIC MECHANISMS

MECHANISMS OF SEIZURE INITIATION AND PROPAGATION

Partial seizure activity can begin in a very discrete region of cortex and then spread to neighboring regions, i.e., there is a *seizure initiation* phase and a *seizure propagation* phase. Studies of experimental models of these phases suggest that the initiation phase is characterized by two concurrent events in an aggregate of neurons: (1) high-frequency bursts of action potentials, and (2) hypersynchronization. The bursting activity is caused by a relatively long-lasting depolarization of the neuronal membrane due to influx of extracellular calcium (Ca^{2+}), which leads to the opening of voltage-dependent sodium (Na^{+}) channels, influx of Na^{+}, and generation of repetitive action potentials. This is followed by a hyperpolarizing afterpotential mediated byg-aminobutyric acid (GABA) receptors or potassium (K^{+}) channels, depending on the cell type. The synchronized bursts from a sufficient number of neurons result in a so-called spike discharge on theEEG.

Normally, the spread of bursting activity is prevented by intact hyperpolarization and a region of surrounding inhibition created by inhibitory neurons. With sufficient activation there is a recruitment of surrounding neurons via a number of mechanisms. Repetitive discharges lead to the following: (1) an increase in extracellular K^{+}, which blunts the extent of hyperpolarization and depolarizes neighboring neurons; (2) accumulation of Ca^{2+} in presynaptic terminals, leading to enhanced neurotransmitter release; and (3) depolarization-induced activation of the *N*-methyl-D-aspartate (NMDA) subtype of the excitatory amino acid receptor, which causes more Ca^{2+}influx and neuronal activation. The recruitment of a sufficient number of neurons leads to a loss of the surrounding inhibition and propagation of seizure activity into contiguous areas via local cortical connections, and to more distant areas via long commissural pathways such as the corpus callosum.

Many factors control neuronal excitability, and thus there are many potential mechanisms for altering a neuron's propensity to have bursting activity. Examples of mechanisms *intrinsic* to the neuron include changes in the conductance of ion channels, response characteristics of membrane receptors, cytoplasmic buffering, second-messenger systems, and protein expression as determined by gene transcription, translation, and posttranslational modification. Mechanisms *extrinsic* to the neuron include changes in the amount or type of neurotransmitters present at the synapse, modulation of receptors by extracellular ions and other molecules, and temporal and spatial properties of both synaptic and nonsynaptic input. Nonneural cells, such as astrocytes and oligodendrocytes, have an important role in many of these mechanisms as well.

Certain known causes of seizures are explained by these mechanisms. For example, accidental ingestion of domoic acid, which is an analogue of glutamate (the principal

excitatory neurotransmitter in the brain), causes profound seizures via direct activation of excitatory amino acid receptors throughout theCNS. Penicillin, which can lower the seizure threshold in humans and is a potent convulsant in experimental models, reduces inhibition by antagonizing the effects ofGABA at its receptor. The basic mechanisms of other precipitating factors of seizures, such as sleep deprivation, fever, alcohol withdrawal, hypoxia, and infection, are not as well understood but presumably involve analogous perturbations in neuronal excitability. Similarly, the endogenous factors that determine an individual's seizure threshold may relate to these properties as well.

Knowledge of the mechanisms responsible for the initiation and propagation of most generalized seizures (including tonic-clonic, myoclonic, and atonic types) remains rudimentary and reflects the limited understanding of the connectivity of the brain at a systems level. Much more is understood about the origin of generalized spike-and-wave discharges in absence seizures. These appear to be related to oscillatory rhythms that are normally generated during sleep by circuits connecting the thalamus and cortex. This oscillatory behavior involves an interaction betweenGABA$_B$receptors, T-type Ca^{2+}channels, and K^+channels located within the thalamus. Pharmacologic studies indicate that modulation of these receptors and channels can induce absence seizures, and there is speculation that the genetic forms of absence epilepsy may be associated with mutations of components of this system.

MECHANISMS OF EPILEPTOGENESIS

Epileptogenesis refers to the transformation of a normal neuronal network into one that is chronically hyperexcitable. For example, there is often a delay of months to years between an initialCNSinjury such as trauma, stroke, or infection and the first seizure. The injury appears to initiate a process that gradually lowers the seizure threshold in the affected region until a spontaneous seizure occurs. In many genetic and idiopathic forms of epilepsy, epileptogenesis is presumably determined by developmentally regulated events.

Pathologic studies of the hippocampus from patients with temporal lobe epilepsy have led to the suggestion that some forms of epileptogenesis are related to *structural changes in neuronal networks*. For example, many patients withMTLEsyndrome have a highly selective loss of neurons that has been proposed to contribute to inhibition of the main excitatory neurons within the dentate gyrus. There is also evidence that, in response to the loss of neurons, there is reorganization or "sprouting" of surviving neurons in a way that affects the excitability of the network. Some of these changes can be seen in experimental models of prolonged electrical seizures or traumatic brain injury. Thus, an initial injury such as head injury may lead to a very focal, confined region of structural change that causes local hyperexcitability. The local hyperexcitability leads to further structural changes that evolve over time until the focal lesion produces clinically evident seizures. Similar models have also provided strong evidence for long-term alterations in *intrinsic, biochemical properties of cells* within the network, such as chronic changes in glutamate receptor function.

GENETIC CAUSES OF EPILEPSY

The most important recent progress in epilepsy research has been the identification of genetic mutations associated with a variety of epilepsy syndromes. Table 360-2 describes some of these in further detail. Although all of the mutations identified to date cause rare forms of epilepsy, they have led to extremely important conceptual advances. For example, it appears that many of the inherited, idiopathic epilepsies (i.e., the relatively "pure" forms of epilepsy in which seizures are the phenotypic abnormality and brain structure and function are otherwise normal) are due to mutations affecting ion channel function. These syndromes are therefore part of the larger group of "channelopathies" causing paroxysmal disorders such as cardiac arrhythmias, episodic ataxia, periodic weakness, and familial hemiplegic migraine (Chap. 15). In contrast, gene mutations observed in symptomatic epilepsies (i.e., disorders in which other neurologic abnormalities, such as cognitive impairment, coexist with seizures) are proving to be associated with pathways influencing CNS development or neuronal homeostasis. A current challenge is to identify the multiple susceptibility genes that underlie the more common forms of idiopathic epilepsies.

MECHANISMS OF ACTION OF ANTIEPILEPTIC DRUGS

Currently available antiepileptic drugs appear to act primarily by blocking the initiation or spread of seizures. This occurs through a variety of mechanisms, and in most cases the drugs have pleiotropic effects. The mechanisms include inhibition of Na^+-dependent action potentials in a frequency-dependent manner (e.g., phenytoin, carbamazepine, topiramate, zonisamide), inhibition of voltage-gated Ca^{2+} channels (phenytoin), decrease of glutamate release (lamotrigine), potentiation of GABA receptor function (benzodiazepines and barbiturates), and increase in the availability of GABA (valproic acid, gabapentin, tiagabine). The two most effective drugs for absence seizures, ethosuximide and valproic acid, probably act by inhibiting T-type Ca^{2+} channels in thalamic neurons.

In contrast to the relatively large number of antiepileptic drugs that can attenuate seizure activity, there are currently no drugs known to prevent the formation of a seizure focus following CNS injury in humans. The eventual development of such "antiepileptogenic" drugs will provide an important means of preventing the emergence of epilepsy following injuries such as head trauma, stroke, and CNS infection.

EVALUATION OF THE PATIENT WITH A SEIZURE

When a patient presents shortly after a seizure, the first priorities are attention to vital signs, respiratory and cardiovascular support, and treatment of seizures if they resume (see "Treatment"). Life-threatening conditions such as CNS infection, metabolic derangement or drug toxicity must be recognized and managed appropriately.

When the patient is not acutely ill, the evaluation will initially focus on whether or not there is a history of earlier seizures (Fig. 360-2). If this is the patient's first seizure, then the emphasis will be to (1) establish whether the reported episode was a seizure rather than another paroxysmal event, (2) determine the cause of the seizure by identifying risk factors and precipitating events, and (3) decide whether anticonvulsant therapy is required in addition to treatment for any underlying illness.

In the patient with prior seizures or a known history of epilepsy, the evaluation is directed toward (1) identification of the underlying cause and precipitating factors, and (2) determination of the adequacy of the patient's current therapy.

HISTORY AND EXAMINATION

The history should first determine whether the event was truly a seizure. It is essential to take the time to gather an in-depth history, for *in many cases the diagnosis of a seizure is based solely on clinical grounds -- the examination and laboratory studies are often normal*. Keeping in mind the characteristics of different seizure types, questions need to focus precisely on the symptoms before, during, and after the episode in order to discriminate a seizure from other paroxysmal events (see "Differential Diagnosis of Seizures"). Seizures frequently occur out-of-hospital, and the patient may be unaware of the ictal and immediate postictal phases; thus witnesses to the event should be interviewed carefully.

The history should also focus on risk factors and predisposing events. Clues for a predisposition to seizures include a history of febrile seizures, earlier auras or brief seizures not recognized as such, and a family history of seizures. Epileptogenic factors such as prior head trauma, stroke, tumor, or vascular malformation should be identified. In children, a careful assessment of developmental milestones may provide evidence for underlyingCNSdisease. Precipitating factors such as sleep deprivation, systemic diseases, electrolyte or metabolic derangements, acute infection, drugs that lower the seizure threshold (Table 360-5), or alcohol or illicit drug use should also be identified.

The general physical examination includes a search for signs of infection or systemic illness. Careful examination of the skin may reveal signs of neurocutaneous disorders, such as tuberous sclerosis or neurofibromatosis, or chronic liver or renal disease. A finding of organomegaly may indicate a metabolic storage disease, and limb asymmetry may provide a clue for brain injury early in development. Signs of head trauma and use of alcohol or illicit drugs should be sought. Auscultation of the heart and carotid arteries may identify an abnormality that predisposes to cerebrovascular disease.

All patients require a complete neurologic examination, with particular emphasis on eliciting signs of cerebral hemispheric disease (Chap. 356). Careful assessment of mental status (including memory, language function, and abstract thinking) may suggest lesions in the anterior frontal, parietal, or temporal lobes. Testing of visual fields will help screen for lesions in the optic pathways and occipital lobes. Screening tests of motor function such as pronator drift, deep tendon reflexes, gait, and coordination may suggest lesions in motor (frontal) cortex, and cortical sensory testing (e.g., double simultaneous stimulation) may detect lesions in the parietal cortex.

LABORATORY STUDIES

Routine blood studies are indicated to identify the more common metabolic causes of seizures, such as abnormalities in electrolytes, glucose, calcium, or magnesium, and hepatic or renal disease. A screen for toxins in blood and urine should also be obtained from all patients in the appropriate risk groups, especially when no clear precipitating factor has been identified. A lumbar puncture is indicated if there is any suspicion of

meningitis or encephalitis and is mandatory in all patients infected with HIV, even in the absence of symptoms or signs suggesting infection.

All patients who have a possible seizure disorder should be evaluated with anEEG(Chap. 357) as soon as possible. The EEG may help to establish the diagnosis of epilepsy, classify the seizure type, and provide evidence for the existence of a particular epilepsy syndrome. If the patient is having frequent seizures, such as a child with absence epilepsy, the EEG may confirm the presence of seizures and help to identify the seizure type. In patients with infrequent seizures, the EEG may reveal potentially abnormal interictal activity that, when combined with clinical or radiologic data, aids in establishing the diagnosis. However, the existence of epileptiform patterns such as spikes or sharp waves are not diagnostic in themselves, since similar patterns can be seen in 1 to 2% of normal individuals. Ideally, the EEG should be performed after sleep deprivation to increase the potential diagnostic yield of the study.

Almost all patients with new-onset seizures should have a brain imaging study to determine whether there is an underlying structural abnormality that is responsible. The main exception to this rule is children who have an unambiguous history and examination suggestive of a benign, generalized seizure disorder such as absence epilepsy.MRI has been shown to be superior to computed tomography (CT) in scanning for the detection of cerebral lesions associated with epilepsy. In some cases MRI will identify lesions such as tumors, vascular malformations, or other pathologies that need immediate therapy. The use of newer MRI methods, such as fluid-attenuated inversion recovery (FLAIR), has increased the sensitivity for detection of abnormalities of cortical architecture, including hippocampal atrophy associated with mesial temporal sclerosis, and abnormalities of cortical neuronal migration. In such cases the findings may not lead to immediate therapy, but they do provide an explanation for the patient's seizures and point to the need for chronic anticonvulsant therapy or possible surgical resection.

In the patient with suspectedCNSinfection or mass lesions,CTscanning should be performed emergently whenMRI is not immediately available. Otherwise, it is usually appropriate to obtain an MRI study within a few days of the initial evaluation. Functional imaging procedures such as positron emission tomography (PET) and single photon emission computed tomography (SPECT) are also used to evaluate certain patients with medically refractory seizures (discussed below).

DIFFERENTIAL DIAGNOSIS OF SEIZURES

The various disorders that may mimic seizures are listed in Table 360-6. In most cases seizures can be distingished from these other conditions by meticulous attention to the history and relevant laboratory studies. On occasion, additional studies, such as video-EEGmonitoring, sleep studies, tilt table analysis, or cardiac electrophysiology, may be required to reach a correct diagnosis. Two of the more common syndromes in the differential diagnosis are detailed below.

Syncope The diagnostic dilemma encountered most frequently is the distinction between a generalized seizure and syncope. Observations by the patient and bystanders that can help discriminate between the two are listed in Table 360-7. Characteristics of a seizure include the presence of an aura, cyanosis,

unconsciousness, motor manifestations lasting more than 30 s, postictal disorientation, muscle soreness, and sleepiness. In contrast, a syncopal episode is more likely if the event was provoked by acute pain or anxiety or occurred immediately after arising from the lying or sitting position. Patients with syncope often describe a stereotyped transition from consciousness to unconsciousness that includes tiredness, sweating, nausea, and tunneling of vision, and they experience a relatively brief loss of consciousness. Headache or incontinence usually suggests a seizure but may on occasion also occur with syncope. A brief period (i.e., 1 to 10 s) of convulsive motor activity is frequently seen immediately at the onset of a syncopal episode, especially if the patient remains in an upright posture after fainting (e.g., in a dentist's chair) and therefore has a sustained decrease in cerebral perfusion. Rarely, a syncopal episode can induce a full tonic-clonic seizure. In such cases the evaluation must focus on both the cause of the syncopal event as well as the possibility that the patient has a propensity for recurrent seizures.

Psychogenic Seizures Psychogenic seizures are nonepileptic behaviors that resemble seizures. The behavior is often part of a conversion reaction precipitated by underlying psychological distress. Certain behaviors, such as side-to-side turning of the head, asymmetric and large-amplitude shaking movements of the limbs, twitching of all four extremities without loss of consciousness, pelvic thrusting, and crying or talking during the event, are more commonly associated with psychogenic rather than epileptic seizures. However, the distinction is sometimes difficult on clinical grounds alone, and there are many examples of diagnostic errors made by experienced epileptologists. This is especially true for psychogenic seizures that resemble complex partial seizures, since the behavioral manifestations of complex partial seizures (especially of frontal lobe origin) can be extremely unusual, and in both cases the routine surfaceEEG may be normal. Video-EEG monitoring is often useful when the clinical observations are nondiagnostic. Generalized tonic-clonic seizures always produce marked EEG abnormalities during and after the seizure. For suspected complex partial seizures of temporal lobe origin, the use of additional electrodes beyond the standard scalp locations (e.g., sphenoidal electrodes) may be required to localize a seizure focus. Measurement of serum prolactin levels may also help to discriminate between organic and psychogenic seizures, since most generalized seizures and many complex partial seizures are accompanied by rises in serum prolactin (during the immediate 30-min postictal period), whereas psychogenic seizures are not. It is important to note that the diagnosis of psychogenic seizures does not exclude a concurrent diagnosis of epilepsy, since the two often coexist.

TREATMENT

Therapy for a patient with a seizure disorder is almost always multimodal and includes treatment of underlying conditions that cause or contribute to the seizures, avoidance of precipitating factors, suppression of recurrent seizures by prophylactic therapy with antiepileptic medications or surgery, and addressing a variety of psychological and social issues. Treatment plans must be individualized, given the many different types and causes of seizures as well as the differences in efficacy and toxicity of antiepileptic medications for each patient. In almost all cases a neurologist with experience in the treatment of epilepsy should design and oversee implementation of the treatment strategy. Furthermore, patients with refractory epilepsy or those who require polypharmacy with antiepileptic drugs should remain under the regular care of a

neurologist.

Treatment of Underlying Conditions If the sole cause of a seizure is a metabolic disturbance such as an abnormality of serum electrolytes or glucose, then treatment is aimed at reversing the metabolic problem and preventing its recurrence. Therapy with antiepileptic drugs is usually unnecessary unless the metabolic disorder cannot be corrected promptly and the patient is at risk of having further seizures. If the apparent cause of a seizure was a medication (e.g., theophylline) or illicit drug use (e.g., cocaine), then appropriate therapy is avoidance of the drug and there is usually no need for antiepileptic medications unless subsequent seizures occur in the absence of these precipitants.

Seizures caused by a structuralCNSlesion such as a brain tumor, vascular malformation, or brain abscess may not recur after appropriate treatment of the underlying lesion. However, despite removal of the structural lesion, there is a risk that the seizure focus will remain in the surrounding tissue or develop de novo as a result of gliosis and other processes induced by surgery, radiation, or other therapies. Most patients are therefore maintained on an antiepileptic medication for at least 1 year, and an attempt is made to withdraw medications only if the patient has been completely seizure-free. If the seizures are refractory to medication, the patient may benefit from surgical removal of the epileptic brain region (see "Surgical Treatment of Refractory Epilepsy").

Avoidance of Precipitating Factors Unfortunately, little is known about the specific factors that determine precisely when a seizure will occur in a patient with epilepsy. Some patients can identify particular situations that appear to lower their seizure threshold; these situations should be avoided. For example, a patient who has seizures in the setting of sleep deprivation should obviously be advised to maintain a normal sleep schedule. Many patients note an association between alcohol intake and seizures, and they should be encouraged to modify their drinking habits accordingly. There are also relatively rare cases of patients with seizures that are induced by highly specific stimuli such as a video game monitor, music, or an individual's voice ("reflex epilepsy"). If there is an association between stress and seizures, stress reduction techniques such as physical exercise, meditation, or counseling may be helpful.

Antiepileptic Drug Therapy Antiepileptic drug therapy is the mainstay of treatment for most patients with epilepsy. The overall goal is to completely prevent seizures without causing any untoward side effects, preferably with a single medication and a dosing schedule that is easy for the patient to follow. Seizure classification is an important element in designing the treatment plan, since some antiepileptic drugs have different activities against various seizure types. However, there is considerable overlap between many antiepileptic drugs, such that the choice of therapy is often determined more by specific needs of the patient, especially the patient's assessment of side effects.

When to Initiate Antiepileptic Drug Therapy Antiepileptic drug therapy should be started in any patient with recurrent seizures of unknown etiology or a known cause that cannot be reversed. Whether to initiate therapy in a patient with a single seizure is controversial. Patients with a single seizure due to an identified lesion such as a CNStumor, infection, or trauma, in which there is strong evidence that the lesion is

epileptogenic, should be treated. The risk of seizure recurrence in a patient with an apparently unprovoked or idiopathic seizure is uncertain, with estimates ranging from 31 to 71% in the first 12 months after the initial seizure. This uncertainty arises from differences in the underlying seizure types and etiologies in various published epidemiologic studies. Generally accepted risk factors associated with recurrent seizures include the following: (1) an abnormal neurologic examination, (2) seizures presenting as status epilepticus, (3) postictal Todd's paralysis, (4) a strong family history of seizures, or (5) an abnormalEEG. Most patients with one or more of these risk factors should be treated. Issues such as employment or driving may influence the decision whether or not to start medications as well. For example, a patient with a single, idiopathic seizure and whose job depends on driving may prefer taking antiepileptic drugs rather than risking a seizure recurrence and the potential loss of driving privileges.

Selection of Antiepileptic Drugs The choices of antiepileptic drugs in the United States for different seizure types are shown inTable 360-8, and the main pharmacologic characteristics of commonly used drugs are listed inTable 360-9. Older medications such as phenytoin, valproic acid, carbamazepine, and ethosuximide are generally used as first-line therapy for most seizure disorders since, overall, they are as effective as recently marketed drugs and significantly less expensive. Of the new drugs that have become available in the United States in the past decade, most are currently being used as add-on or alternative therapy.

In addition to efficacy, other factors influencing the specific choice of an initial medication for a patient include the relative convenience of dosing schedule (e.g., once daily versus three or four times daily) and potential side effects. Almost all of the commonly used antiepileptic drugs can cause similar, dose-related side effects such as sedation, ataxia, and diplopia. Close follow-up is required to ensure these are promptly recognized and reversed. Most of the drugs may also cause idiosyncratic toxicity such as rash, bone marrow suppression, or hepatotoxicity. Although rare, these side effects need to be carefully considered during drug selection, and patients require laboratory tests (e.g., complete blood count and liver function tests) prior to the institution of a drug (to establish baseline values) and during initial dosing and titration of the agent.

ANTIEPILEPTIC DRUG SELECTION FOR PARTIAL SEIZURES Carbamazepine or phenytoin is currently the initial drug of choice for the treatment of partial seizures, including those that secondarily generalize. Overall they have very similar efficacy, but differences in pharmacokinetics and toxicity are the main determinants for use in a given patient. Phenytoin has a relatively long half-life and offers the advantage of once or twice daily dosing compared to two or three times daily dosing for carbamazepine (although a more expensive, extended-release form of carbamazepine is now available). An advantage of carbamazepine is that its metabolism follows first-order pharmacokinetics, and the relationship between drug dose, serum levels, and toxicity is linear. By contrast, phenytoin shows properties of saturation kinetics, such that small increases in phenytoin doses above a standard maintenance dose can precipitate marked side effects. This is one of the main causes of acute phenytoin toxicity. Long-term use of phenytoin is associated with untoward cosmetic effects (e.g., hirsutism, coarsening of facial features, and gingival hypertrophy), so it is often avoided in young patients who are likely to require the drug for many years. Carbamazepine can cause leukopenia, aplastic anemia, or hepatotoxicity and would therefore be

contraindicated in patients with predispositions to these problems.

Valproic acid is an effective alternative for some patients with partial seizures, especially when the seizures secondarily generalize. Gastrointestinal side effects are fewer when using the valproate semisodium formulation (Depakote). Valproic acid also rarely causes reversible bone marrow suppression and hepatotoxicity, and laboratory testing is required to monitor toxicity. This drug should generally be avoided in patients with preexisting bone marrow or liver disease. Irreversible, fatal hepatic failure appearing as an idiosyncratic rather than dose-related side effect is a relatively rare complication; its risk is highest in children<2 years old, especially those taking other antiepileptic drugs or with inborn errors of metabolism. Valproic acid therapy should therefore only be used in infants and young children when the benefits clearly exceed this risk.

Lamotrigine, gabapentin, topiramate, tiagabine, and phenobarbital are additional drugs currently used for the treatment of partial seizures with or without secondary generalization. Lamotrigine appears to have an overall efficacy profile similar to the more standard drugs and is now being used as monotherapy. All patients, particularly children, need to be monitored closely for a lamotrigine-induced rash during the initiation of therapy. Also, lamotrigine must be started very slowly when used as add-on therapy with valproic acid, since valproic acid can inhibit its metabolism, thereby substantially prolonging its half-life. Gabapentin is unique in not having any significant drug interactions. This makes it potentially useful as add-on therapy, especially in patients who are particularly susceptible to side effects of other medications. Until recently, phenobarbital and other barbiturate compounds were commonly used as first-line therapy for many forms of epilepsy. However, the barbiturates frequently cause sedation in adults, hyperactivity in children, and other more subtle cognitive changes; thus, their use should be limited to situations in which no other suitable treatment alternatives exist.

ANTIEPILEPTIC DRUG SELECTION FOR GENERALIZED SEIZURES Valproic acid is currently considered the best initial choice for the treatment of primarily generalized, tonic-clonic seizures and lamotrigine, followed by carbamazepine and phenytoin, are suitable alternatives. Valproic acid is also particularly effective in absence, myoclonic, and atonic seizures and is therefore the drug of choice in patients with generalized epilepsy syndromes having mixed seizure types. Ethosuximide remains the preferred drug for the treatment of uncomplicated absence seizures, but it is not effective against tonic-clonic or partial seizures. Ethosuximide rarely causes bone marrow suppression, so that periodic monitoring of blood cell counts is required. Although approved for use in partial seizure disorders, lamotrigine appears to be effective in epilepsy syndromes with mixed, generalized seizure types such asJME and Lennox-Gastaut syndrome.

Initiation and Monitoring of Therapy Because the response to any antiepileptic drug is unpredictable, patients should be carefully educated about the approach to therapy. Patients need to understand that the goal is to prevent seizures and minimize the side effects of therapy; determination of the optimal dose is often a matter of trial and error. This process may take months or longer if the baseline seizure frequency is low. Most anticonvulsant drugs need to be introduced relatively slowly to minimize side effects, and patients should expect that minor side effects such as mild sedation, slight changes in cognition, or imbalance will typically resolve within a few days. Starting doses are

usually the lowest value listed under the dosage column inTable 360-9. Subsequent increases should be made only after achieving a steady state with the previous dose (i.e., after an interval of five or more half-lives).

Monitoring of serum antiepileptic drug levels can be very useful for establishing the initial dosing schedule. However, the published therapeutic ranges of serum drug concentrations are only an approximate guide for determining the proper dose for a given patient. The key determinants are the clinical measures of seizure frequency and presence of side effects, not the laboratory values. Conventional assays of serum drug levels measure the total drug (i.e., both free and protein-bound), yet it is the concentration of free drug that reflects extracellular levels in the brain and correlates best with efficacy. Thus, patients with decreased levels of serum proteins (e.g., decreased serum albumin due to impaired liver or renal function) may have an increased ratio of free to bound drug, yet the concentration of free drug may be adequate for seizure control. These patients may have a "subtherapeutic" drug level, but the dose should be changed only if seizures remain uncontrolled, not just to achieve a "therapeutic" level. It is also useful to monitor free drug levels in such patients. In practice, other than during the initiation or modification of therapy, monitoring of antiepileptic drug levels is most useful for documenting compliance.

If seizures continue despite gradual increases to the maximum tolerated dose and documented compliance, then it becomes necessary to switch to another antiepileptic drug. This is usually done by maintaining the patient on the first drug while a second drug is added. The dose of the second drug should be adjusted to decrease seizure frequency without causing toxicity. Once this is achieved, the first drug can be gradually withdrawn (usually over weeks unless there is significant toxicity). The dose of the second drug is then further optimized based on seizure response and side effects.

When to Discontinue Therapy Overall, about 70% of children and 60% of adults who have their seizures completely controlled with antiepileptic drugs can eventually discontinue therapy. Clinical studies suggest that the following patient profile yields the greatest chance of remaining seizure-free after drug withdrawal: (1) complete medical control of seizures for 1 to 5 years; (2) single seizure type, either partial or generalized; (3) normal neurologic examination, including intelligence; and (4) normalEEG. The appropriate seizure-free interval is unknown and undoubtedly varies for different forms of epilepsy. However, it seems reasonable to attempt withdrawal of therapy after 2 years in a patient who meets all of the above criteria, is motivated to discontinue the medication, and clearly understands the potential risks and benefits. In most cases it is preferable to reduce the dose of the drug gradually over 2 to 3 months. Most recurrences occur in the first 3 months after discontinuing therapy, and patients should be advised to avoid potentially dangerous situations such as driving or swimming during this period.

Treatment of Refractory Epilepsy Approximately one-third of patients with epilepsy do not respond to treatment with a single antiepileptic drug, and it becomes necessary to try a combination of drugs to control seizures. Patients who have focal epilepsy related to an underlying structural lesion or those with multiple seizure types and developmental delay are particularly likely to require multiple drugs. There are currently no clear guidelines for rational polypharmacy, but in most cases the initial combination therapy

combines first-line drugs, i.e., carbamazepine, phenytoin, valproic acid, and lamotrigine. If these drugs are unsuccessful, then the addition of a newer drug such as topiramate or gabapentin is indicated. Patients with myoclonic seizures resistant to valproic acid may benefit from the addition of clonazepam, and those with absence seizures may respond to a combination of valproic acid and ethosuximide. The same principles concerning the monitoring of therapeutic response, toxicity, and serum levels for monotherapy apply to polypharmacy, and potential drug interactions need to be recognized. If there is no improvement, a third drug can be added while the first two are maintained. If there is a response, the least effective of the first two drugs should be gradually withdrawn.

Surgical Treatment of Refractory Epilepsy Approximately 20% of patients with epilepsy are resistant to medical therapy despite efforts to find an effective combination of antiepileptic drugs. For some, surgery can be extremely effective in substantially reducing seizure frequency and even providing complete seizure control. Understanding the potential value of surgery is especially important when, at the time of diagnosis, a patient has an epilepsy syndrome that is considered likely to be drug-resistant. Rather than submitting the patient to years of unsuccessful medical therapy and the associated psychosocial trauma of ongoing seizures, the patient should have an efficient but relatively brief attempt at medical therapy and then be referred for surgical evaluation.

The most common surgical procedure for patients with temporal lobe epilepsy involves resection of the anteromedial temporal lobe (temporal lobectomy) or a more limited removal of the underlying hippocampus and amygdala. Focal seizures arising from extratemporal regions may be suppressed by a focal neocortical resection or precise removal of an identified lesion (lesionectomy). When the cortical region cannot be removed, multiple subpial transection, which disrupts intracortical connections, is sometimes used to prevent seizure spread. Hemispherectomy or multilobar resection is useful for some patients with severe seizures due to hemispheric abnormalities such as hemimegaloencephaly or other dysplastic abnormalities, and corpus callosotomy has been shown to be effective for disabling tonic or atonic seizures, usually when they are part of a mixed-seizure syndrome (e.g., Lennox-Gastaut syndrome).

Presurgical evaluation is designed to identify the functional and structural basis of the patient's seizure disorder. Inpatient video-EEGmonitoring is used to define the anatomic location of the seizure focus and to correlate the abnormal electrophysiologic activity with behavioral manifestations of the seizure. Routine scalp or scalp-sphenoidal recordings are usually sufficient for localization, and advances in neuroimaging have made the use of invasive electrophysiologic monitoring such as implanted depth electrodes or subdural electrodes much less common. A high-resolutionMRI scan is routinely used to identify structural lesions. Functional imaging studies such asSPECTand PETare adjunctive tests that may help verify the localization of an apparent epileptogenic region with an anatomic abnormality. Once the presumed location of the seizure onset is identified, additional studies, including neuropsychological testing and the intracarotid amobarbital test (Wada test) may be used to assess language and memory localization and to determine the possible functional consequences of surgical removal of the epileptogenic region. In some cases, the exact extent of the resection to be undertaken is determined by performing cortical mapping at the time of the surgical procedure. This involves electrophysiologic recordings and cortical stimulation in the awake patient to identify the extent of

epileptiform disturbances and the function of cortical regions in question.

Advances in presurgical evaluation and microsurgical techniques have led to a steady increase in the success of epilepsy surgery. Clinically significant complications of surgery are<5%, and the use of functional mapping procedures has markedly reduced the neurologic sequelae due to removal or sectioning of brain tissue. For example, about 70% of patients treated with temporal lobectomy will become seizure-free, and another 15 to 25% will have at least a 90% reduction in seizure frequency. Marked improvement is also usually seen in patients treated with hemispherectomy for catastrophic seizure disorders due to large hemispheric abnormalities. Postoperatively, patients generally need to remain on antiepileptic drug therapy, but the marked reduction of seizures following surgery can have a very beneficial effect on their quality of life.

Vagus Nerve Stimulation (VNS) VNS is a new treatment option for patients with medically refractory epilepsy who are not candidates for resective brain surgery. The procedure involves placement of a bipolar electrode on the midcervical portion of the left vagus nerve. The electrode is connected to a small, subcutaneous generator located in the infraclavicular region, and the generator is programmed to deliver intermittent electrical pulses to the vagus nerve. The precise mechanism of action of VNS is unknown, although experimental studies have shown that stimulation of vagal nuclei leads to widespread activation of cortical and subcortical pathways and an associated increased seizure threshold. In practice, the efficacy of VNS appears to be no greater than recently introduced anticonvulsant medications. Adverse effects of the surgery are rare, and stimulation-induced side effects, including transient hoarseness, cough, and dyspnea, are usually mild and well tolerated.

STATUS EPILEPTICUS

Status epilepticus refers to continuous seizures or repetitive, discrete seizures with impaired consciousness in the interictal period. The duration of seizure activity sufficient to meet the definition of status epilepticus has traditionally been specified as 15 to 30 min. However, a more practical definition is to consider status epilepticus as a situation in which the duration of seizures prompts the acute use of anticonvulsant therapy, typically when seizures last beyond 5 min.

Status epilepticus is an emergency and must be treated immediately, since cardiorespiratory dysfunction, hyperthermia, and metabolic derangements can develop as a consequence of prolonged seizures, and these can lead to irreversible neuronal injury. Furthermore,CNSinjury can occur even when the patient is paralyzed with neuromuscular blockade but continues to have electrographic seizures. The most common causes of status epilepticus are anticonvulsant withdrawal or noncompliance, metabolic disturbances, drug toxicity, CNS infection, CNS tumors, refractory epilepsy, and head trauma.

Generalized status epilepticus is obvious when the patient is having overt convulsions. However, after 30 to 45 min of uninterrupted seizures, the signs may become increasingly subtle. Patients may have mild clonic movements of only the fingers, or fine, rapid movements of the eyes. There may be paroxysmal episodes of tachycardia,

hypertension, and pupillary dilation. In such cases, theEEG may be the only method of establishing the diagnosis. Thus, if the patient stops having overt seizures, yet remains comatose, an EEG should be performed to rule out ongoing status epilepticus.

The first step in the management of a patient in status epilepticus is to attend to any acute cardiorespiratory problems or hyperthermia, perform a brief medical and neurologic examination, establish venous access, and send samples for laboratory studies to identify metabolic abnormalities. Anticonvulsant therapy should then begin without delay; a treatment approach is shown inFig. 360-3.

BEYOND SEIZURES: OTHER MANAGEMENT ISSUES

Interictal Behavior The adverse effects of epilepsy often go beyond the occurrence of clinical seizures, and the extent of these effects depends largely upon the etiology of the seizure disorder, the degree to which the seizures are controlled, and the presence of side effects from antiepileptic therapy. Many patients with epilepsy are completely normal between seizures and able to live highly successful and productive lives. In contrast, patients with seizures secondary to developmental abnormalities or acquired brain injury may have impaired cognitive function and other neurologic deficits. Frequent interictalEEGabnormalities have been shown to be associated with subtle dysfunction of memory and attention. Patients with many seizures, especially those emanating from the temporal lobe, often note an impairment of short-term memory that may progress over time.

Patients with epilepsy are at risk of developing a variety of psychiatric problems including depression, anxiety, and psychosis. This risk varies considerably depending on many factors, including the etiology, frequency, and severity of seizures and the patient's age and previous history. Depression occurs in approximately 20% of patients, and the incidence of suicide is higher in epileptic patients than in the general population. Depression should be treated through counseling or medication. The selective serotonin reuptake inhibitors typically have no effect on seizures, while the tricyclic antidepressants may lower the seizure threshold. Anxiety can appear as a manifestation of a seizure, and anxious or psychotic behavior can sometimes be observed as part of a postictal delirium. Interictal psychosis is a rare phenomenon that typically occurs after a period of increased seizure frequency. There is usually a brief lucid interval lasting up to a week, followed by days to weeks of agitated, psychotic behavior. The psychosis will usually resolve spontaneously but may require treatment with antipsychotic or anxiolytic medications.

There is ongoing controversy as to whether some patients with epilepsy (especially temporal lobe epilepsy) have a stereotypical "interictal personality." The predominant view is that the unusual or abnormal personality traits observed in such patients are, in most cases, not due to epilepsy but result from an underlying structural brain lesion, the effects of antiepileptic drugs, or psychosocial factors.

Mortality of Epilepsy Patients with epilepsy have an increased risk of death that is roughly two to three times greater than what would be expected in a matched population without epilepsy. Most of the increased mortality is due to the underlying etiology of epilepsy, i.e., more widespread neurologic or systemic diseases in children and tumors

or strokes in older adults. However, a small number of patients die from a syndrome known as *sudden unexpected death in epileptic patients* (SUDEP), which usually affects young people with convulsive seizures and tends to occur at night. The cause(s) remain unknown, although the leading theories propose brainstem-mediated effects of seizures on cardiac rhythms or pulmonary function.

Psychosocial Issues There continues to be a cultural stigma about epilepsy, although it is slowly declining in societies with effective health education programs. Because of this stigma, many patients with epilepsy harbor fears, such as the fear of becoming mentally retarded or dying during a seizure. These issues need to be carefully addressed by educating the patient about epilepsy and by ensuring that family members, teachers, fellow employees, and other associates are equally well informed. The Epilepsy Foundation of America (1-800-EFA-1000) is a patient advocacy organization and a useful source of educational material.

Employment and Driving Many patients with epilepsy face difficulty in obtaining or maintaining employment, even when their seizures are well controlled. Federal and state legislation is designed to prevent employers from discriminating against patients with epilepsy, and patients should be encouraged to understand and claim their legal rights. Patients in these circumstances also benefit greatly from the assistance of health providers who act as strong patient advocates.

Loss of driving privileges is one of the most disruptive social consequences of epilepsy. Physicians should be very clear about local regulations concerning driving and epilepsy, since the laws vary considerably among states and countries. In all cases, it is the physician's responsibility to warn patients of the danger imposed on themselves and others while driving if their seizures are uncontrolled (unless the seizures are not associated with impairment of consciousness or motor control). In general, most states allow patients to drive after a seizure-free interval (on or off medications) between 3 months and 2 years.

SPECIAL ISSUES RELATED TO WOMEN AND EPILEPSY

Catamenial Epilepsy Some women experience a marked increase in seizure frequency around the time of menses. This is thought to reflect either the effects of estrogen and progesterone on neuronal excitability or changes in antiepileptic drug levels due to altered protein binding. Acetazolamide (250 to 500 mg/d) may be effective as adjunctive therapy in some cases when started 7 to 10 days prior to the onset of menses and continued until bleeding stops. Some patients may benefit from increases in antiepileptic drug dosages during this time or from control of the menstrual cycle through the use of oral contraceptives.

Pregnancy Most women with epilepsy who become pregnant will have an uncomplicated gestation and deliver a normal baby. However, epilepsy poses some important risks to a pregnancy. Seizure frequency during pregnancy will remain unchanged in approximately 50% of women, increase in 30%, and decrease in 20%. Changes in seizure frequency are attributed to endocrine effects on theCNS, variations in antiepileptic drug pharmacokinetics (such as acceleration of hepatic drug metabolism or effects on plasma protein binding), and changes in medication compliance. It is

therefore useful to see patients at more frequent intervals during pregnancy and monitor serum antiepileptic drug levels. Measurement of the unbound drug concentrations may be useful if there is an increase in seizure frequency or worsening of side effects of antiepileptic drugs.

The overall incidence of fetal abnormalities in children born to mothers with epilepsy is 5 to 6%, compared to 2 to 3% in healthy women. Part of the higher incidence is due to teratogenic effects of antiepileptic drugs, and the risk increases with the number of medications used (e.g., 10% risk of malformations with three drugs). A syndrome comprising facial dysmorphism, cleft lip, cleft palate, cardiac defects, digital hypoplasia, and nail dysplasia was originally ascribed to phenytoin therapy, but it is now known to occur with other first-line antiepileptic drugs (i.e., valproic acid and carbamazepine) as well. Also, valproic acid and carbamazepine are associated with a 1 to 2% incidence of neural tube defects compared with a baseline of 0.5 to 1%. Little is currently known about the safety of newer drugs.

Since the potential harm of uncontrolled seizures on the mother and fetus is considered greater than the teratogenic effects of antiepileptic drugs, it is currently recommended that pregnant women be maintained on effective drug therapy. When possible, it seems prudent to have the patient on monotherapy at the lowest effective dose, especially during the first trimester. Patients should also take folate (1 to 4 mg/d), since the antifolate effects of anticonvulsants are thought to play a role in the development of neural tube defects, although the benefits of this treatment remain unproved in this setting.

Enzyme-inducing drugs such as phenytoin, phenobarbital, and primidone cause a transient and reversible deficiency of vitamin K-dependent clotting factors in approximately 50% of newborn infants. Although neonatal hemorrhage is uncommon, the mother should be treated with oral vitamin K (20 mg daily) in the last 2 weeks of pregnancy, and the infant should receive an intramuscular injection of vitamin K (1 mg) at birth.

Contraception Special care should be taken when prescribing antiepileptic medications for women who are taking oral contraceptive agents. Drugs such as carbamazepine, phenytoin, phenobarbital, and topiramate can significantly antagonize the effects of oral contraceptives via enzyme induction and other mechanisms. Patients should be advised to consider alternative forms of contraception, or their contraceptive medications should be modified to offset the effects of the antiepileptic medications.

Breast Feeding Antiepileptic medications are excreted into breast milk to a variable degree. The ratio of drug concentration in breast milk relative to serum is approximately 80% for ethosuximide, 40 to 60% for phenobarbital, 40% for carbamazepine, 15% for phenytoin, and 5% for valproic acid. Given the overall benefits of breast feeding and the lack of evidence for long-term harm to the infant by being exposed to antiepileptic drugs, mothers with epilepsy should be encouraged to breast feed. This should be reconsidered, however, if there is any evidence of drug effects on the infant, such as lethargy or poor feeding.

361. CEREBROVASCULAR DISEASES - *Wade S. Smith*, *Stephen L. Hauser*, *J. Donald Easton*

Cerebrovascular diseases occur predominately in the middle and late years of life. They cause approximately 200,000 deaths in the United States each year, as well as considerable neurologic disability. The incidence of stroke increases with age; thus the disability affects many people in their "golden years," a segment of the population that is growing rapidly in Western countries. Categories of cerebrovascular diseases include ischemia-infarction and intracranial hemorrhage (Table 361-1). Many of the arterial and cardiac disorders underlying these diseases are preventable; the morbidity and mortality from cerebrovascular diseases has been diminishing in recent years, apparently because of better recognition and treatment of hypertension.

Most cerebrovascular diseases are manifest by the abrupt onset of a focal neurologic deficit. The deficit may remain fixed or may rapidly improve or progressively worsen. It is this abrupt onset of a nonconvulsive and focal neurologic deficit that defines a *stroke*, or cerebrovascular accident (CVA).

Cerebral ischemia is caused by a reduction in blood flow that lasts for several seconds to a few minutes. Neurologic symptoms are manifest within 10 s because neurons lack glycogen and suffer rapid energy failure. When blood flow is rapidly restored brain tissue can recover fully, and the patient's symptoms are only transient: a transient ischemic attack (TIA) is said to have occurred. Typically the neurologic signs and symptoms of TIA last for 5 to 15 min but, by definition, must last<24 h. If the cessation of flow lasts for more than a few minutes, *infarction* or death of brain tissue results. Stroke has occurred if the neurologic signs and symptoms last for>24 h. A *generalized* reduction in cerebral blood flow due to systemic hypotension (e.g., cardiac arrhythmia, myocardial infarction, or hemorrhagic shock) usually produces syncope (Chap. 21). If low cerebral blood flow is maintained for a longer duration, then infarction in the border zones between the major cerebral artery distributions or widespread brain necrosis develops. This process is termed *global hypoxia-ischemia* and a patient with cognitive sequelae is said to have *hypoxic-ischemic encephalopathy* (Chap. 376). *Focal* ischemia or infarction, on the other hand, is usually caused by thrombosis of the cerebral vessels themselves or by emboli from a proximal arterial source or the heart. A comprehensive list of causes of ischemia-infarction is shown inTable 361-2.

Cerebral hemorrhage produces neurologic symptoms by producing a mass effect on neural structures or from the toxic effects of blood itself; debate exists as to how much injury occurs from tamponade of surrounding blood vessels. As with ischemia-infarction, the causes are numerous (Tables 361-1 and361-7).

When faced with an acute stroke, the clinician must rapidly differentiate between ischemia-infarction and hemorrhage, because the method of emergency treatment depends on cause. The clinician should focus on two goals: (1) to prevent or reverse acute brain injury, and (2) to prevent future neurologic injury. The first goal involves identifying those patients who may benefit from thrombolysis and attending to acute medical issues of airway, blood pressure, and concomitant organ failure; the second goal is achieved once the mechanism of stroke is elucidated and the proper secondary prevention strategy prescribed.

ISCHEMIC STROKE

MECHANISMS AND DEFINITIONS

Several pathophysiologic processes may produce cerebral ischemia and infarction. A common form is atherosclerotic damage to the aortic arch, carotid bifurcation, or intracranial vessels that produces local thrombosis and distal embolism of the clot. The released clot travels until it occludes a distal vessel and prevents distal cerebral blood flow. Such strokes are called *atherothromboembloic strokes*, or simply *embolic strokes*, and are a subset of *artery-artery embolic strokes*. Stroke produced by thrombosis of large (~0.5 to 3 mm) intracranial vessels in situ from atherosclerosis is termed *atherothrombotic stroke*. Unlike coronary arteries in which vascular occlusion may be sudden and complete, sudden thrombosis of intracranial vessels occurs less frequently. It may be more likely that atherosclerosis of an intracranial vessel will produce stroke by distal embolism rather than by occlusion. Stenosis of an extra- or intracranial vessel may produce a *low-flow stroke* orTIA if cardiac output or systemic blood pressure is reduced below some threshold. This mechanism was thought to be the cause of stroke from carotid atherosclerosis, but it is now clear that carotid disease produces stroke primarily by an embolic mechanism. True flow-related TIAs and stroke are rare, but it is important to identify them since they will respond to revascularization procedures rather than standard antithrombotic treatment. Thrombotic occlusion of smaller intracranial vessels (~30 to 100 um), in contrast to larger vessel thrombosis, is a frequent cause of stroke. These end-arteries typically supply a small volume of brain tissue, and their occlusion may result in a *lacunar syndrome*, of which there are >30 types. A patient who has a stroke from this event is said to have *lacunar stroke*. The underlying pathology of this form of stroke is usually lipohyalinosis or microatheromata with thrombosis of the vascular lumen.

Clinically, thrombotic strokes are more gradual in onset or may stutter. It is common for a person to experience severalTIAs of the lacunar type prior to eventual stroke. *Crescendo TIAs* -- the occurrence of increasing number and frequency of TIAs -- have a particularly high likelihood of evolving to stroke. *Stroke in progression* is said to be present if a patient suffers progressive neurologic deficits over a few hours or days that are not accounted for by cerebral edema. This may happen as a small vessel slowly thromboses or, more ominously, as a larger intracranial vessel such as the basilar artery progressively thromboses, producing an ever enlarging region of cerebral ischemia. Heparin and thrombolytic treatment may arrest progression, but it has been difficult to demonstrate in clinical trials whether or not such treatments improve outcome.

Embolism from a cardiac source is most commonly from red atrial thrombi but can arise from numerous sources. In most cases the clinician does not observe clot within the heart and makes the diagnosis by associating a known cardiac cause (e.g., atrial fibrillation, recent myocardial infarction) with a sudden large-vessel occlusion in the brain. Such strokes are called *cardioembolic strokes*. Some patients, however, may develop sudden occlusion of a large intracranial vessel, and despite extensive evaluation, no cause is apparent. These strokes are called *cryptogenic strokes*.

Clinically, embolic events usually produce a sudden onset of neurologic dysfunction that

is maximum at onset. The extent of neuronal ischemia is determined by the location of the occlusion and the degree to which collateral flow is offered to the ischemic tissue bed, the blood pressure and body temperature, and other factors. Embolic strokes have a higher risk of transforming into hemorrhagic stroke in which petechial bleeding or frank hemorrhage occurs into the infarcted tissue hours or days following the initial embolic occlusion. This natural history risk of spontaneous hemorrhage must be taken into account in acute stroke trials testing the safety of thrombolytic treatment.

RISK FACTORS FOR ISCHEMIC STROKE

Older age, family history of thrombotic stroke, diabetes mellitus, hypertension, tobacco smoking, elevated blood cholesterol levels, and other factors are risk factors for atherosclerosis and hence either proven or probable risk factors for ischemic stroke. Risk of second stroke is strongly influenced by prior stroke or TIA (Table 361-3). Many cardiac conditions predispose to stroke, including atrial fibrillation and recent myocardial infarction. Oral contraceptives may increase stroke risk slightly, and certain inherited and acquired hypercoagulable states predispose to stroke. Identification of modifiable risk factors and prophylactic interventions to lower risk is probably the best treatment for stroke overall, as the total number of strokes could be reduced substantially by these means. (See below for recommendations for risk factor modification.)

ACUTE STROKE

Clinical Encounter Patients with acute stroke often do not seek medical assistance on their own, perhaps because it is rarely painful but also because they may lose the appreciation that something is wrong with them (*anosognosia*). It is often a family member or a bystander who calls for help, and many gain entry into the medical system through emergency medical services, such as the 911 system in the United States. Use of such a system allows rapid evaluation of patients for consideration for time-sensitive treatments such as thrombolysis. Patients at risk for stroke should be counseled to call emergency medical services if they experience the sudden onset of any of the following: loss of sensory and/or motor function on one half of the body; change in vision, gait, or ability to speak or understand; or a sudden, severe headache.

The differential diagnosis of neurologic symptoms of sudden onset includes stroke (ischemic or hemorrhagic),TIA, seizure with postictal Todd's paralysis, intracranial tumor, migraine, and metabolic encephalopathy (Table 361-4). An adequate history from an observer that no convulsive activity occurred at the onset reasonably excludes seizure. Tumors may present with acute neurologic symptoms due to hemorrhage, seizure, or hydrocephalus. Surprisingly, migraine can mimic cerebral ischemia, even in patients without a significant migraine history. When it develops without head pain (*acephalgic migraine*), the diagnosis may remain elusive. Elderly patients without any prior history of complicated migraine may develop acephalgic migraine after age 65. The sensory disturbance is often prominent, and the sensory deficit, as well as any motor deficits, tends to migrate slowly across a limb over minutes. The diagnosis of migraine becomes more likely as the cortical disturbance begins to cross vascular boundaries. At times it may be difficult to make the diagnosis until multiple episodes have occurred leaving behind no residual stroke or brain imaging abnormality. Classically, metabolic encephalopathies produce a fluctuating mental status without

focal neurologic findings. However, in the setting of prior stroke or brain injury, a patient with fever or sepsis will manifest hemiparesis, which clears rapidly when the infection is remedied. The metabolic process serves to "unmask" a prior deficit.

STROKE SYNDROMES

A careful history and neurologic examination can often localize the region of brain dysfunction; if this region corresponds to a particular arterial distribution, the possible causes responsible for the syndrome can be narrowed. This is of particular importance when the patient presents with aTIA and a normal examination. For example, if a patient develops language loss and a right homonymous hemianopia, a search for causes of left middle cerebral emboli should be performed. A finding of an isolated stenosis of the right internal carotid artery in that patient suggests an asymptomatic carotid stenosis, which carries a significantly lower risk than symptomatic stenosis (i.e., stenosis of the left internal carotid artery). The following sections describe the clinical findings of arterial ischemia associated with cerebral vascular territories depicted in Figs. 361-1,361-2,361-3,361-4,361-5,361-6,361-7, 368-8, and361-9. Stroke syndromes are divided into: (1) large vessel stroke within the anterior circulation, (2) large vessel stroke within the posterior circulation, and (3) small vessel disease of either vascular bed.

Large Vessel Stroke within the Anterior Circulation

Pathophysiology The internal carotid artery and its branches comprise the anterior circulation of the brain. These vessels can be occluded by intrinsic disease of the vessel (e.g., atherosclerosis or dissection) or by embolic occlusion from a proximal source. The causes of occlusion are enumerated here, and the clinical manifestations are listed in the next section.

EXTRACRANIAL INTERNAL CAROTID ARTERY The origin of the internal carotid artery is probably the most common site of atherosclerosis that leads toTIA or stroke. Atherosclerosis is usually most severe in the first 2 cm and arises from the posterior wall, often extending downward into the common carotid artery. Atherosclerosis at this site is often manifested by a TIA or minor stroke, presumably caused by embolism or, less frequently, low flow.

Dissection of the carotid artery produces cerebral ischemia by distal embolization and/or low flow to the anterior circulation. When low flow is the mechanism, there is presumably inadequate collateral flow through the circle of Willis. Fibromuscular dysplasia of the carotids may produce distal emboli or dissection.

Rarely a large embolus will lodge in the common or internal carotid artery. Emboli of a size sufficient to block the internal carotid most often originate from pulmonary veins or extensive atrial or myocardial thrombi. *Takayasu's arteritis* (Chap. 317) is the most common form of vasculitis that affects the carotid artery.

INTRACRANIAL INTERNAL CAROTID ARTERY Atheromatous disease at the petrous inlet, the siphon (S-shaped portion of the internal carotid artery in the cavernous sinus), or the proximal segment of the middle or anterior cerebral arteries may produce distal embolization. These intracranial sites predominate in African Americans, Hispanics, and

Asians. *Moyamoya syndrome* results from progressive stenosis and occlusion of the distal internal carotid artery and/or proximal middle and anterior cerebral arteries. It is idiopathic in children and acquired secondary to atherosclerosis in adults. Ischemia is produced by breakdown in lenticulostriate collaterals that form to reconstitute flow in the middle cerebral artery (MCA) or by progressive sclerosis of cortical vessels. Capsular hemorrhage may occur from rupture of the enlarged lenticulostriate vessels.

MIDDLE CEREBRAL ARTERY In contrast to the internal carotid artery, occlusion of the proximalMCA or one of its major branches is most often due to an embolus (artery-to-artery, cardiac, or of unknown source) rather than intracranial atherothrombosis. Atherosclerosis of the proximal MCA may cause distal emboli to the middle cerebral territory or, less commonly, may produce low-flowTIAs. Collateral formation via leptomeningeal vessels often prevents MCA stenosis from becoming symptomatic.

ANTERIOR CEREBRAL ARTERY Atheromatous deposits in the proximal segment of the anterior cerebral artery rarely cause symptoms because the effects of occlusion are usually circumvented by collateral circulation through the anterior communicating artery. If the anterior communicating artery is congenitally atretic or the atheromatous lesion occurs distally in the anterior cerebral artery,TIAs and stroke may occur. The anterior cerebral artery is rarely the recipient of emboli.

Clinical Manifestations

MIDDLE CEREBRAL ARTERY The cortical branches of theMCAsupply the lateral surface of the hemisphere except for (1) the frontal pole and a strip along the superomedial border of the frontal and parietal lobes supplied by the anterior cerebral artery and (2) the lower temporal and occipital pole convolutions supplied by the posterior cerebral artery (Figs. 361-2,361-4, and361-5).

The proximalMCA (M1 segment) gives rise to penetrating branches (termed *lenticulostriate arteries*) that supply the putamen, outer globus pallidus, posterior limb of the internal capsule above the plane of the upper border of the globus pallidus, the adjacent corona radiata, and the body and upper and lateral head of the caudate nucleus. In the sylvian fissure, the middle cerebral artery in most patients divides into *superior* and *inferior* divisions (M2 branches). Branches of the inferior division supply the inferior parietal and temporal cortex, and those from the superior division supply the frontal and superior parietal cortex (Fig. 361-3). There is considerable variability in the parietal lobe supply between the two divisions, with about two-thirds of individuals having an inferior division that supplies regions above the angular gyrus.

If the entireMCA is occluded at its origin (blocking both its penetrating and cortical branches) and the distal collaterals are limited, the clinical findings are contralateral hemiplegia, hemianesthesia, homonymous hemianopia, and a day or two of gaze preference to the ipsilateral side. When the dominant hemisphere is involved, global aphasia is present also, and when the nondominant hemisphere is affected, anosognosia, constructional apraxia, and neglect are found (Fig. 361-3). Dysarthria may also occur.

CompleteMCAsyndromes occur most often when an embolus occludes the stem of the artery. Cortical collateral blood flow and differing arterial configurations are probably responsible for the development of many partial syndromes. Partial syndromes also may be due to emboli that enter the proximal MCA without complete occlusion, occlude distal MCA branches, or fragment and move distally.

Partial syndromes due to embolic occlusion of a single branch include hand, or arm and hand, weakness alone (brachial syndrome) or facial weakness with nonfluent (expressive, Broca) aphasia (Chap 25), with or without arm weakness (frontal opercular syndrome). A combination of sensory disturbance, motor weakness, and nonfluent aphasia suggests that an embolus has occluded the proximal superior division and infarcted large portions of the frontal and parietal cortices (Fig. 361-3). If a fluent (Wernicke's) aphasia occurs without weakness, the inferior division of theMCAsupplying the posterior part (temporal cortex) of the dominant hemisphere is probably involved (Fig. 361-3). Jargon speech and an inability to comprehend written and spoken language are prominent features, often accompanied by a contralateral, homonymous superior quadrantanopia. Hemineglect or spatial agnosia without weakness indicates that the inferior division of the MCA in the nondominant hemisphere is involved.

ANTERIOR CEREBRAL ARTERY The anterior cerebral artery is divided into two segments: the precommunal (A1) circle of Willis, or stem, which connects the internal carotid artery to the anterior communicating artery, and the postcommunal (A2) segment distal to the anterior communicating artery (Figs. 361-1 and361-4). The A1 segment gives rise to several deep penetrating branches that supply the anterior limb of the internal capsule, the anterior perforate substance, amygdala, anterior hypothalamus, and the inferior part of the head of the caudate nucleus (Fig. 361-2).

Occlusion of the proximal anterior cerebral artery is usually well tolerated because of collateral flow. Occlusion of a single A2 segment results in the contralateral symptoms noted in the legend of Fig. 361-4. If both A2 segments arise from a single anterior cerebral stem (contralateral A1 segment atresia), the occlusion affects both hemispheres. Profound abulia (a delay in verbal and motor response) and bilateral pyramidal signs with paraparesis and urinary incontinence result.

ANTERIOR CHOROIDAL ARTERY This artery arises from the internal carotid artery and supplies the posterior limb of the internal capsule and the white matter posterolateral to it, through which pass some of the geniculocalcarine fibers (Figs. 361-2 and361-5). The complete syndrome of anterior choroidal artery occlusion consists of contralateral hemiplegia, hemianesthesia (hypesthesia), and homonymous hemianopia. However, because this territory is also supplied by penetrating vessels of the proximalMCA and the posterior communicating and posterior choroidal arteries, minimal deficits may occur, and patients frequently recover substantially.

INTERNAL CAROTID ARTERY The clinical picture of internal carotid occlusion varies depending on whether the cause of ischemia is propagated thrombus, embolism, or low flow. The cortex supplied by the middle cerebral territory is affected most often. With a competent circle of Willis, occlusion may go unnoticed. If the thrombus propagates up the internal carotid artery into theMCA, or embolizes it, symptoms are identical to proximal MCA occlusion (see above). Sometimes there is massive infarction of the

entire deep white matter and cortical surface. When the origins of both the anterior and middle cerebral arteries are occluded at the top of the carotid artery, abulia or stupor occurs with hemiplegia, hemianesthesia, and aphasia or anosognosia. When the posterior cerebral artery arises from the internal carotid artery (an unusual configuration called a *fetal posterior cerebral artery*), it also may become occluded and give rise to symptoms referable to its peripheral territory (Figs. 361-4 and361-5).

In addition to supplying the ipsilateral brain, the internal carotid artery perfuses the optic nerve and retina via the ophthalmic artery. In about 25% of symptomatic internal carotid disease, recurrent transient monocular blindness (TMB or amaurosis fugax) warns of the lesion. Patients typically describe a horizontal shade that sweeps down or up across the field of vision. They may also complain that their vision was blurred in that eye or that the upper or lower half of vision disappeared. In most cases, these symptoms last only a few minutes. Rarely, ischemia or infarction of the ophthalmic artery or central retinal arteries occurs at the time of cerebralTIA or infarction.

A high-pitched prolonged carotid bruit fading into diastole is often associated with tightly stenotic lesions. As the stenosis grows tighter and flow distal to the stenosis becomes reduced, the bruit becomes fainter and may disappear when occlusion is imminent. A stenosis is said to be *asymptomatic* if the patient has never experiencedTIA or stroke that can be explained by the carotid lesion. The risk of stroke with this finding is low. *Symptomatic carotid stenosis*, in distinction, carries a significantly higher risk for stroke (see "Treatment," below).

COMMON CAROTID ARTERY All symptoms and signs of internal carotid occlusion may also be present with occlusion of the common carotid artery. Bilateral common carotid artery occlusions at their origin may occur in Takayasu's arteritis (Chap. 317).

Large Vessel Stroke within the Posterior Circulation The posterior circulation is composed of the paired vertebral arteries, the basilar artery, and the paired posterior cerebral arteries. The vertebral arteries join to form the basilar artery at the pontomedullary junction. The basilar artery divides into two posterior cerebral arteries in the interpeduncular fossa (Fig. 361-1). These major arteries gives rise to long and short circumferential branches and to smaller deep penetrating branches that supply the cerebellum, medulla, pons, midbrain, subthalamus, thalamus, hippocampus, and medial temporal and occipital lobes. Occlusion of each vessel produces its own distinctive syndrome.

Pathophysiology

POSTERIOR CEREBRAL ARTERY In 75% of cases, both posterior cerebral arteries arise from the bifurcation of the basilar artery; in 20%, one has its origin from the ipsilateral internal carotid artery via the posterior communicating artery; in 5%, both originate from the respective ipsilateral internal carotid arteries (Fig. 361-1). The precommunal, or P1, segment of the true posterior cerebral artery is atretic in such cases.

Atheroma formation or emboli that lodge at the top of the basilar artery or along the P1 segment may cause symptoms by occluding one or more of the small

brainstem-penetrating branches (Figs. 361-1 and361-5) that supply the middle cerebral peduncles, the substantia nigra, red nucleus, oculomotor nuclei, midbrain reticular formation, subthalamic nucleus, decussation of the superior cerebellar peduncles, the medial longitudinal fasciculus, and the medial lemniscus. The *artery of Percheron* arises from either the right or the left precommunal segment of the posterior cerebral artery; it divides in the subthalamus to supply the inferomedial and anterior portions of the thalamus and subthalamus bilaterally. The *thalamogeniculate branches*, which also originate from the precommunal portion of the posterior cerebral artery, supply the dorsal, dorsomedial, anterior and inferior thalamus, and the medial geniculate body. The *medial posterior choroidal artery* supplies the superior dorsomedial and dorsoanterior thalamus and the medial geniculate body in addition to the tela choroidea of the third ventricle. The *lateral posterior choroidal artery* supplies the choroid plexus of the lateral ventricle.

Occlusions in the posterior cerebral artery distal to the junction with the posterior communicating artery (P2 segment) (Fig. 361-5) may disrupt small circumferential branches that course around the midbrain to supply the lateral part of the cerebral peduncles, medial lemniscus, tegmentum of the midbrain, superior colliculi, lateral geniculate body, and posterolateral nucleus of the thalamus, choroid plexus, and hippocampus. On the rare occasions when atheroma occur more distally in the posterior cerebral artery (Fig. 361-5), occlusion may produce ischemia in the inferomedial temporal lobe, parahippocampal and hippocampal gyri, and occipital lobe -- including the primary visual cortex and the visual association areas.

In addition to atherothrombosis and embolism, posterior circulation disease may also be caused by dissection of either vertebral artery and fibromuscular dysplasia.

VERTEBRAL AND POSTERIOR INFERIOR CEREBELLAR ARTERIES The vertebral artery, which arises from the innominate artery on the right and the subclavian artery on the left, divides into four anatomic segments. The first (V1) extends from its origin to its entrance into the sixth or fifth transverse vertebral foramen. The second segment (V2) transverses the vertebral foramina from C6 to C2. The third (V3) passes through the transverse foramen and circles around the arch of the atlas to pierce the dura at the foramen magnum. The fourth (V4) segment courses upward to join the other vertebral artery to form the basilar artery; only the fourth segment gives rises to branches that supply the brainstem and cerebellum. The *posterior inferior cerebellar artery* (PICA) in its proximal segment supplies the lateral medulla and, in its distal branches, the inferior surface of the cerebellum. Anastomotic channels exist among the ascending cervical arteries, the thyrocervical arteries, the occipital artery (branch of the external carotid artery), and the second segment of the vertebral artery.

Atherothrombotic lesions have a predilection for V1 and V4 segments of the vertebral artery. The first segment may become diseased at the origin of the vessel and may produce posterior circulation emboli; collateral flow from the contralateral vertebral artery or the ascending cervical, thyrocervical, or occipital arteries is usually sufficient to prevent low-flowTIAs or stroke. When one vertebral artery is atretic and an atherothrombotic lesion threatens the origin of the other, the collateral circulation, which may also include retrograde flow down the basilar artery, is often insufficient (Figs. 361-1 and361-5). In this setting, low-flow TIAs may occur, consisting of syncope,

vertigo, and alternating hemiplegia; this state also sets the stage for thrombosis. Disease of the distal fourth segment of the vertebral artery can promote thrombus formation manifest as embolism or with propagation as basilar artery thrombosis. Stenosis proximal to the origin of the posterior inferior cerebellar artery can threaten the lateral medulla and posterior inferior surface of the cerebellum.

If the subclavian artery is occluded proximal to the origin of the vertebral artery, there is a reversal in the direction of blood flow in the ipsilateral vertebral artery. Exercise of the ipsilateral arm may increase demand on vertebral flow, producing posterior circulationTIAs, or "subclavian steal."

Although atheromatous disease rarely narrows the second and third segments of the vertebral artery, this region is subject to dissection, fibromuscular dysplasia, and, rarely, encroachment by osteophytic spurs within the vertebral foramina.

BASILAR ARTERY Branches of the basilar artery supply the base of the pons and superior cerebellum and fall into three groups: (1) paramedian, 7 to 10 in number, which supply a wedge of pons on either side of the midline; (2) short circumferential, 5 to 7 in number, which supply the lateral two-thirds of the pons and middle and superior cerebellar peduncles; and (3) bilateral long circumferential (superior cerebellar and anterior inferior cerebellar arteries), which course around the pons to supply the cerebellar hemispheres.

Atheromatous lesions can occur anywhere along the basilar trunk but are most frequent in the proximal basilar and distal vertebral segments. Typically, lesions occlude either the proximal basilar and one or both vertebral arteries. The clinical picture varies depending on the availability of retrograde collateral flow from the posterior communicating arteries. Rarely, dissection of a vertebral artery may involve the basilar artery and, depending on the location of true and false lumen, may produce multiple penetrating artery strokes.

Although atherothrombosis occasionally occludes the distal portion of the basilar artery, emboli from the heart or proximal vertebral or basilar segments are more commonly responsible for "top of the basilar" syndromes.

Clinical Manifestations

POSTERIOR CEREBRAL ARTERY Embolic occlusion is the usual cause of stroke in this vascular territory. Two syndromes are commonly observed: (1) midbrain, subthalamic, and thalamic signs, which are due to disease of the P1 segment or of its penetrating branches; and (2) cortical temporal and occipital lobe signs, due to occlusion of the P2 segment.

1. *P1 syndromes*. If the P1 segment is occluded, infarction usually occurs in the ipsilateral subthalamus and medial thalamus and in the ipsilateral cerebral peduncle and midbrain (Fig. 361-5). A third nerve palsy with contralateral ataxia (Claude's syndrome) or with contralateral hemiplegia (Weber's syndrome) may result. The ataxia indicates involvement of the red nucleus or dentatorubrothalamic tract; the hemiplegia is localized to the cerebral peduncle. If the subthalamic nucleus is involved, contralateral

hemiballismus may occur. Occlusion of the artery of Percheron produces paresis of upward gaze and drowsiness, and often abulia. Extensive infarction in the midbrain and subthalamus occurring with bilateral proximal posterior cerebral artery occlusion presents as coma, unreactive pupils, bilateral pyramidal signs, and decerebrate rigidity.

Atheromatous occlusion of the penetrating branches of thalamic and thalamogeniculate arteries produces less extensive thalamic and thalamocapsular lacunar syndromes. The *thalamic Dejerine-Roussy syndrome* is the best known. Its main feature is contralateral hemisensory loss followed later by an agonizing, searing or burning pain in the affected areas. It is persistent and responds poorly to analgesics. Anticonvulsants (carbamazepine or gabapentin) or tricyclic antidepressants may be beneficial. Associated motor signs include hemiparesis, hemiballismus, choreoathetosis, intention tremor, incoordination, and posturing of the hand and arm, particularly while walking.

2. *P2 syndromes* (see alsoFig. 361-5). Occlusion of the distal posterior cerebral artery causes infarction of the medial temporal and occipital lobes. Contralateral homonymous hemianopia with macula sparing is the usual manifestation. Occasionally, only the upper quadrant of visual field is involved. If the visual association areas are spared and only the calcarine cortex is involved, the patient may be aware of visual defects. Medial temporal lobe and hippocampal involvement may cause an acute disturbance in memory, particularly if it occurs in the dominant hemisphere. The defect usually clears because memory has bilateral representation. If the dominant hemisphere is affected and the infarct extends to involve the splenium of the corpus callosum, the patient may demonstrate alexia without agraphia. Visual agnosia for faces, objects, mathematical symbols, and colors and anomia with paraphasic errors (amnestic aphasia) may also occur in this setting, even without callosal involvement. Occlusion of the posterior cerebral artery can produce *peduncular hallucinosis* (visual hallucinations of brightly colored scenes and objects).

Bilateral infarction in the distal posterior cerebral arteries produces cortical blindness (blindness with preserved pupillary light reaction). The patient is often unaware of the blindness or may even deny it (*Anton's syndrome*). Tiny islands of vision may persist, and the patient may report that vision fluctuates as images are captured in the preserved portions. Rarely, only peripheral vision is lost and central vision is spared, resulting in "gun-barrel" vision. A constellation of symptoms termed *Balint's syndrome* can occur, usually with bilateral visual association area lesions. It includes optic ataxia (inability to visually guide limb movements), ocular ataxia (inability to direct eyes to a precise point in the visual field), inability to enumerate objects in a picture (simultagnosia) or extract meaning from a picture, and inability to avoid objects in one's path. Balint's syndrome occurs most often with infarctions secondary to low flow in the "watershed" between the distal posterior and middle cerebral artery territories, as occurs after cardiac arrest. Patients may even experience persistence of a visual image for several minutes despite gazing at another scene (*palinopia*). Embolic occlusion of the top of the basilar artery can produce any or all of the central or peripheral territory symptoms. The hallmark is the sudden onset of bilateral signs, including ptosis, pupillary asymmetry or lack of reaction to light, and somnolence.

VERTEBRAL AND POSTERIOR INFERIOR CEREBELLAR ARTERIES Embolic occlusion or thrombosis of a V4 segment causes ischemia of the lateral medulla. The

constellation of vertigo, numbness of the ipsilateral face and contralateral limbs, diplopia, hoarseness, dysarthria, dysphagia, and ipsilateral Horner's syndrome is called the lateral medullary (or Wallenberg's) syndrome (Fig. 361-6). Most cases result from ipsilateral vertebral artery occlusion; in the remainder,PICAocclusion is responsible. Occlusion of the medullary penetrating branches of the vertebral artery or PICA results in partial syndromes. *Hemiparesis is not a feature of vertebral artery occlusion*.

Rarely, a *medial medullary syndrome* occurs with infarction of the pyramid and contralateral hemiparesis of the arm and leg, sparing the face. If the medial lemniscus and emerging hypoglossal nerve fibers are involved, contralateral loss of joint position sense and ipsilateral tongue weakness occur.

Cerebellar infarction with edema can lead to *sudden respiratory arrest* due to raised intracranial pressure (ICP) in the posterior fossa. Drowsiness, Babinski signs, dysarthria, and bifacial weakness may be absent, or present only briefly, before respiratory arrest ensues. Gait unsteadiness, dizziness, nausea, and vomiting may be the only early symptoms and signs and should arouse suspicion of this impending complication, which may require neurosurgical decompression, often with an excellent outcome.

BASILAR ARTERY Because the brainstem contains many structures in close apposition, a diversity of clinical syndromes may emerge with ischemia, reflecting involvement of the corticospinal and corticobulbar tracts, ascending sensory tracts, and cranial nerve nuclei (Figs. 361-7,361-8, and361-9).

The symptoms of transient ischemia or infarction in the territory of the basilar artery often do not indicate whether the basilar artery itself or one of its branches is diseased, yet this distinction has important implications for therapy. *The picture of complete basilar occlusion, however, is easy to recognize as a constellation of bilateral long tract signs (sensory and motor) with signs of cranial nerve and cerebellar dysfunction*. A "locked-in" state of preserved consciousness with quadriplegia and cranial nerve signs suggest complete pontine and lower midbrain infarction. The therapeutic goal is to identify *impending* basilar occlusion before devastating infarction occurs. A series ofTIAs and a slowly progressive, fluctuating stroke are extremely significant as they often herald an atherothrombotic occlusion of the distal vertebral or proximal basilar artery.

TIAsin the proximal basilar distribution may produce dizziness (often described by patients as "swimming," "swaying," "moving," "unsteadiness" or "light-headedness"). Other symptoms that warn of basilar thrombosis include diplopia, dysarthria, facial or circumoral numbness, and hemisensory symptoms. In general, symptoms of basilar branch TIAs affect one side of the brainstem, whereas symptoms of basilar artery TIAs usually affect both sides, though a "herald" hemiparesis has been emphasized as an initial symptom of basilar occlusion. Most often TIAs, whether due to impending occlusion of the basilar artery or a basilar branch, are short-lived (5 to 30 min) and repetitive, occurring several times a day. The pattern suggests intermittent reduction of flow. Many neurologists treat with heparin to prevent clot propagation.

Atherothrombotic occlusion of the basilar artery with infarction usually causes *bilateral* brainstem signs. A gaze paresis or internuclear ophthalmoplegia associated with

ipsilateral hemiparesis may be the only manifestations of bilateral brainstem ischemia. More often, unequivocal signs of bilateral pontine disease are present. Complete basilar thrombosis carries a high mortality.

Occlusion of a branch of the basilar artery usually causes *unilateral* symptoms and signs involving motor, sensory, and cranial nerves. As long as symptoms remain unilateral, concern over pending basilar occlusion should be reduced.

SUPERIOR CEREBELLAR ARTERY Occlusion results in severe ipsilateral cerebellar ataxia, nausea and vomiting, dysarthria, and contralateral loss of pain and temperature sensation over the extremities, body, and face (spino- and trigeminothalamic tract). Partial deafness, ataxic tremor of the ipsilateral upper extremity, Horner's syndrome, and palatal myoclonus may occur rarely. Partial syndromes occur frequently (Fig. 361-7). With large strokes, swelling and mass effects may compress the midbrain or produce hydrocephalus; these symptoms may evolve rapidly. Neurosurgical intervention may be lifesaving in such cases.

ANTERIOR INFERIOR CEREBELLAR ARTERY Occlusion produces variable degrees of infarction because the size of this artery and the territory it supplies vary inversely with those of thePICA. The principal symptoms include: (1) ipsilateral deafness, facial weakness, vertigo, nausea and vomiting, nystagmus, tinnitus, cerebellar ataxia, Horner's syndrome, and paresis of conjugate lateral gaze; and (2) contralateral loss of pain and temperature sensation. An occlusion close to the origin of the artery may cause corticospinal tract signs (Fig. 361-9).

Occlusion of one of the short circumferential branches of the basilar artery affects the lateral two-thirds of the pons and middle or superior cerebellar peduncle, whereas occlusion of one of the paramedian branches affects a wedge-shaped area on either side of the medial pons (Figs. 361-7,361-8, and361-9).

Small Vessel "Lacunar" Stroke The term *lacunar infarction* refers to infarction following atherothrombotic or lipohyalinotic occlusion of one of the small, penetrating branches of the circle of Willis, middle cerebral artery stem, or vertebral and basilar arteries. The term *small vessel stroke* denotes occlusion of a small penetrating artery, regardless of mechanism.

Pathophysiology The middle cerebral artery stem, the arteries comprising the circle of Willis (A1 segment, anterior and posterior communicating arteries, and P1 segment), and the basilar and vertebral arteries all give rise to 100- to 300-um branches that penetrate the deep gray and white matter of the cerebrum or brainstem (Fig. 361-1). Each of these small branches can occlude either by atherothrombotic disease at its origin or by the development of lipohyalinotic thickening. Thrombosis of these vessels causes small infarcts that are referred to as *lacunes* (Latin for "lake" of fluid noted at autopsy). They range in size from 3 or 4 mm to 1 or 2 cm. Hypertension and age are the principal risk factors. Lacunar infarcts cause approximately 20% of all strokes.

Clinical Manifestations The most common *lacunar syndromes* are the following: (1) Pure motor hemiparesis from an infarct in the posterior limb of the internal capsule or basis pontis; the face, arm and leg are almost always involved. (2) Pure sensory stroke from

an infarct in the ventrolateral thalamus. (3) Ataxic hemiparesis from an infarct in the base of the pons. (4) Dysarthria and a clumsy hand or arm due to infarction in the base of the pons or in the genu of the internal capsule. (5) Pure motor hemiparesis with "motor (Broca's) aphasia" due to thrombotic occlusion of a lenticulostriate branch supplying the genu and anterior limb of the internal capsule and adjacent white matter of the corona radiata.

Syndromes 1 and 2 often overlap. Syndromes resulting from occlusion of the penetrating arteries of the proximal posterior cerebral artery were discussed above. Syndromes resulting from occlusion of the penetrating arteries of the basilar artery (Figs. 361-7, 261-8, and361-9) include ipsilateral ataxia and contralateral crural (leg) paresis, hemiparesis with horizontal gaze palsy, and hemiparesis with a crossed sixth nerve palsy. Lower basilar branch syndromes include internuclear ophthalmoplegia, horizontal gaze palsy, and appendicular cerebellar ataxia.

An anarthric pseudobulbar syndrome due to bilateral infarctions in the internal capsule can occur from disease in the lenticulostriate arteries. Before the advent of effective therapy for hypertension, multiple lacunes often caused pseudobulbar palsy (predominantly dysarthria and dysphagia) with emotional instability, a slowed abulic state, and bilateral pyramidal signs.

Transient symptoms (lacunarTIAs) may herald a lacunar infarct; they may occur several times a day and last only a few minutes. Recovery from a lacunar stroke often begins within hours or days, and over weeks or months may be nearly complete; in some cases, however, there is severe permanent disability. Often, institution of combined antithrombotic treatments does not prevent eventual stroke in "stuttering lacunes."

A large vessel source (either thrombosis or embolism) may manifest initially as a lacunar syndrome with small vessel infarction. Therefore, the search for embolic sources (carotid and heart) should not be abandoned in the evaluation of these patients.

FINDING THE CAUSE OF STROKE

The clinical presentation, temporal profile, and signs found on examination often establish the cause or narrow the possibilities to a few. Judicious use of laboratory testing and imaging studies complete the initial evaluation. For stroke without an identified cause (cryptogenic stroke), the exact diagnosis may be made months or years later as new symptoms develop. Unfortunately, nearly 30% of strokes remains unexplained despite extensive evaluation; nevertheless, they occur in patients with the same clinical profiles as those whose strokes are due to atherothrombosis.

Clinical examination should be focused on the peripheral vascular system (carotid auscultation for bruits, blood pressure, and pressure comparison between arms), the heart (dysrhythmia, murmurs), extremities (peripheral emboli), and retina [effects of hypertension and cholesterol emboli (Hollenhorst plaques)]; with a complete neurologic examination to localize the site of stroke. A chest x-ray, electrocardiogram (ECG), urinalysis, complete blood count, erythrocyte sedimentation rate, serum electrolytes, blood urea nitrogen, creatinine, blood sugar, serologic test for syphilis, serum lipid profile, prothrombin time, and partial thromboplastin time should be evaluated in all

patients. An ECG may demonstrate conduction abnormalities and arrhythmias or reveal evidence of recent myocardial infarction. A lumbar puncture (LP) will generally confirm or exclude subarachnoid hemorrhage (SAH) and can reveal meningitis as a cause for stroke. However, an LP should not be performed on patients with a possible intracranial mass lesion and therefore should generally be avoided in patients with a suspected stroke who are comatose or who have lateralizing neurologic signs with indications of increasedICP. Finally, an imaging study of the brain is nearly always performed and is required for patients being considered for thrombolysis.

BRAIN IMAGING (See alsoChap. 358)

Computed Tomographic Scans Computed tomography (CT) images identify or exclude hemorrhage as the cause of stroke, and they identify extraparenchymal hemorrhages, neoplasms, abscesses, and other conditions masquerading as stroke. Scans obtained in the first several hours after an infarction generally show no abnormality, and the infarct may not be seen reliably for 24 to 48 h. Even later, CT may fail to show small ischemic strokes in the posterior fossa because of bone artifact and may also miss small infarcts on the cortical surface. The CT scan documents most supratentorial lacunar infarcts. Lacunar infarction is diagnosed when the infarct size is <2 cm and its location is consistent with occlusion of a small penetrating branch of a major artery at the base of the brain. Larger deep white matter infarcts in the territory of theMCA may present as a lacunar syndrome but are caused by occlusions of large vessels and compensatory collateral perfusion.

Contrast-enhancedCT scans add specificity by showing contrast enhancement of subacute infarcts and allow visualization of venous structures. Coupled with newer generation scanners, administration of intravenous contrast allows visualization of large cerebral arteries. Such "CT angiograms" may be useful in acute stroke management to reveal the presence or absence of large vessel pathology.

Magnetic Resonance Imaging (MRI) MRI reliably documents the extent and location of infarction in all areas of the brain, including the posterior fossa and cortical surface, if appropriate imaging sequences are obtained. It also identifies intracranial hemorrhage and other abnormalities. The higher the field strength, the more reliable and precise the image. Diffusion-weighted imaging is more sensitive for early brain infarction than standard magnetic resonance (MR) sequences (Fig. 361-10) as is FLAIR (fluid-attenuated inversion recovery) imaging (Chap. 358). MR angiography is highly sensitive for extracranial internal carotid plaque as well as intracranial stenosis of large vessels. With higher degrees of stenosis, MR angiography tends to overestimate the degree of stenosis when compared to conventional x-ray angiography. MRI with fat saturation is an imaging sequence used to visualize extra- or intracranial arterial dissection. This sensitive technique images clotted blood within the dissected vessel wall and has revealed carotid or vertebral dissection as the cause of stroke in a sizable fraction of young patients (age<45). Stroke with neck, jaw, or retroauriclar pain, with or without Horner's syndrome, should prompt this imaging modality or conventional x-ray angiography.

MRIis less sensitive for acute blood products thanCT and is more expensive and less readily available. Claustrophobia also limits its application. Most acute stroke protocols

use CT because of these limitations. However, outside this setting, MRI provides superior information compared with CT in nearly every case of stroke.

Cerebral Angiography Conventional x-ray cerebral angiography is the "gold standard" for identifying and quantifying atherosclerotic stenoses of the cerebral arteries and other pathologies, including aneurysm, vasospasm, intraluminal thrombi, fibromuscular dysplasia, arteriovenous fistula, vasculitis, and collateral channels of blood flow. Endovascular techniques, which are evolving rapidly, can be used to deploy stents within delicate intracranial vessels and perform balloon angioplasty of stenotic lesions. Recent studies have documented that intraarterial delivery of thrombolytic agents to patients with acuteMCAstroke can effectively recanalize vessels and improve clinical outcomes. Although investigational in many centers, use of cerebral angiography coupled with endovascular techniques for cerebral revascularization may become routine in the near future.

Ultrasound Techniques Stenosis at the origin of the internal carotid artery can be identified and quantified reliably by ultrasonography that combines a B-mode ultrasound image with a Doppler ultrasound assessment of flow velocity ("Duplex" ultrasound). Transcranial Doppler (TCD) assessment of middle, anterior, and posterior cerebral artery flow and of vertebrobasilar flow is also useful. This latter technique can detect stenotic lesions in the middle cerebral stem, the distal vertebral arteries, and the basilar artery because such lesions increase systolic flow velocity. When there is an occlusion or hemodynamically significant stenosis at the origin of the internal carotid artery or in the carotid siphon, TCD assesses collateral flow across the anterior or posterior circle of Willis. In many cases,MRangiography combined with carotid and transcranial ultrasound studies eliminates the need for conventional x-ray angiography in evaluating carotid artery lesions for surgery. The combination of the two studies is less expensive than x-ray angiography and reduces the risk of stroke secondary to the procedure.

Ultrasound cannot distinguish reliably between complete and near-complete carotid occlusion; this distinction can be made reliably only by x-ray angiography.

Other Techniques Both xenon techniques (principally xenon-CT) and positron emission tomography (PET) can quantify cerebral blood flow. These tools are generally used for research (Chap. 358) but can be useful for determining the significance of arterial stenosis and planning for revascularization surgery. Single photon emission tomography (SPECT), CT-perfusion, andMR-perfusion techniques report relative cerebral blood flow and currently are research tools.

FINDING EMBOLIC SOURCES

If the clinical syndrome of stroke suggests large vessel ischemia or is sudden in onset or if imaging studies reveal infarction consistent with embolism, a search for the cause of embolism is warranted. Documentation of the exact embolic source can direct therapy that can lessen mortality and morbidity. Embolic stroke is classified by the artery involved (e.g., embolicMCAstroke, as discussed above) or by the source of embolism, either from another artery (artery-to-artery embolic stroke) or cardioembolic. Both causes of embolic stroke are discussed below.

Cardioembolic Stroke

Pathophysiology Cardioembolism causes approximately 20% of all ischemic strokes. Stroke caused by heart disease is primarily due to embolism of thrombotic material forming on the atrial or ventricular wall or the left heart valves. These thrombi then detach and embolize the arterial circulation. The thrombus may fragment or lyse quickly, producing onlyTIA. Alternatively, the arterial occlusion may last longer, producing stroke. Subsequent thrombosis distal to the obstruction may occur, producing stroke in progression.

Emboli from the heart most often lodge in theMCA or one of its branches; infrequently, the anterior cerebral artery territory is involved. Emboli large enough to occlude the stem of the MCA (3 to 4 mm) lead to large infarcts that involve both deep gray and white matter and some portions of the cortical surface and its underlying white matter. A smaller embolus may occlude a small cortical or penetrating arterial branch. The location and size of an infarct within a vascular territory often depend on the extent of the collateral circulation.

Vascular congestion of varying degree is common to all ischemic strokes, but extravasation of blood is often associated with embolic infarcts. Because emboli migrate and lyse, recirculation into the infarcted brain may cause petechial hemorrhages. Sometimes there is enough seepage of blood into the infarct to cause visible hemorrhagic infarction on aCT scan. This *hemorrhagic transformation* of a pale infarct typically occurs from 12 to 36 h after embolization and is often asymptomatic. Frank hemorrhage into the infarct sometimes occurs and almost always causes clinical worsening. This is more likely to occur when the stem of theMCA is occluded and a large infarct develops in the territory of the lenticulostriate arteries before recirculation occurs. Edema invariably accompanies the tissue necrosis. In large infarcts, massive edema may compress adjacent tissue, adding to the ischemic process; it also increasesICP and may cause herniation of the brain from one intracranial compartment to another.

The most frequent causes of cardioembolic stroke in most of the world are nonrheumatic (often called nonvalvular) atrial fibrillation, myocardial infarction, prosthetic valves, rheumatic heart disease, and ischemic cardiomyopathy (Table 361-2). Cardiac disorders causing brain embolism are discussed in the respective chapters on heart diseases. A few pertinent aspects are highlighted here.

Nonrheumatic atrial fibrillation is the most common cause of cerebral embolism. Patients with atrial fibrillation have an average annual risk of stroke of ~5%. The risk varies according to the presence of certain risk factors, including older age, hypertension, poor left ventricular function, prior cardioembolism, diabetes, and thyrotoxicosis. Patients younger than 60 with none of these risk factors have an annual risk for stroke of about 0.5%, while those with most of the factors have a rate of about 15%. Guidelines for the use of warfarin are based on risk factors (Table 361-5). The presumed stroke mechanism is thrombus formation in the fibrillating atrium or atrial appendage with subsequent embolization. Left atrial enlargement and congestive heart failure are additional risk factors for formation of atrial thrombi. Rheumatic heart disease usually causes ischemic stroke when there is prominent mitral stenosis or atrial

fibrillation.

The cardioembolic causes of stroke are enumerated in Table 361-2. A recent myocardial infarction may be a source of emboli, especially when transmural and involving the anteroapical ventricular wall. Mitral valve prolapse is not usually a source of emboli unless the prolapse is severe.

Paradoxical embolization occurs when venous thrombi migrate to the arterial circulation, usually via a patent foramen ovale or atrial septal defect, which may be occult. Bubble-contrast echocardiography (intravenous injection of agitated saline coupled with either transthoracic or transesophageal echocardiography) can demonstrate a right-to-left shunt, revealing the conduit for paradoxical embolization. Alternatively, a right-to-left shunt is implied if immediately following intravenous injection of agitated saline, high-intensity transients (HITs) can be observed duringTCDinsonation of theMCA. Both techniques are highly sensitive for detection of right-to-left shunts. Fat and tumor emboli, bacterial endocarditis, and air and amniotic fluid emboli associated with delivery may occasionally be responsible.

Bacterial endocarditis causes valvular vegetations that can give rise to multiple septic emboli (Chap. 126). The appearance of multifocal or diffuse symptoms and signs in a patient with stroke makes bacterial endocarditis a more likely consideration. Infarcts of microscopic size occur, and large septic infarcts may evolve into brain abscesses. Large septic emboli may cause hemorrhage into the infarct, which usually precludes use of anticoagulation or thrombolytics. Mycotic aneurysms caused by septic emboli give rise toSAH or intracerebral hemorrhage.

Clinical Manifestations The stroke is nearly always sudden and maximal at onset. Certain neurologic syndromes suggest embolism, often cardioembolism, as their cause. In theMCAterritory these include (1) the frontal opercular syndrome, with facial weakness and severe aphasia or dysarthria; (2) the brachial or hand plegia syndrome, in which the arm or hand is paralyzed with or without cortical sensory abnormalities; (3) Broca's or Wernicke's aphasia alone; or (4) left visual neglect, when the nondominant parietal lobe is involved. Sudden hemianopia suggests a posterior cerebral artery embolus, and sudden foot and shoulder weakness suggests an anterior cerebral embolus. Sudden sleepiness and inability to look up associated with bilateral ptosis suggest an embolus to the top of the basilar artery, specifically to the artery of Percheron (see above).

Seizures at the time of stroke occur in 3 to 5% of infarctions, are more often associated with embolic stroke rather than thrombosis, and are usually associated with supratentorial cortical surface infarctions. Another 3 to 5% of patients develop epilepsy 6 to 18 months after stroke. Many cases of idiopathic epilepsy in the elderly are probably the result of silent cortical infarction.

Artery-to-Artery Stroke Thrombus formation on atherosclerotic plaques may embolize to distant arteries. The most common source is the carotid bifurcation, but any diseased vessel may be a source, including the aortic arch and common carotid, internal carotid, and vertebral-basilar arteries.

Dissection of the internal carotid or vertebral arteries or even vessels beyond the circle of Willis is a common source of embolic stroke in young patients. The dissection is usually painful and precedes stroke by several hours or days. Extracranial dissections rarely cause hemorrhage because of the tough adventitia of these vessels. Intracranial dissections, on the other hand, may produceSAHbecause the adventitia of intracranial vessels is thin, and pseudoaneurysms may form, requiring treatment to prevent rerupture. The cause of dissection is usually unknown and recurrence is rare. Ehlers-Danlos type IV, Marfan's disease, cystic medial necrosis, and fibromuscular dysplasia are associated with dissections. Trauma (usually a motor vehicle accident or a sports injury) can cause carotid and vertebral artery dissections. Chiropractic neck manipulation is also associated with dissection and stroke.

Laboratory and Imaging Evaluation for Embolic Stroke A thorough cardiac evaluation should be undertaken in patients in whom the suspicion of cardioembolism is high. This includes the young, those with a history of heart disease, those with multifocal or hemorrhagic infarcts, and those with seizures at onset. ContinuousECGmonitoring may reveal intermittent atrial fibrillation. An echocardiogram may disclose mitral valve disease, an intracardiac thrombus or tumor, or a dyskinetic area of myocardium. Spontaneous echo contrast within the atrial appendage is associated with stroke and may represent a tendency for spontaneous clotting of blood within the atrium. Transesophageal echocardiography is superior to the transthoracic technique for visualization of valves, left atrium, and aortic arch. Intravenous bubble contrast should be administered to all patients undergoing echocardiography in search of an embolic source. The presence of atrial fibrillation alone is sufficient to establish cause, even in the absence of a left atrial clot.

Embolic infarction may appear as a single low-density area compatible with pale infarction onCTimaging. Petechial hemorrhages within the area may be seen as well and are more likely a day or two after the infarction.MRIscanning better documents infarction both supra- and infratentorially; when coupled withMRangiography, it can help identify arterial sources of emboli from either the extra- or intracranial vessels. MRI with fat saturation should be performed on patients with neck pain preceding stroke, as this technique is highly sensitive for detecting arterial dissection. Carotid ultrasonography andTCDtechniques may reveal carotid atherosclerosis or intracranial stenosis, respectively. Conventional x-ray angiography is rarely indicated.

Arterial imaging (CT orMRangiography orTCD) performed in the early hours of stroke often shows occlusion of one or more vessels. Complete lysis of emboli often occurs, and angiography performed after several days may be normal.

LESS COMMON CAUSES OF STROKE (Table 361-2)

Hypercoagulable disorders (Chap. 62) primarily cause increased venous thrombotic risk and therefore may cause venous sinus thrombosis. Protein S deficiency and homocysteinemia may cause arterial thromboses as well. Systemic lupus erythematosus with Libman-Sacks endocarditis can be a cause of embolic stroke. These conditions overlap with the antiphospholipid syndrome, which probably requires long-term anticoagulation to prevent further stroke.

Venous sinus thrombosis of the lateral or sagittal sinus or of small cortical veins (cortical vein thrombosis) occurs as a complication of pregnancy and the postpartum period, sepsis, and intracranial infections (meningitis). It is seen with increased incidence in patients with laboratory-confirmed thrombophilia (Table 361-2) including polycythemia, sickle cell anemia, proteins C and S deficiency, factor V Leiden mutation (resistance to activated protein C), antithrombin III deficiency, homocysteinemia, and the prothrombin G20210 mutation. Women who take oral contraceptives and have the prothrombin G20210 mutation may be at high risk for sinus thrombosis. Patients present with headache, focal neurologic signs (especially paraparesis), and seizures. Often,CTimaging is normal unless an intracranial venous hemorrhage has occurred, but the venous sinus occlusion is readily visualized usingMRvenography or conventional x-ray angiography. With greater degrees of sinus thrombosis, the patient may develop signs of increasedICP and coma. Intravenous heparin, regardless of the presence of intracranial hemorrhage, has been shown to reduce morbidity and mortality, and the long-term outcome is generally good. Heparin prevents further thrombosis and reduces venous hypertension and ischemia. If an underlying hypercoagulable state is not found, many physicians treat with warfarin for 3 to 6 months then convert to aspirin, depending on the degree of resolution of the venous sinus clot, and continue indefinite anticoagulation if thrombophilia is diagnosed.

Fibromuscular dysplasia affects the cervical arteries and occurs mainly in women. The carotid or vertebral arteries show multiple rings of segmental narrowing alternating with dilatation. Occlusion is usually incomplete. The process is often asymptomatic but occasionally is associated with an audible bruit,TIAs, or stroke. The cause and natural history of fibromuscular dysplasia is unknown (Chap. 248). TIA or stroke generally occurs only when the artery is severely narrowed or dissects. Anticoagulation or antiplatelet therapy may be helpful.

Temporal (giant cell) arteritis (Chap. 317) (Figs. 28-CD1 and28-CD2) is a relatively common affliction of elderly persons in which the external carotid system, particularly the temporal arteries, becomes the site of a subacute granulomatous inflammation with giant cells. Occlusion of posterior ciliary arteries derived from the ophthalmic artery results in blindness in one or both eyes and can be prevented with glucocorticoids. It rarely causes stroke as the internal carotid artery is usually not inflamed. Idiopathic giant cell arteritis involving the great vessels arising from the aortic arch (Takayasu's arteritis) may cause carotid or vertebral thrombosis; it is rare in the western hemisphere.

Necrotizing (or granulomatous) arteritis, occurring alone or in association with generalized polyarteritis nodosa or Wegener's granulomatosis, involves the distal small branches (<2 mm diameter) of the main intracranial arteries and produces small ischemic infarcts in the brain, optic nerve, and spinal cord. The cerebrospinal fluid often shows pleocytosis, and the protein level is elevated. *Primary central nervous system vasculitis* is rare; small or medium-sized vessels are usually affected. Brain biopsy or high-resolution conventional x-ray angiography is usually required to make the diagnosis. Patients with any form of vasculitis may present with insidious progression of combined white and gray matter infarctions, prominent headache, and cognitive decline. Aggressive immunosuppression with glucocorticoids, and often cyclophosphamide, is usually necessary to reverse the ischemia. Depending upon the duration of the disease, many patients can make an excellent recovery.

Drugs, in particular amphetamines and perhaps cocaine, may cause stroke on the basis of acute hypertension and drug-induced vasculitis. Abstinence appears to be the best treatment, as no data exist on use of any treatment.

Arteritis can also occur as a consequence of bacterial, tuberculous, and syphilitic meningitis.

Moyamoya disease is a poorly understood occlusive disease involving large intracranial arteries, especially the distal internal carotid artery and the stem of the middle and anterior cerebral arteries. Vascular inflammation is absent. The lenticulostriate arteries develop a rich collateral circulation around the occlusive lesion, which gives the impression of a "puff of smoke" ("moyamoya" in Japanese) on conventional x-ray angiography. Other collaterals include transdural anastomoses between the cortical surface branches of the meningeal and the scalp arteries. The disease occurs mainly in Asian children or young adults but can occur in adults who have atherosclerosis. The etiology of the childhood form is unknown. Because of the occurrence ofSAH from rupture of the transdural anastomotic channels, anticoagulation is risky. Breakdown of dilated lenticulostriate arteries may produce parenchymal hemorrhage, and progressive occlusion of large surface arteries can occur, producing large artery distribution strokes. Bypass of extracranial carotid arteries to the dura orMCAs may prevent stroke and hemorrhage.

Reversible widespread cerebral segmental vasoconstriction is hypothesized to occur in certain patients with headache and fluctuating neurologic symptoms and signs. Sometimes cerebral infarction ensues. The cause is unknown. Head injury, migraine, sympathomimetic drug use, eclampsia, and the postpartum period have all been associated with this entity. Conventional x-ray angiography is the only means of establishing the diagnosis, but because angiography itself can cause spasm of vessels, even the existence of this vascular entity is debated.

Binswanger's disease (chronic progressive subcortical encephalopathy) is a rare condition in which infarction of the subcortical white matter occurs subacutely.CT orMRIscans detect periventricular white matter infarcts and gliosis. There is lipohyalinosis in the small arteries of the deep white matter, as in hypertension. There are usually associated lacunar infarcts. Binswanger's disease may represent a type of border zone ischemic infarction in the deep white matter between the penetrating arteries of the circle of Willis and of the cortex. The pathophysiologic basis of the disease is unclear, but it typically occurs in older patients with severe long-standing hypertension.

CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leukoencephalopathy) is an inherited disorder that presents as small vessel strokes, progressive dementia, and extensive symmetric white matter changes visualized byMRI. Approximately 40% of patients have migraine with aura, often manifest as transient motor or sensory deficits. Onset is usually in the fourth or fifth decade of life. This autosomal dominant condition is caused by a missense mutation in Notch-3, a member of a highly conserved gene family characterized by epidermal growth factor repeats in its extracellular domain. Definitive diagnosis is made by brain biopsy revealing typical

osmophilic inclusions within smooth-muscle cells of blood vessels; these inclusions may also be present in skin biopsy sections. CADASIL is the only monogenic ischemic stroke syndrome so far described. Genetic testing is not currently available except on a research basis.

TREATMENT

Acute Stroke Management After the clinical diagnosis of stroke is made, an orderly process of evaluation and treatment should follow (Table 361-4). The first goal is to prevent or reverse brain injury. After initial stabilization, an emergency noncontrast headCT scan should be performed to differentiate ischemic from hemorrhagic stroke; there are no reliable clinical findings that conclusively separate ischemia from hemorrhage, although a more depressed level of consciousness and higher initial blood pressure favor hemorrhage, and a deficit that remits suggests ischemia. The second goal is to obtain an accurate understanding of the stroke mechanism so one can halt progression of brain injury or begin to prevent a second stroke. Often this is done during an acute hospitalization, but depending on stroke severity, it may be performed in the outpatient setting. There exists no consensus on the rate with which this evaluation should proceed, primarily because there are few data on the daily risks of recurrence following an initial stroke.

General Principles During focal brain ischemia, a gradation in brain perfusion exists such that a core of tissue is infarcted within minutes but a shell of surrounding tissue is only marginally ischemic. This *ischemic penumbra* may progress to infarction within minutes to hours depending on a number of factors (Chap. 376). Salvage of this "at risk" tissue is the goal of emergency stroke therapy. The penumbral tissue will infarct with only minor drops in systemic blood pressure because cerebral autoregulation within this zone is impaired. *Therefore, a patient's blood pressure at presentation should not be lowered* unless it is >185/110 and thrombolytic therapy will be given (see below). Revascularization of the parent vessel occlusion can restore blood flow to the penumbra and prevent infarction. This concept fuels research into intravenous and intraarterial thrombolysis as well as mechanical means of arterial thrombectomy.

Treatments designed to reverse or lessen the amount of tissue infarction fall within five categories: (1) medical support, (2) thrombolysis, (3) anticoagulation, (4) antiplatelet agents, and (5) neuroprotection.

Medical Support When cerebral infarction occurs, the immediate goal is to optimize cerebral perfusion in the surrounding ischemic area. Attention is also directed toward preventing the common complications of bedridden patients -- infections (pneumonia, urinary tract, and skin) and deep venous thrombosis with pulmonary embolism.

Elevated blood pressure should not be lowered unless there is malignant hypertension (Chap. 246) or concomitant myocardial ischemia. When faced with the competing demands of myocardium and brain, heart rate lowering with the β_1-adrenergic blocker esmolol can be a first step to decrease cardiac work and maintain blood pressure. If the blood pressure is low, raising it is advisable, using intravenous fluids or vasopressor drugs to enhance perfusion within the ischemic penumbra. Fever is detrimental and should be treated with antipyretics.

Between 5 and 10% of patients develop enough cerebral edema to cause obtundation or brain herniation. Edema peaks on the second or third day but causes mass effect for 10 days. The larger the infarct, the greater the likelihood that clinically significant edema will develop. Even small amounts of cerebellar edema can acutely increaseICP in the posterior fossa. The resulting brainstem compression may result in coma and respiratory arrest and require emergency surgical decompression. Water restriction and intravenous mannitol may be used to raise the serum osmolarity, but hypovolemia should be avoided as this may contribute to hypotension and worsening infarction. Trials are under way to test the clinical benefits of craniotomy and elevation of the skull (hemicraniectomy) for large hemispheric infarcts with marked cerebral edema.

Thrombolysis The use of thrombolytic agents in acute cerebral infarction has been studied extensively. Angiography performed within a few hours of infarction frequently demonstrates arterial occlusions corresponding to patients' presenting signs and symptoms. It is this association of arterial occlusion with acute neurologic symptoms that prompted the study of thrombolytic agents in stroke patients.

Three early intravenous streptokinase trials were stopped because of a higher death rate in the streptokinase-treated patients, mainly due to symptomatic intracranial bleedings. These trials enrolled patients several hours into the stroke process, which may account for the high hemorrhage rates.

The European Cooperative Acute Stroke Study (ECASS) tested intravenous recombinant tissue plasminogen activator (rtPA; 1.1 mg/kg to a 100 mg max.; 10% as a bolus, then the remainder over 60 min) vs. placebo in patients with ischemic stroke within 6 h of onset of symptoms. The median time to treatment was 4 h. Overall, thrombolysis was not beneficial because of an excess of cerebral hemorrhage. However, in those patients who had no signs of major infarction on the initialCT scan, the functional outcome was improved.

The National Institute of Neurological Disorders and Stroke (NINDS) rtPA Stroke Study showed a clear benefit forrtPA in selected patients with acute stroke. The NINDS study used intravenous rtPA (0.9 mg/kg to a 90 mg max.; 10% as a bolus, then the remainder over 60 min) vs. placebo in patients with ischemic stroke within 3 h of onset. Half of the patients were treated within 90 min. Symptomatic intracerebral hemorrhage occurred in 6.4% of patients on rtPA and 0.6% on placebo. There was a nonsignificant 4% reduction in mortality on rtPA, (21% on placebo and 17% on rtPA) and a significant 12% absolute increase in the number of patients with only minimal disability (32%on placebo and 44% on rtPA.) Thus, despite an increased incidence of symptomatic intracerebral hemorrhage, treatment with intravenous rtPA within 3 h of the onset of ischemic stroke improved clinical outcome. A lower dose of rtPA was used than in theECASS, and half of the patients were treated within 90 min of stroke onset. These two features may account for much of the increase in benefit and decrease in bleeding hazard compared to the results seen in ECASS.

Finally,ECASS-II tested theNINDSdose ofrtPA(0.9 mg/kg, maximum dose 90 mg) but allowed patients to receive drug up to the sixth hour, as in ECASS-I. No significant benefit was found, but improvement was found in post hoc analyses.

Because of the marked differences in trial design, including drug and dose used, time to thrombolysis, and severity of stroke, the precise efficacy of intravenous thrombolytics for acute ischemic stroke remains unclear. The risk of intracranial hemorrhage appears to rise with larger strokes, longer times from onset of symptoms, and higher doses of rtPA administered. The established dose of 0.9 mg/kg administered intravenously within 3 h of stroke onset appears safe. Many hospitals have developed expert stroke teams to facilitate this treatment. The drug is now approved in the United States and Canada for acute stroke when given within 3 h from the time the stroke symptoms began, and efforts should be made to give it as early in this 3-h window as possible. The time of stroke onset is defined as the time the patient's symptoms began or the time the patient was last seen as normal. A patient who awakens with stroke has the onset defined as when they went to bed.Table 361-6 summarizes eligibility criteria and instructions for administration ofrtPA.

A recent trial of the fibrinolytic agent ancrod provides further evidence that this approach is effective in acute ischemic stroke.

There is growing interest in using thrombolytics via an intraarterial route to increase the concentration of drug at the clot and minimize systemic bleeding complications. Two recent trials [PROACT and PROACT II (prolyse in acute cerebral thromboembolism)] using intraarterial thrombolysis for acuteMCAocclusions up to the sixth hour following onset of stroke showed benefit. Nevertheless, intraarterial use in ischemic stroke is not approved by the FDA. Intraarterial treatment of basilar artery occlusions may also be beneficial for selected patients, but all intraarterial therapy remains experimental.

Anticoagulation The role of anticoagulation in atherothrombotic cerebral ischemia is uncertain. Several recent trials have investigated antiplatelet versus anticoagulant medications given within 12 to 24 h of the initial event. The U.S. Trial of Organon 10172 in Acute Stroke Treatment (TOAST), an investigational low-molecular-weight heparin, failed to show any benefit over aspirin. Use of subcutaneous unfractionated heparin versus aspirin was tested in two trials, the International Stroke Trial (IST) and the Chinese Acute Stroke Trial (CAST). Taken together, the trials, which studied an aggregate of 40,541 patients, showed a reduction in stroke and death by 1% within 2 to 4 weeks in patients treated with aspirin rather than placebo. Heparin given subcutaneously [without monitoring the partial thromboplastin time (PTT)] afforded no additional benefit over aspirin and increased bleeding rates. Therefore, trials do not support the use of heparin for patients with atherothrombotic stroke of ^{3}12 h duration.

The use of antiplatelet or anticoagulant medication in acute stroke (i.e., <6 h) is less well studied. Heparin is widely used for crescendoTIAs, despite the absence of data from controlled studies regarding this indication. In approximately 20% of patients with acute stroke, deficits will progress over several hours to 1-2 days. Many physicians heparinize all patients with recent mild ischemic stroke in order to prevent some of this worsening. Theoretically, heparin may prevent propagation of clot within a thrombosed vessel or may prevent more emboli from occurring. Some neurologists use heparin until carotid and intracranial vessel patency can be assessed then convert to aspirin if the large vessels are patent. The bleeding complication rate for 7 days of heparin is about 10% with a serious bleed rate of ~2%. Clearly the value of this approach must be clarified.

Heparinization is generally accomplished by beginning an infusion without bolus and is monitored to maintain the activatedPTT at approximately twice normal. This regimen is maintained for 2 to 5 days. During this time the patient is monitored for hemorrhagic complications, the evaluation is completed, and a decision is made regarding the need for carotid endarterectomy, long-term anticoagulation, or an antiplatelet therapy. If long-term anticoagulation is chosen, warfarin is administered and heparin discontinued when the international normalized ratio (INR) is in the range of 2 to 3.

Antiplatelet Agents Aspirin is the only antiplatelet agent that has been prospectively studied for the treatment of acute ischemic stroke. The recent large trials,IST andCAST, found that the use of aspirin within 48 h of stroke onset reduced both stroke recurrence risk and mortality minimally. Among 19,435 patients in IST, those allocated to aspirin had slightly fewer deaths within 14 days (9.0 vs. 9.4%), significantly fewer recurrent ischemic strokes (2.8 vs. 3.9%), no excess of hemorrhagic strokes (0.9 vs. 0.8%), and a trend towards a reduction in death or dependence at 6 months (61.2 vs. 63.5%). In CAST, 21,106 patients with ischemic stroke received 160 mg/d of aspirin or a placebo for up to 4 weeks. There were very small reductions in the aspirin group in early mortality (3.3 vs. 3.9%), recurrent ischemic strokes (1.6 vs. 2.1%), and dependency at discharge or death (30.5 vs. 31.6%). These trials demonstrate that the use of aspirin in the treatment of acute ischemic stroke is safe and produces a small but definite net benefit. For every 1000 acute strokes treated with aspirin, about 9 deaths or nonfatal stroke recurrences will be prevented in the first few weeks and approximately 13 fewer patients will be dead or dependent at 6 months.

Agents that act at the glycoprotein IIb/IIIa receptor are undergoing clinical trials in acute stroke treatment.

Neuroprotection Neuroprotection is the concept of providing a treatment that prolongs the brain's tolerance to ischemia long enough to allow other measures to be employed to mitigate ischemia. Hypothermia is probably the most powerful neuroprotectant but is only now the subject of clinical trials. Drugs that block the excitatory amino acid pathways have been shown to protect neurons and glia in animals, but despite multiple clinical trials they have not yet been proven to be beneficial in humans.

Primary and Secondary Prevention

General Principles A number of medical and surgical interventions, as well as life-style modifications, are available for preventing stroke. Some of these can be widely applied because of their low cost and minimal risk; others are expensive and carry substantial risk, but may be valuable for selected high-risk patients.

Evaluation of a patient's *clinical risk profile* can help determine which preventive treatments to offer. In addition to known risk factors for ischemic stroke (above), certain clinical characteristics also contribute to an increased risk of stroke (Table 361-3). The North American Symptomatic Carotid Endarterectomy Trial (NASCET; see below) found that even in patients with the same degree of carotid artery stenosis, specifically 70 to 99%, nine prospectively selected risk factors predicted the risk of vascular outcomes in the medically treated patients. The overall risk of stroke was much greater in a high-risk

group (those with more than six risk factors) than in a low-risk group (those with fewer than six risk factors). Fully 39% of patients in the high-risk group treated medically experienced an ipsilateral stroke within 2 years. The rate for the low-risk group was less than half that but was still 17%.

Atherosclerosis Risk Factors The relationship of various factors to the risk of atherosclerosis is described in Chap. 241. Older age, family history of thrombotic stroke, diabetes mellitus, hypertension, tobacco smoking, elevated blood cholesterol, and other factors are either proven or probable risk factors for ischemic stroke, largely by their link to atherosclerosis. Hypertension is the most significant of the risk factors; in general, all hypertension should be treated. The presence of known cerebrovascular disease is not a contraindication to treatment aimed at achieving normotension. Also, the value of treating systolic hypertension in older patients has been clearly established. Care must be taken to avoid overtreatment of hypertension, however; the treatment goal is to achieve normotension gradually.

Treatment of hypercholesterolemia has been well established for coronary artery disease but has been studied little in the prevention of stroke. In several recent studies, statin drugs were found to lower stroke risk. Since coronary artery disease is the most common cause of death in patients with cerebrovascular disease, treatment of hypercholesterolemia seems prudent for both the heart and brain. Tobacco smoking should be discouraged in all patients (Chap. 390). Whether or not tight control of blood sugar in patients with diabetes lowers stroke risk is uncertain.

Antiplatelet Agents

ATHEROTHROMBOTIC STROKE Platelet antiaggregation agents can prevent atherothrombotic events, includingTIA and stroke, by inhibiting the formation of intraarterial platelet aggregates. These can form on diseased arteries, induce thrombus formation, and occlude the artery or embolize into the distal circulation. Aspirin, clopidogrel, and the combination of aspirin plus extended-release dipyridamole are the antiplatelet agents used most for this purpose. Ticlopidine has been largely abandoned because of its adverse effects.

Aspirin is the most widely studied antiplatelet agent. Its antiplatelet effect is accomplished by acetylating the cyclooxygenase enzyme in platelets. This irreversibly inhibits the formation in platelets of thromboxane A_2, a platelet aggregating and vasoconstricting prostaglandin. This effect is permanent and lasts for the usual 8-day life of the platelet. Paradoxically, aspirin also inhibits the formation in endothelial cells of prostacyclin, an antiaggregating and vasodilating prostaglandin. This effect is transient. As soon as the aspirin is cleared from the blood, the nucleated endothelial cells again produce prostacyclin. Aspirin in low doses given once daily inhibits the production of thromboxane A_2 in platelets without substantially inhibiting prostacyclin formation. The FDA recommends 50 to 325 mg of aspirin daily for stroke prevention.

Ticlopidine blocks the ADP receptor on platelets and thus prevents the cascade resulting in activation of the glycoprotein IIb/IIIa receptor that leads to fibrinogen binding to the platelet and consequent platelet aggregation. Ticlopidine is more effective than aspirin; however, it has the disadvantage of causing diarrhea, skin rash, a low incidence

of neutropenia, and thrombotic thrombocytopenic purpura. Clopidogrel works by the same mechanism as ticlopidine and is not associated with these important side effects. Although many physicians have accepted clopidogrel as equivalent to ticlopidine in stroke prevention, the CAPRIE (Clopidogrel versus Aspirin in Patients at Risk of Ischemic Events) trial, which led to FDA approval, showed less robust efficacy. Studies of clopidogrel in combination with aspirin are in progress in both cerebrovascular and cardiovascular patients.

Dipyridamole is an antiplatelet agent that inhibits the uptake of adenosine by a variety of cells, including those of the vascular endothelium. The accumulated adenosine is an inhibitor of aggregation. At least in part through its effects on platelet and vessel wall phosphodiesterases, dipyridamole also potentiates the antiaggregatory effects of prostacyclin and nitric oxide produced by the endothelium and acts by inhibiting platelet phosphodiesterase, which is responsible for the breakdown of cyclic AMP. The resulting elevation in cyclic AMP inhibits aggregation of platelets. Dipyridamole has a controversial history in stroke prevention. The European Stroke Prevention Study-2 showed efficacy of both 50 mg daily of aspirin and extended-release dipyridamole in preventing stroke, and a significantly better risk reduction when the two agents were combined. A combination capsule of extended-release dipyridamole and aspirin is approved for prevention of stroke.

Many large clinical trials have demonstrated clearly that most antiplatelet agents reduce the risk of all important vascular atherothrombotic events (i.e., ischemic stroke, myocardial infarction, and death due to all vascular causes) in patients at risk for these events. The overall *relative* reduction in risk of nonfatal stroke is about 25 to 30% and of all vascular events is about 25%. The *absolute* reduction varies considerably depending on the particular patient's risk. Individuals at very low risk for stroke seem to experience the same relative reduction, but their risk may be so low that the "benefit" is meaningless. On the other hand, individuals with a 10 to 15% risk of vascular events per year experience a reduction to about 7.5 to 11%.

Aspirin is inexpensive, can be given in low doses, and could be recommended for all adults to prevent both stroke and myocardial infarction. However, it causes epigastric discomfort, gastric ulceration, and gastrointestinal hemorrhage, which may be asymptomatic or life-threatening. Consequently, not every 40- or 50-year old should be advised to take aspirin regularly because the risk of atherothrombotic stroke is extremely low and is outweighed by the risk of adverse side effects. Conversely, every patient who has experienced an atherothrombotic stroke and has no contraindication should be taking an antiplatelet agent regularly because the average annual risk of another stroke is 8 to 10%; another few percent will experience a myocardial infarction or vascular death. Clearly, the likelihood of benefit far outweighs the risks of treatment.

The choice of antiplatelet agent, and dose, similarly must balance the risk of stroke against the risks and cost of the treatments against the expected benefits. But these data are less definitive, and opinions therefore vary. Many authorities believe low-dose (30 to 75 mg daily) and high-dose (650 to 1300 mg daily) aspirin are about equally effective. Some advocate very low doses to avoid adverse effects, and still others advocate very high doses to be sure the benefit is maximal. Most physicians in North America recommend 325 mg daily, while most Europeans recommend 50 to 100 mg.

Similarly, the choice of aspirin, clopidogrel, or dipyridamole plus aspirin must balance the fact that the latter are more effective than aspirin but the cost is higher.

EMBOLIC STROKE Although warfarin is more effective than aspirin in preventing ischemic stroke associated with atrial fibrillation, some patients with atrial fibrillation have a low rate of ischemic stroke, and others have a high risk of hemorrhage and lose all of the expected benefit of anticoagulation by this complication. Still others are at such high risk for ischemic stroke that the benefits of warfarin override even the high hemorrhage rate. Preventive treatment depends on knowing the relative risks and benefits for the particular patient.

The Stroke Prevention in Atrial Fibrillation II trial showed that in "low-risk" patients (those without hypertension, recent heart failure, or prior thromboembolism) younger than 75 years given aspirin, the thromboembolism rate was only 0.5% per year. Consequently, one could reasonably recommend that patients <75 years with no risk factors be treated with aspirin only (Table 361-5).

Anticoagulation Therapy

ATHEROTHROMBOTIC STROKE There are few data to support the use of long-term warfarin for preventing atherothrombotic stroke, either intracranially or extracranially. Several large trials are in progress.

EMBOLIC STROKE Several recent trials demonstrated that anticoagulation (INRrange 2 to 3) in patients with chronic nonvalvular (nonrheumatic) atrial fibrillation prevents cerebral embolism and is safe. For primary prevention and for patients who have experienced stroke orTIA, anticoagulation with warfarin reduces the risk by about 65% and clearly outweighs the 1% per year rate of major bleeding complication.

The decision to use anticoagulation for primary prevention is based primarily on risk factors (Table 361-5). The presence of any risk factor tips the balance in favor of anticoagulation.

Because of the high annual stroke risk in untreated rheumatic heart disease, primary prophylaxis against stroke has not been studied in a double-blind fashion. These patients generally receive long-term anticoagulation.

Anticoagulation also reduces the risk of embolism in acute myocardial infarction. Most clinicians recommend a 3-month course of anticoagulation when there is anterior Q-wave infarction, substantial left ventricular dysfunction, congestive heart failure, mural thrombosis, or atrial fibrillation. Warfarin is recommended long-term if atrial fibrillation persists.

Thromboembolism is one of the most serious complications of prosthetic heart valve implantation. Anticoagulation has been proven effective for preventing strokes in this situation, while antiplatelet therapy alone has not. However, coupled with warfarin anticoagulation, aspirin adds substantial benefit. A greater degree of anticoagulation (INR of 3 to 4, depending on valve type) is recommended for prosthetic heart valve patients.

If the embolic source cannot be eliminated, anticoagulation should in most cases be continued indefinitely. Many neurologists recommend combining antiplatelet agents with anticoagulants for patients who "fail" one form of therapy (i.e., have another stroke ofTIA). This empirical approach subjects the patient to an increased bleeding risk.

Secondary prophylaxis for ischemic stroke of unknown origin is controversial. Some physicians prescribe anticoagulation for 3 to 6 months followed by antiplatelet treatment. The results of ongoing stroke trials may help to clarify the best treatment.

SURGICAL THERAPY Surgery for atherosclerotic occlusive disease is largely limited to *carotid endarterectomy* for plaques located at the origin of the internal carotid artery in the neck (see below).

Balloon angioplasty coupled with stenting is being used with increasing frequency to open stenotic carotid arteries and maintain their patency. This method has not been compared prospectively with endarterectomy. Concern exists about distal embolization of plaque during vessel dilation. Some neurointerventional centers are treating *intracranial* atherosclerotic disease with angioplasty and stenting. Surgery in the proximal common carotid, the subclavian, and the vertebral arteries is uncommon and is being replaced by endovascular stenting and angioplasty. Extracranial to intracranial bypass surgery has been proven ineffective for atherosclerotic stenoses that are inaccessible to conventional carotid endarterectomy. Although experimental, bypass surgery may have a role in patients with moyamoya disease or the unusual patient with intracranial stenosis and flow-relatedTIA.

Carotid Disease Carotid endarterectomy is a proven effective prophylaxis against stroke andTIA. Approximately 100,000 of these procedures are performed annually in the United States to remove obstructing atherosclerotic plaques. The most important clinical distinction is between symptomatic and asymptomatic carotid stenosis. Symptomatic stenosis is defined as carotid stenosis ipsilateral to the vascular distribution of a stroke or TIA; e.g., a left carotid stenosis in a patient with transient expressive aphasia. Asymptomatic carotid stenosis is defined by the absence of clinical signs or symptoms of stroke or TIA relevant to the carotid lesion. The distinction is important because the natural history of these conditions is markedly different.

Symptomatic carotid stenosis was studied in theNASCETand the European Carotid Surgery Trial (ECST). Both showed a substantial benefit for surgery in patients with a stenosis of>70%. In NASCET, the average cumulative ipsilateral stroke rate at 2 years was 26% for patients treated medically and 9% for those receiving the same medical treatment plus a carotid endarterectomy. This 17% *absolute* reduction in the surgical group is a 65%*relative* risk reduction favoring surgery. NASCET also showed a significant benefit for patients with 50 to 70%stenosis, although less robust. ECST found harm for patients with stenosis in the 0 to 30% range treated surgically.

A patient's risk of stroke and possible benefit from surgery is related to the presence of retinal versus hemispheric symptoms, degree of arterial stenosis, extent of associated medical conditions, institutional surgical morbidity and mortality, and other factors. A patient with multiple atherosclerosis risk factors, symptomatic hemispheric ischemia,

very high grade stenosis in the appropriate internal carotid artery, and an institutional perioperative morbidity and mortality rate of£6% generally should undergo carotid endarterectomy. If the perioperative stroke rate is>6% for any particular surgeon, however, the benefits of carotid endarterectomy are lost.

The indications for surgical treatment of *asymptomatic carotid disease* have been clarified by the results of the Asymptomatic Carotid Atherosclerosis Study (ACAS), which randomized patients with ³60% stenosis to medical treatment with aspirin or the same medical treatment plus carotid endarterectomy. The surgical group had a risk over 5 years for ipsilateral stroke (and any perioperative stroke or death) of 5.1%, compared to a risk in the medical group of 11%. While this demonstrates a 53% *relative* risk reduction, the *absolute* risk reduction is only 5.9% over 5 years, or 1.2% annually. The perioperative complication rate was higher in women, so they received only a 17% relative risk reduction over 5 years. Nearly half of the strokes in the surgery group were caused by preoperative angiograms.

The natural history of asymptomatic stenosis is an approximate 2% per year stroke rate, while symptomatic patients experience a 13% per year risk of stroke. Whether to recommend carotid revascularization for an asymptomatic patient remains controversial and depends on many factors including patient preference, age, and comorbidities. Medical therapy for reduction of atherosclerosis risk factors and aspirin, 325 mg/d, are generally recommended for patients with asymptomatic carotid stenosis. As with atrial fibrillation, it is imperative to counsel the patient aboutTIAs so their therapy can be revised if they become symptomatic.

Stroke Centers and Rehabilitation Comprehensive stroke units that care for the acute patient followed by rehabilitation services have been shown to improve neurologic outcomes and reduce mortality. Use of clinical pathways and dedicating staff to the stroke patient can improve the efficacy of care. Stroke teams that provide emergency 24-h evaluation of acute stroke patients for consideration of thrombolysis and acute medical management are essential components of the care process.

Proper rehabilitation of the stroke patient includes early physical, occupational, and speech therapy. It is directed toward educating the patient and family about the patient's neurologic deficit, preventing the complications of immobility (e.g., pneumonia, deep vein thrombosis and pulmonary embolism, pressure sores of the skin, muscle contractures), and providing encouragement and instruction in overcoming the deficit. The goal of rehabilitation is to return the patient to home and to maximize recovery by providing a safe, progressive regimen suited to the individual patient.

INTRACRANIAL HEMORRHAGE

Blood can extravasate anywhere within the cranial vault or spinal column. Hemorrhages are classified by their location and the underlying vascular pathology. Bleeding into subdural and epidural spaces is principally produced by trauma (Chap. 369). Intraparenchymal, intraventricular, and subarachnoid hemorrhage will be considered here.

DIAGNOSIS

Intracranial hemorrhage is often discovered on noncontrastCTimaging of the brain during the acute evaluation of stroke. CT is more sensitive than routineMRI for acute blood. The location of hemorrhage narrows the differential diagnosis to a few entities. Table 361-7 lists the causes and anatomic spaces involved in hemorrhages.

EMERGENCY MANAGEMENT

Close attention should be paid to airway management since a reduction in the level of consciousness is common. The initial blood pressure should be maintained until the results of theCT scan are reviewed. Patients with acuteSAHshould have blood pressure lowered to a normal range with nonvasodilating agents such as labetalol or esmolol. Patients with cerebellar hemorrhages or with depressed mental status and radiographic evidence of hydrocephalus should undergo urgent neurosurgical evaluation. Based on the clinical examination and CT findings, further imaging studies may be necessary, includingMRI or conventional x-ray angiography. Stuporous or comatose patients generally are treated presumptively for elevatedICP, with tracheal intubation and hyperventilation, mannitol administration, and elevation of the head of the bed while surgical consultation is obtained (Chap. 376).

INTRAPARENCHYMAL HEMORRHAGE

Intraparenchymal hemorrhage is the most common type of intracranial hemorrhage. It is an important cause of stroke, especially in Asians and blacks. Hypertension, trauma, and cerebral amyloid angiopathy cause the majority of these hemorrhages. Advanced age and heavy alcohol consumption increase the risk, and cocaine use is one of the most important causes in the young.

Hypertensive Intraparenchymal Hemorrhage

Pathophysiology Hypertensive parenchymal hemorrhage (hypertensive hemorrhage or hypertensive intracerebral hemorrhage) usually results from spontaneous rupture of a small penetrating artery deep in the brain. The most common sites are the basal ganglia (putamen, thalamus, and adjacent deep white matter), deep cerebellum, and pons. When hemorrhages occur in other brain areas or in nonhypertensive patients, greater consideration should be given to hemorrhagic disorders, neoplasms, vascular malformations, and other causes. The small arteries in these areas seem most prone to hypertension-induced vascular injury. The hemorrhage may be small or a large clot may form and compress adjacent tissue, causing herniation and death. Blood may dissect into the ventricular space, which substantially increases morbidity and may cause hydrocephalus. If the patient survives, the clot liquefies, is absorbed, and leaves only a small residual cleft.

Most hypertensive intraparenchymal hemorrhages develop over 30 to 90 min, whereas those associated with anticoagulant therapy may evolve for as long as 24 to 48 h. Within 48 h macrophages begin to phagocytize the hemorrhage at its outer surface. After 1 to 6 months, the hemorrhage is generally resolved to a slitlike orange cavity lined with glial scar and hemosiderin-laden macrophages.

Clinical Manifestations Although not particularly associated with exertion, intracerebral hemorrhages almost always occur while the patient is awake and sometimes when stressed. The hemorrhage generally presents as the abrupt onset of focal neurologic deficit. Seizures are uncommon. The focal deficit typically worsens steadily over 30 to 90 min and is associated with a diminishing level of consciousness and signs of increasedICP, such as headache and vomiting.

The putamen is the most common site for hypertensive hemorrhage, and the adjacent internal capsule is invariably damaged (Fig. 361-11). Contralateral hemiparesis is therefore the sentinel sign. When mild, the face sags on one side over 5 to 30 min, speech becomes slurred, the arm and leg gradually weaken, and the eyes deviate away from the side of the hemiparesis. The paralysis may worsen until the affected limbs become flaccid or extend rigidly with a Babinski sign on the same side. When hemorrhages are large, drowsiness gives way to stupor as signs of upper brainstem compression appear. Coma ensues, accompanied by deep, irregular, or intermittent respiration; a dilated and fixed ipsilateral pupil; bilateral Babinski signs; and decerebrate rigidity. In milder cases, edema in adjacent brain tissue may cause progressive deterioration over 12 to 72 h.

Thalamic hemorrhages also produce a contralateral hemiplegia or hemiparesis from pressure on, or dissection into, the adjacent internal capsule. A prominent sensory deficit involving all modalities is usually present. Aphasia, often with preserved verbal repetition, may occur after hemorrhage into the dominant thalamus, and apractognosia or mutism occurs in some cases of nondominant hemorrhage. There may also be a homonymous visual field defect. Thalamic hemorrhages cause several typical ocular disturbances by virtue of extension medially into the upper midbrain. These include deviation of the eyes downward and inward so that they appear to be looking at the nose, unequal pupils with absence of light reaction, skew deviation with the eye opposite the hemorrhage displaced downward and medially, ipsilateral Horner's syndrome, absence of convergence, paralysis of vertical gaze, and retraction nystagmus. Patients may later develop a chronic, contralateral pain syndrome (see Dejerine-Roussy syndrome, above).

In pontine hemorrhages, deep coma with quadriplegia usually occurs over a few minutes. There is often prominent decerebrate rigidity and "pin-point" (1 mm) pupils that react to light. There is impairment of reflex horizontal eye movements evoked by head turning (doll's-head or oculocephalic maneuver) or by irrigation of the ears with ice water (Chap. 24). Hyperpnea, severe hypertension, and hyperhidrosis are common. Death usually occurs within a few hours, but there are occasional survivors.

Cerebellar hemorrhages usually develop over several hours and are characterized by occipital headache, repeated vomiting, and ataxia of gait. In mild cases there may be no other neurologic signs other than gait ataxia. Dizziness or vertigo may be prominent. There is often paresis of conjugate lateral gaze toward the side of the hemorrhage, forced deviation of the eyes to the opposite side, or an ipsilateral sixth nerve palsy. Less frequent ocular signs include blepharospasm, involuntary closure of one eye, ocular bobbing, and skew deviation. Dysarthria and dysphagia may occur. There are no Babinski signs until late in the evolution of the hemorrhage as it compresses or dissects into the ventral brainstem. As the hours pass, the patient often becomes stuporous and

then comatose from brainstem compression or obstructive hydrocephalus; immediate surgical evacuation may be lifesaving.

Laboratory and Imaging Evaluation TheCT scan reliably detects acute focal hemorrhages in the supratentorial space. Small pontine hemorrhages may not be identified because of motion and bone-induced artifact that obscure structures in the posterior fossa. After the first 2 weeks, x-ray attenuation values of clotted blood diminish until they become isodense with surrounding brain. Mass effect and edema may remain. In some cases, a surrounding rim of contrast enhancement appears after 2 to 4 weeks and may persist for months.MRI, though more sensitive for delineating posterior fossa lesions, is generally not necessary in most instances. Images of flowing blood on MRI scan may identify arteriovenous malformations (AVMs) as the cause of the hemorrhage. MRI and conventional x-ray angiography are used when the cause of intracranial hemorrhage is uncertain, particularly if the patient is young or not hypertensive and the hematoma is not in one of the four usual sites for hypertensive hemorrhage. For example, hemorrhage into the temporal lobe suggests rupture of aMCAsaccular aneurysm.

Since these patients typically have focal neurologic signs and obtundation, and often show signs of increasedICP, anLPshould be avoided as it may induce cerebral herniation.

TREATMENT

Acute Management Nearly 50% of patients with a hypertensive intracerebral hemorrhage die. The volume and location of the hematoma determine the prognosis. In general, supratentorial hematomas with volumes <30 mL have a good prognosis, 30 to 60 mL an intermediate prognosis, and >60 mL a poor prognosis during initial hospitalization. Infratentorial pontine hematomas>3 cm are usually fatal. Extension into the ventricular system, especially the fourth ventricle, worsens the prognosis. Except in patients who are on therapeutic anticoagulation or who have a bleeding disorder, little can be done about the hemorrhage itself. Hematomas may expand for several hours following the initial hemorrhage, so treating severe hypertension seems reasonable to prevent hematoma progression. As with ischemic stroke, lowering blood pressure too much or too quickly might cause cerebral ischemia around the hemorrhage cavity.

Evacuation of the hematoma is usually not helpful, except in cerebellar hemorrhages. For cerebellar hemorrhages, a neurosurgeon should be consulted immediately to assist with the evaluation; most cerebellar hematomas >3 cm in diameter will require surgical evacuation. If the patient is alert without focal brainstem signs and if the hematoma is <1 cm in diameter, surgical removal is usually unnecessary. Patients with hematomas between 1 and 3 cm require careful observation for signs of impaired consciousness, which usually means surgery is required.

Tissue surrounding hematomas is displaced and compressed but not necessarily infarcted. Hence, in survivors, major improvement commonly results as the hematoma is reabsorbed and the adjacent tissue regains its function. Careful management of the patient during the acute phase of the hemorrhage can lead to considerable recovery.

Surprisingly, despite large intraparenchymal hemorrhages,ICP is often not elevated. However, if the hematoma causes marked midline shift of structures with consequent obtundation or coma or hydrocephalus, osmotic agents coupled with induced hyperventilation can be instituted to lower ICP (Chap. 376). These maneuvers will provide enough time to place a ventriculostomy or ICP monitor. Once ICP is recorded, further hyperventilation and osmotic therapy can be tailored to the individual patient. For example, if ICP is found to be high, cerebrospinal fluid (CSF) can be drained from the ventricular space and osmotic therapy continued; persistent or progressive elevation in ICP may prompt surgical evacuation of the clot or withdrawal of support. Alternately, if ICP is normal or only mildly elevated, induced hyperventilation can be reversed and osmotic therapy tapered. Since hyperventilation may actually produce ischemia by cerebral vasoconstriction, as a general management principal induced hyperventilation should be limited to acute resuscitation of the patient with presumptive high ICP and eliminated once other treatments (osmotic therapy or surgical treatments) have been instituted. Glucocorticoids are not helpful for the edema from intracerebral hematoma.

Prevention Hypertension is the leading cause of primary intracerebral hemorrhage. Prevention is aimed at reducing hypertension, excessive alcohol use, and use of illicit drugs such as cocaine and amphetamines.

OTHER CAUSES OF INTRACEREBRAL HEMORRHAGE

Cerebral amyloid angiopathy is a disease of the elderly in which arteriolar degeneration occurs and amyloid is deposited in the walls of the cerebral arteries but not elsewhere. Amyloid angiopathy causes both single and recurrent lobar hemorrhages and is probably the most common cause of lobar hemorrhage in the elderly. It accounts for some intracranial hemorrhages associated with intravenous thrombolysis given for myocardial infarction. This disorder can be suspected in patients who present with multiple hemorrhages (and infarcts) over several months or years, but it is definitively diagnosed by demonstration of Congo red staining of amyloid in cerebral vessels.

Cocaine-induced stroke is an important cause of stroke, particularly in patients<40. Intracerebral hemorrhage, ischemic stroke, andSAH are all associated with cocaine use. Angiographic findings vary from completely normal arteries to large vessel occlusion or stenosis, vasospasm, or changes consistent with vasculitis. The mechanism of cocaine-related stroke is not known, but cocaine enhances sympathetic activity causing acute, sometimes severe, hypertension, and this may lead to hemorrhage. Slightly more than half of cocaine-related intracranial hemorrhages are intracerebral, and the rest are subarachnoid. In cases of SAH, a saccular aneurysm is usually identified. Presumably, acute hypertension causes aneurysmal rupture.

Head injury often causes intracranial bleeding. The common sites are intracerebral (especially temporal and inferior frontal lobes) and into the subarachnoid, subdural, and epidural spaces. Trauma must be considered in any patient with an unexplained acute neurologic deficit (hemiparesis, stupor, or confusion), particularly if the deficit occurred in the context of a fall (Chap. 369).

Intracranial hemorrhages associated with *anticoagulant therapy* can occur at any location; they are often lobar or subdural. Anticoagulant-related intracerebral

hemorrhages may evolve slowly, over 24 to 48 h. Coagulopathy should be reversed with fresh-frozen plasma and vitamin K to limit the volume of hemorrhage. When intracerebral hemorrhage is associated with thrombocytopenia (platelet count<50,000/ul), transfusion of fresh platelets is indicated. Intracerebral hemorrhage associated with *hematologic disorders* (leukemia, aplastic anemia, thrombocytopenic purpura) can occur at any site and may present as multiple intracerebral hemorrhages. Skin and mucous membrane bleeding is usually evident and offers a diagnostic clue.

Hemorrhage into a *brain tumor* may be the first manifestation of neoplasm. Choriocarcinoma, malignant melanoma, renal cell carcinoma, and bronchogenic carcinoma are among the most common metastatic tumors associated with intracerebral hemorrhage. Glioblastoma multiforme in adults and medulloblastoma in children may also have areas of intracerebral hemorrhage.

Hypertensive encephalopathy is a complication of malignant hypertension. In this acute syndrome, severe hypertension is associated with headache, nausea, vomiting, convulsions, confusion, stupor, and coma. Focal or lateralizing neurologic signs, either transitory or permanent, may occur but are infrequent and therefore suggest some other vascular disease (hemorrhage, embolism, or atherosclerotic thrombosis). There are retinal hemorrhages, exudates, papilledema (hypertensive retinopathy grade IV), and evidence of renal and cardiac disease. In most casesICP andCSFprotein levels are elevated. The hypertension may be essential or due to chronic renal disease, acute glomerulonephritis, acute toxemia of pregnancy, pheochromocytoma, or other causes. Lowering the blood pressure reverses the process, but stroke can occur. Neuropathologic examination reveals multifocal to diffuse cerebral edema and hemorrhages of various sizes from petechial to massive. Microscopically, there are necrosis of arterioles, minute cerebral infarcts, and hemorrhages. The term *hypertensive encephalopathy* should be reserved for this syndrome and not for chronic recurrent headaches, dizziness, recurrentTIAs, or small strokes that often occur in association with high blood pressure.

Primary intraventricular hemorrhage is rare. It usually begins within the substance of the brain and dissects into the ventricular system without leaving signs of intraparenchymal hemorrhage. Vasculitis, usually polyarteritis nodosa or lupus erythematosus, can produce hemorrhage into any region of the central nervous system; most hemorrhages are associated with hypertension, but the arteritis itself may cause bleeding by disrupting the vessel wall. *Sepsis* can cause small petechial hemorrhages throughout the cerebral white matter. *Moyamoya disease*, mainly an occlusive arterial disease that causes ischemic symptoms, may on occasion produce multiple small aneurysms that rupture. Hemorrhages into the spinal cord are usually the result of anAVM or metastatic tumor. *Epidural spinal hemorrhage* produces a rapidly evolving syndrome of spinal cord or nerve root compression (Chap. 368).

Clinical Manifestations Symptoms and signs appear over several minutes. Most lobar hemorrhages are small and cause a restricted clinical syndrome that simulates an embolus to an artery supplying one lobe. For example, the major neurologic deficit with an occipital hemorrhage is hemianopia; with a left temporal hemorrhage, aphasia and delirium; with a parietal hemorrhage, hemisensory loss; and with frontal hemorrhage, arm weakness. Large hemorrhages may be associated with stupor or coma if they

compress the thalamus or midbrain. Most patients with lobar hemorrhages have focal headaches, and more than half vomit or are drowsy. Stiff neck and seizures are uncommon. Spinal hemorrhages usually present with sudden back pain and some manifestation of myelopathy.

Laboratory and Imaging Evaluation CTscanning reliably detects even very small supratentorial hemorrhages.MRI is more sensitive for delineating associated abnormalities, such as aneurysm, vascular malformation, and neoplasm, and is superior for imaging the posterior fossa and spinal column. MRI with gadolinium contrast enhancement is useful for revealing tumors andAVMs. Using special sequences sensitive for hemosiderin, MRI may show evidence of multiple prior hemorrhages, suggesting amyloid angiopathy and vascular anomalies. Repeating an MRI scan at 4 to 8 weeks may be necessary to reveal the underlying cause of hemorrhage, as the acute hematoma may obscure an underlying vascular anomaly or tumor. Conventional x-ray angiography is used when the cause of hemorrhage is uncertain, especially in the young and the middle-aged, or when better delineation of vascular anomalies is necessary.

Treatment The recommendations for management of hypertensive intracerebral hemorrhage generally apply. If a causative lesion is found, it is treated appropriately.

SUBARACHNOID HEMORRHAGE

Excluding head trauma, the most common cause ofSAH is rupture of a saccular aneurysm. Other causes include bleeding from a vascular anomaly and extension into the subarachnoid space from a primary intracerebral hemorrhage. Many idiopathic SAHs are localized to the perimesencephalic cisterns and are benign; they probably have a venous or capillary source, and angiography is unrevealing.

Saccular Aneurysm Autopsy studies have found that 3 to 4% of the population harbor aneurysms, for a prevalence of 8 to 10 million people in the United States. The incidence of bleeding is only 25,000 to 30,000 cases per year. The mortality rate for patients who arrive alive at hospital is about 50% during the first month. Of those who survive, more than half are left with major neurologic deficits as a result of the initial hemorrhage, cerebral vasospasm with infarction, or hydrocephalus. If the patient survives but the aneurysm is not obliterated, the annual rebleed rate is about 3%. Given these alarming figures, the major therapeutic emphasis is on preventing the predictable early complications of the rupture.

Unruptured, asymptomatic aneurysms are much less dangerous than a recently ruptured aneurysm. The annual risk of rupture for aneurysms <10 mm in size is approximately 0.1%, and for aneurysms³10 mm in size is approximately 0.5%; the surgical morbidity far exceeds these percentages. As more data become available, a true risk-benefit analysis for treating these aneurysms will result.

Giant aneurysms, those >2.5 cm in diameter, occur at the same sites (see below) as small aneurysms and account for 5% of cases. The three most common locations are the terminal internal carotid artery,MCAbifurcation, and top of the basilar artery. Their risk of rupture is about 6% in the first year after identification and may remain high

indefinitely. They often cause symptoms by compressing the adjacent brain or cranial nerves.

Mycotic aneurysms are usually located distal to the first bifurcation of major arteries of the circle of Willis. Most result from infected emboli due to bacterial endocarditis causing septic degeneration of arteries and subsequent dilatation and rupture. Whether these lesions should be sought and repaired prior to rupture, or left to heal spontaneously, is controversial.

Pathophysiology Saccular aneurysms occur at the bifurcations of the large arteries at the base of the brain; rupture is into the subarachnoid space in the basal cisterns and often into the parenchyma of the adjacent brain. Approximately 85% of aneurysms occur in the anterior circulation, mostly on the circle of Willis. Common sites include the junction of the anterior communicating artery with the anterior cerebral artery, the junction of the posterior communicating artery with the internal carotid artery, the bifurcation of theMCA, the top of the basilar artery, the junction of the basilar artery and the superior cerebellar artery or the anterior inferior cerebellar artery, and the junction of the vertebral artery and the posterior inferior cerebellar artery. About 20% of patients have multiple aneurysms, many at mirror sites bilaterally. As an aneurysm develops, it typically forms a neck with a dome. The length of the neck and the size of the dome vary greatly and are factors that are important in planning both neurosurgical obliteration or endovascular embolization. The arterial internal elastic lamina disappears at the base of the neck. The media thins, and connective tissue replaces smooth-muscle cells. At the site of rupture (most often the dome) the wall thins, and the tear that allows bleeding is often no more than 0.5 mm long. It is not currently possible to predict which aneurysms are likely to rupture, but limited data suggest that most ruptured aneurysms are>7 mm in diameter.

Clinical Manifestations Most aneurysms present as a suddenSAH. At the moment of aneurysmal rupture with major SAH, theICPsuddenly rises. Abrupt, severe, and generalized vasospasm may occur transiently. These events may account for the sudden transient loss of consciousness that occurs in nearly half of patients. Sudden loss of consciousness may be preceded by a brief moment of excruciating headache, but most patients first complain of headache upon regaining consciousness. In 10% of cases, aneurysmal bleeding is severe enough to cause loss on consciousness for several days. In about 45% of cases, severe headache associated with exertion is the presenting complaint. The patient often calls the headache "the worst headache of my life." However, the clinician should be sensitive to the less dramatic features of sudden onset of headache or to a new or different headache than what the patient has ever experienced. The headache is usually generalized, and vomiting is common.

Although sudden headache in the absence of focal neurologic symptoms is the hallmark of aneurysmal rupture, focal neurologic deficits may occur. Anterior communicating artery or middle cerebral bifurcation aneurysms may rupture into the adjacent brain or subdural space and form a hematoma large enough to produce mass effect. The common deficits that result include hemiparesis, aphasia, and abulia.

Occasionally, prodromal symptoms suggest the location of a progressively enlarging unruptured aneurysm. A third cranial nerve palsy (Video 28-1), particularly when

associated with pupillary dilatation, loss of light reflex, and focal pain above or behind the eye, may occur with an expanding aneurysm at the junction of the posterior communicating artery and the internal carotid artery. A sixth nerve palsy (Video 28-2) may indicate an aneurysm in the cavernous sinus, and visual field defects can occur with an expanding supraclinoid carotid or anterior cerebral artery aneurysm. Occipital and posterior cervical pain may signal a posterior inferior cerebellar artery or anterior inferior cerebellar artery aneurysm. Pain in or behind the eye and in the low temple can occur with an expandingMCAaneurysm. Growing aneurysms rarely cause head pain in the absence of neurologic symptoms and signs.

Aneurysms can undergo small ruptures and leaks of blood into the subarachnoid space, so-called sentinel bleeds. Sudden unexplained headache at any location should raise suspicion ofSAH and be investigated because a major hemorrhage may be imminent.

DELAYED NEUROLOGIC DEFICITS There are four major causes of delayed neurologic deficits; rerupture, hydrocephalus, vasospasm, and hyponatremia.

1. *Rerupture* The incidence of rerupture of an untreated aneurysm in the first month followingSAH is about 30% with the peak at 7 days. It is associated with a 60% mortality and poor outcome. Early treatment eliminates this risk.

2. *Hydrocephalus* Acute hydrocephalus can cause stupor and coma. More often, subacute hydrocephalus develops over a few days or weeks and causes progressive drowsiness or slowed mentation (abulia) with incontinence. Differentiating hydrocephalus from cerebral vasospasm is accomplished with aCT scan,TCDultrasound, or conventional x-ray angiography. Hydrocephalus may clear spontaneously or require temporary ventricular drainage. Chronic hydrocephalus may develop weeks to months afterSAH and manifest as gait difficulty, incontinence, or impaired mentation. Subtle signs may be a lack of initiative in conversation or a failure to recover independence.

3. *Vasospasm* Narrowing of the arteries at the base of the brain followingSAHoccurs regularly. This vasospasm causes symptomatic ischemia and infarction in approximately 30% of patients and is the major cause of delayed morbidity or death. Signs of ischemia appear 4 to 14 days after the hemorrhage, most frequently at about 7 days. The severity and distribution of vasospasm determine whether infarction will occur.

The mechanism of delayed vasospasm is likely to be related to direct effects of clotted blood and its breakdown products on the artery. In general, the more blood that surrounds the arteries, the greater the chance of symptomatic vasospasm. Spasm of theMCAtypically causes contralateral hemiparesis and dysphasia (dominant hemisphere). Proximal anterior cerebral artery vasospasm causes abulia and incontinence, while severe vasospasm of the posterior cerebral artery causes hemianopia. Severe spasm of the basilar or vertebral arteries occasionally produces focal brainstem ischemia. All of these focal symptoms may present abruptly, fluctuate, or develop over a few days.

Vasospasm can be detected reliably with conventional x-ray angiography, but this invasive procedure is expensive and carries risk of stroke and other

complications.TCDultrasound is based on the principle that the velocity of blood flow within an artery will rise as the lumen diameter is narrowed. By directing the probe along the MCAand proximal anterior cerebral, carotid terminus, vertebral, and basilar arteries on a daily or every-other-day basis, vasospasm can be reliably detected noninvasively and treatments initiated to prevent cerebral ischemia (see below).

Severe cerebral edema in patients with infarction from vasospasm may increase theICPenough to reduce cerebral perfusion pressure. Treatment is with mannitol and hyperventilation (Chap. 376).

4. *Hyponatremia* Hyponatremia may be profound and develop quickly in the first 2 weeks followingSAH. It usually results from inappropriate secretion of vasopressin (Chap. 329) and secretion of atrial and brain natriuretic factors, which produce a natriuresis. This "cerebral salt-wasting syndrome" clears over the course of 1 to 2 weeks and, in the setting of SAH, arguably should not be treated with free-water restriction (see below).

Laboratory Evaluation and Imaging (Fig. 361-12) The hallmark of aneurysmal rupture is blood in theCSF. More than 95% of cases have enough blood to be visualized on a high-quality noncontrastCT scan obtained within 72 h. If the scan fails to establish the diagnosis ofSAH and no mass lesion or obstructive hydrocephalus is found, anLPshould be performed to establish the presence of subarachnoid blood. Lysis of the red blood cells and subsequent conversion of hemoglobin to bilirubin stains the spinal fluid yellow within 6 to 12 h of SAH. This xanthochromic spinal fluid peaks in intensity at 48 h and lasts for 1 to 4 weeks, depending on the amount of subarachnoid blood.

The extent and location of subarachnoid blood on noncontrastCT scan help locate the underlying aneurysm, identify the cause of any neurologic deficit, and predict delayed vasospasm. A high incidence of symptomatic vasospasm in the middle and anterior cerebral arteries has been found when early CT scans show subarachnoid clots >5´ 3 mm in the basal cisterns or layers of blood>1 mm thick in the cerebral fissures. CT scans less reliably predict vasospasm in the vertebral, basilar, or posterior cerebral arteries.

LPprior to scanning is indicated only if aCT scan is not available at the time of the suspectedSAH. Once the diagnosis of hemorrhage from a ruptured saccular aneurysm is suspected, four-vessel conventional x-ray angiography (both carotids and both vertebrals) is generally performed to localize and define the anatomic details of the aneurysm and to determine if other unruptured aneurysms exist. At certain centers, the ruptured aneurysm can be treated using endovascular techniques at the time of the initial angiogram (see following treatment).

TheECGfrequently shows ST-segment and T-wave changes similar to those associated with cardiac ischemia. Prolonged QRS complex, increased QT interval, and prominent "peaked" or deeply inverted symmetric T waves are usually secondary to the intracranial hemorrhage. The cause of these changes is debated, but there is evidence that structural myocardial lesions produced by circulating catecholamines may occur afterSAH.

Serum electrolytes are obtained because hyponatremia may develop. Close monitoring (daily or twice daily) of serum sodium is important since hyponatremia can occur precipitously during the first 2 weeks followingSAH (see above).

TCDultrasound assessment of proximal middle, anterior, and posterior cerebral and basilar artery flow is helpful in detecting the onset of vasospasm and in following its course and response to therapy.

TREATMENT

Aneurysm rerupture is common in the early days afterSAH and is associated with a 60% incidence of death or poor outcome. Early aneurysm repair prevents future hemorrhage and allows the safe application of techniques to improve blood flow (e.g., induced hypertension and hypervolemia) should symptomatic vasospasm develop. An aneurysm can be "clipped" by a neurosurgeon or "coiled" by a neurointerventional radiologist. Surgical repair involves placing a metal clip across the aneurysm neck, with the advantage that rebleeding risk is eliminated immediately. This approach requires craniotomy and brain retraction, which is associated with neurologic deficits. The newer endovascular technique involves placing platinum coils within the aneurysm via a catheter from the femoral artery. The aneurysm is packed tightly to enhance thrombosis and over time is walled-off from the circulation. The safety and efficacy of these two techniques are being compared in an ongoing European trial.

The medical management ofSAHcenters on airway protection, blood pressure management before and after aneurysm treatment, preventing rebleeding prior to treatment, managing vasospasm, treating hydrocephalus, and treating hyponatremia.

Intracranial hypertension following aneurysmal rupture occurs secondary to subarachnoid blood, parenchymal hematoma, acute hydrocephalus, or loss of vascular autoregulation. Patients who are stuporous should undergo emergent ventriculostomy to prevent cerebral ischemia from highICP. Medical therapies designed to combat raised ICP (e.g., mild hyperventilation, mannitol, and sedation) can also be used as needed (Chap. 376). High ICP refractory to treatment carries a poor prognostic sign.

Prior to definitive treatment of the ruptured aneurysm, care is required to maintain adequate cerebral perfusion pressure while avoiding excessive elevation of arterial pressure. Occasionally an intracranial hematoma causing neurologic deterioration requires removal.

Because rebleeding is common, all patients who are not candidates for early surgical treatment are put on bed rest in a quiet, preferably darkened, room and are given stool softeners to prevent constipation. If headache or neck pain is severe, mild sedation and analgesia are prescribed. Extreme sedation is avoided because it can obscure changes in neurologic status. Adequate hydration is necessary to avoid a decrease in blood volume predisposing to brain ischemia.

Seizures are uncommon at the onset of aneurysmal rupture. The quivering, jerking, and extensor posturing that often accompany loss of consciousness are probably related to the sharp rise inICP or, perhaps, acute generalized vasospasm. However, phenytoin is

often given as prophylactic therapy since a seizure may promote rebleeding.

Glucocorticoids may help reduce the head and neck ache caused by the irritative effect of the subarachnoid blood. There is no good evidence they reduce cerebral edema, are neuroprotective, or reduce vascular injury, and their routine use therefore is controversial.

Antifibrinolytic agents are not routinely prescribed but may be considered in patients in whom aneurysm treatment cannot proceed immediately. They are associated with a reduced incidence of aneurysmal rerupture but are also associated with an increased incidence of delayed cerebral infarction and deep venous thrombosis.

Vasospasm remains the leading cause of morbidity and mortality following aneurysmalSAH and treatment of the aneurysm. Treatment with the calcium channel antagonist nimodipine (60 mg orally q6h) has been reported to be beneficial, but the effects seem to be modest. Nimodipine can cause significant hypotension in some patients, which may worsen cerebral ischemia in patients with vasospasm. The most widely accepted therapy for symptomatic cerebral vasospasm is to increase the cerebral perfusion pressure by raising mean arterial pressure through plasma volume expansion and the judicious use of vasopressor agents, usually phenylephrine or dopamine. Raised perfusion pressure has been associated with clinical improvement in many patients, but high arterial pressure may promote rebleeding in unprotected aneurysms. Treatment with induced hypertension and hypervolemia generally requires monitoring of arterial and central venous pressures and in severe cases, the pulmonary artery wedge pressure. Volume expansion helps prevent hypotension, augments cardiac output, and reduces blood viscosity by reducing hematocrit. This method is called "triple-H" (hypertension, hemodilution, and hypervolemic) therapy.

If symptomatic vasospasm persists despite optimal medical therapy, intraarterial papaverine and percutaneous transluminal angioplasty are considered. Vasodilatation following angioplasty appears to be permanent, allowing triple-H therapy to be tapered sooner. The vasodilating effects of papaverine do not last more than 12 to 24 h.

Acute hydrocephalus can cause stupor or coma. It may clear spontaneously or require temporary ventricular drainage. When chronic hydrocephalus develops, ventricular shunting is the treatment of choice.

Free-water restriction is contraindicated in patients withSAH at risk for vasospasm because hypovolemia and hypotension may occur and precipitate cerebral ischemia. Many patients continue to experience a decline in serum sodium despite normal saline parenteral fluids. Frequently, supplemental oral salt coupled with normal saline will mitigate hyponatremia, but often patients will need hypertonic saline in addition. Care must be taken to not correct serum sodium too quickly in patients with marked hyponatremia of several days' duration, as central pontine myelinolysis (Chap. 376) may occur. All patients should have pneumatic compression stockings applied to prevent pulmonary embolism. Systemic heparin is contraindicated in patients with ruptured and untreated aneurysms; it is a relative contraindication following craniotomy, and it may delay thrombosis of a coiled aneurysm.

Vascular Anomalies Vascular anomalies can be divided into congenital vascular malformations and acquired vascular lesions.

Congenital Vascular Malformations TrueAVMs, venous anomalies, and capillary telangiectasias are congenital lesions that usually remain clinically silent through life.

True *arteriovenous malformations* are congenital shunts between the arterial and venous systems that may present as headache, focal seizures, and intracranial hemorrhage. AVMs consist of a tangle of abnormal vessels across the cortical surface or deep within the brain substance. AVMs vary in size from a small blemish a few millimeters in diameter to a huge mass of tortuous channels composing an arteriovenous shunt of sufficient magnitude to raise cardiac output. The blood vessels forming the tangle interposed between arteries and veins are usually abnormally thin and do not have a normal structure. AVMs occur in all parts of the cerebral hemispheres, brainstem, and spinal cord, but the largest ones are most frequently in the posterior half of the hemispheres, commonly forming a wedge-shaped lesion extending from the cortex to the ventricle.

Although the lesion is present from birth, bleeding or other symptoms are most common between the ages of 10 and 30, occasionally as late as the fifties.AVMs are more frequent in men, and rare familial cases have been described.

Headache (without bleeding) may be hemicranial and throbbing, like migraine, or diffuse. Focal seizures, with or without generalization, occur in about 30% of cases. Half ofAVMsbecome evident as intracerebral hemorrhages. In most, the hemorrhage is mainly intraparenchymal with a small amount of spillage into the subarachnoid space. Blood is usually not deposited in the basal cisterns, and symptomatic cerebral vasospasm is rare. The threat of rerupture in the early weeks is low. Hemorrhages may be massive, leading to death, or may be as small as 1 cm in diameter, leading to minor focal symptoms or no deficit. The AVM may be large enough to steal blood away from adjacent normal brain tissue or to increase venous pressure significantly to produce venous ischemia locally and in remote areas of the brain. This is seen most often with large AVMs in the territory of theMCA.

LargeAVMs of the anterior circulation may be associated with a systolic and diastolic bruit (sometimes self-audible) over the eye, forehead, or neck and a bounding carotid pulse. Headache at the onset of AVM rupture is not generally as explosive as with aneurysmal rupture. MRI is better than CT for diagnosis, although contrastCTscanning sometimes detects calcification of the AVM.

Surgical treatment of symptomaticAVMs, often with preoperative embolization to reduce operative bleeding, is generally indicated for accessible lesions. Sterotaxic radiation, an alternative to surgery, can produce a slow sclerosis of arterial channels over 1 to 2 years.

Most data suggest that patients with asymptomaticAVMshave a low risk for hemorrhage; the risk increases after a first hemorrhage to about 2 to 3% annually. Several angiographic features of the AVM can be used to help predict future bleeding risk. Paradoxically, smaller lesions seem to have a higher hemorrhage rate. The

mortality rate with each bleed is about 15%.

Venous anomalies are the result of development of anomalous cerebral, cerebellar, or brainstem drainage. These structures, unlikeAVMs, are functional venous channels. They are of little clinical significance and should be ignored if found incidentally on brain imaging studies. Surgical resection of these anomalies may result in venous infarction and hemorrhage. Venous anomalies may be associated with cavernous malformations (see below), which do carry some bleeding risk. If resection of a cavernous malformation is attempted, the venous anomaly should not be disturbed.

Capillary telangiectasias are true capillary malformations that often form extensive vascular networks through an otherwise normal brain structure. The pons and deep cerebral white matter are typical locations, and these capillary malformations can be seen in patients with hereditary hemorrhagic telangiectasia (Osler-Rendu-Weber) syndrome. If bleeding does occur, it rarely produces mass effect or significant symptoms. No treatment options exist.

Acquired Vascular Lesions Cavernous angiomas are tufts of capillary sinusoids that form within the deep hemispheric white matter and brainstem with no normal intervening neural structures. The pathogenesis is unclear. Familial cavernous angiomas have been mapped to several different chromosomal loci; the gene responsible for 7q-linked form encodes a protein that interacts with a member of the RAS family of GTPases. Cavernous angiomas are typically<1 cm in diameter and are often associated with a venous anomaly. Bleeding is usually of small volume, causing slight mass effect only. The bleeding risk for single cavernous malformations is 0.7 to 1.5% per year and may be higher for patients with prior clinical hemorrhage or multiple malformations. Seizures may occur if the malformation is located near the cerebral cortex. Surgical resection eliminates bleeding risk and may reduce seizure risk, but it is reserved for those malformations that form near the brain surface. Radiation treatment has not been shown to be of benefit.

Dural arteriovenous fistulas are acquired connections usually from a dural artery to a dural sinus. Patients may complain of a pulse-synchronous cephalic bruit ("pulsatile tinnitus") and headache. Depending on the magnitude of the shunt, venous pressures may rise high enough to cause cortical ischemia or venous hypertension and hemorrhage. Surgical and endovascular techniques are usually curative. These fistulas may form because of trauma, but most are idiopathic. There is an association between fistulas and dural sinus thrombosis. Fistulas have been observed to appear months to years following venous sinus thrombosis, suggesting that angiogenesis factors elaborated from the thrombotic process may cause these anomalous connections to form. Alternatively, dural arteriovenous fistulas can produce venous sinus occlusion over time, perhaps from the high pressure and high flow through a venous structure.

362. ALZHEIMER'S DISEASE AND OTHER PRIMARY DEMENTIAS- *Thomas D. Bird*

ALZHEIMER'S DISEASE

Alzheimer's disease (AD) is the most common cause of dementia in western countries. Approximately 10% of all persons over the age of 70 have significant memory loss; in more than half the cause is AD. This translates into approximately 3 to 4 million persons with AD in the United States, with a total health care cost of more than $80 billion per year. It is estimated that the annual total cost of caring for a single AD patient in an advanced stage of the disease is $47,000. The disease also exacts a heavy emotional toll on family members and caregivers. AD was first described in 1907 in a 55-year-old woman by Professor Alois Alzheimer in Germany. The condition was initially thought to represent a relatively uncommon form of presenile dementia. However, it has become clear that AD can occur in any decade of adulthood and is the most common cause of dementia in the elderly. The disease is defined as a clinical-pathologic entity. Clinically, AD most often presents with subtle onset of memory loss followed by a slowly progressive dementia that has a course of several years. Pathologically there is gross, diffuse atrophy of the cerebral cortex with secondary enlargement of the ventricular system. Microscopically there are extracellular neuritic plaques containing Abamyloid, silver-staining neurofibrillary tangles in neuronal cytoplasm, and accumulation of Ab amyloid in arterial walls of cerebral blood vessels (see "Pathogenesis," below). The recent identification of four different susceptibility genes for AD has provided a foundation for rapid progress in understanding the biologic basis of the disease.

Clinical Manifestations In the early stages of the disease, the memory loss may go unrecognized or may be ascribed to benign forgetfulness. Slowly the cognitive problems begin to interfere with daily activities, such as keeping track of finances, following instructions on the job, driving, shopping, and housekeeping. Some patients are unaware of these difficulties (agnosognosia), and others have considerable insight, resulting in frustration and anxiety. These major differences in insight have no clear explanation. Change of environment may be bewildering, and the patient may become lost on walks or while driving an automobile. In the middle stages of the disease, the patient is unable to work, is easily lost and confused, and requires daily supervision. Social graces, routine behavior, and superficial conversation may be surprisingly retained. Language may be impaired, especially comprehension and naming of objects. In some patients, aphasia is an early and prominent feature. Word-finding difficulties and circumlocution may be a problem even when formal testing demonstrates intact naming and fluency. Although confrontation naming is frequently deficient, there are often other language deficits as well, including impairments in fluency, comprehension, and repetition. Various apraxias are also common, i.e., deficits in performing sequential motor tasks such as dressing, eating, solving simple puzzles, and copying geometric figures. Patients may be unable to do simple calculations or tell time. Rarely,ADpatients may have a form of cortical blindness in which they deny their inability to see. This correlates at autopsy with severe neuropathologic changes in the visual cortex. In the late stages of the disease, some persons remain ambulatory but wander aimlessly and may have complete loss of judgment, reason, and cognitive abilities. Hallucinations and delusions are common; they are usually concrete and not too complex or bizarre. For example, patients may falsely accuse a spouse of infidelity, not recognize an old friend, think a visitor is a burglar, or become frightened of their own image in a mirror. Loss of

inhibitions and belligerence may occur and may even alternate with passivity and social withdrawal. Sleep-wake patterns may be disturbed, and nighttime wandering may be very disruptive to the household. Some patients develop a shuffling gait with generalized muscle rigidity associated with slowness and awkwardness of movement. The patients often look parkinsonian but rarely have a rapid, rhythmic, resting tremor. In end-stage AD, patients frequently, but not always, become rigid, mute, incontinent, and bedridden. Help may be needed with the simplest tasks, such as eating, dressing, and toilet function. They may show hyperactive tendon reflexes and primitive sucking and snouting reflexes. Myoclonic jerks (sudden brief contractions of various muscles or the whole body) may occur spontaneously or in response to physical or auditory stimulation. This phenomenon raises the possibility of Creutzfeldt-Jakob disease (CJD) (Chap. 375), but the course of AD is much more prolonged. Generalized seizures may also occur. Death usually results from malnutrition, secondary infections, or heart disease. The typical duration of AD is 8 to 10 years, but the course can range from 1 to 25 years. For unknown reasons, some AD patients show a steady downhill decline in function, while others have prolonged plateaus without major deterioration.

Differential Diagnosis Early in the disease course, other etiologies of dementia should be excluded. These include treatable entities such as thyroid disease, vitamin deficiencies, brain tumor, drug and medication intoxication, chronic infection, and severe depression (pseudodementia) (see Chap. 26). Neuroimaging studies [computed tomography (CT) and magnetic resonance imaging (MRI)] are not specific forAD and may be normal early in the course of the disease. However, neuroimaging helps to exclude other disorders, such as primary and secondary neoplasms, multi-infarct dementia, diffuse white matter disease, and normal-pressure hydrocephalus. As AD progresses, diffuse cortical atrophy becomes apparent, and detailed MRI scans show atrophy of the hippocampus (Fig. 362-1*A*). The electroencephalogram (EEG) in AD may be normal or show nonspecific slowing. Routine spinal fluid examination gives normal results. Research studies have indicated a general decrease in cerebrospinal fluid (CSF) Ab amyloid levels with an increase in tau protein. There is considerable overlap of these levels with those of the normal aged population, and the usefulness of these measurements in diagnosis remains unclear. Combining the results of both measurements may prove to be most helpful. The use of blood apolipoprotein (Apo) E genotyping is discussed under "Pathogenesis," below. Slowly progressive decline in memory and orientation, normal results on laboratory tests, and an MRI or CT scan showing only diffuse cortical atrophy including the hippocampus is highly suggestive of AD. A clinical diagnosis of AD reached after careful evaluation is confirmed at autopsy 80 to 90% of the time. The misdiagnosed cases usually represent one of the other dementing disorders described later in this chapter. Relatively simple clinical clues are useful in the differential diagnosis. Early prominent gait disturbance with only mild memory loss suggests normal-pressure hydrocephalus (see below). Resting tremor with stooped posture, bradykinesia, and masked face suggests Parkinson's disease (Chap. 363). Chronic alcoholism suggests vitamin deficiency. Loss of sensibility to position and vibration stimuli accompanied by Babinski responses suggests vitamin B_{12}deficiency (Chap. 368). Early onset of a seizure suggests a metastatic or primary brain neoplasm (Chap. 370). A past history of long-term depression suggests pseudodementia (see below). A history of treatment for insomnia, anxiety, psychiatric disturbance, or epilepsy suggests chronic drug intoxication. Rapid progression over a few weeks or months associated with ataxia, rigidity, and myoclonus suggestsCJD(Chap. 375). Prominent

behavioral changes with intact memory and lobar atrophy on brain imaging suggests frontotemporal dementia (FTD). A positive family history of dementia suggests either one of the familial forms of AD or one of the other genetic disorders associated with dementia, such as Huntington's disease (see below), familial FTD (see below), familial forms of prion diseases, or rare forms of hereditary ataxias (Chap. 364).

Pathogenesis The most important risk factors forAD are old age and a positive family history. The frequency of AD increases with each decade of adult life to reach 20 to 40% of the population over the age of 85. A positive family history of dementia suggests a genetic cause of AD, as discussed below. Female gender may also be a risk factor independent of the greater longevity of women. Unconfirmed studies have suggested that postmenopausal estrogen use is associated with a decreased frequency of AD. Some AD patients have a past history of head trauma with concussion, but this appears to be a relatively minor risk factor. There is some suggestion that AD is more common in groups with lower educational attainment, but education influences test-taking ability, and it is clear that AD can affect persons of all intellectual levels. One unconfirmed study found that the capacity to express complex written language in early adulthood correlated with a decreased risk for AD. Numerous environmental factors, including aluminum, mercury, viruses, and prions, have been proposed as causes of AD, but none has been proved to play a role. Preliminary studies have suggested that inflammation may play some role in the pathogenesis of AD, as the use of nonsteroidal anti-inflammatory agents is associated with decreased risk. Vascular disease does not seem to be a direct cause of AD, even though there is an associated amyloid angiopathy.

Positron emission tomography (PET) has indicated that the earliest metabolic changes inAD occur in parietal cortex (Fig. 362-1*C, D*). At autopsy, the most severe pathology is usually seen in the hippocampus, temporal cortex, and nucleus basalis. The most important microscopic findings are neuritic "senile" plaques and cytoplasmic neurofibrillary tangles (NFTs). These two lesions accumulate in small numbers during normal aging of the brain but occur in quantitative excess in the dementia of AD. The neuritic plaques contain a central core that includes Ab amyloid, proteoglycans, Apo E,$a_1$antichymotrypsin, and other proteins. Ab amyloid is a 4.2-kDa protein of 39 to 42 amino acids that is derived proteolytically from a larger transmembrane protein (amyloid precursor protein, APP) through cleavage by two enzymes termed b andg secretase. The normal function of Ab amyloid is unknown. APP has been shown to have neurotrophic and neuroprotective activities. The plaque core is surrounded by the debris of degenerating neurons, microglia, and macrophages. The accumulation of Ab amyloid in cerebral arterioles is termed *amyloid angiopathy*. The NFTs were first noted by Alzheimer. They are silver-staining, twisted neurofilaments in neuronal cytoplasm that represent abnormally phosphorylated tau (t) protein and appear as paired helical filaments by electron microscopy. Tau is a microtubule-associated protein that may function to assemble and stabilize the microtubules that convey cell organelles, glycoproteins, and other important materials through the neuron. The ability of tau protein to bind to microtubule segments is determined partly by the number of phosphate groups attached to it. Increased phosphorylation of tau protein may disturb this normal process. Biochemically, AD is associated with a decrease in the cerebral cortical levels of several proteins and neurotransmitters, especially acetylcholine, its synthetic enzyme choline acetyltransferase (CAT), and nicotinic cholinergic receptors.

Reduction of acetylcholine may be related in part to degeneration of cholinergic neurons in the nucleus basalis of Meynert that project to many areas of cortex. There is also reduction in norepinephrine levels in brainstem nuclei such as the locus coeruleus.

Several genetic factors are known to play important roles in the pathogenesis of at least some cases ofAD. One is the*APP*gene on chromosome 21. Adults with trisomy 21 (Down's syndrome) consistently develop the typical neuropathologic hallmarks of AD if they survive beyond age 40. Many also develop a progressive dementia superimposed on their baseline mental retardation. APP is a membrane-spanning protein that is subsequently processed into smaller units, including the Ab amyloid that is deposited in the neuritic plaques of AD. Presumably the extra dose of the *APP* gene on chromosome 21 is the initiating cause of AD in adult Down's syndrome and eventually results in an excess of cerebral Ab amyloid. Furthermore, a few families with early-onset familial AD (FAD) have been discovered to have point mutations in the *APP* gene. Although very rare, these families were the first indication of a single-gene autosomal dominant transmission of AD. The most frequent of these *APP* mutations is substitution of valine for isoleucine at position 717. Elevated plasma Ab peptide may be a risk factor for developing AD in the general population.

Investigation of large families with multigenerationalFAD led subsequently to the discovery of two additionalADgenes, termed the *presenilins*. Presenilin-1 (*PS-1*) is on chromosome 14 and encodes a protein called S182. Mutations in this gene cause an early-onset AD (onset before age 60 and often before age 50) that is transmitted in an autosomal dominant, highly penetrant fashion. More than 40 different mutations have been found in the *PS-1* gene in families from a wide range of ethnic backgrounds. Presenilin-2 (*PS-2*) is on chromosome 1 and encodes a protein called STM2. A mutation in the *PS-2* gene was first found in a group of American families with Volga German ethnic background. The two genes (*PS-1* and *PS-2*) are highly homologous and encode similar proteins that at first appeared to have seven transmembrane domains (hence the designation *STM*), but subsequent studies have suggested eight such domains with a ninth submembrane region. The normal function of these proteins and the means by which mutations affecting them result in AD is unknown. Both S182 and STM2 are cytoplasmic neuronal proteins that are widely expressed throughout the nervous system. They are homologous to a cell-trafficking protein, sel 12, that is found in the nematode *Coenorhabditis elegans*. Knockout of the *PS-1* gene in mice causes embryonic death, but PS-2 knockout mice have only mild pulmonary pathology, suggesting very different primary functions of the two proteins. The AD pathology in transgenic mice carrying both APP and PS-1 mutations is worse than that in mice with only a single mutation. Also, the mutant human *PS-1* gene protects PS-1 knockout mice from embryonic lethality, and this observation fits with the idea that *PS-1* mutations cause disease by a toxic gain of function. Patients with mutations in these genes have elevated plasma levels of Ab amyloid, suggesting a possible link between the presenilins andAPP. There is evidence that presenilin-1 may normally cleave APP at theg secretase site, and mutations in either gene (*PS-1* or *APP*) may disturb this function. Mutations in *PS-1* have thus far proved to be the most common cause of early-onset FAD, representing 40 to 70% of this relatively rare syndrome. Mutations in *PS-1* tend to produce AD with an earlier age of onset (mean, 45 years) and a shorter, more rapidly progressive course (mean duration, 6 to 7 years) than the disease caused by mutations in *PS-2* (onset, 53 years; duration, 11 years). Some carriers of uncommon

PS-2 mutations have had onset of dementia after the age of 70. Mutations in the presenilins are rarely involved in the more common sporadic cases of late-onset AD occurring in the general population. Molecular DNA blood testing for these uncommon mutations is now possible on a research basis, and mutation analysis of *PS-1* is commercially available. Such testing is likely to be positive only in early-onset cases of FAD. Any testing of asymptomatic persons at risk must be done in the context of formal, thoughtful genetic counseling (Chap. 359).

A discovery of great importance has implicated the *Apo E* gene on chromosome 19 in the pathogenesis of late-onset familial and sporadic forms ofAD. Apo E is involved in cholesterol transport (Chap. 344) and has three alleles:e2, e3, ande4. The e4 allele of *Apo E* shows a strong association with AD in the general population, including sporadic and late-onset familial cases. Approximately 24 to 30% of the normal white population has at least onee4 allele (12 to 15% allele frequency), and about 2% aree4/4 homozygotes. In a group of AD patients, approximately 40 to 65% have at least onee4 allele, a highly significant difference compared with controls. On the other hand, many AD patients have noe4 allele, and individuals withe4 may never develop AD. Therefore,e4 is neither necessary nor sufficient as a cause of AD. Nevertheless, it is clear that the Apo E e4 allele, especially in the homozygous 4/4 state, is an important risk factor for AD. It appears to act as a dose-dependent modifier of age of onset, with the earliest onset associated with the e4/4 homozygous state. One study found a 45% risk for developing AD by age 73 in females who were 4/4 homozygotes. It is unknown how Apo E functions as a risk factor modifying age of onset. Apo E is present in the neuritic amyloid plaques of AD, and may also be involved inNFTformation, because it binds to tau protein. Apo E4 decreases neurite outgrowth in cultures of dorsal root ganglion neurons. There is suggestive evidence that the e2 allele may be "protective." Interesting but unconfirmed reports suggest that AD patients with ane4 allele may be less responsive cholinesterase inhibitor drugs. The use of Apo E testing in the diagnosis of AD is controversial. It is not indicated as a predictive test in normal persons, because its precise predictive value is unclear, and many individuals with thee4 allele never develop dementia. However, some cognitively normal e4/4 homozygotes have been found byPET to have decreased cerebral cortical metabolic rates, suggesting possible presymptomatic abnormalities compatible with the earliest stage of AD. Studies show that in demented persons who meet clinical criteria for AD, the finding of an e4 allele increases the reliability of diagnosis. However, the absence of an e4 allele does not eliminate the diagnosis of AD. Furthermore, all patients with dementia, including those with an e4 allele, require a search for reversible causes of their cognitive impairment. Nevertheless, Apo E remains the single most important biologic marker associated with risk for AD, and studies of its functional role and diagnostic usefulness are progressing rapidly. Its association (or lack thereof) with other dementing illnesses needs to be fully evaluated. The e4 allele is not associated with the dementia of Parkinson's disease,FTD, orCJD.

Additional genes are also likely to be involved inAD, including a potential candidate on chromosome 12 (a_2-macroglobulin).

TREATMENT

The management of Alzheimer's disease is difficult and frustrating, because there is no

specific treatment and the primary focus is on long-term amelioration of associated behavioral and neurologic problems. Building rapport with the patient, family members, and other caregivers is essential to successful management.

Tacrine (tetrahydroaminoacridine) and donepezil (Aricept) are the only drugs presently approved by the U.S. Food and Drug Administration (FDA) for treatment ofAD. Their pharmacologic action is presumed to be inhibition of cholinesterase, with a resulting increase in cerebral levels of acetylcholine. Double-blind, placebo-controlled, crossover studies with cholinesterase inhibitors have shown them to be associated with improved caregiver ratings of patients' functioning and with an apparent decreased rate of decline in cognitive test scores over periods of up to 2 years. Such studies are difficult to perform because of the subjective nature of many of the observations and the lack of a uniform rate of decline among patients. Nevertheless, a small but important minority of AD patients (approximately 10 to 20%) appear to show a modest response to these agents and tolerate their side effects (which include dose-related nausea, vomiting, diarrhea, bradycardia, and dizziness). Even without actual improvement these agents may provide stabilization of the patient's condition for a period of months. There is no evidence that these drugs are beneficial in the late stages of AD. Tacrine may be hepatotoxic, necessitating frequent testing of liver function and adjustment of the dose. Donepezil is not hepatotoxic and can be administered once daily (5 to 10 mg). Contraindications for cholinesterase inhibitor treatment include liver disease, alcoholism, peptic ulcer disease, chronic obstructive pulmonary disease; and bradycardia. Clinical trials of other anticholinesterase drugs are in progress.

In a recent prospective observational study, the use of estrogen replacement therapy appeared to protect -- by about 50% -- against development ofAD in women. This study appeared to confirm the results of two earlier case-controlled studies. On the other hand, a prospective treatment study of women with AD found no difference between estrogen and placebo. The mechanism of possible estrogen effects on Alzheimer's disease is unknown but may result from direct effects on cholinergic neurons, antioxidant properties, or a lowering of levels of Apo E. A prospective randomized clinical trial of estrogen replacement therapy in women is underway.

In patients with moderately advancedAD, a prospective trial of the antioxidants selegiline, atocopherol (vitamin E), or both demonstrated no significant benefit on primary outcomes of progression. However, a modest beneficial effect of each treatment compared to placebo was present in secondary analyses that controlled for intergroup difference in baseline dementia scores. These possible beneficial effects are small in magnitude and require confirmation.

A randomized, double-blind, placebo-controlled trial of an extract of *Ginkgo biloba* found modest improvement in cognitive function in subjects withAD and vascular dementia. This study requires confirmation before *G. biloba* is considered an effective treatment for dementia, because there was a high subject dropout rate and no improvement on a clinician's judgment scale.

As noted above, several retrospective studies have also suggested a protective effect on dementia of nonsteroidal anti-inflammatory agents. Controlled prospective studies are in progress.

In anAPPmutation mouse model ofAD, weekly immunization with Ab peptide both prevented the occurrence and reversed the accumulation of amyloid plaques in the brain. The possible benefit of this treatment strategy in humans is unknown and is under evaluation. In addition, the identification of a protease that acts as the APPb secretase has raised the possibility that inhibiting this enzyme might decrease amyloid accumulation in brain, another potential therapeutic strategy for AD.

Mild to moderate depression is common in the early stages ofAD and may respond to antidepressant medication. Selective serotonin reuptake inhibitors (SSRIs) are commonly used, as are tricyclic antidepressants with low anticholinergic side effects (desipramine and nortriptyline). Generalized seizures should be treated with an appropriate anticonvulsant, such as phenytoin or carbamazepine. Agitation, insomnia, hallucinations, and belligerence are especially troublesome characteristics of some AD patients and often are responsible for nursing home placement. Mild sedation with benadryl may help insomnia, and agitation has been variously treated with phenothiazines (such as thioridazine), haloperidol, risperidone, and benzodiazepines (such as lorazepam). These medications frequently have untoward side effects, including sedation, confusion, increased muscle tone, and adventitious movements. Low-dose haloperidol (0.5 to 2 mg), trazodone, buspirone, propranolol, and olanzapine may be the most helpful and have the fewest side effects. The few controlled studies comparing drugs with behavioral intervention in the treatment of agitation suggest that both approaches are equally effective. However, careful, daily, nondrug behavior management is often not available, rendering medication necessary. In the early stages of AD, memory aids such as notebooks and posted daily reminders are helpful. Common sense and clinical studies have shown that family members should emphasize activities that are pleasant and deemphasize those that are unpleasant. Kitchens, bathrooms, and bedrooms need to be made safe, and patients eventually must stop driving. Loss of independence and change of environment may worsen confusion, agitation, and anger. Communication and repeated calm reassurance are necessary. Caregiver "burnout" is common, often resulting in nursing home placement of the patient and respite breaks for the caregiver help to maintain successful long-term management of the patient. Use of adult daycare centers can be most helpful. Local and national support groups, such as the Alzheimer's Disease and Related Disorders Association, are valuable resources.

VASCULAR DEMENTIA

Dementia associated with cerebral vascular disease can be divided into two general categories: multi-infarct dementia and diffuse white matter dementia (also called subcortical arteriosclerotic encephalopathy or Binswanger's disease). Cerebral vascular disease appears to be a more common cause of dementia in Asia than in Europe and North America. Individuals who have had several strokes may develop chronic cognitive deficits, commonly called *multi-infarct dementia*. The strokes may be large or small (sometimes lacunar) and usually involve several different brain regions. In fact, one study has shown that lacumar stroke is the most common stroke subtype associated with dementia. The occurrence of dementia seems to depend partly on the total volume of damaged cortex, but it is also more common in individuals with left-hemisphere lesions, independent of any language disturbance, and when the stroke involves the

hippocampus. Subcortical infarction has been associated with both frontal and global cerebral hypometabolism, which may in turn lead to dementia. The patients give a history of episodes of sudden neurologic deterioration. Multi-infarct dementia patients usually also have a history of hypertension, diabetes, coronary artery disease, or other manifestations of diffuse atherosclerosis. Physical examination usually reveals focal neurologic deficits such as hemiparesis, unilateral Babinski reflex, a visual field defect, or pseudobulbar palsy. The recurrent strokes result in a stepwise progression of disease. Neuroimaging studies clearly show the multiple areas of infarction. Thus, the history and neuroimaging findings differentiate this condition fromAD. However, AD and multiple infarctions are both common and sometimes occur together. With normal aging, there is also an accumulation of amyloid in cerebral blood vessels, leading to a condition called *cerebral amyloid angiopathy of aging* (not associated with dementia), which predisposes older persons to hemorrhagic lobar stroke. AD patients with amyloid angiopathy and hypertension also appear to be at increased risk of cerebral infarction. Apo Ee4 has been reported to be a risk factor for amyloid angiopathy independent of AD.

Some persons with dementia are discovered onMRIstudies to have bilateral abnormalities of subcortical white matter, termed *diffuse white matter disease* (or leukoaraiosis) (Fig. 362-2). The dementia may be of subtle onset and slow progression, features that distinguish it from multi-infarct dementia. (A few such patients have been described with apparently sudden onset of cognitive impairment.) Early symptoms are mild confusion, apathy, change in personality, and memory deficit. Marked difficulties in judgment and orientation and dependence on others for daily activities develop later. Euphoria, elation, or aggressive behavior are common. A mixed picture of pyramidal and cerebellar signs may be present in the same patient. Lateralizing motor signs are uncommon. A gait disorder appears in at least half the patients. In advanced cases, urinary incontinence and dysarthria with or without pseudobulbar features are frequent. Seizures and myoclonic jerks appear in a minority of patients. This disorder appears to be the result of chronic ischemia due to occlusive disease of small penetrating cerebral arteries and arterioles (microangiopathy). The patients usually, but not always, have a history of hypertension, but any disease causing stenosis of small cerebral vessels may be the critical underlying factor. An association with abnormalities of the coagulation-fibrinolysis pathway has been reported. Binswanger described several patients with this condition, but the term *Binswanger's disease* should be used with caution, because it does not really identify a single entity. Other rare causes of white matter disease may also present with dementia, such as adult metachromatic leukodystrophy and progressive multifocal leukoencephalopathy (papovavirus infection). The term *CADASIL* refers to an inherited form of diffuse white matter disease described as *c*erebral *a*utosomal *d*ominant *a*rteriopathy with *s*ubcortical *i*nfarcts and *l*eukoencephalopathy. Clinically there is a progressive dementia developing in the fifth to seventh decades in multiple family members who may also have a history of migraine and recurrent stroke without hypertension. Skin biopsy may show characteristic dense bodies in the media of arterioles. The disease is caused by mutations in the notch 3 gene, but there is no commercially available genetic test. The frequency of this disorder is unknown.

Treatment of vascular dementia must be focused on the underlying causes, such as hypertension, atherosclerosis, and diabetes. Recovery of lost cognitive function is not

likely to occur.

FRONTOTEMPORAL DEMENTIA AND PICK'S DISEASE

FTDmay be the cause of as many as 10% of all cases of dementia and an even greater proportion of presenile onset (<65 years) cases. The patients are often irritable; have loss of inhibitions; and do better on construction, copying, and calculation tasks than patients withAD. Memory is often intact early in the disease. Patients may be socially inappropriate or remote and withdrawn. Hoarding, overeating, and weight gain are common. Rigidity and mutism often occur late in the disease. Imaging studies reveal atrophy confined to the frontal or frontal and temporal lobes. The condition is heterogeneous, and the broad designation FTD usually includes Pick's disease (discussed below) as a subcategory. An autosomal dominant genetic form of FTD has been linked to DNA markers on chromosome 17. Some of these families have disinhibition dementia associated with motor neuron disease, whereas others display parkinsonian features. Cytoplasmic aggregations of tau protein are found in many neurons of cortex, striatum, and substantia nigra. These aggregates sometimes resemble those found in progressive supranuclear palsy (Chap. 363) or AD. This condition is referred to as *frontotemporal dementia with parkinsonism linked to chromosome 17* (FTDP-17). Many FTDP-17 families have been found to inherit missense mutations in the tau gene that disturb the microtubule-binding function of tau or alter the carefully regulated alternative splicing of the gene. Recent studies show that only a small portion of sporadic FTD patients have tau mutations, which are more commonly found in familial FTD cases with known tau neuropathology at autopsy.

Pick's disease is a commonly discussed disorder that is difficult to differentiate clinically fromAD and is less well defined as a distinct entity. The major distinguishing hallmark is marked symmetric lobar atrophy of temporal and/or frontal lobes, which can be visualized by neuroimaging studies (CT,MRI, or single photon emission CT) and is readily apparent at autopsy. The atrophy is sometimes asymmetric and may involve the basal ganglia. Microscopic findings include gliosis, neuronal loss, and swollen or ballooned neurons, which frequently contain silver-staining cytoplasmic inclusions referred to as *Pick bodies*. Pick bodies consist of straight and constricted fibrils that share antigenic determinants with theNFTs of AD, including the microtubule-associated protein tau, suggesting that Pick bodies derive from altered components of the neuronal cytoskeleton. Onset is usually in the fifth through seventh decades. Clinically, there is a slowly progressive dementia often associated with hyper-oral behavior, bulimia, language disturbance, emotional disinhibition, irritability, and persistent aimless wandering. In the early stages the behavioral changes are more prominent than memory loss. The language disturbance may be aphasia or forced repetitive speech patterns, sometimes progressing to echolalia, language impoverishment, and mutism. These clinical characteristics may sometimes occur in AD, so that the clinical diagnosis of Pick's disease often requires confirmation at autopsy. Some brains containing Pick bodies may also have varying quantities of amyloid plaques and NFTs, blurring the distinction from AD. Examples of familial Pick's disease that display an autosomal dominant-like pattern of inheritance have been reported. There is no specific treatment.

DIFFUSE LEWY BODY DISEASE

Lewy bodies are intraneuronal cytoplasmic inclusions that stain with periodic acid-Schiff and ubiquitin. They are composed of straight neurofilaments 7 to 20 nm long with surrounding amorphous material. They contain epitopes recognized by antibodies against phosphorylated and nonphosphorylated neurofilament proteins, ubiquitin, and a presynaptic protein called a-synuclein. Lewy bodies are traditionally found in the substantia nigra of patients with idiopathic Parkinson's disease (Chap. 363). Large numbers of such inclusions have also been discovered in cortical neurons in patients with dementia. In patients without other pathologic features, the condition is referred to as *diffuse Lewy body disease*. In patients whose brains also contain amyloid plaques andNFTs, the condition is called the *diffuse Lewy body variant of Alzheimer's disease*. The quantity of Lewy bodies required to establish the diagnosis is uncertain. The diagnosis is primarily a neuropathologic entity; however, there is some evidence that there is a characteristic clinical syndrome. In addition to chronic progressive dementia, these patients often also have parkinsonian features, in particular rigidity, which may be combined with an intention tremor. Frequent fluctuations of behavior, cognitive ability, and level of alertness may occur. These fluctuations can be marked, with the occurrence of episodic confusion and lucid intervals suggesting delirium. However, despite the fluctuating pattern, the clinical features persist over a long period, unlike a typical transient delirium. Delusions and visual hallucinations are common, and auditory hallucinations may also occur. Repeated unexplained falls are often noted. Frequently there is an unusual sensitivity to neuroleptic medications and benzodiazepines, with exaggerated adverse responses to standard doses. In most patients, this condition is difficult to distinguish fromAD or Parkinson's disease with dementia. The population prevalence of diffuse Lewy body disease is not known, but it is now more commonly diagnosed than in the past because of the use of ubiquitin staining during neuropathologic studies. At autopsy, 10 to 30% of demented patients may show cortical Lewy bodies. It is not yet clear what role Apo E may play in Lewy body disease without AD changes. There is no specific treatment.

NORMAL-PRESSURE HYDROCEPHALUS (VIDEO 361-4)

Normal-pressure hydrocephalus (NPH) is a syndrome with distinct clinical, physiologic, and neuroimaging characteristics. The clinical triad includes an abnormal gait (ataxic or apractic), dementia (usually mild to moderate), and urinary incontinence. Neuroimaging studies of the brain reveal enlarged lateral ventricles (hydrocephalus) with little or no cortical atrophy. This is a communicating hydrocephalus with a patent aqueduct of Sylvius and upward stretching of the corpus callosum (Fig. 362-3). Lumbar puncture opening pressure is in the high normal range, and theCSFprotein and sugar concentrations and cell count are normal. NPH is presumed to be caused by obstruction to normal flow of CSF over the cerebral convexity and delayed absorption into the venous system. The indolent nature of the process results in enlarged lateral ventricles but relatively little increase in CSF pressure. There is presumably stretching and distortion of white matter tracts in the corona radiata, but the exact physiologic cause of the clinical syndrome is unclear. Some patients with NPH have a history of conditions producing scarring of the basilar meninges (blocking upward flow of CSF) such as previous meningitis, subarachnoid hemorrhage, or head trauma. Most patients seem to have no pertinent past history. In contrast to patients withAD, the patient with NPH has an early and prominent gait disturbance and no evidence of cortical atrophy onCT orMRI. A number of attempts have been made to use various special studies to improve

the diagnosis of NPH and predict the success of ventricular shunting. These include radionuclide cisternography (showing a delay in CSF absorption over the convexity) and various attempts to monitor and alter CSF flow dynamics, including a constant-pressure infusion test. None of these studies has proven to be specific or consistently useful. There is sometimes a transient improvement in gait or cognition following lumbar puncture (or serial punctures) with removal of 30 to 50 mL of CSF, but this finding also has not proved to be consistently predictive of post-shunt improvement. One study determined that no more than 1 to 2% of a large group of demented patients had NPH. AD often masquerades as NPH, because the gait may be abnormal in AD and cortical atrophy is sometimes difficult to determine by CT or MRI early in the disease. Hippocampal atrophy on MRI may be a clue suggesting AD (Fig. 362-1). Approximately 30 to 50% of patients identified by careful diagnosis as having NPH will show improvement with a ventricular shunting procedure. Gait may improve more than memory. Transient, short-lasting improvement is common. Patients should be carefully selected for this operation, because subdural hematoma and infection are known complications. A recent study limited to four patients showed benefit from aggressive siphoning of CSF to reduce ventricular size, but there were frequent perioperative complications.

HUNTINGTON'S DISEASE

Huntington's disease (HD) is a genetic, autosomal dominant, degenerative brain disorder. It has a population frequency of about 10/100,000. The two clinical hallmarks of the disease are chorea and behavioral disturbance. The illness may begin with either or both of these symptoms predominating. Onset is usually in the fourth or fifth decade, but there is a wide range in age of onset, from childhood to>75 years. The chorea begins as subtle fidgeting that may be unrecognized by the patient and family. However, the movement disorder is usually slowly progressive and eventually may become disabling. There are frequent, irregular, sudden jerks and movements of any of the limbs or trunk. Grimacing, grunting, and poor articulation of speech may be prominent. The gait is disjointed and poorly coordinated and has a so-called dancing (choreic) quality. Memory is frequently not impaired until late in the disease, but attention, judgment, awareness, and executive functions may be seriously deficient at an early stage. Depression, apathy, social withdrawal, irritability, and intermittent disinhibition are common. Delusions and obsessive-compulsive behavior may occur. Schizophrenia is occasionally the initial diagnosis. The disease duration is typically about 15 years but also shows a wide range. Early onset before the age of 20 (juvenile HD) is associated with rigidity, ataxia, cognitive decline, and more rapid progression, with a typical duration of about 8 years. Seizures are rare with adult-onset HD but more common with juvenile-onset disease. There is no specific treatment, but the adventitious movements and behavioral changes may partially respond to phenothiazines, haloperidol, benzodiazepines, or olanzepine.SSRIsmay help with the frequently associated depression.

Neuropathologically, the disease predominantly strikes the striatum. Atrophy of the caudate nuclei, which form the lateral margins of the lateral ventricles, can be visualized on neuroimaging studies in the middle and late stages of the disease (Fig. 362-4). More diffuse cortical atrophy can be seen late in the disease. Microscopically there are no dramatic pathologic characteristics, such as the plaques and tangles seen withAD.

However, there is gliosis and neuronal loss, especially of medium-sized spiny neurons in the caudate and putamen. Some neurons contain intranuclear inclusions that stain with antibodies to polyglutamine. There is relative sparing of large cholinergic aspiny neurons. (Treatment with 3-nitroproprionic acid, a succinate dehydrogenase inhibitor, has producedHD-like pathologic changes in experimental animals). Neurochemically there is a marked decrease of g-aminobutyric acid (GABA) and its synthetic enzyme glutamic acid decarboxylase throughout the basal ganglia. The levels of other neurotransmitters, including substance P and enkephalins, are also reduced. Magnetic resonance spectroscopy (MRS) in living subjects with HD has shown elevated levels of lactate in the basal ganglia.

TheHD gene, called *IT15*, is located on chromosome 4p, contains a CAG trinucleotide repeat expansion, and codes for a protein called *huntingtin*. The protein is found in neurons throughout the brain; its normal function is unknown. Inactivation of the homologous gene in mice causes embryonic death in homozygotes, but heterozygotes are phenotypically normal. Transgenic mice with an expanded CAG repeat in the HD gene develop a progressive movement disorder. The CAG repeat codes for a long polyglutamine domain in the expressed protein. The disease process may result from a toxic gain of function (Chap. 359). One hypothesis is that these polyglutamine tracts cause abnormal protein-binding reactions, which then interfere with other cell processes such as mitochondrial activity. The HD mutation may lead to abnormal cleavage of the huntingtin protein, passage of protein fragments from cytoplasm to nucleus, and interference of nuclear mechanisms leading to apoptosis and neuronal death.

The DNA repeat expansion forms the basis of a diagnostic blood test for the disease gene. Persons having 38 or more CAG repeats in theHD gene have inherited the disease mutation and will eventually develop symptoms if they live to an advanced age. Each of their children has a 50% risk of also inheriting the abnormal gene. There is a rough correlation between a larger number of repeats and an earlier age of onset, but most patients fall into a range of intermediate repeat numbers (40 to 49 repeats) in which this correlation is not clinically useful. For unclear reasons, juvenile onset with a large repeat expansion most often occurs when the father is the affected parent (a form of genetic anticipation). There is a CAG repeat range (about 26 to 37) in the HD gene that is rarely associated with clinical symptoms, but it is unstable and may expand to a symptomatic range when passed to a child. Asymptomatic adult children at risk for HD should receive careful genetic counseling prior to DNA testing, because a positive result may have serious emotional and social consequences. Detailed testing and counseling protocols have been published. In addition to use in genetic counseling of persons at risk for HD, the DNA test can also be used in differential diagnosis. For example, some persons with late-onset, apparently sporadic "senile" chorea have been found to carry the HD mutation. Also, disorders that may mimic HD, such as schizophrenia, benign familial chorea, inherited ataxias, neural acanthocytosis, andFAD, will not show the CAG expansion in the HD gene.

OTHER DEGENERATIVE DEMENTIAS

Several other primary neurologic disorders have been associated with dementia and are the result of various poorly understood degenerative neuronal processes. These conditions include progressive supranuclear palsy, cortical basal degeneration, primary

progressive aphasia, and the amyotrophic lateral sclerosis (ALS)/parkinsonian/dementia complex of Guam. These are progressive dementing illnesses of unknown cause whose names are descriptive of the typical clinical signs or the anatomic brain areas that are involved with nonspecific atrophy and neuronal degeneration.

Progressive supranuclear palsy (Chap. 363) is a degenerative disease that involves both the brainstem and neocortex with diffuseNFTs. Clinically, this disorder begins with vertical supranuclear gaze paresis and progresses slowly to include symmetric rigidity and dementia. Stiff, unstable posture with hyperextension of the neck and slow gait with frequent falls are common. Early in the disease, the patients have difficulty with downgaze and lose vertical opticokinetic nystagmus on downward movement of the target. Although the patients have very limited voluntary eye movements, their eyes still retain oculocephalic reflexes (doll's head maneuver). The dementia is considered to be of the subcortical type, with slowed thought processes, impaired verbal fluency, and difficulty with sequential actions and with shifting from one task to another. Seizures and sleep apnea may occur. There is only a limited response to L-dopa, and there is no other effective treatment. Death occurs within 5 to 10 years. At autopsy, the NFTs are found in multiple subcortical structures (including the subthalamus, globus pallidus, substantia nigra, locus coeruleus, periaqueductal gray matter, superior colliculi, and oculomotor nuclei) as well as in the neocortex. The NFTs have similar staining characteristics to those ofAD, but on electron microscopy they generally are seen to consist of straight tubules rather than the paired helical filaments found in AD.

Progressive supranuclear palsy is often confused with idiopathic *Parkinson's disease* (Chap. 363). Although elderly Parkinson's patients may have some difficulty with upgaze, they do not develop significant downgaze paresis or progressive supranuclear palsy, and neurologic findings in Parkinson's disease are more likely to be asymmetric. However, dementia does occur in approximately 20% of Parkinson's disease patients. The occurrence of dementia in Parkinson's disease is more likely with increasing age, increasing severity of extrapyramidal signs, and the presence of depression. These patients may also show cortical atrophy on brain imaging. Neuropathologically, there may be Alzheimer changes in the cortex (amyloid plaques andNFTs), neuronal Lewy body inclusions in both the substantia nigra and the cortex, or no specific microscopic changes other than gliosis and neuronal loss.

Cortical basal ganglionic degeneration is a slowly progressive dementing illness associated with severe gliosis and neuronal loss in both the neocortex and basal ganglia (substantia nigra and striatum). There is often a unilateral onset with rigidity, dystonia, and apraxia of one arm and hand ("alien hand" syndrome). Eventually the condition becomes bilateral and includes dysarthria, slow gait, action tremor, and dementia. The microscopic features include enlarged, achromatic neurons in the cortex, and there may also beNFTs and amyloid plaques. The condition is rarely familial; the cause is unknown; and there is no specific treatment.

Another entity is *primary progressive aphasia* (Chap. 25). Patients with this disorder have aphasia associated with asymmetric atrophy of the left hemisphere and occasionally go on to develop dementia. Neuroimaging studies show the left hemisphere atrophy. Some patients are nonfluent, with hesitant, telegraphic speech associated with impaired comprehension and naming. Neuropathologic studies have

shown a heterogeneous group of abnormalities, including Pick's disease,AD,CJD, and nonspecific gliosis.

The*ALS*/*parkinsonian/dementia complex of Guam* is a rare degenerative disease that occurs in the Chamorro natives on the island of Guam. Individual patients may have any combination of parkinsonian features, dementia, and motor neuron disease. The most characteristic pathologic features are the presence ofNFTs in degenerating neurons of the cortex and substantia nigra and loss of motor neurons in the spinal cord. Epidemiologic evidence supports a probable environmental cause, such as exposure to a neurotoxin with a long latency period. One interesting but unproven candidate neurotoxin occurs in the seed of the false palm tree (cycad), which Guamanians traditionally used to make flour. The possibility of a contributing genetic factor has not been excluded. The ALS syndrome is decreasing in frequency on Guam, but a dementing illness with rigidity continues to be seen.

Finally, rare forms of degenerative dementia continue to be reported, such as dementia lacking specific histologic features and an early-onset hereditary dementia caused by mutations in neuroserpin, a type of serine protease inhibitor.

363. PARKINSON'S DISEASE AND OTHER EXTRAPYRAMIDAL DISORDERS - *Michael J. Aminoff*

PARKINSON'S DISEASE

Parkinsonism is a syndrome consisting of a variable combination of tremor, rigidity, bradykinesia, and a characteristic disturbance of gait and posture. Parkinson's disease is a chronic, progressive disorder in which idiopathic parkinsonism occurs without evidence of more widespread neurologic involvement.

Parkinson's disease generally commences in middle or late life and leads to progressive disability with time. The disease occurs in all ethnic groups, has an equal sex distribution, and is common, with a prevalence of 1 to 2 per 1000 of the general population and 2 per 100 among people older than 65 years. Signs of parkinsonism are extremely common in the elderly; one survey indicated that 15% of individuals between 65 and 74 years of age, and more than half of all individuals after age 85, have abnormalities on examination consistent with the presence of an extrapyramidal disorder.

Neuroanatomy Symptoms of Parkinson's disease are caused by loss of nerve cells in the pigmented substantia nigra pars compacta and the locus coeruleus in the midbrain. Cell loss also occurs in the globus pallidus and putamen. Eosinophilic intraneural inclusion granules (Lewy bodies) are present in the basal ganglia, brainstem, spinal cord, and sympathetic ganglia.

Pars compacta neurons of the substantia nigra provide dopaminergic input to the striatum, which is part of the basal ganglia (Fig. 22-4*A*). In Parkinson's disease, loss of pars compacta neurons leads to striatal dopamine depletion and ultimately to reduced thalamic excitation of the motor cortex (Fig. 22-4*B*). Other neurotransmitters, such as norepinephrine, are also depleted, with clinical consequences that are uncertain but perhaps contribute to depression, dysautonomia, and "freezing" episodes of marked akinesia.**The neural pathways that modulate motor activity are considered in detail in Chap. 22.*

Pathogenesis Parkinsonism can be induced in primates by exposure to 1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine (MPTP), which is converted by monoamine oxidase B to *N*-methyl-4-phenylpyridinium (MPP^+), an active toxin. MPP^+ is taken up by dopaminergic nigral neurons through an active transport system that is normally involved in dopamine reuptake, and then inhibits oxidative phosphorylation, possibly at the level of complex I in the respiratory chain. This results in the death of nigrostriatal neurons, dopamine depletion in the basal ganglia, and parkinsonism. In addition to energy failure, MPP^+ may also generate free radicals and oxidative stress.

The cause of Parkinson's disease is unknown. One suggested cause is exposure to an unrecognized environmental toxin, perhaps structurally similar toMPTP. Such exposure may have occurred years before the onset of any clinical disturbance, because symptoms will not develop until the cumulative cell loss from toxin exposure and natural aging approximates 80% of the original cell population. Alternatively or additionally, endogenous toxins may be responsible. In particular, the normal neurotransmitter

dopamine readily oxidizes to produce free radicals, which can cause cell death. Although the precise role of dopamine itself remains unclear, the evidence relating Parkinson's disease to damage by free radicals is compelling.

Oxidative stress is likely when dopamine turnover is increased, glutathione is reduced (leaving neurons more vulnerable to oxidant stress), and reactive iron is increased (promoting the generation of potentially toxic hydroxyl radicals). A mitochondrial complex 1 defect occurs in Parkinson's disease and may contribute to neuronal vulnerability and loss through free radical generation.

Accumulating evidence suggests a genetic susceptibility to the disease. An increased incidence of parkinsonism has been noted in the monozygotic twins of patients developing Parkinson's disease prior to the age of 50. First-degree relatives of patients are twice as likely to develop the disease as controls. Approximately 5% of parkinsonian patients have a familial form of the disorder. Three genes for the parkinsonian phenotype have recently been identified. Two different mutations of thea synuclein gene (in the q21-23 region of chromosome 4) have been identified in dominantly inherited parkinsonism; thea synuclein protein is of uncertain function but is abundant in neurons, especially at synaptic terminals, and in Lewy bodies. Homozygous deletions of the parkin gene (6q25.2-q27) have been associated with autosomal recessive parkinsonism; parkin is a protein expressed in the substantia nigra. Finally, a heterozygous missense mutation of the gene for ubiquitin carboxy-terminal hydrolase L1 has been identified in a parkinsonian family. The mechanism by which these mutations leads to parkinsonism remains to be determined, but the phenotype clearly has genetic heterogeneity.

Clinical Manifestations (Video 361-1) The 4- to 6-Hz *tremor* is typically most conspicuous at rest and worsens with emotional stress. It often begins with rhythmic flexion-extension of the fingers, hand, or foot, or with rhythmic pronation-supination of the forearm, and may be confined initially to one limb or to the two limbs on one side before becoming more generalized. It may also involve the mouth and chin. In 10 to 15% of patients, however, the tremor is faster (7 to 8 Hz) and postural, resembling essential tremor (see below) both clinically and in its response to pharmacotherapy.

Rigidity, defined as an increase in resistance to passive movement (Chap. 22), is a common clinical feature that accounts for the flexed posture of many patients. The most disabling feature, however, is *bradykinesia* (or, in its most severe form, akinesia), a slowness of voluntary movement and an associated reduction in automatic movements, such as swinging of the arms when walking. There is a fixity of facial expression, with widened palpebral fissures and infrequent blinking. There may be blepharoclonus (fluttering of the closed eyelids), blepharospasm (involuntary closure of the eyelids), and drooling of saliva from the mouth. The voice is hypophonic and poorly modulated. Power is preserved, but fine or rapidly alternating movements are impaired. The combination of tremor, rigidity, and bradykinesia results in small, tremulous, and often illegible handwriting. Patients have difficulty in rising from bed or an easy chair and tend to assume a flexed posture when erect. Walking is often difficult to initiate, and patients may have to lean forward increasingly until they can advance. They walk with small, shuffling steps, have no arm swing, are unsteady (especially on turning), and may have difficulty in stopping. Some patients walk with a *festinating gait*, i.e., at an increasing

speed to prevent themselves from falling because of their abnormal center of gravity.

The tendon reflexes are unaltered, and the plantar responses are flexor. Repetitive tapping (at about 2 Hz) over the glabella produces a sustained blink response (Myerson's sign), in contrast to the response of normal subjects. A depressed mood is common, and an impairment of cognitive function -- sometimes amounting to a frank dementia -- is frequently evident in advanced cases.

Differential Diagnosis Parkinsonism is simulated by certain disorders. *Depression* is associated with changes in the voice and facial appearance and a poverty of spontaneous activity, such as occur in Parkinson's disease. A trial of treatment with antidepressant drugs helps to clarify the diagnosis if uncertainty persists and other signs of parkinsonism are absent. *Essential (benign, familial) tremor* may be mistaken for parkinsonian tremor, but a family history of tremor is common; alcohol in small quantities may ameliorate the tremor, and other neurologic signs are lacking. Moreover, essential tremor commonly involves the head (with a nodding or no-no tremor), whereas parkinsonism spares the head but affects the face and lips. *Normal-pressure hydrocephalus* (Chap. 362) causes an apraxic gait disturbance (sometimes resembling the gait of parkinsonism), urinary incontinence, and dementia. Imaging studies reveal dilation of the ventricular system without cortical atrophy, and surgical shunting procedures to bypass any obstruction to the flow of cerebrospinal fluid (CSF) may be helpful.

Parkinsonism may occur as part of various neurologic diseases that are important to distinguish from Parkinson's disease for prognostic and therapeutic purposes. In *Wilson's disease* (Chap. 348), other abnormal movements are also usually present. The family history, early age of onset, associated Kayser-Fleischer rings, and low serum copper and ceruloplasmin levels distinguish it from Parkinson's disease. *Huntington's disease* (Chap. 362) sometimes presents with rigidity and akinesia, but the family history and any accompanying dementia point to the correct diagnosis, which can be confirmed by genetic studies. The *Shy-Drager syndrome* (Chap. 366) is a degenerative disorder characterized by parkinsonism, impaired autonomic function (resulting in postural hypotension, abnormal thermoregulatory sweating, disturbances of bladder and bowel control, impotence, and gastroparesis) and by signs of more widespread neurologic involvement (pyramidal, cerebellar, or lower motor neuron signs). There is generally no treatment except for the postural hypotension, which may respond to the measures discussed in Chap. 366. The response to antiparkinsonian agents is usually disappointing. *Striatonigral degeneration* (see below) leads to bradykinesia and rigidity, but tremor is usually inconspicuous. Cerebellar deficits sometimes occur (multisystem atrophy), and there may be autonomic insufficiency (Shy-Drager syndrome). Antiparkinsonian drugs are generally ineffective. *Progressive supranuclear palsy* (discussed separately, below) causes bradykinesia and rigidity, but conspicuous abnormalities of voluntary eye movements (especially vertical gaze), dementia, pseudobulbar palsy, and axial dystonia distinguish it from Parkinson's disease. There is little or no response to antiparkinsonian drugs. *Cortical-basal ganglionic degeneration* may be mistaken for Parkinson's disease, but intellectual decline, aphasia, apraxia, sensory neglect, and other evidence of cortical dysfunction should suggest the correct diagnosis. In *diffuse Lewy body disease*, parkinsonism is joined with a conspicuous dementia and with evidence of more widespread neurologic involvement. In

Creutzfeldt-Jakob disease, any parkinsonian features are overshadowed by the rapidly progressive dementia; myoclonus is common, ataxia or pyramidal signs may occur, visual disturbances are sometimes conspicuous, and the electroencephalographic findings are often characteristic. Similarly, in *Alzheimer's disease* there may be minor extrapyramidal deficits, but these are generally inconsequential compared with the marked cognitive impairment that characterizes the disorder.**Alzheimer's disease and diffuse Lewy body disease are considered in Chap. 362, and Creutzfeldt-Jakob disease is discussed in Chap. 375.*

Parkinsonism sometimes occurs as a consequence of a systemic disorder. Drug-induced *secondary parkinsonism* is especially common (discussed below).MPTP-induced parkinsonism has occurred in several humans who inadvertently took this meperidine analogue for recreational purposes. The mechanisms involved are discussed above, and the history of exposure, unusually early age of onset, and rapid progression should suggest the correct diagnosis. Exposure to various toxins, such as manganese dust or carbon disulfide, also causes parkinsonism, and the diagnosis is suggested by an accurate occupational history. Parkinsonism sometimes occurs as a result of severe carbon monoxide poisoning or develops after an encephalitic illness. Postencephalitic parkinsonism was especially common after the outbreak of encephalitis lethargica that occurred in an early part of the twentieth century.

TREATMENT

Approaches to treatment are summarized in Fig. 363-1.

Symptomatic Pharmacologic Treatment Nonselective muscarinic antagonists (*anticholinergic drugs*) are sometimes helpful, especially in relieving tremor. Various preparations are available, including trihexyphenidyl, benztropine, procyclidine, and orphenadrine. The usual maintenance doses are shown in Table 363-1. Common side effects include dryness of the mouth, constipation, urinary retention, and blurred vision. Narrow-angle glaucoma may be aggravated. Confusion and hallucinations are especially troublesome in the elderly. Treatment is started with the preparation of choice in a small initial dose that is gradually increased, depending on response and tolerance. If the drug is unhelpful, another anticholinergic preparation is substituted.

Amantadine, either alone or combined with an anticholinergic agent, is sometimes helpful for mild parkinsonism; it acts by potentiating the release of endogenous dopamine. It may improve all major clinical features of the disorder, has relatively uncommon side effects (restlessness, confusion, skin rashes, edema, disturbances of cardiac rhythm), and is given in a standard dose (100 mg twice daily). However, many patients derive only transient, if any, benefit from it.

Levodopa, the metabolic precursor of dopamine (Fig. 363-2), provides symptomatic benefit in most patients with parkinsonism and is often particularly helpful in relieving bradykinesia. The presence in the intestinal mucosa of dopa decarboxylase, which converts levodopa to dopamine, means that most of an ingested dose of levodopa is lost before it even enters the general circulation. Administration of levodopa in combination with an extracerebral dopa-decarboxylase inhibitor reduces the extracerebral metabolism of levodopa and also reduces the incidence of peripheral side

effects. Levodopa is therefore administered routinely in combination with a peripheral dopa-decarboxylase inhibitor (carbidopa in the United States; benserazide in Europe). In the United States, the combination of carbidopa and levodopa (in 1:10 and 1:4 ratios) is available commercially as Sinemet. Standard formulations are Sinemet 25/100, 10/100, and 25/250 mg. A common starting dose is 25/100 mg three times daily, which is increased gradually to 25/250 mg three or four times daily, taken 1 h before or 2 h after meals to maximize absorption and transport across the blood-brain barrier.

There was initially concern that the early introduction of levodopa might accelerate the death of nigrostriatal neurons because of a hypothetical increase in dopamine-mediated neurotoxity. It is now clear that levodopa should be introduced as soon as is warranted by the patient's clinical state, rather than postponed out of concern for this theoretical possibility. However, initial treatment with a dopamine agonist may provide similar benefit to levodopa and thus allow introduction of the latter to be postponed; in consequence, emergence of late side effects may be delayed. The most common initial side effects of levodopa are nausea, vomiting, postural hypotension, and, occasionally, cardiac arrhythmias. Abnormal movements (dyskinesias), restlessness (akathisia), and confusion tend to occur somewhat later and are dose-related. Dyskinesias may be present during most of the day, occur only when plasma levodopa levels peak, or develop when the plasma levodopa concentration reaches a certain submaximal level. Management depends on distinguishing these possibilities by the temporal profile of the dyskinesia. When dyskinesias occur only at a certain submaximal blood level of levodopa, adjustment of the daily dose to produce higher or lower blood levels may alleviate them; dyskinesias related to peak blood levels of levodopa are helped by a reduction in dose.

Important late complications of levodopa therapy are the wearing-off effect (transient deterioration shortly before the next dose is due) and the "on-off" phenomenon -- abrupt but transient fluctuations in clinical state that occur frequently during the day, without warning or an obvious relationship to dosing schedule, resulting in alternating periods of marked akinesia or greater mobility accompanied by iatrogenic dyskinesias. Response fluctuations can be controlled in part by reducing dosing intervals, administering levodopa 1 h before meals and restricting dietary protein intake (to reduce any competition by various amino acids with levodopa for the active carrier system that transports it into the blood and from the blood into the brain), or treatment with dopamine agonists. The addition of selegiline (5 mg at breakfast and lunch), a monoamine oxidase B inhibitor, reduces the metabolic breakdown of dopamine and may also be helpful (see "Neuroprotective Treatment," below).

Response fluctuations to oral levodopa may also be reduced or eliminated by catechol-*O*-methyltransferase (COMT) inhibitor agents or by frequent or continuous administration of levodopa intravenously, intraduodenally, or by intragastric infusion. A commercially available controlled-release formulation of Sinemet (Sinemet CR 25/100 or 50/200 mg) sometimes helps in reducing the dosing frequency and maintaining steady blood levels of levodopa, but it is of only limited benefit in reducing response fluctuations. Surgical treatment is also effective (see later). The pathogenesis of the on-off phenomenon is obscure, but proposed mechanisms relate to the pharmacokinetics of levodopa, degeneration of presynaptic dopaminergic nerve terminals, altered sensitivity of dopamine receptors, and abnormalities of

nondopaminergic neurotransmitter systems.

Dopamine agonist drugs may produce symptomatic benefit by direct stimulation of dopamine receptors (Fig. 363-2). There are five major dopamine-receptor subtypes classified into two groups. The D_1 group is made of the D_1 and D_5subtypes, and the D_2 group consists of D_2, D_3, and D_4subtypes. Drug efficacy and toxicity may relate to receptor specificity of dopamine agonists. The absorption and cerebral distribution of dopamine agonist drugs are less erratic than with levodopa, and they do not require enzymatic conversion to an active metabolite. Their early introduction either prior to Sinemet or in conjunction with low-dose Sinemet therapy (25/100 mg three times daily) yields sustained benefit and a lower incidence of late complications (such as response fluctuations and dyskinesias) than when levodopa is used alone and in a higher dose.

The agonists initially available were bromocriptine and pergolide, which are ergot derivatives. Bromocriptine, which stimulates dopamine D_2receptors (Fig. 22-4), is introduced in a dose of 1.25 mg/d for 1 week and 2.5 mg/d for the next week, after which the daily dose is increased by 2.5-mg increments every 2 weeks, depending on response and tolerance. Maintenance doses range between 2.5 and 10 mg three times daily when the drug is taken with Sinemet. Pergolide activates both D_1 and D_2dopamine receptors. It is introduced in a dose of 0.05 mg daily for 2 days; the dose is then increased by 0.1 to 0.15 mg/d every 3 days for 12 days and by 0.25 mg/d every 3 days thereafter. The usual maintenance dose is 1 mg three times daily. Side effects are similar to those of levodopa, but psychiatric effects such as delusions or hallucinations are more common, and dyskinesias are less common, than with levodopa. Other adverse effects include headache, nasal congestion, erythromelalgia, pleural and retroperitoneal fibrosis, pulmonary infiltrates, and vasopasm. These agonists are contraindicated in patients with psychotic disorders and are best avoided in those with recent myocardial infarction, severe peripheral vascular disease, or active peptic ulceration.

Pramipexole and ropinirole are new dopamine agonists. Their selective nature suggested that they might be more effective and have fewer side effects that the first-generation agonists, but this remains uncertain from the few studies comparing them to bromocriptine or pergolide. Because of their non-ergoline structure, adverse effects such as erythromelalgia, vasospasm, and pleural or retroperitoneal fibrosis are unlikely. Both agents, however, may cause postural hypotension, lassitude, sleep disturbances, peripheral edema, constipation, nausea, dyskinesias, and confusion. Excessive or uncontrollable somnolence may require withdrawal of the medication.

Pramipexole, an aminobenzthiazol-derived selective D_3agonist, provides worthwhile benefit when used alone for mild parkinsonism or when taken together with Sinemet for advanced disease. It permits a reduction in Sinemet dosage and smooths response fluctuations. It may also benefit associated affective symptoms. Pramipexole is absorbed rapidly from the gastrointestinal tract, reaches peak plasma concentrations in about 2 h, and is excreted by the kidneys; renal failure may therefore necessitate reduction in daily dose. The starting dose is 0.125 mg three times daily, with doubling of the dose after 1 week, and again after another week. The daily dose is then increased by 0.75 mg at weekly intervals depending on need and tolerance. The usual maintenance dose is 0.5 to 1.5 mg three times daily. Ropinirole, a selective D_2agonist, is

also effective for mild or advanced disease. It is started at 0.25 mg three times daily; total daily dose is increased by 0.75 mg at weekly intervals until the fourth week and then by 1.5 mg as needed. The usual maintenance dose is between 2 and 8 mg three times daily. It is metabolized by CYP1A2, and its clearance may be reduced by drugs undergoing hepatic metabolism.

Various new dopamine agonists are being evaluated, and new means of administering them (e.g., by subcutaneous infusion pump or transdermally) may lead to a steadier clinical response.

SelectiveCOMTinhibitors such as tolcapone and entacapone enhance the benefits of levodopa therapy by reducing the conversion of levodopa to 3-*O*-methyldopa (which competes with levodopa for an active carrier mechanism) and by increasing the availability in the brain of levodopa. They are helpful in patients with response fluctuations to Sinemet, leading to a smoother response, greater "on" time, and reduction in daily levodopa requirement. Both agents are absorbed rapidly, bound to plasma proteins, and metabolized before being excreted. Both have peripheral effects, but tolcapone is also active centrally. Tolcapone is slightly more potent, has a longer duration of action, and is usually taken in a dose of 100 mg (rarely, 200 mg) three times daily, whereas entacapone (200 mg) is taken with each dose of Sinemet and may thus be taken four to six times daily. When COMT inhibitors are introduced, the daily dose of Sinemet may have to be reduced by up to 30% in the first 48 h to prevent or minimize such complications as dyskinesias, nausea, and confusion. Other adverse effects include diarrhea, abdominal pain, postural hypotension, sleep disturbances, and discolored urine. Acute hepatic failure has occurred in rare patients receiving tolcapone, and a transient increase in liver enzymes is not uncommon. Accordingly, when tolcapone is prescribed, a consent form should be signed by the patient and liver function monitored every 2 weeks for the first year and less frequently thereafter, as recommended by the manufacturer.

Experimental studies suggest that glutamate antagonists may benefit patients with Parkinson's disease, and clinical studies of such agents are planned. G_{M1}ganglioside and various neurotrophic factors influence dopaminergic nigrostriatal cells, and work is continuing to develop delivery systems that will permit their use in the treatment of Parkinson's disease.

Surgical Treatment Destructive neurosurgical procedures were used for some years to treat parkinsonism, but their use declined with the advent of levodopa. Unilateral posteroventral pallidotomy or thalamotomy was resurrected in the 1990s as a therapeutic approach for relieving rigidity, bradykinesia, and tremor in patients with advanced disease in whom antiparkinsonian medication was ineffective or poorly tolerated. A positive (but incomplete) response to surgery is reported in>90% of patients; the beneficial effect predominates on the side contralateral to the procedure. Complications include cerebral infarction or hemorrhage, dysarthria or hypophonia, cognitive disturbances, and -- after pallidotomy -- visual field defects. Bilateral procedures have a higher morbidity and are generally discouraged. Such surgery is being replaced in some centers by high-frequency stimulation of selected locations in the brain, using an implanted electrode and stimulator, to induce a functional but reversible lesion. Thalamic stimulation is very effective in relieving tremor, and

preliminary studies suggest that stimulation of the globus pallidus internus or subthalamic nucleus increases "on" time and improves clinical status in those with advanced parkinsonism and response fluctuations. Brain stimulation surgery has a lower morbidity than ablative surgery, but neither approach is warranted in patients with secondary or atypical parkinsonism or dementia.

There is ongoing interest in transplantation of fetal midbrain dopaminergic (nigral) cells into the putamen of patients with Parkinson's disease. Survival of engrafted cells has been documented by enhancement of fluorodopa uptake as visualized by positron emission tomography (PET), and in one autopsy study there was extensive striatal reinnervation by the transplanted cells. Fetal nigral transplantation remains an experimental procedure, and the nature of any long-term benefit is uncertain. Transplantation of autologous adrenal medullary tissue has also been attempted for Parkinson's disease, with mixed results; benefit seems most likely to occur in individuals younger than 50 years of age.

Neuroprotective Treatment Selective inhibitors of monoamine oxidase B such as selegiline (Eldepryl; Deprenyl) may reduce oxidative damage and thus slow disease progression, but the evidence for this effect is incomplete. In a large multicenter study, treatment with selegiline delayed the need for symptomatic therapy in patients with untreated parkinsonism, suggesting that progression of the disease had been retarded, but it was subsequently found that selegiline itself has a mild effect on symptoms. Thus, the basis of the observed effect is uncertain. The use of selegiline for protective purposes should probably be discussed with all patients unless they have end-stage disease or are very elderly, but the uncertainty of any benefit should be indicated. Selegiline in a standard dose (5 mg with breakfast and 5 mg with lunch) is not associated with the hypertensive ("cheese") effect of nonselective monoamine oxidase inhibitors. Acute toxic interactions may, however, occur with meperidine, tricyclic drugs, or serotonin reuptake inhibitors, and selegiline should not be prescribed to patients receiving those medications. Selegiline is metabolized to amphetamine and methamphetamine, so some patients may experience anxiety or insomnia. Moreover, an increased mortality rate has recently been found among patients receiving selegiline, raising concerns about its long-term safety. Patients must understand that selegiline is not intended to relieve symptoms and that there is no means of determining whether it is affecting disease progression in individual cases. Other inhibitors of monamine oxidase B are currently being evaluated for their effect on the natural history of Parkinson's disease and may clarify the issue.

Tocopherol (vitamin E) is an important scavenger of free radicals, but in a large study it failed to provide any protective benefit when taken in a dose of 2000 units daily. The extent to which it penetrates the brain, however, is not clear.

General Measures Physical therapy and speech therapy may help patients with moderately severe parkinsonism. In advanced cases, the quality of life can be improved by certain aids to daily living, such as extra rails or banisters placed in the home, table cutlery with large handles, nonslip table mats, voice amplifiers, and chairs that can gently eject the occupant.

FAMILIAL OR BENIGN ESSENTIAL TREMOR (VIDEO 361-2)

A postural tremor (Chap. 22) may develop in otherwise normal individuals, sometimes on a familial basis with autosomal dominant inheritance. The pathophysiologic basis of the disorder is unknown.

Symptoms can develop at any age but often do not appear until middle or later life. Typically one or both hands, the head, and the voice are affected in any combination; the legs are generally spared. Apart from the tremor, no other abnormalities are present on neurologic examination. The tremor may worsen with time and ultimately become an embarrassment, but it generally causes no disability except when it disturbs handwriting or performance of fine tasks with the hands. A small quantity of alcohol sometimes relieves the tremor for a short period.

TREATMENT

Treatment is often unnecessary and is best delayed for as long as possible because, once initiated, it generally needs to be continued indefinitely. Propranolol, 40 to 120 mg orally twice daily, may reduce the amplitude of the tremor. A single oral dose (40 to 120 mg) may be taken in anticipation of known precipitating circumstances. Primidone is also effective but has to be introduced gradually. Other agents that may be helpful include alprazolam and mirtazapine. Thalamic stimulation (discussed earlier) may be helpful for severe tremor unresponsive to medical treatment.

PROGRESSIVE SUPRANUCLEAR PALSY

Progressive supranuclear palsy (also referred to as *Steele-Richardson-Olszewski syndrome*) is a sporadic degenerative disorder characterized pathologically by neuronal loss, gliosis, and neurofibrillary tangles in the midbrain, pons, basal ganglia, and dentate nuclei of the cerebellum. The neurofibrillary tangles of this disorder are distinct from those of Alzheimer's disease in that they are composed of straight filaments rather than paired helical filaments. The microtubule-associated protein tau is a constituent of the tangles, and a genetic association between an intrinsic polymorphism of tau and progressive supranuclear palsy has recently been reported. Thus, progressive supranuclear palsy may represent a tau pathologic process. There are also decreased concentrations of dopamine and homovanillic acid in the caudate nucleus and putamen.

Clinical Manifestations This uncommon disorder generally begins between the ages of 45 and 75 years; it affects men twice as frequently as women. Supranuclear ophthalmoplegia is characteristic. There is conspicuous failure of voluntary saccadic gaze (and of the fast phase of optokinetic nystagmus) in a vertical plane, especially downward, with later involvement of horizontal gaze. Eventually, smooth pursuit movements are also affected. Oculocephalic (e.g., doll's-head) and oculovestibular (caloric) reflexes are intact. Axial dystonia in extension, especially of the neck, is common and is frequently accompanied by limb rigidity and bradykinesia that may mimic Parkinson's disease. Tremor, however, is unusual. The combination of supranuclear ophthalmoplegia and axial rigidity accounts for the common presenting complaint of frequent falls. There may be facial weakness, dysarthria, dysphagia, and exaggerated jaw jerk and gag reflexes (pseudobulbar palsy) as well as exaggerated and inappropriate emotional responses (pseudobulbar affect). Brisk tendon reflexes,

extensor plantar responses, and cerebellar signs are sometimes encountered. A global impairment of intellectual function is frequent, but focal cortical dysfunction is rare.

Progressive supranuclear palsy should be considered whenever a middle-aged or elderly person with repeated falls has an extrapyramidal syndrome accompanied by nuchal dystonia and paralysis of voluntary downgaze. The marked impairment of voluntary downward and horizontal gaze distinguishes this disorder from Parkinson's disease, as does the extended rather than flexed dystonic posturing of the axial musculature, the absence of tremor, and the poor response to antiparkinsonian medications.

TREATMENT

The course is generally progressive, with aspiration or inanition leading to a fatal outcome within 10 years. Dopaminergic preparations sometimes reduce rigidity and bradykinesia, and anticholinergic (trihexyphenidyl, 6 to 15 mg/d) or tricyclic drugs (amitriptyline, 50 to 75 mg at bedtime) may benefit speech, gait, and pseudobulbar affect, but any benefit is limited and not sustained.

CORTICAL-BASAL GANGLIONIC DEGENERATION

This rare sporadic disorder typically begins in middle or later life with functional impairment of one or more limbs. Examination reveals signs of parkinsonism, but the extrapyramidal abnormalities are generally insufficient to account for the clinical deficit, which results from apraxia. As the disorder progresses, other evidence of cortical dysfunction also appears, such as aphasia, agnosia, sensory inattention, and mild dementia. Pathologically there is cell loss and gliosis in the cerebral cortex as well as the substantia nigra. The response to antiparkinsonian medication is disappointing, and the course is generally progressive, with increasing disability and dependence leading ultimately to death.

STRIATONIGRAL DEGENERATION

In a few patients with seemingly classic Parkinson's disease, there is little or no response to dopaminergic medication, and pathologic study at autopsy reveals neuronal loss and gliosis in the putamen, globus pallidus, caudate and subthalamic nuclei, and substantia nigra. This disorder has therefore been called *striatonigral degeneration*. It has an age and gender distribution similar to those of Parkinson's disease. Clinical examination reveals the findings of parkinsonism, but tremor is usually relatively inconspicuous. Cognitive function is preserved.

There may be an accompanying impairment of autonomic function (Shy-Drager syndrome;Chap. 366), and examination in such cases often reveals that a combination of pyramidal and cerebellar signs is also present. Indeed, in some cases the cerebellar findings are so conspicuous that the disorder is more properly called *spinocerebellar ataxia type 1* (olivopontocerebellar atrophy; Chap. 364).

The management of patients with striatonigral degeneration is difficult. Antiparkinsonian medications generally are prescribed but are usually ineffective.

MACHADO-JOSEPH DISEASE (SPINOCEREBELLAR ATAXIA TYPE 3)

Machado-Joseph disease is an autosomal dominant form of striatonigral degeneration that generally begins in the third or fourth decade. Most affected individuals are of Portuguese ancestry. There may be only mild parkinsonian signs, whereas spasticity, hyperreflexia, extensor plantar responses, cerebellar findings, external ophthalmoplegia and, sometimes, peripheral neuropathy are conspicuous. Cognitive function is preserved. Pathologically the findings are similar to those of striatonigral degeneration, but the dentate nucleus of the cerebellum is also involved. There is no specific treatment.**The different clinical subtypes of the disease, their genetic basis, and related autosomal dominant ataxias with some extrapyramidal features are discussed in Chap. 364.*

IDIOPATHIC TORSION DYSTONIA

The occurrence of dystonic movements and postures without other neurologic signs in patients with a normal birth and developmental history is designated *idiopathic torsion dystonia*. The pathophysiologic and biochemical basis of this entity is unknown. Pathologic examination reveals no specific abnormalities, but the disorder is attributed to basal ganglia dysfunction partly because of observations made in cases of secondary dystonia. Other possible causes of dystonia (Chap. 22) should be excluded before this diagnosis is made. The disorder may occur on a sporadic or hereditary basis. In cases with onset in childhood or adolescence, inheritance is commonly autosomal dominant, with the gene, designated DYT1, localized to 9q32-34 and involving a GAG deletion. The gene codes for the protein Torsin A, the function of which is unclear. Onset is typically in a limb (commonly the leg), with subsequent spread to the other limbs and trunk, but sparing of the cranial muscles. Other autosomal dominant forms present in children or adults and begin in limb, axial, or cranial muscles; cranial involvement (facial, laryngeal, cervical) is common. This gene (DYT6) has been mapped to chromosome 8 in certain families. In a few families with autosomal dominant, adult-onset cranial, cervical, or upper limb dystonia, the responsible gene (DYT7) has been mapped to chromosome 18p. In other families, other unmapped genetic loci appear to be involved. Autosomal recessive and X-linked recessive (Xq21.3) forms are also described. Onset in childhood is associated with a positive family history, symptoms that begin in the legs, and greater disability than with later onset. About one-third of patients eventually become chair- or bedbound.**A summary of the genetic loci responsible for the various dystonic disorders is provided in Table 359-1.*

Examination reveals the abnormal movements and sustained postures that characterize the disorder. There may be involvement of the neck, trunk, limbs, and face (blepharospasm or oromandibular dystonia). A description of these various motor abnormalities is provided in Chap. 22. Initially they may be brought out by voluntary activity, but eventually they are present constantly, leading to deformity and disability.

Occasional patients have *dopa-responsive dystonia*, which is inherited in an autosomal dominant manner with incomplete penetrance. The responsible gene (DYT5) maps to chromosome 14q. Onset is usually in childhood, and examination typically reveals associated bradykinesia and rigidity. The response to low-dose levodopa therapy is

dramatic.

TREATMENT

Treatment is symptomatic and is often unsatisfactory. Anticholinergic drugs in high doses (e.g., trihexyphenidyl, 30 to 50 mg/d) are probably the most effective means of providing some relief of the abnormal movements and postures. They are introduced in a low dose and built up gradually, depending on response and tolerance. Phenothiazines or haloperidol are sometimes helpful but usually cause mild parkinsonism. Diazepam, baclofen, and carbamazepine are helpful occasionally. Stereotactic thalamotomy may be beneficial when dystonia is predominantly unilateral and involves the limbs.

FOCAL TORSION DYSTONIA

Dystonia may occur as an isolated phenomenon affecting a discrete part of the body, rather than having the more generalized distribution described above. Such focal or segmental dystonias probably represent variants of idiopathic torsion dystonia; its genetic basis was discussed earlier. Both *blepharospasm* (spontaneous, involuntary forced closure of the eyelids) and *oromandibular dystonia* can occur as isolated focal dystonias. Oromandibular dystonia consists of involuntary contractions of the masticatory, lingual, and perioral muscles, leading to opening or closure of the mouth; pouting, pursing, or retraction of the lips; and roving or protruding movements of the tongue. The combination of blepharospasm and oromandibular dystonia is called *Meige syndrome*.

Spasmodic torticollis is characterized by a tendency for the head to turn to one side. The designation *anterocollis* indicates that the head is flexed forward, and *retrocollis* that it is pulled backward. These cervical dystonias are often intermittent initially, but eventually the head is held continuously in the abnormal position. Spontaneous remission occurs occasionally, especially in the first few months after onset, but thereafter the disorder is likely to be permanent and may worsen with time.

TREATMENT

Pharmacotherapy is usually unrewarding, but the drugs used in treating idiopathic torsion dystonia are helpful in some patients. Local injection of botulinum toxin into the overactive muscles often produces a benefit lasting several weeks or months by producing a temporary presynaptic block of neuromuscular transmission, and injections can be repeated as needed. This is the most effective treatment available for most focal dystonias. Selective section of the spinal accessory nerve (cranial nerve XI) and the upper cervical nerve roots is sometimes helpful for patients with cervical dystonia unresponsive to other measures.

TASK-SPECIFIC FOCAL DYSTONIA

Writer's cramp is a task-specific dystonia in which abnormal posturing of the hand and forearm occurs when the hand is used for writing. As the disorder worsens, abnormal posturing may also occur with other tasks, such as applying cosmetics, shaving, or

using table cutlery. Drug treatment is usually unrewarding, and it is often necessary for patients to learn to use the other hand for these tasks. Injections of botulinum toxin into the involved muscles are sometimes helpful, but function usually remains impaired. Other task-specific dystonias include violinist's cramp, barber's cramp, and telegrapher's cramp, in each of which dystonic posturing occurs when the hand is used for a skilled, occupationally related function. The pathophysiologic basis of these disorders is uncertain, but recent work relates it to abnormal processing of sensory input from the affected extremity during the activity.

DRUG-INDUCED MOVEMENT DISORDERS

Parkinsonism Parkinsonism is a frequent complication of treatment with dopamine-depleting agents such as reserpine or antipsychotic dopamine antagonists such as the phenothiazines or butyrophenones. The antipsychotic drugs most likely to cause parkinsonism are those that are potent D_2receptor antagonists having little anticholinergic effect, such as piperazine phenothiazines, haloperidol, and thiothixene. Women and the elderly have an increased risk of this complication. In comparison with Parkinson's disease, tremor is less common and bradykinesia is typically symmetric, but the two disorders are sometimes impossible to distinguish except by the history of drug ingestion. Signs usually develop within 3 months of starting the causal agent and may persist for several months (or longer) after its withdrawal. Drug-induced parkinsonism is best managed by discontinuing the antipsychotic drug when possible, substituting an antipsychotic with greater anticholinergic potency, or adding an anticholinergic drug such as trihexyphenidyl. Levodopa should not be prescribed -- it is of no help if the offending neuroleptic agent is continued, and it may worsen the underlying psychotic disorder.

Acute Dystonia or Dyskinesia Acute dystonia (such as blepharospasm or torticollis) or dyskinesia (such as chorea or facial grimacing) may complicate treatment with a dopamine receptor antagonist. It typically commences within 1 week of the introduction of such medication, usually in the first 48 h, and is more common in young patients. Its pathophysiologic basis is uncertain. Treatment with an anticholinergic drug (e.g., benztropine, 2 mg, or diphenhydramine, 50 mg intravenously) is usually helpful.

Tardive Akathisia *Akathisia* denotes a motor restlessness. Patients are unable to sit still and feel obliged to move about. It is commonly induced by chronic antipsychotic drug treatment, especially in women, and is treated like drug-induced parkinsonism.

Tardive Dyskinesia or Dystonia Tardive dyskinesia or dystonia is a common complication of long-term antipsychotic drug treatment (with dopamine receptor antagonists). The risk of its development increases with advancing age, but its pathogenesis is unclear. One suggestion is that it is related to drug-induced supersensitivity of striatal dopamine receptors. However, although supersensitivity is an inevitable accompaniment of chronic antipsychotic drug treatment, tardive dyskinesia does not always occur. Moreover, the time courses of the two phenomena are different. Supersensitivity occurs relatively early during treatment and reverses when medication is withdrawn, whereas tardive dyskinesia usually requires exposure for at least 6 months before it develops and may persist indefinitely. Another suggestion is that it involves an abnormality of g-aminobutyric acid (GABA)-ergic neurons. This is supported

by observations that GABA and glutamic acid decarboxylase (its synthesizing enzyme) are depleted in the basal ganglia by long-term administration of antipsychotic drugs to animals and thatCSFlevels of GABA are reduced in patients with tardive dyskinesia.

The clinical features of tardive dyskinesia include abnormal choreoathetoid movements, especially involving the face and mouth in adults and the limbs in children. Tardive dystonia may be focal, producing, for example, blepharospasm, torticollis, or oromandibular dystonia, or it may affect contiguous body parts (e.g., the face and neck or arm and trunk). Generalized dystonia is uncommon, especially in older patients. It may be impossible to distinguish these disturbances from those of Huntington's disease (Chap. 362), Sydenham's chorea (Chap. 235), or idiopathic torsion dystonia except by the history of drug exposure. The iatrogenic disorder often resolves spontaneously in children or young adults but frequently persists in middle-aged or older individuals.

TREATMENT

Treatment of the established disorder is often unsatisfactory. It is therefore important that antipsychotic drugs be prescribed only when necessary and that their long-term use be accompanied by periodic drug holidays to determine whether treatment is still required. Drug holidays may actually unmask incipient dyskinesias, which often worsen on withdrawal of the causal agent. In such circumstances, permanent withdrawal of the antipsychotic medication, if this is possible, may lead to remission of the dyskinesia. Treatment with antidopaminergic agents such as haloperidol or phenothiazines (which cause the disorder) often suppresses the dyskinesias at least for a period, but these agents are best avoided, because they may exacerbate the underlying problem. Treatment with dopamine-depleting agents, such as reserpine, 0.25 mg gradually increased to 2 to 4 mg/d, or tetrabenazine (in countries where it is available), 12.5 mg gradually increased to as much as 200 mg/d, is sometimes worthwhile in reducing the severity of the dyskinesia. Other pharmacologic approaches are unrewarding in most instances. Tardive dystonia may respond to tetrabenazine (if available) or to anticholinergic drugs used as for idiopathic torsion dystonia.

Tardive tic resembles Gilles de la Tourette's syndrome (see below) and is best treated with clonidine or clonazepam.

Neuroleptic Malignant Syndrome Rigidity, hyperthermia, altered mental status resembling catatonia, labile blood pressure, and autonomic dysfunction characterize this serious complication of treatment with antipsychotic (neuroleptic) agents, especially haloperidol. Associated clinical features include tachycardia, tachypnea, metabolic acidosis, and myoglobinuria that may be fatal. The cause is unknown, but antagonism of dopamine is a likely contributor. The prevalence of this syndrome among patients receiving neuroleptics is<2%, with the disorder occurring most commonly in young adults. Symptoms evolve over 1 to 2 days. The syndrome can develop at any time during exposure to the medication, but it usually occurs within the first 30 days of use.

The differential diagnosis includes infection, malignant hyperthermia, and alcohol- or drug-withdrawal states. Drug-induced parkinsonism may be similar but is not associated with fever or the autonomic features described above.

TREATMENT

Treatment includes immediate withdrawal of antipsychotic drugs and also of lithium and anticholinergic agents, which may increase the risk of developing the disorder. Symptomatic treatment is also necessary and includes antipyretics and artificial cooling, rehydration, and measures to maintain the blood pressure. Serum potassium should be monitored. Dantrolene, bromocriptine or another dopamine agonist, levodopa, amantadine, or benzodiazepines are sometimes helpful, but the mortality rate is on the order of 5 to 20%. Subcutaneous heparin administration reduces the risk of venous thrombosis. Most survivors recover completely, but potential complications include renal failure, pulmonary embolism, and a chronic cerebellar syndrome (related to the hyperthermia). Recovery generally occurs over 2 to 3 weeks.

Other Drug-Induced Movement Disorders Dyskinesia or dystonia may complicate therapy with levodopa or dopamine agonists as a dose-related phenomenon that is reversed by withdrawal of the medication or reduction of the dose. Reversible chorea may also complicate treatment with anticholinergic drugs, phenytoin, carbamazepine, amphetamines, lithium, and oral contraceptives; dystonia may follow treatment with lithium, carbamazepine, and metoclopramide; and postural tremor from theophylline, caffeine, lithium, thyroid hormone, tricyclic antidepressants, valproic acid, and isoproterenol.

GILLES DE LA TOURETTE'S SYNDROME

Gilles de la Tourette's syndrome, which has a prevalence in the United States of approximately 0.05%, consists of chronic multiple motor and phonic tics that have no known cause. The disorder is not related to social or ethnic background or to perinatal abnormalities. Symptoms typically begin between 5 and 15 years of age and follow a relapsing and remitting course. A family history is sometimes obtained, and partial expression of the trait may occur in siblings or offspring of patients. In most families with chronic tic disorders, there is an autosomal dominant mode of inheritance with variable penetrance that is gender related. Boys are affected much more commonly than girls.

The pathophysiology is obscure, and no structural pathology has been recognized. A dopaminergic excess has been suggested by the clinical observation that the tics may respond to treatment with dopamine-blocking drugs.

Clinical Manifestations The first signs consist of single or multiple motor tics in 80% of cases and of phonic tics in 20%. Motor tics commonly affect the face and may consist of repetitive sniffing, winking, blinking, elevation of the eyelids, eye closure, pursing of the lips, or facial twitching. Patients eventually develop several different motor and phonic tics, the latter frequently taking the form of grunts, barks, hisses, sighs, throat-clearing, coughing, and verbal utterances that may involve coprolalia (involuntary and inappropriate swearing or obscene speech), echolalia (involuntary repetition of the phrases of others), and palilalia (repetition of words or phrases). The tics may change in location, severity, complexity, and character with time; are worsened by emotional stress; and can be suppressed voluntarily for short periods. In some cases, tics are complex (such as jumping up in the air) or involve repetitive self-mutilating activities (such as nail-biting, hair-pulling, or lip-biting). Tics that involve repetitive sensory

phenomena, such as pressure, tickle, or thermal sensations, also occur. Many patients have associated behavioral abnormalities, especially obsessive-compulsive disorder and attention deficit hyperactivity disorder.

Apart from the presence of tics, physical examination typically reveals no other abnormalities, but the incidence of left-handedness or ambidexterity is greater than among normal persons, and many patients have nonspecific electroencephalographic abnormalities of no diagnostic significance.

The diagnosis is often delayed for years, the symptoms sometimes being attributed to psychiatric illness. Patients may be subjected to unnecessary and expensive treatment before the correct diagnosis is made. Depression, sometimes leading to suicide, may result from social embarrassment caused by the tics.

Differential Diagnosis Many children develop transient or chronic simple tics, and these have a benign prognosis and require no treatment. In some instances, simple or multiple tics persist for several years but resolve in late adolescence. Wilson's disease, a treatable cause of dyskinesias and tics, is generally associated with hepatic and renal involvement, Kayser-Fleischer corneal rings, low serum copper and ceruloplasmin levels, and increased 24-h urinary copper excretion (Chap. 348). The associated dementia, the character of the abnormal movements, and genetic studies distinguish Huntington's disease (Chap. 362). Sydenham's chorea (Chap. 235) may be confused with Gilles de la Tourette's syndrome when a history of rheumatic fever or polyarthritis is lacking and there is no cardiac involvement, but it usually resolves over 3 to 6 months. Tics may also occur in postencephalitic syndromes and as a side effect of stimulant or neuroleptic medication.

TREATMENT

Treatment is symptomatic and may need to be continued indefinitely.

Clonidine alleviates motor and phonic tics in some children, possibly by reducing activity in noradrenergic neurons of the locus coeruleus. The initial dose is 2 to 3 ug/kg per day, increased after 2 weeks to 4 ug/kg per day and then, if required, to 5 ug/kg per day. There may be a transient fall in blood pressure when this agent is introduced. Other side effects are sedation, reduced or excessive salivation, and diarrhea.

Haloperidol has been used widely for many years. It is introduced in a low daily dose (0.25 mg), which is gradually increased by 0.25 mg every 5 days, depending on response and tolerance. The optimal dose is usually 2 to 8 mg/d. Side effects include extrapyramidal movement disorders, sedation, xerostomia, blurred vision, and gastrointestinal disturbances. Pimozide, another dopaminergic-receptor antagonist, may be of benefit when haloperidol is unhelpful or poorly tolerated. It may produce widening of the QT interval and sudden death at high doses, so the electrocardiogram should be monitored routinely. Its long-term safety is unknown. It is introduced in a dose of 1 mg/d, and the dose is then increased by 2 mg every 10 days; most patients require 7 to 16 mg/d. The total dose should not exceed 0.3 mg/kg per day. Phenothiazines such as fluphenazine sometimes help, but patients unresponsive to haloperidol do not usually benefit from these drugs. Clonazepam or carbamazepine can also be tried. Family

counseling and psychotherapy are sometimes helpful.

RESTLESS LEGS SYNDROME

The restless legs syndrome is a common, chronic disorder that often has a familial basis, with evidence of autosomal dominant inheritance. It is characterized by a need to move because of unpleasant creeping sensations that arise deep within the legs and occasionally also in the arms, especially when patients are relaxed. For this reason, there is often difficulty in settling down to sleep at night. Periodic leg movements may also occur during sleep and can be documented by polysomnography. The cause is unknown, although the disorder is common during pregnancy and is sometimes associated with uremic or diabetic neuropathy, primary amyloidosis, or malignancy. Clinical examination may reveal evidence of underlying systemic disease or mild peripheral neuropathy but is more often normal. Symptoms may respond to correction of coexisting iron-deficiency anemia or to treatment with dopaminergic medication (such as levodopa, bromocriptine, or pergolide), benzodiazepines (diazepam or clonazepam), or opiates (codeine, propoxyphene, or oxycodone).

364. ATAXIC DISORDERS - *Roger N. Rosenberg*

Approach to the Patient

Ataxia is a common and important neurologic finding. Symptoms and signs of ataxia consist of gait impairment, unclear ("scanning") speech, visual blurring due to nystagmus, hand incoordination, and tremor with movement (Chap. 22). These result from the involvement of the cerebellum and its afferent and efferent pathways including the spinocerebellar pathways, and the frontopontocerebellar pathway originating in the rostral frontal lobe (Brodmann's area 10). True cerebellar ataxia must be distinguished from ataxia associated with vestibular nerve or labyrinthine disease, as the latter results in a disorder of gait associated with a significant degree of dizziness, light-headedness, or the perception of movement (Chap. 21). True cerebellar ataxia is devoid of these vertiginous complaints and is clearly an unsteady gait due to imbalance. Weakness of proximal leg muscles and a variant of acute idiopathic polyneuritis (Miller-Fisher syndrome) can on occasion simulate the imbalance of cerebellar disease. In the patient who presents with ataxia, the rate and pattern of the development of cerebellar symptoms are important in determining the diagnostic possibilities (Table 364-1). A gradual and progressive increase in symptoms with bilateral and symmetric involvement suggests a biochemical, metabolic, immune, or toxic etiology. Conversely, focal, unilateral symptoms with headache and impaired level of consciousness accompanied by ipsilateral cranial nerve palsies and contralateral weakness imply a space-occupying cerebellar lesion.

Symmetric Ataxia Progressive and symmetric ataxia can be classified with respect to onset as acute (over hours or days), subacute (weeks or months), or chronic (months to years). Acute and reversible ataxias include those caused by intoxication with alcohol, phenytoin, lithium, barbiturates, and other drugs. Intoxication caused by toluene exposure, gasoline sniffing, glue sniffing, spray painting, or exposure to methyl mercury or bismuth are additional causes of acute or subacute ataxia, as is treatment with cytotoxic chemotherapeutic drugs such as flourouracil and paclitaxel. Children with a postinfectious syndrome (especially after varicella) may develop gait ataxia and mild dysathria, which are both reversible (Chap. 371). Rare infectious causes of acquired ataxia include poliovirus, coxsackievirus, echovirus, Epstein-Barr virus, toxoplasmosis, *Legionella*, and the prion protein responsible for Creutzfeldt-Jakob disease. The subacute development of ataxia of gait over weeks to months (acute cerebellar degeneration of the vermis) may be due to the combined effects of alcoholism and malnutrition, particularly with deficiencies of vitamins B_1 and B_{12}. Hyponatremia has also been associated with ataxia. A paraneoplastic syndrome, which may be associated with myoclonus and opsoclonus, may present as incapacitating gait ataxia. Specific autoantibodies (Yo, Ri, and PCD) have been identified that are responsible for cerebellar degeneration involving principally the midline or vermis (Chap. 101). Female patients may present with cerebellar ataxia before the identification of a breast or ovarian carcinoma. Removal of the tumor may prevent further progression of symptoms and in some patients result in gait improvement. Chronic symmetric gait ataxia of months' to years' duration suggests an inherited ataxia (discussed below), a metabolic disorder, or a chronic infection. Hypothyroidism must always be considered as a readily treatable and reversible form of gait ataxia. Infectious diseases that can present with ataxia are meningovascular syphilis and tabes dorsalis due to degeneration of the

posterior columns and spinocerebellar pathways in the spinal cord. Lyme disease may cause ataxic symptoms.

Focal Ataxia Acute focal ataxia commonly results from cerebrovascular disease, usually ischemic infarction, hemorrhagic infarction, or cerebellar hemorrhage. These lesions typically produce cerebellar symptoms ipsilateral to the injured cerebellum and may be associated with an impaired level of consciousness due to brainstem compression and increased intracranial pressure; ipsilateral pontine signs, including sixth and seventh nerve palsies, may be present. Focal and worsening signs of acute ataxia should also prompt consideration of a posterior fossa subdural hematoma, bacterial abscess, primary or metastatic cerebellar tumor, or acute demyelinating lesion of multiple sclerosis. Computed tomography (CT) or magnetic resonance imaging (MRI) studies will reveal clinically significant processes of this type, which may require surgical decompression. Many of these lesions represent true neurologic emergencies, as sudden herniation, either rostrally through the tentorium or caudal herniation of cerebellar tonsils through the foramen magnum can occur and is usually devastating (Chap. 376). Lymphoma or progressive multifocal leukoencephalopathy (PML) in a patient with AIDS may present with an acute or subacute focal cerebellar syndrome. Chronic etiologies of ataxia include multiple sclerosis and congenital lesions such as the Chiari type I malformation, and congenital cysts of the posterior fossa (Dandy-Walker syndrome).

THE INHERITED ATAXIAS

Of the syndromes that constitute the inherited ataxias, some show autosomal dominant or autosomal recessive modes of inheritance, and some are caused by mitochondrial mutations and thus show a maternal mode of inheritance. Substantial progress has been made in recent years in identifying the molecular basis of these syndromes (Table 364-2), so that a genomic classification is superseding previous ones based on clinical expression alone.

Although the clinical manifestations and neuropathologic findings of cerebellar disease dominate the clinical picture, there may also be characteristic changes in the basal ganglia, brainstem, spinal cord, optic nerves, retina, and peripheral nerves. In large families with dominantly inherited disease, there are many gradations from purely cerebellar manifestations to mixed cerebellar and brainstem disorders, cerebellar and basal ganglia syndromes, and spinal cord or peripheral nerve disease. Rarely, dementia is present as well. The clinical picture may be consistent within a family with dominantly inherited ataxia, but sometimes most affected family members show one characteristic syndrome, while one or several members have an entirely different phenotype.

The autosomal spinocerebellar ataxias (SCAs) are caused by CAG triplet repeat expansions in different genes including SCA1, SCA2, MJD, SCA6, SCA7, and SCA13. SCA8 is due to a CTG repeat expansion (Table 364-2). The clinical phenotypes of these SCAs overlap. A single phenotype can result from several different genotypes, and conversely a single genotype can be associated with more than one different phenotype. The genotype has become the gold standard for diagnosis and classification. CAG encodes glutamine, and these expanded CAG triplet repeat expansions result in expanded polyglutamine proteins, termed *ataxins*, that produce a

toxic gain of function with autosomal dominant inheritance. Although the phenotype is variable for any given disease gene, a pattern of neuronal loss with gliosis is produced that is relatively unique for each ataxia. Immunohistochemical and biochemical studies have shown cytoplasmic (SCA2), neuronal (SCA1, MJD, SCA7), and nucleolar (SCA7) accumulation of the specific mutant polyglutamine containing ataxin proteins. Expanded polyglutamine ataxins with more than approximately 40 glutamines are potentially toxic to neurons for a variety of reasons including the following: high levels of gene expression for the mutant polyglutamine ataxin in affected neurons; conformational change of the aggregated protein to ab-pleated structure; abnormal transport of the ataxin into the nucleus (SCA1, MJD, SCA7); binding to other polyglutamine proteins, including the TATA-binding transcription protein and the CREB-binding protein, impairing their functions; altering the efficiency of the ubiquitin-proteosome system of protein turnover; and inducing neuronal apoptosis. An earlier age of onset (anticipation) and more aggressive disease in subsequent generations are due to further expansion of the CAG triplet repeat and increased polyglutamine number in the mutant ataxin. A new classification based on the genotype and its specific mutant ataxin is presented inTable 364-2, and the salient features of the most common disorders are discussed below.

AUTOSOMAL DOMINANT ATAXIAS

The new genomic classification of the dominantly inherited ataxias includes SCA type 1 through SCA13, dentatorubropallidoluysian atrophy (DRPLA), and episodic ataxia (EA) types 1 and 2 (Table 364-2).

SCA1 SCA1 was previously referred to as *olivopontocerebellar atrophy*, but genomic data have shown that that entity represents several different genotypes with overlapping clinical features.

Symptoms and signs SCA1 is characterized by the development in early or middle adult life of progressive cerebellar ataxia of the trunk and limbs, impairment of equilibrium and gait, slowness of voluntary movements, scanning speech, nystagmoid eye movements, and oscillatory tremor of the head and trunk. Dysarthria, dysphagia, and oculomotor and facial palsies may also occur. Extrapyramidal symptoms include rigidity, an immobile face, and parkinsonian tremor. The reflexes are usually normal, but knee and ankle jerks may be lost, and extensor plantar responses may occur. Dementia may be noted but is usually mild. Impairment of sphincter function is common, with urinary and sometimes fecal incontinence. Cerebellar and brainstem atrophy are evident onMRI(Fig. 364-1).

Marked shrinkage of the ventral half of the pons, disappearance of the olivary eminence on the ventral surface of the medulla, and atrophy of the cerebellum are evident on gross postmortem inspection of the brain. Variable loss of Purkinje cells, reduced numbers of cells in the molecular and granular layer, demyelination of the middle cerebellar peduncle and the cerebellar hemispheres, and severe loss of cells in the pontine nuclei and olives are found on histologic examination. Degenerative changes in the striatum, especially the putamen, and loss of the pigmented cells of the substantia nigra may be found in cases with extrapyramidal features. More widespread degeneration in the central nervous system (CNS), including involvement of the posterior columns and the spinocerebellar fibers, is often present, especially in the

cases with autosomal dominant inheritance.

GENETIC CONSIDERATIONS

SCA1 was mapped positionally to chromosome 6 (6p22-p23), and the causal gene was found to contain CAG expanded DNA repeats (Chap. 359). The mutant allele has>40 CAG repeats, whereas alleles from unaffected individuals have £36 repeats. A few patients with 38 to 40 CAG repeats have been described. There is a direct correlation between a larger number of repeats and a younger age of onset for SCA1. Juvenile patients have higher numbers of repeats, and anticipation is present in subsequent generations. The SCA1 gene is 450 kilobases (kb) long and has nine exons, with the first seven exons located in a 5¢untranslated region and the last two exons containing the coding region. The SCA1 transcript contains 10,660 bases and is transcribed from both the wild-type allele and SCA1 alleles. The CAG repeat, which codes for a polyglutamine tract, lies within the coding region. The SCA1 gene product, called ataxin-1, is a novel protein of unknown function. Recently, polyglutamine aggregates bound to ubiquitin have been described in neuronal nuclei that are undergoing degeneration. Similar neuronal nuclear inclusions have been seen in cerebellar Purkinje cells of transgenic mice overexpressing an expanded variant of the ataxin-1 gene that causes human SCA1. Other transgenic mice carrying the SCA1 gene but with the self-association region deleted, so that polyglutamine aggregation did not occur, still developed ataxia and Purkinje cell pathology. Thus, although nuclear localization of ataxin-1 is necessary, nuclear aggregation of ataxin-1 is not required to initiate pathogenesis in transgenic mice.

SCA2

Symptoms and signs Another clinical phenotype, SCA2, has been described in Cubans. These patients probably are descendants of a common ancestor, and the population may be the largest homogeneous group of patients with ataxia yet described. The age of onset ranges from 2 to 65 years, and there is considerable clinical variability within families. Although neuropathologic and clinical findings are compatible with a diagnosis of SCA1, including parkinsonian rigidity, optic disk pallor, mild spasticity, and retinal degeneration, it appears that SCA2 is a unique form of cerebellar degenerative disease.

GENETIC CONSIDERATIONS

The gene inSCA2 families has been mapped to 12q23-q24.1. Thus, the similar clinical phenotypes of SCA1 and SCA2, mapped respectively to 6p and 12q, represent different genotypes. The gene has recently been identified, and it also contains CAG repeat expansions coding for a polyglutamine-containing protein, ataxin-2. Normal alleles contain 15 to 24 repeats; mutant alleles have 35 to 59 repeats.

Machado-Joseph Disease/SCA3 Machado-Joseph disease (MJD) is an autosomal dominant spinocerebellar degenerative disease first described among the Portuguese and their descendants in New England and California. Subsequently, MJD has been found in families from Portugal, Australia, Brazil, Canada, China, England, France, India, Israel, Italy, Japan, Spain, Taiwan, and the United States. In most populations, it is the most common inherited autosomal dominant ataxia.

Symptoms and signs MJD has been classified into three clinical types. In type I MJD (amyotrophic lateral sclerosis-parkinsonism-dystonia type), neurologic deficits appear in the first two decades and involve weakness and spasticity of extremities, especially the legs, often with dystonia of the face, neck, trunk, and extremities. Patellar and ankle clonus are common, as are extensor plantar responses. The gait is slow and stiff, with a slightly broadened base and lurching from side to side; this gait results from spasticity, not true ataxia. There is no truncal titubation. Pharyngeal weakness and spasticity cause difficulty with speech and swallowing. Of note is the prominence of horizontal and vertical nystagmus, loss of fast saccadic eye movements, hypermetric and hypometric saccades, and impairment of upward vertical gaze. Facial fasciculations, facial myokymia, lingual fasciculations without atrophy, ophthalmoparesis, and ocular prominence are common and early manifestations.

In type IIMJD(ataxic type), true cerebellar deficits appear, including dysarthria and gait and extremity ataxia, beginning in the second to fourth decades, along with corticospinal and extrapyramidal deficits of spasticity, rigidity, and dystonia. Type II is the most common form of MJD. Ophthalmoparesis, upward vertical gaze deficits, and facial and lingual fasciculations are also present. Type II MJD must be distinguished from the clinically similar disordersSCA1 and SCA2.

Type IIIMJD(ataxic-amyotrophic type) presents in the fifth to the seventh decades with a pancerebellar disorder that includes dysarthria and gait and extremity ataxia. Distal sensory loss involving pain, touch, vibration, and position senses and distal atrophy are prominent, indicating the presence of peripheral neuropathy. The deep tendon reflexes are depressed to absent, and there are no corticospinal or extrapyramidal findings.

The mean age of onset of symptoms inMJD is 25 years. Neurologic deficits invariably progress and lead to death from debilitation within 15 years of onset, especially in patients with types I and II disease. Usually, patients retain full intellectual function.

The major pathologic findings are variable loss of neurons and glial replacement in the corpus striatum and severe loss of neurons in the pars compacta of the substantia nigra. A moderate loss of neurons occurs in the dentate nucleus of the cerebellum and in the red nucleus. Purkinje cell loss and granule cell loss occur in the cerebellar cortex. Cell loss also occurs in the dentate nucleus and in the cranial nerve motor nuclei. Sparing of the inferior olives distinguishesMJD from other dominantly inherited ataxias.

GENETIC CONSIDERATIONS

The gene locus forMJD has been mapped to 14q24.3-q32. The genes from families with MJD in Japan and North and South America all map to the same locus. Unstable CAG repeat expansions are present in the MJD gene coding for a polyglutamine-containing protein named ataxin-3 or MJD-ataxin. An earlier age of onset is associated with longer repeats. Alleles from normal individuals have between 12 and 37 CAG repeats, and MJD alleles have 60 to 84 CAG repeats. A patient with autonomic dysfunction and ataxia has been described with 56 CAG repeats. Polyglutamine-containing aggregates of ataxin-3 (MJD-ataxin) have been described in neuronal nuclei undergoing degeneration.

SCA6 Genomic screening for CAG repeats in other families with autosomal dominant ataxia and vibratory and proprioceptive sensory loss have yielded another locus. Of interest is that different mutations in the same gene for the a_{1A} voltage-dependent calcium channel subunit (CACNLIA4) (also referred to as the CACNA1A gene) at 19p13 result in different clinical disorders. CAG repeat expansions (21 to 27 in patients; 4 to 16 triplets in normal individuals) result in late onset progressive ataxia with cerebellar degeneration. Missense mutations in this gene result in familial hemiplegic migraine. Non-sense mutations resulting in termination of protein synthesis of the gene product yield hereditary paroxysmal cerebellar ataxia or episodic ataxia. Some patients with familial hemiplegic migraine develop progressive ataxia and also have cerebellar atrophy.

Dentatorubropallidoluysian Atrophy DRPLA is a disorder of variable clinical presentation that is characterized by progressive ataxia, choreoathetosis, dystonia, seizures, myoclonus, and dementia. DRPLA is due to unstable CAG triplet repeats in the open reading frame of a gene named atrophin located on chromosome 12p12-ter. Larger expansions are found in patients with earlier onset. The number of repeats is ^{3}49 in patients with DRPLA; it is£26 in normal individuals. Anticipation occurs; successive generations in individual families show progressively earlier onset of disease in association with an increasing CAG repeat number. Larger expansions occur in children who inherit the disease from their father.

Episodic Ataxia Types 1 and 2 are two rare dominantly inherited disorders that have been mapped to chromosomes 12p (a potassium channel gene) for type 1 and 19p for type 2. Patients with EA-1 have brief episodes of ataxia with myokymia and nystagmus that last only minutes. Startle, sudden change in posture, and exercise can induce episodes. Acetazolamide or anticonvulsants may be therapeutic. Patients with EA-2 have episodes of ataxia with nystagmus that can last for hours or days. Stress, exercise, or excessive fatigue may be precipitants. Acetazolamide may be therapeutic and can reverse the relative intracellular alkalosis detected by MR spectroscopy. Stop codon, non-sense mutations causing EA-2 have been found in the CACNA1A gene, encoding the a_{1A} voltage-dependent calcium channel subunit (see SCA6 above). SeeTable 364-2 for details.

AUTOSOMAL RECESSIVE ATAXIAS

Friedreich's Ataxia This is the most common form of inherited ataxia, comprising one-half of all hereditary ataxias. It can occur in a classic form or in association with a genetically determined vitamin E deficiency syndrome; the two forms are clinically indistinguishable.

Symptoms and signs Friedreich's ataxia presents before 25 years of age with progressive staggering gait, frequent falling, and titubation. The lower extremities are more severely involved than the upper ones. Dysarthria occasionally is the presenting symptom; and rarely progressive scoliosis, foot deformity, nystagmus, or cardiopathy are initial signs.

The neurologic examination reveals nystagmus, loss of fast saccadic eye movements,

truncal titubation, dysarthria, dysmetria, and ataxia of extremity and truncal movements. Extensor plantar responses (with normal tone in trunk and extremities), absence of deep tendon reflexes, and weakness (greater distally than proximally) are usually found. Loss of vibratory and proprioceptive sensation occurs. The median age of death is 35 years. Women have a significantly better prognosis than men; the 20-year survival rate is 100% in women and 63% in men.

Cardiac involvement occurs in 90% of patients. Cardiomegaly, symmetric hypertrophy, murmurs, and conduction defects are reported. Idebenone, a free-radical scavenger, has been shown in preliminary studies to protect heart muscle from iron-induced injury and to decrease myocardial hypertrophy. Iron chelators and antioxidant drugs are potentially harmful. Moderate mental retardation or psychiatric syndromes are present in a small percentage of patients. A high incidence of diabetes mellitus (20%) is found and is associated with insulin resistance and pancreaticb-cell dysfunction. However, no linkage is reported between the Friedreich's ataxia gene and loci predisposing to diabetes mellitus. Musculoskeletal deformities are common and include pes cavus, pes equinovarus, and scoliosis.MRI of the spinal cord shows significant cord atrophy in affected patients (Fig. 364-2).

The primary sites of pathology are the spinal cord, dorsal root ganglion cells, and the peripheral nerves. Slight atrophy of the cerebellum and cerebral gyri may occur. Sclerosis and degeneration occur predominantly in the spinocerebellar tracts, lateral corticospinal tracts, and posterior columns. Degeneration of the glossopharyngeal, vagus, hypoglossal, and deep cerebellar nuclei is described. The cerebral cortex is histologically normal except for loss of Betz cells in the precentral gyri. The peripheral nerves are extensively involved, with a loss of large myelinated fibers. The density of small myelinated fibers is normal, but axonal size and myelin thickness are diminished. Cardiac pathology consists of myocytic hypertrophy and fibrosis, focal vascular fibromuscular dysplasia with subintimal or medial deposition of periodic acid-Schiff (PAS)-positive material, myocytopathy with unusual pleomorphic nuclei, and focal degeneration of myelinated and unmyelinated nerves and cardiac ganglia.

GENETIC CONSIDERATIONS

The classic form of Friedreich's ataxia has been mapped to 9q13-q21.1, and the mutant gene, frataxin, contains expanded GAA triplet repeats in the first intron. There is homozygosity for expanded GAA repeats in most patients. Normal persons have 7 to 22 GAA repeats, and patients have 200 to 900 GAA repeats. Patients with Friedreich's ataxia have undetectable or extremely low levels of frataxin mRNA, as compared with carriers and unrelated individuals; thus, disease appears to be caused by a loss of expression of the frataxin protein. Frataxin is a mitochondrial protein involved in iron homeostasis. Mitochondrial iron accumulation due to loss of the iron transporter coded by the mutant frataxin gene results in oxidized intramitochondrial iron. Excess oxidized iron results in turn in the oxidation of cellular components and irreversible cell injury.

Two forms of hereditary ataxia associated with abnormalities in the interactions of vitamin E (a-tocopherol) with very-low-density lipoprotein (VLDL) have been delineated. Ataxia of the Friedreich's phenotype with vitamin E deficiency (AVED) and abetalipoproteinemia (Bassen-Kornzweig syndrome) have both been clarified at the

molecular genetic level. Abetalipoproteinemia is caused by mutations in the gene coding for the larger subunit of the microsomal triglyceride transfer protein (MTP). Defects in MTP result in impairment of formation and secretion of VLDL in liver. This defect results in a deficiency of delivery of vitamin E to tissues, including the central and peripheral nervous system, as VLDL is the transport molecule for vitamin E and other fat-soluble substitutes. AVED is due to mutations in the gene fora-tocopherol transfer protein (a-TTP) on chromosome 8 (8q13). These patients have an impaired ability to bind vitamin E into the VLDL produced and secreted by the liver, resulting in a deficiency of vitamin E in peripheral tissues. Hence, either absence of VLDL (abetalipoproteinemia) or impaired binding of vitamin E to VLDL (AVED) causes an ataxic syndrome. Once again, a genotype classification has proved to be essential in sorting out the various clinical forms of the Friedreich's disease syndrome.

Ataxia Telangiectasia

Symptoms and signs Patients present in the first decade of life with progressive telangiectatic lesions associated with deficits in cerebellar function and nystagmus. The neurologic manifestations correspond to those in Friedreich's disease, which should be included in the differential diagnosis. Truncal ataxia, extremity ataxia, dysarthria, extensor plantar responses, myoclonic jerks, areflexia, and distal sensory deficits may develop. There is a high incidence of recurrent pulmonary infections and neoplasms of the lymphatic and reticuloendothelial system in patients with ataxia telangiectasia (AT) as well as an increased incidence of cancer. Thymic hypoplasia with cellular and humoral (IgA and IgG2) immunodeficiencies, premature aging, and endocrine disorders such as insulin-dependent diabetes mellitus are described. There is an increased incidence of lymphomas, Hodgkin's disease, and acute leukemias of the T cell type. There is also an increased incidence of breast cancer in women who are heterozygous for AT. The immunologic defects and increased susceptibility to cancer have been causally linked to cellular disorders in AT. Exposure of cultured cells to ionizing radiation slows the rate of DNA replication and increases the frequency of chromosomal aberrations.

The most striking neuropathologic changes include loss of Purkinje, granule, and basket cells in the cerebellar cortex as well as of neurons in the deep cerebellar nuclei. The inferior olives of the medulla also may have neuronal loss. There is a loss of anterior horn neurons in the spinal cord and of dorsal root ganglion cells associated with posterior column spinal cord demyelination. A poorly developed or absent thymus gland is the most consistent defect of the lymphoid system.

GENETIC CONSIDERATIONS

The gene forAT (the *ATM* gene) has been positionally mapped to chromosome 11q22-q23. *ATM*, which has a 12-kb transcript, was mutated in AT patients from all complementation groups described previously. A partial *ATM* cDNA clone of 5.9 kb encodes a protein that is similar to several yeast and mammalian phosphatidylinositol-3¢-kinases involved in mitogenic signal transduction, meiotic recombination, and cell cycle control. Defective DNA repair in AT fibroblasts exposed to ultraviolet light has been demonstrated. The discovery of *ATM* will make possible the identification of heterozygotes who are at risk for cancer (e.g., breast cancer) and permit

early diagnosis.

Mitochondrial Ataxias Spinocerebellar syndromes have been identified with mutations in mitochondrial DNA (mtDNA). Thirty pathogenic mtDNA point mutations and>60 different types of mtDNA deletions are known, several of which cause or are associated with ataxia (Chap. 383).

Xeroderma Pigmentosum Xeroderma pigmentosum is a rare autosomal recessive neurocutaneous disorder caused by the inability to repair damage to DNA, such as that produced by ultraviolet radiation. In addition to skin lesions, patients may show progressive mental deterioration, microcephaly, ataxia, spasticity, choreoathetosis, and hypogonadism. Nerve deafness, peripheral neuropathy (predominantly axonal), electroencephalographic abnormalities, and seizures are reported. Neuronal death occurs in pyramidal cells, cerebellar Purkinje cells, the deep nuclei of the cerebellum, the brainstem, the spinal cord, and peripheral nerves.

Cockayne Syndrome This is a rare autosomal recessive disorder first described by Cockayne in 1936. Clinical features are mental retardation, optic atrophy, dwarfism, neural deafness, hypersensitivity of skin to sunlight, cataracts, and retinal pigmentary degeneration. Cerebellar, pyramidal, and extrapyramidal deficits and peripheral neuropathy may occur, with a "bird-headed" facial appearance and normal-pressure hydrocephalus. Skin fibroblasts exposed to ultraviolet light demonstrate defective DNA repair.

Marinesco-Sjogren Syndrome This rare syndrome, in which progressive cerebellar deficits begin early in childhood, is another example in which a Friedreich's syndrome is associated with additional specific features. In this case, cataracts, mental retardation, multiple skeletal abnormalities, hypogonadotropic hypogonadism, and severe cerebellar atrophy are associated. The syndrome is likely a lysosomal storage disorder caused by an enzymatic defect, but the pathophysiology is unknown.

TREATMENT

The physician's most important task in the management of patients with ataxia is to identify treatable disease entities. Malignancies may present with chronic progressive ataxia either directly with a mass effect in the posterior fossa or indirectly by paraneoplastic degeneration. Other mass lesions can be treated appropriately. Malabsorption syndromes leading to vitamin E deficiency may lead to ataxia. The vitamin E deficiency form of Friedreich's ataxia must be considered, and serum vitamin E levels measured. Vitamin E therapy is indicated for these rare patients. There is preliminary evidence that idebenone, a free-radical scavenger, is therapeutic for patients with classic Friedreich ataxia by reducing myocardial hypertrophy. There is no current evidence that it improves neurologic function. Iron chelators and antioxidant drugs are potentially harmful as they may increase heart muscle injury. Vitamin B_1 and B_{12}levels in serum must be measured, and the vitamins should be administered to patients having deficient levels. The deleterious effects of diphenylhydantoin and alcohol on the cerebellum are well known. Hypothyroidism is easily treated. Aminoacidopathies, leukodystrophies, urea-cycle abnormalities, and mitochondrial encephalomyopathies may produce ataxia, and some dietary or metabolic therapies are

available. The cerebrospinal fluid should be tested for a syphilitic infection in patients with progressive ataxia and other features of tabes dorsalis. Similarly, antibody titers for Lyme disease and *Legionella* should be measured, and appropriate antibiotic therapy should be instituted in antibody-positive patients. There is no proven therapy for the dominant ataxias (SCA1 to 13). The identification of gene defects will, it is hoped, lead to specific pharmacologic therapy. At present, identification of an at-risk person's genotype, together with appropriate family and genetic counseling, can reduce the incidence of these cerebellar syndromes (Chaps. 68,359).

365. AMYOTROPHIC LATERAL SCLEROSIS AND OTHER MOTOR NEURON DISEASES - *Robert H. Brown, Jr.*

AMYOTROPHIC LATERAL SCLEROSIS

Amyotrophic lateral sclerosis (ALS) is the most common form of progressive motor neuron disease. It is a prime example of a neuronal system disease and is arguably the most devastating of the neurodegenerative disorders.

Pathology The pathology of motor neuron degenerative disorders involves lower motor neurons (consisting of anterior horn cells in spinal cord and their brainstem homologues innervating bulbar muscles) and upper, or corticospinal, motor neurons (emanating from layer five of motor cortex to descend via the pyramidal tract to synapse with lower motor neurons, either directly or indirectly via interneurons; (Chap. 22). Although at its onsetALS may involve selective loss of function of only upper or lower motor neurons, it ultimately causes progressive loss of both categories of motor neurons. Indeed, in the absence of clear involvement of both motor neuron types, the diagnosis of ALS is questionable.

Other motor neuron diseases involve only particular subsets of motor neurons (Tables 365-1 and365-2). Thus, in bulbar palsy and spinal muscular atrophy (SMA, also called progressive muscular atrophy), the lower motor neurons of brainstem and spinal cord, respectively, are most severely involved. By contrast, pseudobulbar palsy, primary lateral sclerosis (PLS), and familial spastic paraplegia (FSP) affect only upper motor neurons innervating the brainstem and spinal cord.

In each of these diseases, the affected motor neurons undergo shrinkage, often with accumulation of the pigmented lipid (lipofuscin) that normally develops in these cells with advancing age. InALS, the motor neuron cytoskeleton is typically affected early in the illness. Focal enlargements are frequent in proximal motor axons; ultrastructurally, these "spheroids" are composed of accumulations of neurofilaments. Beyond some astroglial proliferation, which is the inevitable accompaniment of all degenerative processes in the central nervous system (CNS), the interstitial and supportive tissues and the macrophage system remain largely inactive, and there is no inflammation.

The death of the peripheral motor neurons in the brainstem and spinal cord leads to denervation and consequent atrophy of the corresponding muscle fibers. Histochemical and electrophysiologic evidence indicates that in the early phases of the illness denervated muscle can be reinnervated by sprouting of nearby distal motor nerve terminals, although reinnervation in this disease is considerably less extensive than in most other disorders affecting motor neurons (e.g., poliomyelitis, peripheral neuropathy). As denervation progresses, muscle atrophy is readily recognized in muscle biopsies and on clinical examination. This is the basis for the term *amyotrophy* in the name for the disease. The loss of cortical motor neurons results in thinning of the corticospinal tracts that travel via the internal capsule and brainstem to the lateral and anterior white matter columns of the spinal cord. The loss of fibers in the lateral columns and resulting fibrillary gliosis impart a particular firmness (*lateral sclerosis*) (Fig. 365-1). A remarkable feature of the disease is the selectivity of neuronal cell death. By light microscopy, the entire sensory apparatus, the regulatory mechanisms for the control

and coordination of movement, and the components of the brain that are needed for cognitive processes remain intact. However, immunostaining indicates that neurons bearing ubiquitin, a marker for degeneration, are also detected in nonmotor systems. Moreover, studies of glucose metabolism in the illness also indicate that there is neuronal dysfunction outside of the motor system. Within the motor system, there is some selectivity of involvement. Thus, motor neurons required for ocular motility remain unaffected, as do the parasympathetic neurons in the sacral spinal cord (the nucleus of Onufrowicz, or Onuf) that innervate the sphincters of the bowel and bladder.

Clinical Manifestations The manifestations ofALS are somewhat variable depending on whether corticospinal or lower motor neurons in the brainstem and spinal cord are more prominently involved. Typically, with lower motor neuron dysfunction and early denervation, the initial sign of the disease is insidiously developing asymmetric weakness, usually first evident distally in one of the limbs. A detailed history often discloses recent development of cramping with volitional movements, typically in the early hours of the morning (e.g., while stretching in bed). Weakness caused by denervation is associated with progressive wasting and atrophy of muscles and, particularly early in the illness, spontaneous twitching of motor units, or fasciculations. In the hands, a preponderance of extensor over flexor weakness is common. When the initial denervation involves bulbar rather than limb muscles, the problem at onset is difficulty with chewing, swallowing, and movements of the face and tongue. Early involvement of the muscles of respiration may lead to death before the disease is far advanced elsewhere.

With prominent corticospinal involvement, there is hyperactivity of the muscle-stretch reflexes (tendon jerks) and, often, spastic resistance to passive movements of the affected limbs. Patients with significant reflex hyperactivity complain of muscle stiffness often out of proportion to weakness. Degeneration of the corticobulbar projections innervating the brainstem results in dysarthria and exaggeration of the motor expressions of emotion. The latter leads to involuntary excess in weeping or laughing (so-called pseudobulbar affect).

Virtually any muscle group may be the first to show signs of the disease, but, as time passes, more and more muscles become involved until ultimately the disorder takes on a symmetric distribution in all regions. It is characteristic ofALSthat, regardless of whether the initial disease involves upper or lower motor neurons, both will eventually be implicated. Even in the late stages of the illness, sensory, bowel and bladder, and cognitive functions are preserved. Even when there is severe brainstem disease, ocular motility is spared until the very late stages of the illness. Dementia is not a component of sporadic ALS. In some families, ALS is co-inherited with frontotemporal dementia, characterized by early behavioral abnormalities with prominent behavioral features indicative of frontal lobe dysfunction.

A committee of the World Federation of Neurology has established diagnostic guidelines forALS. Essential for the diagnosis is the presence of simultaneous upper and lower motor neuron involvement with progressive weakness, and the exclusion of all alternative diagnoses. The disorder is classified as "definite" ALS when three or four of the following sites are involved: bulbar, cervical, thoracic, and lumbosacral motor neurons. When two sites are involved, the diagnosis is "probable"; when only one site is

implicated, the diagnosis is "possible." An exception is made for those who have progressive upper and lower motor neuron signs at only one site and a mutation in the gene encoding superoxide dismutase (below).

Epidemiology The illness is relentlessly progressive, leading to death from respiratory paralysis; the median survival is from 3 to 5 years. There are very rare reports of stabilization or even regression ofALS. In most societies there is an incidence of 1 to 3 per 100,000 and a prevalence of 3 to 5 per 100,000. Several endemic foci of higher prevalence exist in the western Pacific (e.g., in specific regions of Guam or Papua New Guinea). In the United States and Europe, males are somewhat more frequently affected than females. While ALS is overwhelmingly a sporadic disorder, some 5 to 10% of cases are inherited as an autosomal dominant trait.

Familial ALS Several forms of selective motor neuron disease are heritable (Table 365-2). Two involve both corticospinal and lower motor neurons. The most common is familialALS(FALS). Apart from its inheritance as an autosomal dominant trait, it is clinically indistinguishable from sporadic ALS. Genetic studies have identified mutations in the gene encoding the cytosolic enzyme superoxide dismutase (SOD1) as the cause of one form of FALS. However, this accounts for only 20% of inherited cases of ALS; there clearly are other ALS genes to be identified. There is a juvenile-onset, dominantly inherited form of ALS that is genetically mapped to the long-arm of chromosome 9. Two recessively inherited forms of juvenile-onset ALS with long survival map to chromsomes 2 and 15. Another familial, adult-onset disorder that may mimic aspects of ALS is Kennedy's syndrome, described below.

Differential Diagnosis BecauseALS is currently untreatable, it is imperative that potentially remediable causes of motor neuron dysfunction be excluded (Table 365-3). This is particularly true in cases that are atypical by virtue of (1) restriction to either upper or lower motor neurons, (2) involvement of neurons other than motor neurons, and (3) evidence of motor neuronal conduction block on electrophysiologic testing. Compression of the cervical spinal cord or cervicomedullary junction from tumors in the cervical regions or at the foramen magnum or from cervical spondylosis with osteophytes projecting into the vertebral canal can produce weakness, wasting, and fasciculations in the upper limbs and spasticity in the legs, closely resembling ALS. The absence of cranial nerve involvement may be helpful in differentiation, although some foramen magnum lesions may compress the twelfth cranial (hypoglossal) nerve, with resulting paralysis of the tongue. Absence of pain or of sensory changes, normal bowel and bladder function, normal roentgenographic studies of the spine, and normal cerebrospinal fluid (CSF) all favor ALS. Where doubt exists, magnetic resonance imaging (MRI) scans should be performed to visualize the cervical spinal cord.

Another important entity in the differential diagnosis ofALS is multifocal motor neuropathy (MMN) with conduction block, discussed below and inChap. 378. A diffuse, lower motor axonal neuropathy mimicking ALS sometimes evolves in association with hematopoietic disorders such as lymphoma (Chap. 101). The underlying marrow pathology is often signaled by the presence of an M-component in serum which, in this clinical setting, should prompt consideration of a bone marrow biopsy. Lyme infection may also cause an axonal, lower motor neuropathy.

Other treatable disorders that occasionally mimicALS are chronic lead poisoning and thyrotoxicosis. These disorders may be suggested by the patient's social or occupational history or by unusual clinical features. When the family history is positive, disorders involving the genes encoding SOD1, hexosaminidase A, or a-glucosidase deficiency must be excluded (Chap. 349). These are readily identified by appropriate laboratory tests. Benign fasciculations are occasionally a source of concern because on inspection they resemble the fascicular twitchings that accompany motor neuron degeneration. The absence of weakness, atrophy, or denervation phenomena on electrophysiologic examination usually excludes ALS or other serious neurologic disease. Patients who have recovered from poliomyelitis may experience a delayed deterioration of motor neurons that presents clinically with progressive weakness, atrophy, and fasciculations. Its cause is unknown but is thought to reflect sublethal prior injury to motor neurons by poliovirus (Chap. 193).

Rarely,ALSdevelops concurrently with features indicative of more widespread neurodegeneration. Thus, one infrequently encounters otherwise typical ALS patients with a Parkinsonian movement disorder or dementia. It remains unclear whether this reflects the unlikely simultaneous occurrence of two disorders or a primary defect triggering two forms of neurodegeneration. The latter is suggested by the observation that multisystem neurodegenerative diseases may be inherited. For example, prominent amyotrophy has been described as a dominantly inherited disorder in individuals with bizarre behavior and a movement disorder suggestive of parkinsonism; many such cases have now been ascribed to mutations that alter the expression of isoforms of tau protein in brain (Chap. 362). In other cases, ALS develops simultaneously with a striking frontotemporal dementia. These disorders may be dominantly co-inherited; in some families, this trait is linked to a locus on chromosome 9q, although the underlying genetic defect is not established.

Pathogenesis The cause of sporadicALS is not well defined. Some data suggest that excitotoxic neurotransmitters such as glutamate may participate in the death of motor neurons in ALS. This may be a consequence of diminished uptake of synaptic glutamate by an astroglial glutamate transporter, EAAT2. In one study of sporadic ALS brains, this loss of transport function was attributed to abnormal splicing of the mRNA transcript for the EAAT2 transporter selectively in motor cortex. It is striking that one cellular defense against such excitotoxicity is the enzyme SOD1, which detoxifies the free radical superoxide anion. Because SOD1 is mutated in some familial cases of ALS, it may be that glutamate excitotoxicity and ALS result from free radical accumulations in motor neurons. Precisely why the SOD1 mutations are toxic to motor nerves is not established, although it is clear that the effect is not simply loss of normal scavenging of the superoxide anion.

TREATMENT

There is no treatment capable of arresting the underlying pathologic process inALS. The drug riluzole was approved for use in ALS because it produces a modest lengthening of survival. In one trial, the survival rate at 18 months with riluzole (100 mg/d) was similar to placebo at 15 months. The mechanism of this effect is not known with certainty; it may reduce excitotoxicity by diminishing glutamate release. Side effects of riluzole may include nausea, dizziness, weight loss, and elevated liver enzymes. In a single study,

insulin-like growth factor (IGF-1) was found to slow the progression of ALS modestly; because this effect was not confirmed in a second trial, IGF-1 is not routinely available as an ALS treatment at this time. Clinical trials of several other agents are in progress, including brain-derived neurotrophic factor, glial-derived neurotrophic factor, the anti-glutamate compound topiramate, and creatine. Creatine has proven to be beneficial in SOD-1 transgenic ALS mice, perhaps by augmenting intracellular ATP stores. In a single study in France, vitamin E was beneficial in sporadic ALS. It is also modestly beneficial in the ALS mice and thus is now used empirically by many individuals with ALS. On the basis of successful animal experiments, trials of neural stem therapy of the spinal cord are also being developed in ALS.

In the absence of a primary therapy forALS, a variety of rehabilitative aids may substantially assist ALS patients. Foot-drop splints facilitate ambulation by avoiding tripping on a floppy foot and obviating excessive hip flexion. Finger-extension splints can potentiate grip. Respiratory support may be life-sustaining. For patients electing against long-term ventilation by tracheostomy, positive-pressure ventilation by mouth or nose provides transient (several weeks) relief from hypercarbia and hypoxia. Also extremely beneficial for some patients is a respiratory device (In-exsufflator, Emerson) that produces an artificial cough. This is highly effective in clearing airways and preventing aspiration pneumonia. When bulbar disease prevents normal chewing and swallowing, gastrostomy is uniformly helpful, restoring normal nutrition and hydration. Fortunately, an increasing variety of speech synthesizers are now available to augment speech when there is advanced bulbar palsy. Because they facilitate oral communication and may be effective for telephone use, such devices are helpful in preserving patient autonomy.

In contrast toALS, several of the disorders (Table 365-2) that bear some clinical resemblance to ALS are treatable; for this reason, a careful search for such forms of secondary motor neuron disease is warranted.

SELECTED DISORDERS OF THE LOWER MOTOR NEURON

In the varieties of motor neuron disease grouped under this heading, the peripheral motor neurons are affected without evidence of involvement of the corticospinal motor system (Table 365-1).

X-Linked Spinobulbar Muscular Atrophy (Kennedy's Disease) This is an X-linked lower motor neuron disorder in which progressive weakness and wasting of limb and bulbar muscles begins in males in midadult life and is conjoined with androgen insensitivity manifested by gynecomastia and reduced fertility (Chap. 335). In addition to gynecomastia, which may be subtle, two findings distinguishing this disorder fromALS are the absence of signs of pyramidal tract disease (spasticity) and the presence of a subtle sensory neuropathy in some patients. The underlying molecular defect is an expanded trinucleotide repeat (-CAG-) in the first exon of the androgen receptor gene on the X chromosome; this may be readily screened from DNA from blood. An inverse correlation appears to exist between the number of -CAG- repeats and the age of onset of the disease (Chap. 359).

Adult Tay-Sach's Disease Several reports have described adult-onset, predominantly

lower motor neuropathies arising from deficiency of the enzymeb-hexosaminidase (hex A). These tend to be distinguishable fromALSbecause they are very slowly progressive; dysarthria and radiographically evident cerebellar atrophy may be prominent. In rare cases, spasticity may also be present, although it is generally absent (Chap. 349).

Spinal Muscular Atrophy TheSMAs are a family of selective lower motor neuron diseases of early onset. Despite some phenotypic variability (largely in age of onset), the defect in the majority of families with SMA is genetically linked to a locus on the proximal long arm of chromosome 5. The affected gene at this locus is a putative motor neuron survival protein (SMN, for survival motor neuron) that is important in the formation and trafficking of RNA complexes across the nuclear membrane. All types of SMA are transmitted as traits. Neuropathologically these disorders are characterized by extensive loss of large motor neurons; muscle biopsy reveals evidence of denervation atrophy. Several clinical forms are described.

Infantile SMA (SMA I, Werdnig-Hoffmann Disease) has the earliest onset and most rapidly fatal course. In some instances it is apparent even before birth, as indicated by decreased fetal movements late in the third trimester. Though alert, afflicted infants are weak and floppy (hypotonic) and lack muscle stretch reflexes. Death generally ensues within the first year of life. When the family history is unclear, it is difficult in the early weeks and months to distinguishSMA I from benign congenital hypotonia. An electromyogram is often particularly helpful as SMA I usually demonstrates fulminant denervation; in congenital hypotonia the electromyogram is often myopathic or normal.

Chronic childhood SMA (SMA II) begins later in childhood and evolves with a more slowly progressive course. *Juvenile SMA* (SMAIII, Kugelberg-Welander disease) manifests during late childhood and runs a slow, indolent course. Unlike most denervating diseases, in this chronic disorder weakness is greatest in the proximal muscles; indeed, the pattern of clinical weakness can suggest a primary myopathy such as limb-girdle dystrophy. Electrophysiologic and muscle biopsy evidence of denervation distinguish SMA III from the myopathic syndromes.

Multifocal Motor Neuropathy with Conduction Block In this disorder lower motor neuron function is regionally and chronically disrupted by remarkably focal blocks in conduction. Many patients have elevated serum titers of mono- and polyclonal antibodies to ganglioside G_{MI}; it is hypothesized that the antibodies produce selective, focal, paranodal demyelination of motor neurons.MMN is not typically associated with corticospinal signs. In contrast toALS, MMN may respond dramatically to therapy such as intravenous immunoglobulin or chemotherapy; it is thus imperative that MMN be excluded when considering a diagnosis of ALS.**A detailed discussion of this condition can be found in Chap. 378.*

Other Forms of Lower Motor Neuron Disease In individual families, other syndromes characterized by selective lower motor neuron dysfunction in anSMA-like pattern have been described. There are rare X-linked and autosomal dominant forms of apparent SMA. There is anALSvariant of juvenile onset, the Fazio-Londe syndrome, which involves mainly the musculature innervated by the brainstem. A component of lower motor neuron dysfunction is also found in degenerative disorders such as Machado-Joseph disease and the related olivopontocerebellar degenerations (Chap.

364).

SELECTED DISORDERS OF THE UPPER MOTOR NEURON

Primary Lateral Sclerosis This exceedingly rare disorder arises sporadically in adults in mid- to late life. ClinicallyPLS is characterized by progressive spastic weakness of the limbs, preceded or followed by spastic dysarthria and dysphagia, indicating combined involvement of the corticospinal and corticobulbar tracts. Fasciculations, amyotrophy, and sensory changes are absent; neither electromyography nor muscle biopsy shows denervation. On neuropathologic examination there is selective loss of the large pyramidal cells in the precentral gyrus and degeneration of the corticospinal and corticobulbar projections. The peripheral motor neurons and other neuronal systems are spared. The course of PLS is variable; while long-term survival is documented, the course may be as aggressive as inALS, with approximately 3-year survival from onset to death. Early in its course, PLS raises the question of multiple sclerosis or other demyelinating diseases such as adrenoleukodystrophy as diagnostic considerations. A myelopathy suggestive of PLS is infrequently seen with infection with the human T cell leukemia virus (HTLV-I) (Chap. 368). The clinical course and laboratory testing will distinguish these possibilities.

Familial Spastic Paraplegia In its pure form,FSP is usually transmitted in families as an autosomal dominant trait; most adult-onset cases are dominantly inherited. It arises in the third or fourth decade and is characterized by progressive spastic weakness beginning in the distal lower extremities. Patients with FSP typically have long survival, presumably because respiratory function is spared. Late in the illness there may be urinary urgency and incontinence and sometimes fecal incontinence; sexual function tends to be preserved. In pure forms of FSP, ataxia, posterior column sensory loss, and amyotrophy are absent or minimal; however, in some patients, minor sensory changes (impaired vibration and position sense) may be observed in late stages. Some family members may show isolated spasticity without other clinical symptoms. Neuropathologically, in FSP there is degeneration of the corticospinal tracts, which appear nearly normal in the brainstem but show increasing atrophy at more caudal levels in the spinal cord. It is now apparent that defects at several different loci underlie both dominantly and recessively inherited forms of FSP (Table 365-2). An infantile-onset form of X-linked, recessive FSP arises from mutations in the gene for proteolipid protein. This is an example of rather striking allelic variation, as most other mutations in the same gene cause not FSP but Pelizaeus-Merzbacher disease, a disorder ofCNSmyelin. Defects in two other genes encoding the proteins "spastin" and "paraplegin" have recently been associated, respectively, with dominantly and recessively inherited FSP. The latter gene is of particular interest as it has homology to metalloproteases that are important in mitochondrial function in yeast.

Rarely,FSP may arise concomitantly with significant involvement of other regions of the nervous system. Thus, it has been described concurrently with amyotrophy, mental retardation, mental retardation with skin thickening, optic atrophy, and sensory neuropathy. In some cases there is loss of fibers in the ascending posterior columns and the spinocerebellar tracts, features reminiscent of Friedreich's ataxia. These complicated forms of FSP emphasize the challenge inherent in classifying the neurodegenerative disorders; there may be considerable overlap of the clinical

phenotypes in diseases otherwise classified as distinct. Fortunately, it is likely that increasingly available genetic testing will clarify these nosologic difficulties.

366. DISORDERS OF THE AUTONOMIC NERVOUS SYSTEM - *John W. Engstrom*, *Joseph B. Martin*

Rapid adjustments in vital physiologic mechanisms critical to survival are accomplished by the autonomic nervous system (ANS). The importance of this regulation is emphasized by the extent and severity of disability resulting from compromised ANS function. This chapter describes the clinical manifestations, diagnosis, and treatment of ANS disorders.**The functional anatomy and relevant pharmacology of the sympathetic and parasympathetic components of the ANS are discussed in Chap. 72. Hypothalamic disorders that cause disturbances in homeostasis are discussed in Chaps. 17 and 328.*

CLINICAL MANIFESTATIONS

Classification Disorders of theANS may result from central nervous system (CNS) or peripheral nervous system (PNS) causes (Table 366-1). In many instances, the clinical signs and symptoms are due to interruption of a reflex arc controlling autonomic responses. The interruption can occur in the afferent limb, CNS processing centers, or efferent limb of the reflex arc. For example, a lesion of the medulla produced by a posterior fossa tumor can impair blood pressure (BP) responses to postural changes and result in orthostatic hypotension. Hypotension can also be caused by lesions of the spinal cord or peripheral vasomotor nerve fibers (diabetes mellitus). Diagnosis of the site of reflex interruption is dependent on the clinical context, ANS tests, and neuroimaging. Important elements of the clinical context include the presence or absence of CNS signs (pathophysiology and prognosis differ), association with sensory or motor polyneuropathy, family history, and pathologic findings. Some syndromes do not fit easily into any classification scheme because little is known about etiology, pathology, or treatment.

Symptoms of Autonomic Dysfunction The clinical manifestations of autonomic lesions are influenced by the organ involved, the normal balance of sympathetic-parasympathetic innervation, the nature of the underlying illness, and the severity and stage of progression. *Impotence* often heralds autonomic failure in men and may precede other symptoms by more than a decade (Chap. 51). A decrease in the frequency of spontaneous early morning erections may occur months before loss of nocturnal penile tumescence and development of total impotence. *Bladder dysfunction* may appear early in men and women, particularly in those withCNSinvolvement. Brain and spinal cord disease above the level of the lumbar spine results first in urinary frequency and small bladder volumes, and eventually in incontinence (*upper motor neuron* or *spastic bladder*). Disease ofPNSautonomic nerve fibers to and from the bladder results in large bladder volumes, urinary frequency, and overflow incontinence (*lower motor neuron bladder* or *flaccid bladder*). Measurement of bladder volume (postvoid residual) is a useful bedside test for distinguishing between upper and lower motor neuron bladder dysfunction. *Gastrointestinal autonomic dysfunction* typically presents as severe constipation. Diarrhea occurs occasionally (as in diabetes mellitus) due to rapid transit of contents or uncoordinated small bowel motor activity, or on an osmotic basis from bacterial overgrowth associated with small bowel stasis. Impaired glandular secretory function may cause difficulty with food intake due to decreased salivation or eye irritation due to decreased lacrimation. Occasionally, temperature elevation and vasodilation can result from *anhidrosis* because sweating is normally

important for heat dissipation (Chap. 17).

Orthostatic hypotension (OH) (also called "postural hypotension") is the most disabling feature of autonomic dysfunction. OH can cause a variety of symptoms, including dimming or loss of vision, lightheadedness, diaphoresis, diminished hearing, pallor, and weakness. Syncope results when the drop inBPimpairs cerebral perfusion. Other manifestations of impaired cardiovascular control from baroreflex dysfunction include supine hypertension, a heart rate that is fixed regardless of posture, and postprandial hypotension. The most common causes of OH are not neurologic in origin (Table 366-2) and must be distinguished from neurogenic etiologies (Table 366-1).**Neurocardiogenic and cardiac syncope are considered in Chap. 20.*

Approach to the Patient

The most common, clinically significant autonomic disorders present with symptoms ofOH. The first step in the evaluation of symptomatic orthostasis is the exclusion of treatable causes. The history should include a review of current medications which may cause OH (e.g., diuretics, antihypertensives, antidepressants, phenothiazines, ethanol, narcotics, insulin, barbiturates, andb-adrenergic and calcium channel blockers). Exaggerated responses to medications may be the first sign of an underlying autonomic disorder. The history may reveal a potential underlying cause for symptoms (e.g., diabetes, Parkinson's disease) or may reveal specific underlying mechanisms (e.g., cardiac pump failure, reduced intravascular volume). Inappropriate or extreme venous pooling may contribute to symptomatic OH. The relationship of symptoms to meals (splanchnic shunting of blood), or standing on awakening in the morning (due to relative intravascular volume depletion) should be sought.

Physical examination includes measurement of supine and standing pulse andBP, with a period of at least 2 min between positions. Sustained drops in systolic (>20 mmHg) or diastolic (>10 mmHg) BP after standing for at least 2 min that are not associated with an increase in pulse rate of>15 beats per minute suggest an autonomic deficit. In nonneurogenic causes of OH, the BP drop is accompanied by a compensatory increase in heart rate of >15 beats per minute. The requirement that the hypotension is sustained differentiates autonomic failure from sluggish baroreceptor responses that are common in the elderly. Other common signs ofANSdysfunction include supine hypertension or postprandial hypotension. Neurologic evaluation should include a mental status examination (to exclude neurodegenerative disorders), cranial nerve examination (to detect the impaired downgaze found with progressive supranuclear palsy), motor examination (for Parkinson's disease and parkinsonian syndromes), and sensory examination (for polyneuropathies). In patients without a clear initial diagnosis, follow-up neurologic evaluations performed over years may reveal an evolution of neurologic findings that makes it possible to reach a specific diagnosis.

Disorders of autonomic function should be considered in the differential diagnosis of patients with symptoms of altered sweating (hyperhidrosis or hypohidrosis), constipation, impotence, or bladder dysfunction (urinary frequency, hesitancy, or incontinence). An initial practical approach to the patient withOH or autonomic symptoms is summarized inTable 366-3.

Autonomic Testing (See also Chap. 357) Autonomic function tests are helpful when the history and physical examination findings are inconclusive, when detection of subclinical involvement is important to evaluate the extent and severity of abnormalities, or to monitor the effects of therapy. Both physiologic and pharmacologic tests are available to assess the functional characteristics of theANS. Commonly used physiologic tests assess autonomic aspects of cardiovascular function. These tests are noninvasive and provide quantitative and regional data about autonomic function. Pharmacologic tests can elucidate pathophysiologic abnormalities and guide the development of rational therapy.

HEART RATE VARIATION WITH DEEP BREATHING This is a test of parasympathetic influence on cardiovascular function. Results are influenced by the subject's posture, rate and depth of respiration [5 to 6 breaths per minute and a forced vital capacity (FVC)>1.5 L are optimal], age, medications, and hypocapnea. Interpretation of results requires comparison of test data with results from normal individuals collected under the same test conditions. For example, the lower limit of normal heart rate variation with deep breathing in persons younger than 20 years is >15 to 20 beats/min, but for persons over age 60 it is 5 to 8 beats/min. Heart rate variation with deep breathing (respiratory sinus arrhythmia) is abolished by the administration of atropine.

VALSALVA RESPONSE This response assesses integrity of the afferent limb, central processing, and efferent limb of the baroreceptor reflex (Table 366-4). The response is obtained with the subject sitting or supine. A constant expiratory pressure of 40 mmHg is maintained for 15 s while changes in heart rate and beat-to-beatBP are measured. There are four phases of BP and heart rate response to the Valsalva maneuver. Phases I and III are mechanical and related to changes in intrathoracic and intraabdominal pressure. In early phase II, reduced stroke volume and venous return results in a fall in BP, reflex tachycardia, and increased total peripheral resistance. Increased total peripheral resistance arrests the BP drop approximately 5 to 8 s after the onset of the maneuver. Late phase II begins with a progressive rise in BP toward baseline. Venous return and cardiac output return to normal in phase IV. Persistent peripheral arteriolar vasoconstriction results in a temporary BP overshoot and phase IV bradycardia (mediated by the baroreceptor reflex).

Autonomic function during the Valsalva maneuver can be measured in several ways. The *Valsalva ratio* is calculated from heart rate changes during the maneuver and is defined as the maximum phase II tachycardia divided by the minimum phase IV bradycardia. The ratio reflects the integrity of the entire baroreceptor reflex arc and of sympathetic efferents to blood vessels; sympathetic efferent function is assessed in the phase IIBPresponse and the BP overshoot. Test results depend on the age and posture of the subject, the expiratory pressure, the duration of expiration, theFVC, and medications. Noninvasive recording of beat-to-beat BP changes provides a direct measure of sympathetic efferent input to blood vessels during phases II and IV that does not depend on the presence of a normal baroreceptor reflex arc.

SUDOMOTOR FUNCTION The capacity to produce sweat can be assessed quantitatively or qualitatively. Sweating is induced by release of acetylcholine from sympathetic postganglionic fibers. The *quantitative sudomotor axon reflex test* (QSART) is a measure of regional autonomic function mediated by acetylcholine-induced

sweating. A reduced or absent response indicates a lesion of the postganglionic sudomotor axon. For example, sweating may be reduced in the legs as a result of peripheral neuropathy (e.g., in diabetes) before other signs of autonomic dysfunction emerge. The *thermoregulatory sweat test* (TST) is a *qualitative* measure of regional sweat production in response to an elevation of body temperature. An indicator powder placed on the anterior body surface changes color with sweat production during temperature elevation. The pattern of color changes is a measure of regional sweat secretion. The pattern of sweat abnormality may suggest a peripheral or central cause for the deficit. For example, a unilateral decrease over half the body suggests a central lesion. Measurement of galvanic skin responses in the limbs after an induced electrical potential is another qualitative test for detecting the presence or absence of sweating. The response is simple to measure, but habituation occurs.

ORTHOSTATIC BLOOD PRESSURE RECORDINGS Beat-to-beatBPmeasurements determined in supine, 80° tilt, and tilt-back positions are useful to quantitate orthostatic failure of BP control. It is important to allow a 20-min period of supine rest before assessing changes in BP during tilting. The test can be useful for the evaluation of patients with unexplained syncope and to detect vagally mediated syncope.

COLD PRESSOR TEST The cold pressor test assesses sympathetic function. The individual immerses one hand in ice water (1° to 4°C) andBP is measured at 30 s and 1 min. The systolic and diastolic pressures normally rise by 10 to 20 mmHg. The afferent pathway is spinothalamic and thus is distinct from the afferent limb of the baroreceptor reflex arc. When spinothalamic pathways are intact, an abnormal response indicates an abnormality of autonomic central processing or sympathetic efferent function. When the response to the cold pressor test is normal and the Valsalva response is abnormal, the lesion is located in the afferent limb of the baroreceptor reflex arc.

PHARMACOLOGIC TESTS Pharmacologic assessments can help localize an autonomic defect to theCNS or the PNS. The test is controlled for time of day, position of the patient, level of patient activity, and food intake. Measures should be taken to minimize patient stress. Measurement of plasma levels of neurotransmitter metabolites andBPresponses to infused drugs helps to distinguish between central and peripheral causes of autonomic dysfunction (Table 366-5); however, these studies are not routine clinical tools.

SPECIFIC SYNDROMES OF ANS DYSFUNCTION

Multiple System Atrophy Multiple system atrophy (MSA) is an uncommon entity that comprises several overlapping clinical syndromes, including striatonigral degeneration (Shy-Drager syndrome), progressive supranuclear palsy (Chap. 363), and olivopontocerebellar atrophy (Chap. 364). The clinical syndrome can include various combinations of symptoms of autonomic dysfunction (OH, impotence, bladder and bowel dysfunction, and defective sweating), as well as additional symptoms ofCNSdisease such as rigidity, tremor, loss of associative movements, or abnormal eye movements. Most patients present with autonomic dysfunction alone, and other neurologic manifestations usually develop within 5 years. Patients with the striatonigral variant exhibit a form of parkinsonism in which bradykinesia and rigidity are more prominent than tremor. Patients with either a pure cerebellar syndrome or striatonigral

degeneration may also develop pyramidal tract involvement. Some patients have features of both subtypes.

These disorders progress relentlessly to death 7 to 10 years after onset. Pharmacologic differences distinguishMSA from peripheral causes of autonomic failure (Table 366-4). Neuropathologic changes include primary neuronal degeneration with loss of neurons and gliosis in manyCNSregions, including the brainstem, the cerebellum, the striatum, and the intermediolateral cell column of the thoracolumbar spinal cord.ANSabnormalities are also associated with Parkinson's disease and Huntington's disease.

Spinal Cord Lesions Spinal cord lesions from any cause may result in focal autonomic deficits or autonomic hyperreflexia. Descending pathways from the brain normally modulate organized patterns of sympathetic activity and modulate segmental autonomic reflexes. Spinal cord transection or hemisection may be attended by autonomic hyperreflexia affecting bowel, bladder, sexual, temperature-regulation, or cardiovascular functions. Dangerous increases or decreases in body temperature may result from inability to experience the sensory accompaniments of heat or cold exposure below the level of the injury. Quadriparetic patients exhibit both supine hypertension andOH after upward tilting. Markedly increased autonomic discharge can be elicited by bladder pressure or stimulation of the skin or muscles; suprapubic palpation of the bladder, catheter insertion, catheter obstruction, or urinary infection are common and correctable precipitants. This phenomenon, termed autonomic dysreflexia, affects 85% of patients with a traumatic spinal cord lesion above the C6 level. In patients with supine hypertension,BP can be lowered by tilting the head upward. Vasodilator drugs may be used to treat acute elevations in BP. Clonidine is used prophylactically to reduce the hypertension resulting from bladder stimulation. Sudden, dramatic increases in BP can lead to intracranial hemorrhage and death.

Peripheral Nerve and Neuromuscular Junction Disorders Peripheral neuropathies (Chap. 377) are the most common cause of chronic autonomic insufficiency. Neuropathies that affect small myelinated and unmyelinated fibers of the sympathetic and parasympathetic nerves occur in diabetes mellitus, amyloidosis, chronic alcoholism, porphyria, and Guillain-Barre syndrome. Neuromuscular junction disorders include botulism and Lambert-Eaton syndrome.

Diabetes Mellitus Autonomic involvement in diabetes may begin at any stage in the disease (Chap. 333) and often presents with asymptomatic abnormalities in vagal function that can be detected as reduced heart rate variation with deep breathing. Loss of small myelinated and unmyelinated nerve fibers in the splanchnic distribution, carotid sinus, and vagus nerves is characteristic. Widespread enteric neuropathy can cause profound disturbances in gut motility (gastroparesis), nausea and vomiting, malnutrition, achlorhydria, and bowel incontinence. Other symptoms may include impotence, urinary incontinence, pupillary abnormalities, andOH. Typical symptoms and signs of hypoglycemia may fail to appear because damage to the sympathetic innervation of the adrenal gland can result in a lack of epinephrine release. Insulin excess may also cause profound hypotension. Autonomic dysfunction may lengthen the QT interval and enhance the risk of sudden death. Hyperglycemia appears to be one risk factor for autonomic involvement. Biochemical and pharmacologic studies in diabetic neuropathy

are compatible with autonomic failure localized to thePNS [low supine plasma norepinephrine (NE) levels and exaggerated pressor responsiveness].

Amyloidosis Autonomic neuropathy occurs in both sporadic and familial forms of amyloidosis (Chap. 319). Although patients usually present with a distal painful neuropathy accompanied by sensory loss, autonomic insufficiency can precede the development of the polyneuropathy. Death is usually due to cardiac or renal impairment. Postmortem studies reveal amyloid deposition in many organs, including two sites that contribute to autonomic failure: intraneural blood vessels and autonomic ganglia. Pathologic examination reveals a loss of unmyelinated and myelinated nerve fibers.

Alcoholic Neuropathy Abnormal parasympathetic vagal and efferent sympathetic function occurs in individuals with chronic alcoholism. Pathologic changes can be demonstrated in the parasympathetic (vagus) and sympathetic fibers and in ganglia. Impotence is a major problem, but concurrent gonadal hormone abnormalities may obscure the parasympathetic component to this symptom. Clinical symptoms of autonomic failure generally appear when the polyneuropathy is severe.OH may also be prominent in Wernicke's encephalopathy (Chap. 376). Autonomic involvement may contribute to the high mortality rates associated with alcoholism (Chap. 387).

Porphyria Although each of the porphyrias can cause autonomic dysfunction, the condition is most extensively documented in the acute intermittent type (Chap. 346). Autonomic symptoms include tachycardia, sweating, urinary retention, and hypertension or, less commonly, hypotension. Other prominent symptoms include anxiety, abdominal pain, nausea, and vomiting. Abnormal autonomic function can occur both during acute attacks and during remissions. Elevated catecholamine levels during acute attacks correlate with the degree of tachycardia and hypertension.

Guillain-Barre syndrome BP fluctuations and arrhythmias can be severe (Chap. 378). It is estimated that 2 to 10% of seriously ill patients with Guillain-Barre syndrome suffer fatal cardiovascular collapse. Abnormal sweating, sphincter disturbance, and pupillary dysfunction also occur. Demyelination has been described in the vagus and glossopharyngeal nerves, the sympathetic chain, and the white rami communicantes. The presence of autonomic involvement is not clearly related to the severity of motor or sensory involvement.

Botulism The toxin binds presynaptically to cholinergic nerve terminals and, after uptake into the cytosol, blocks acetycholine release by digesting key proteins involved in neurotransmitter release. Manifestations of this blockade consist of motor paralysis and autonomic disturbances, including blurred vision, dry mouth, nausea, unreactive or sluggishly reactive pupils, constipation, and urinary retention (Chap. 144).

Pure Autonomic Failure (PAF) This sporadic syndrome consists of postural hypotension, impotence, bladder dysfunction, and defective sweating. The disorder begins in the middle decades and occurs in women more than in men. The symptoms can be disabling, but the disease does not shorten life span. The clinical and pharmacologic characteristics suggest a primary involvement of postganglionic sympathetic neurons. There is a severe reduction in the density of neurons within sympathetic ganglia, resulting in low supine plasmaNElevels and noradrenergic

supersensitivity (Table 366-5). The clinical diagnosis may be difficult in early stages because patients may present with isolatedOH, raising a question of PAF, but they later develop signs of multiple system atrophy (discussed above).

Postural Orthostatic Tachycardia Syndrome (POTS) This syndrome is characterized by symptomatic orthostatic intolerance (*not*OH) and an increase in heart rate to >120 beats per minute or by 30 beats per minute with standing. The condition affects young adult women most commonly, but it can occur over a wide age range. Associated symptoms include light-headedness, shortness of breath, and exercise intolerance. The pathogenesis is unclear in most cases; hypovolemia, venous pooling, impaired brainstem regulation, or b-receptor supersensitivity may play a role. In one affected individual, a mutation in theNEtransporter resulting in impaired NE clearance from synapses was responsible. Only one-fourth of patients eventually resume their usual daily activities. Expansion of fluid volume and postural training are initial approaches to treatment. If the response to treatment is inadequate, then fludrocortisone, phenobarbital, beta blockers, and clonidine have been used with some success.

Postprandial Hypotension The importance of postprandial hypotension (PPH) among healthy elderly persons, hypertensive patients, and elderly patients in nursing homes has probably been underestimated. Abnormally reduced peripheral vasoconstriction in response to shunting of blood to the splanchnic circulation after a meal contributes to PPH. The wisdom of administering cardiovascular medications that have hypotensive effects at mealtimes to healthy and hypertensive elderly patients is questionable. PPH is also associated with diabetes, Parkinson's disease, renal failure treated with hemodialysis, cardiovascular disease, paraplegia, and autonomic failure.

Inherited Disorders Riley-Day syndrome (familial dysautonomia) is an autosomal recessive disorder of infants and children that occurs among Ashkenazi Jews. The defective gene, located on the long arm of chromosome 9, has not been identified. Decreased tearing, hyperhidrosis, reduced sensitivity to pain, areflexia, absent fungiform papillae on the tongue, and labileBP may be present. Episodic abdominal crises and fever are common. Increased sensitivity to intraocular methacholine and absent axon flare response to intradermal histamine injection are useful diagnostic markers. Normal resting plasmaNElevels that do not increase on standing are consistent with an afferent lesion. Pathologic examination of nerves reveals a loss of small myelinated and unmyelinated nerve fibers.

Primary Hyperhidrosis This syndrome presents with excess sweating of the palms of the hands and soles of the feet. The disorder affects 0.6 to 1.0% of the population; the etiology is unclear (there may be a genetic component). While not dangerous, the condition can be socially embarrassing (e.g., shaking hands) or disabling (e.g., inability to write without soiling the paper). Onset of symptoms is usually in adolescence; the condition tends to improve with age. Topical antiperspirants (e.g., Drysol) are occasionally helpful. T2 ganglionectomy or sympathectomy is successful in>90% of patients with palmar hyperhidrosis. The advent of endoscopic transaxillary T2 sympathectomy has lowered the complication rate of the procedure. The most common complication is compensatory hyperhidrosis, which improves spontaneously over months; other potential complications include recurrent hyperhidrosis (16%), Horner's syndrome (<2%), gustatory sweating, wound infection, hemothorax, and intercostal

neuralgia. Local injection of botulinum toxin has been used to block cholinergic, post-ganglionic sympathetic fibers to sweat glands in patients with palmar hyperhidrosis; however, the technique is limited by the need for repetitive injections (the effect usually lasts 4 months before waning), pain with injection, the high cost of botulinum toxin, and the possibility of temporary intrinsic hand muscle weakness. Tap water iontophoresis has been successful for some patients.

Miscellaneous The importance of autoimmunity in the pathogenesis of autonomic failure has been underestimated; autoantibodies against acetylcholine receptors in autonomic ganglia have been found in some patients with acute pandysautonomia and paraneoplastic autonomic neuropathy. Other conditions associated with autonomic failure include infections, poisoning (organophosphates), malignancy, and aging. Disorders of the hypothalamus can affect autonomic function and produce abnormalities in temperature control, satiety, sexual function, and circadian rhythms (Chap. 328).

Reflex Sympathetic Dystrophy and Causalgia The failure to identify a primary role of theANS in the pathogenesis of these disorders has resulted in a change of nomenclature. *Complex regional pain syndrome* (CRPS) *types I* and *II* are now used in place of reflex sympathetic dystrophy (RSD) and causalgia, respectively.

CRPStype I is a regional pain syndrome that usually develops after tissue trauma. Examples of associated trauma include myocardial infarction, minor shoulder or limb injury, and stroke. *Allodynia* (the perception of a nonpainful stimulus as painful), *hyperpathia* (an exaggerated pain response to a mildly painful stimulus), and spontaneous pain occur; these symptoms are unrelated to the severity of the initial trauma and are not confined to the distribution of a single peripheral nerve. CRPS type II is a regional pain syndrome that develops after injury to a peripheral nerve. Spontaneous pain initially develops within the territory of the affected nerve but eventually may spread outside the nerve distribution.

Pain is the primary clinical feature ofCRPS. Vasomotor abnormalities, sudomotor abnormalities, or focal edema may occur alone or in combination, but must be present for diagnosis. Limb pain syndromes that do not meet these criteria are best classified as "limb pain -- not otherwise specified (NOS)". In CRPS, localized sweating (increased resting sweat output) and changes in blood flow may produce temperature differences between affected and unaffected limbs.

CRPStype I (RSD) has classically been divided into three clinical phases but is now considered to be more variable than previously thought. Phase I consists of pain and swelling in the distal extremity occurring within weeks to 3 months after the precipitating event. The pain is diffuse, spontaneous, and either burning, throbbing, or aching in quality. The involved extremity is warm and edematous, and the joints are tender. Increased sweating and hair growth are present. In phase II (3 to 6 months after onset), thin, shiny, cool skin appears. After an additional 3 to 6 months (phase III), atrophy of the skin and subcutaneous tissue plus flexion contractures complete the clinical picture.

Therapy for both types ofCRPS is unsatisfactory. The desire to provide relief for these severely disabling pain syndromes has produced a variety of surgical and medical treatments with conflicting reports of efficacy. Clinical trials suggest that early

mobilization with physical therapy or a brief course of steroids may be helpful for CRPS type I. The long-term results of this treatment are unclear. Other medical treatments have included the use of adrenergic blockers, nonsteroidal anti-inflammatory drugs (NSAIDs), calcium channel blockers, phenytoin, opioids, and calcitonin. Stellate ganglion blockade is a commonly used invasive therapeutic technique. Although stellate ganglion blocks often provide temporary pain relief, the efficacy of repetitive blocks is uncertain.

TREATMENT

Management of autonomic failure is usually limited to alleviating the disability caused by symptoms. Treatment of the primary disorder does not generally improve autonomic function. The history and examination are key to the identification of easily reversible conditions (Table 366-3).

OHis often severely disabling but may be mild. Neurogenic OH should be treated only if symptoms are present that limit activities of daily living. Nonpharmacologic interventions can be helpful. Patients should avoid sodium depletion or dehydration by maximizing salt intake (eating salty foods) and deliberately drinking at least 2 to 2.5 L/d of water. Sleeping in a head-up tilt position reduces nocturnal diuresis, morning postural hypotension and hypovolemia, and minimizes supine hypertension. Patients are often advised to sit with legs dangling over the edge of the bed for several minutes before attempting to stand in the morning. Isotonic exercise is desirable, but vigorous exercise or prolonged recumbency should be avoided. Circumstances that accentuate vasodilation (alcohol intake, high ambient temperature) may precipitate severe hypotension. Nonprescription medicines containing sympathomimetics must be used carefully because they may cause severe hypertension in the setting of autonomic failure accompanied by denervation supersensitivity. Compressive garments are of questionable value.

Most patients require pharmacologic therapy for the management ofOH. Fludrocortisone is the initial drug of choice; at doses between 0.1 mg/d and 0.3 mg bid orally, it enhances renal sodium conservation and increases the sensitivity of arterioles to norepinephrine. Susceptible patients may develop fluid overload, congestive heart failure, supine hypertension, or hypokalemia; with chronic administration, potassium supplements are often necessary. Sustained elevations of supineBP above 200/110 should be avoided.

OHof moderate severity can be treated with a combination of fludrocortisone and theα_1-receptor agonist midodrine. Midodrine is well absorbed when given orally and causes arteriolar and venous constriction withoutCNS or cardiac stimulation. It is administered orally 30 to 45 min before meals at an initial dose of 5 mg tid, increasing to a maximum of 10 mg q4h. Side effects include pruritus, uncomfortable piloerection, and supine hypertension.

OHwith a postprandial component may respond to several measures. Frequent, small, low-carbohydrate meals may diminish splanchnic shunting of blood after meals and reducePPH. Prostaglandin inhibitors (ibuprofen or indomethacin) taken with meals can prevent PPH. Caffeine (250 mg or two cups of coffee) can be given once per day,

usually in the morning. The somatostatin analogue octreotide can be useful in the treatment of postprandial syncope by inhibiting the release of gastrointestinal peptides that have vasodilator and hypotensive effects. The dose ranges from 25 ug subcutaneously bid to 100 to 200 ug subcutaneously tid. Despite the lack of a pressor effect, octreatide may also be useful for preventing the PPH that occurs in normal elderly patients.

OH accompanied by diarrhea may respond to the$a_2$agonist clonidine; coincident causes of nonneurogenicOH must be excluded before this treatment is begun because the risk of associated hypotension is significant. Initial doses are 0.1 to 0.2 mg orally every morning; the dose is gradually increased if drowsiness, dry mouth, constipation, supine hypertension, or hypotension are not dose-limiting. Octreotide may also be useful for some patients with this condition.

OH associated with anemia may respond to erythropoietin. One study found that systolicBPincreased by 20 mmHg and orthostatic symptoms improved with normalization of the hematocrit. Erythropoietin is administered subcutaneously at doses of 25 to 75 U/kg three times per week. The hematocrit increases after 2 to 6 weeks. A weekly maintenance dose is usually necessary. The increased intravascular volume that accompanies the rise in hematocrit can exacerbate supine hypertension.

Many patients withANSfailure exhibit exaggerated sensitivity to various drugs. Compounds with hypotensive actions should generally be avoided. For example, anticholinergic agents are a better initial choice than dopaminergic compounds for parkinsonism. Anesthetic management poses unique problems since these patients may have abnormal baroreceptor reflexes, impaired sympathetic innervation of peripheral arterioles, exaggerated pharmacologic responses, abnormal fluid balance, or adrenal medullary insufficiency. More important than the choice of anesthetic is awareness by the physician of the implications that autonomic failure may have for peri- and postoperative monitoring and management.

367. COMMON DISORDERS OF THE CRANIAL NERVES - *M. Flint Beal*, *Stephen L. Hauser*

Symptoms and signs of cranial nerve pathology are common in internal medicine. They often develop in the context of a widespread neurologic disturbance, and in such situations cranial nerve involvement may represent the initial manifestation of the illness. In other disorders, involvement is largely restricted to one or several cranial nerves; these distinctive disorders are reviewed in this chapter. Disorders of ocular movement are discussed inChap 28; disorders of smell, taste, and hearing inChap 29; and vertigo and disorders of vestibular function inChap 21.

DISORDERS OF FACIAL SENSATION

The trigeminal (fifth cranial) nerve supplies sensation to the skin of the face and anterior half of the head (Fig. 367-1). Its motor part innervates the masseter and pterygoid masticatory muscles.

TRIGEMINAL NEURALGIA (TIC DOULOUREUX)

The most striking disorder of trigeminal nerve function is tic douloureux, a condition characterized by excruciating paroxysms of pain in the lips, gums, cheek, or chin and, very rarely, in the distribution of the ophthalmic division of the fifth nerve. The disorder occurs almost exclusively in middle-aged and elderly persons. The pain seldom lasts more than a few seconds or a minute or two but may be so intense that the patient winces, hence the term *tic*. The paroxysms recur frequently, both day and night, for several weeks at a time. Another characteristic feature is the initiation of pain by stimuli applied to certain areas on the face, lips, or tongue ("trigger zones") or by movement of these parts. *Objective signs of sensory loss cannot be demonstrated*. The adequate stimulus to a trigger zone for precipitating an attack is a tactile one and possibly tickle, rather than a noxious or thermal stimulus. Usually a spatial and temporal summation of impulses is necessary to trigger an attack, which is followed by a refractory period of up to 2 or 3 min.

The *diagnosis* of this disorder rests on these strict clinical criteria, and the condition must be distinguished from other forms of facial and cephalic neuralgia and pain arising from diseases of the jaw, teeth, or sinuses (Chap. 15). Tic douloureux is usually without assignable cause; in typical cases, neuroimaging studies are not necessary. On occasion, when trigeminal neuralgia develops in a younger adult, it may be due to a plaque of multiple sclerosis at the root entry zone of the fifth nerve in the pons. Very rarely it occurs with herpes zoster or a tumor. To a degree that remains uncertain, pain of tic douloureux may be caused by a redundant or tortuous blood vessel in the posterior fossa, causing an irritative lesion of the nerve or its root. Usually, however, lesions such as aneurysms, neurofibromas, or meningiomas affecting the nerve produce a loss of sensation (trigeminal neuropathy, see below).

TREATMENT

Drug therapy with carbamazepine is the initial treatment of choice and is effective in approximately 50 to 75% of patients. Carbamazepine should be started as a single daily

dose of 100 mg taken with food, and increased gradually (by 100 mg daily every 1 to 2 days) until substantial (>50%) pain relief is achieved. Most patients require a maintenance dose of 200 mg qid. Doses >1200 mg daily provide no additional benefit. Dizziness, imbalance, sedation, and rare cases of agranulocytosis are the most important side effects of carbamazepine. If treatment is effective, it is usually continued for approximately 1 month and then tapered as tolerated. If carbamazepine is not well tolerated or is ineffective, phenytoin, 300 to 400 mg daily, can be tried. Baclofen may also be administered, either alone or in combination with carbamazepine or phenytoin. The initial dose is 5 to 10 mg tid, gradually increasing as needed to 20 mg qid.

If drug treatment fails, surgical therapy should be offered. The most widely applied procedure creates a heat lesion of the trigeminal (gasserian) ganglion or nerve, a method termed *radiofrequency thermal rhizotomy*. Injection of glycerol in Meckel's cave is a method preferred by some surgeons. Either procedure produces short-term relief in >95% of patients; however, long-term studies indicate that pain recurs in a substantial percentage of treated patients in some series. Complications and morbidity are infrequent in experienced hands. These procedures result in partial numbness of the face and carry a risk of corneal denervation with secondary keratitis when used for the rare instances of first-division trigeminal neuralgia.

A third treatment, microvascular decompression, requires a suboccipital craniectomy, a major procedure requiring several days of hospitalization. It has an 80% efficacy rate, but the pain may recur, and, in a small number of cases, there is damage to the eighth or seventh nerve.

TRIGEMINAL NEUROPATHY

A variety of diseases in addition to tic douloureux may affect the trigeminal nerve (Table 367-1). Most present with sensory loss on the face or with weakness of the jaw muscles. Deviation of the jaw on opening indicates weakness of the pterygoids on the side to which the jaw deviates. Tumors of the middle cranial fossa (meningiomas), of the trigeminal nerve (schwannomas), or of the base of the skull (metastatic tumors) may cause a combination of motor and sensory signs. Lesions in the cavernous sinus can affect the first and second divisions of the trigeminal nerve, and lesions of the superior orbital fissure can affect the first (ophthalmic) division. The accompanying corneal anesthesia increases the risk of ulceration (neurokeratitis).

Loss of sensation over the chin (mental neuropathy) can be the only manifestation of systemic malignancy. Rarely, an idiopathic form of trigeminal neuropathy is observed. It is characterized by feelings of numbness and paresthesias, sometimes bilaterally, with loss of sensation in the territory of the trigeminal nerve but without weakness of the jaw. Recovery is the rule, but the symptoms may be troublesome for many months, or even years. Leprosy may involve the trigeminal nerves.

Tonic spasm of the masticatory muscles, known as *trismus*, is symptomatic of tetanus (Chap. 143). It may also occur as an idiosyncratic reaction in patients treated with phenothiazine drugs; lesser degrees may be associated with disease of the pharynx, temporomandibular joint, teeth, and gums.

DISORDERS OF THE FACIAL NERVE

The seventh cranial nerve supplies all the muscles concerned with facial expression. The sensory component is small (the nervus intermedius); it conveys taste sensation from the anterior two-thirds of the tongue and probably cutaneous impulses from the anterior wall of the external auditory canal. The motor nucleus of the seventh nerve lies anterior and lateral to the abducens nucleus. After leaving the pons, the seventh nerve enters the internal auditory meatus with the acoustic nerve. The nerve continues its course in its own bony channel, the facial canal, and exits from the skull via the stylomastoid foramen. It then passes through the parotid gland and subdivides to supply the facial muscles.

A complete interruption of the facial nerve at the stylomastoid foramen paralyzes all muscles of facial expression. The corner of the mouth droops, the creases and skin folds are effaced, the forehead is unfurrowed, and the eyelids will not close. Upon attempted closure of the lids, the eye on the paralyzed side rolls upward (Bell's phenomenon). The lower lid sags also, and the punctum falls away from the conjunctiva, permitting tears to spill over the cheek. Food collects between the teeth and lips, and saliva may dribble from the corner of the mouth. The patient complains of a heaviness or numbness in the face, but sensory loss is rarely demonstrable and taste is intact.

If the lesion is in the middle ear portion, taste is lost over the anterior two-thirds of the tongue on the same side. If the nerve to the stapedius is interrupted, there is hyperacusis (painful sensitivity to loud sounds). Lesions in the internal auditory meatus may also affect the adjacent auditory and vestibular nerves, causing deafness, tinnitus, or dizziness. Intrapontine lesions that paralyze the face usually affect the abducens nucleus as well, and often the corticospinal and sensory tracts.

If the peripheral facial paralysis has existed for some time and recovery of motor function is incomplete, a continuous diffuse contraction of facial muscles may appear. The palpebral fissure becomes narrowed, and the nasolabial fold deepens. Attempts to move one group of facial muscles may result in contraction of all of them (associated movements, or *synkinesis*). Facial spasms may develop and persist indefinitely, being initiated by every facial movement (*hemifacial spasm*). This condition may represent a transient or permanent sequela to a Bell's palsy but may also be due to an irritative lesion of the facial nerve (e.g., an acoustic neuroma, an aberrant artery that compresses the nerve and is relieved by surgery, or a basilar artery aneurysm). However, in the most common form of hemifacial spasm, the cause and pathology are unknown. Anomalous regeneration of the seventh nerve fibers may result in other troublesome phenomena. If fibers originally connected with the orbicularis oculi come to innervate the orbicularis oris, closure of the lids may cause a retraction of the mouth, or if fibers originally connected with muscles of the face later innervate the lacrimal gland, anomalous tearing ("crocodile tears") may occur with any activity of the facial muscles, such as eating. Yet another unusual facial synkinesia is one in which jaw opening causes a closure of the eyelids on the side of the facial palsy (jaw-winking).

BELL'S PALSY

The most common form of facial paralysis is idiopathic, i.e., *Bell's palsy*. The incidence rate of this disorder is about 23 per 100,000 annually, or about 1 in 60 or 70 persons in a lifetime. The pathogenesis of the paralysis is unproven, but an association with herpes simplex virus type 1 DNA in endoneurial fluid and posterior auricular muscle has been documented.

Clinical Manifestations The onset of Bell's palsy is fairly abrupt, maximal weakness being attained by 48 h as a general rule. Pain behind the ear may precede the paralysis for a day or two. Taste sensation may be lost unilaterally, and hyperacusis may be present. In some cases there is mild cerebrospinal fluid (CSF) lymphocytosis. Magnetic resonance imaging (MRI) may reveal swelling and uniform enhancement of the geniculate ganglion and facial nerve, and, in some cases, entrapment of the swollen nerve in the temporal bone is noted. Fully 80% of patients recover within a few weeks or months. Electromyography may be of some prognostic value; evidence of denervation after 10 days indicates that there has been axonal degeneration and that there will be a long delay (3 months, as a rule) before regeneration occurs and that it may be incomplete. The presence of incomplete paralysis in the first week is the most favorable prognostic sign.

Differential Diagnosis There are many other causes of facial palsy that must be considered in the differential diagnosis of idiopathic Bell's palsy. Tumors that invade the temporal bone (carotid body, cholesteatoma, dermoid) may produce a facial palsy, but the onset is insidious and the course progressive. The *Ramsay Hunt syndrome*, presumably due to herpes zoster of the geniculate ganglion, consists of a severe facial palsy associated with a vesicular eruption in the pharynx, external auditory canal, and other parts of the cranial integument; often the eighth cranial nerve is affected as well. *Acoustic neuromas* frequently involve the facial nerve by local compression. Infarcts, demyelinating lesions of multiple sclerosis, and tumors are the common pontine lesions that interrupt the facial nerve fibers; other signs of brainstem involvement are usually present. Bilateral facial paralysis (facial diplegia) occurs in *Guillain-Barre syndrome* (Chap. 378) and also in a form of sarcoidosis known as *uveoparotid fever* (*Heerfordt syndrome*). Lyme disease is a frequent cause of facial palsies in endemic areas. The *Melkersson-Rosenthal syndrome* consists of a rarely encountered triad of recurrent facial paralysis, recurrent -- and eventually permanent -- facial (particularly labial) edema, and less constantly, plication of the tongue; its cause is unknown. Leprosy frequently involves the facial nerve, and facial neuropathy may also occur in diabetes mellitus.

All these forms of nuclear or peripheral facial palsy must be distinguished from the supranuclear type. In the latter, the frontalis and orbicularis oculi muscles are involved less than those of the lower part of the face, since the upper facial muscles are innervated by corticobulbar pathways from both motor cortices, whereas the lower facial muscles are innervated only by the opposite hemisphere. In supranuclear lesions there may be a dissociation of emotional and voluntary facial movements, and often some degree of paralysis of the arm and leg or an aphasia (in dominant hemisphere lesions) is conjoined.

Laboratory Evaluation The diagnosis of Bell's palsy can usually be made clinically in patients with (1) a typical presentation, (2) no risk factors or preexisting symptoms for

other causes of facial paralysis, (3) absence of cutaneous lesions of herpes zoster in the external ear canal, and (4) a normal neurologic examination with the exception of the facial nerve. Particular attention to the eighth cranial nerve, which courses near to the facial nerve in the pontomedullary junction and in the temporal bone, and to other cranial nerves is essential. In atypical or uncertain cases, an erythrocyte sedimentation rate, testing for diabetes mellitus, a Lyme titer, chest x-ray for possible sarcoidosis, orMRIscanning may be indicated.

TREATMENT

Symptomatic measures include (1) the use of paper tape to depress the upper eyelid during sleep and prevent corneal drying, and (2) massage of the weakened muscles. A course of glucocorticoids, given as prednisone 60 to 80 mg daily during the first 5 days and then tapered over the next 5 days, appears to shorten the recovery period and modestly improve the functional outcome. In one double-blind study, patients treated within 3 days of onset with both prednisone and acyclovir (400 mg five times daily for 10 days) had a better outcome than patients treated with prednisone alone.

OTHER FACIAL DISORDERS

Facial hemiatrophy occurs mainly in females and is characterized by a disappearance of fat in the dermal and subcutaneous tissues on one side of the face. It usually begins in adolescence or early adult years and is slowly progressive. In its advanced form, the affected side of the face is gaunt, and the skin is thin, wrinkled, and rather brown. The facial hair may turn white and fall out, and the sebaceous glands become atrophic. The muscles and bones are not involved as a rule. Sometimes the atrophy becomes bilateral. The condition is a form of lipodystrophy. Treatment is cosmetic, consisting of transplantation of skin and subcutaneous fat.

Facial myokymia refers to a fine rippling activity of the facial muscles; it may be caused by a plaque of multiple sclerosis. *Blepharospasm* is an involuntary recurrent spasm of both eyelids that occurs in elderly persons as an isolated phenomenon or with varying degrees of spasm of other facial muscles. Severe, persistent cases of blepharospasm or hemifacial spasm can be treated by local injection of botulinus toxin into the orbicularis oculi; the spasms are relieved for 3 to 4 months, and the injections can be repeated.

GLOSSOPHARYNGEAL NERVE DISORDERS

GLOSSOPHARYNGEAL NEURALGIA

This form of neuralgia resembles trigeminal neuralgia in many respects but is much less common. The pain is intense and paroxysmal; it originates in the throat, approximately in the tonsillar fossa. In some cases the pain is localized in the ear or may radiate from the throat to the ear because of involvement of the tympanic branch of the glossopharyngeal nerve. Spasms of pain may be initiated by swallowing. There is no demonstrable sensory or motor deficit. Cardiac symptoms -- bradycardia, hypotension, and fainting -- have been reported. A trial of carbamazepine or phenytoin is the recommended therapy, but if that is unsuccessful, division of the glossopharyngeal

nerve near the medulla is the definitive treatment. Percutaneous rhizotomy of glossopharyngeal and vagal fibers in the jugular foramen alleviates pain in some patients.

Very rarely, herpes zoster involves the glossopharyngeal nerve. Glossopharyngeal neuropathy in conjunction with vagus and accessory nerve palsies may also occur with a tumor or aneurysm in the posterior fossa or in the jugular foramen. Hoarseness due to vocal cord paralysis, some difficulty in swallowing, deviation of the soft palate to the intact side, anesthesia of the posterior wall of the pharynx, and weakness of the upper part of the trapezius and sternocleidomastoid muscles make up the syndrome (Table 367-2, jugular foramen syndrome).

DISORDERS OF THE VAGUS NERVE

DYSPHAGIA AND DYSPHONIA

Complete interruption of the intracranial portion of one vagus nerve results in a characteristic paralysis. The soft palate droops ipsilaterally and does not rise in phonation. There is loss of the gag reflex on the affected side, as well as of the "curtain movement" of the lateral wall of the pharynx, whereby the faucial pillars move medially as the palate rises in saying "ah." The voice is hoarse and slightly nasal, and the vocal cord lies immobile midway between abduction and adduction. There may also be a loss of sensibility at the external auditory meatus and the posterior pinna.

The pharyngeal branches of both vagi may be affected in diphtheria; the voice has a nasal quality, and regurgitation of liquids through the nose occurs during the act of swallowing.

The vagus nerve may be involved at the meningeal level by neoplastic and infectious processes and within the medulla by tumors, vascular lesions (e.g., the lateral medullary syndrome of Wallenberg), and motor neuron disease. This nerve may be involved by the inflammatory lesion of herpes zoster. Polymyositis and dermatomyositis, which cause hoarseness and dysphagia by direct involvement of laryngeal and pharyngeal muscles, may be confused with diseases of the vagus nerves. Also, dysphagia is a symptom in some patients with myotonic dystrophy.**See Chap. 40 for discussion of nonneurologic forms of dysphagia.*

The recurrent laryngeal nerves, especially the left, are most often damaged as a result of intrathoracic disease. Aneurysm of the aortic arch, an enlarged left atrium, and tumors of the mediastinum and bronchi are much more frequent causes of an isolated vocal cord palsy than are intracranial disorders.

When confronted with a case of laryngeal palsy, the physician must attempt to determine the site of the lesion. If it is intramedullary, there are usually other signs, such as ipsilateral cerebellar dysfunction, loss of pain and temperature sensation over the ipsilateral face and contralateral arm and leg, and an ipsilateral Horner syndrome. If the lesion is extramedullary, the glossopharyngeal and spinal accessory nerves are frequently involved (see jugular foramen syndrome, Table 367-2). If it is extracranial in the posterior laterocondylar or retroparotid space, there may be a combination of ninth,

tenth, eleventh, and twelfth cranial nerve palsies and a Horner syndrome (Table 367-2). If there is no sensory loss over the palate and pharynx and no palatal weakness or dysphagia, the lesion is below the origin of the pharyngeal branches, which leave the vagus nerve high in the cervical region; the usual site of disease is then the mediastinum.

DISORDERS OF THE ACCESSORY NERVE

Isolated involvement of the accessory, or eleventh cranial, nerve can occur anywhere along its route, resulting in partial or complete paralysis of the sternocleidomastoid and trapezius muscles. More commonly, involvement occurs in combination with deficits of the ninth and tenth cranial nerves in the jugular foramen or after exit from the skull (Table 367-2). An idiopathic form of accessory neuropathy, akin to Bell's palsy, has been described, and it may be recurrent in some cases. Most but not all patients recover.

DISORDERS OF THE HYPOGLOSSAL NERVE

The twelfth cranial nerve supplies the ipsilateral muscles of the tongue. The nucleus of the nerve or its fibers of exit may be involved by intramedullary lesions such as tumor, poliomyelitis, or most often motor neuron disease. Lesions of the basal meninges and the occipital bones (platybasia, invagination of occipital condyles, Paget's disease) may compress the nerve in its extramedullary course or in the hypoglossal canal. Isolated lesions of unknown cause can occur. Atrophy and fasciculation of the tongue develop weeks to months after interruption of the nerve.

MULTIPLE CRANIAL NERVE PALSIES

Several cranial nerves may be affected by the same disease process. In this situation, the main clinical problem is to determine whether the lesion lies within the brainstem or outside it. Lesions that lie on the surface of the brainstem are characterized by involvement of adjacent cranial nerves (often occurring in succession) and late and rather slight involvement of the long sensory and motor pathways and segmental structures lying within the brainstem. The opposite is true of intramedullary, intrapontine, and intramesencephalic lesions. The extramedullary lesion is more likely to cause bone erosion or enlargement of the foramens of exit of cranial nerves. The intramedullary lesion involving cranial nerves often produces a crossed sensory or motor paralysis (cranial nerve signs on one side of the body and tract signs on the opposite side).

Involvement of multiple cranial nerves outside the brainstem is frequently the result of diabetes or trauma (sudden onset), localized infections such as herpes zoster (acute onset), infectious and noninfectious causes of meningitis (Chap. 374) or granulomatous diseases such as Wegener's granulomatosis (subacute onset), Behcet's disease, or tumors and enlarging saccular aneurysms (chronic development). Of the tumors, lymphomas, neurofibromas, meningiomas, chordomas, cholesteatomas, carcinomas, and sarcomas have all been observed to involve a succession of lower cranial nerves. Owing to their anatomic relationships, the multiple cranial nerve palsies form a number of distinctive syndromes, listed inTable 367-2. Sarcoidosis is the cause of some cases of multiple cranial neuropathy, and chronic glandular tuberculosis (scrofula) the cause of

a few others. Midline granuloma of the nasopharynx may also affect multiple cranial nerves, as do nasopharyngeal tumors, platybasia, basilar invagination of the skull, and the adult Chiari malformation. A purely motor disorder without atrophy always raises the question of myasthenia gravis (Chap. 380). Guillain-Barre syndrome commonly affects the facial nerves bilaterally (facial diplegia). In the Fisher variant of the Guillain-Barre syndrome, oculomotor paresis occurs with ataxia and areflexia in the limbs (Chap. 378). Wernicke encephalopathy can cause a severe ophthalmoplegia combined with other brainstem signs.

The *cavernous sinus syndrome* is a distinctive and frequently life-threatening disorder. It often presents as orbital or facial pain; orbital swelling and chemosis due to occlusion of the ophthalmic veins; fever; oculomotor neuropathy affecting the third, fourth, and sixth cranial nerves; and trigeminal neuropathy affecting the ophthalmic (V_1) and occasionally the maxillary (V_2) divisions of the trigeminal nerve. Cavernous sinus thrombosis, often secondary to infection from orbital cellulitis (frequently *Staphylococcus aureus*), a cutaneous source on the face, or sinusitis (especially with mucormycosis in diabetic patients), is the most frequent cause; other etiologies include aneurysm of the carotid artery, a carotid-cavernous fistula (orbital bruit may be present), meningioma, nasopharyngeal carcinoma or other tumor, or an idiopathic granulomatous disorder (Tolosa-Hunt syndrome). Due to the anatomy of the cavernous sinus (Fig. 367-2) the syndrome may extend to become bilateral. Early diagnosis is essential, especially in cases due to infection, and treatment depends upon the underlying etiology. In infectious cases, prompt administration of broad-spectrum antibiotics, drainage of any abcess cavities, and identification of the offending organism is essential. Anticoagulant therapy may benefit cases of primary thrombosis. Repair or occlusion of the carotid artery may be required for treatment of fistulas or aneurysms. The Tolosa-Hunt syndrome generally responds to glucocorticoids.

An idiopathic form of multiple cranial nerve involvement on one or both sides of the face is occasionally seen (see Juncos and Beal). The syndrome consists of a subacute onset of boring facial pain, followed by paralysis of motor cranial nerves. The clinical features overlap those of the Tolosa-Hunt syndrome and appear to be due to idiopathic inflammation of the dura mater, which may be visualized byMRI. The syndrome is frequently responsive to glucocorticoids.

ACKNOWLEDGEMENT

368. DISEASES OF THE SPINAL CORD - *Stephen L. Hauser*

Diseases of the spinal cord are frequently devastating. They can produce quadriplegia, paraplegia, and sensory deficits far beyond the damage they would inflict elsewhere in the nervous system because the spinal cord contains, in a small cross-sectional area, almost the entire motor output and sensory input systems of the trunk and limbs. Many spinal cord diseases are reversible if recognized and treated at an early stage (Table 368-1); thus, they are among the most critical of neurologic emergencies. The efficient use of diagnostic procedures, guided by a working knowledge of the relevant anatomy and clinical features of common spinal cord diseases, is often the key to a successful outcome.

Approach to the Patient

Spinal Cord Anatomy Relevant to Clinical Signs The spinal cord is a thin, tubular extension of the central nervous system contained within the bony spinal canal. It originates at the medulla and continues caudally to terminate at the filum terminale, a fibrous extension of the conus medullaris that terminates at the coccyx. The adult spinal cord is approximately 18 inches long, oval or round in shape, and enlarged in the cervical and lumbar regions, where neurons that innervate the upper and lower extremities, respectively, are located. The white matter tracts containing ascending sensory and descending motor pathways are located peripherally, whereas nerve cell bodies are clustered in an inner region shaped like a four-leaf clover that surrounds the central canal (anatomically an extension of the fourth ventricle). The membranes that cover the spinal cord -- the pia, arachnoid, and dura -- are continuous with those of the brainstem and cerebral hemispheres.

The spinal cord is somatotopically organized, consisting of 31 segments, each containing an exiting ventral motor root and entering dorsal sensory root (Fig. 368-1). During embryologic development, growth of the cord lags behind that of the vertebral column, and in the adult the spinal cord ends at approximately the first lumbar vertebral body. The lower spinal nerves take an increasingly downward course to exit via the appropriate intervertebral foramina. The first seven pairs of cervical spinal nerves exit above the same-numbered vertebral bodies, whereas all the subsequent nerves exit below the same-numbered vertebral bodies; this situation is due to the presence of eight cervical spinal cord segments but only seven cervical vertebrae. The approximate relationship between spinal cord segments and the corresponding vertebral bodies is shown in Table 368-2. These relationships assume importance for localization of lesions that cause spinal cord compression; a T10 spinal cord level, for example, indicates involvement of the cord adjacent to the seventh or eighth thoracic vertebral body.

LEVEL OF THE LESION The presence of a *level* below which sensory, motor, and/or autonomic function is disturbed is a hallmark of spinal cord disease. A sensory level is sought by asking the patient to identify as sharp a pinprick stimulus or as cool a cold stimulus (a dry tuning fork after immersion in cold water) applied to the low back and sequentially moved up toward the neck on each side. In general, a sensory level to pinprick or temperature, indicating damage to the spinothalamic tract, is located one to two segments below the actual level of a unilateral spinal cord lesion, but it may be at the level of the lesion when bilateral. That is because sensory fibers enter the cord at

the dorsal root, synapse in the dorsal horn, and then ascend ipsilaterally for several segments before crossing just anterior to the central canal to join the opposite spinothalamic tract. Lesions that disrupt descending corticospinal and bulbospinal tracts cause paraplegia or quadriplegia, with increased muscle tone, exaggerated deep tendon reflexes, and extensor plantar signs. Such lesions also typically produce autonomic disturbances, with disturbed sweating and bladder, bowel, and sexual dysfunction. A sweat level may be determined by drawing a spoon up the torso. There will be little resistance to movement of the spoon along the dry, nonsweating skin; at the level at which sweating begins, resistance will suddenly increase.

The uppermost level of a spinal cord lesion is often localized by attention to *segmental signs* corresponding to disturbed motor or sensory innervation by an individual cord segment. A band of altered sensation (hyperalgesia or hyperpathia) at the upper end of the sensory disturbance, fasciculations or atrophy in muscles innervated by one or several segments, or a single diminished or absent deep tendon reflex may be noted. These signs may also occur with focal root or peripheral nerve disorders; thus, segmental signs are most useful when they occur with other signs of cord disease. With severe and acute transverse lesions, the limbs may be flaccid rather than spastic (so-called spinal shock). This state may last for several days, rarely for weeks, and may be initially mistaken for extensive damage to many segments of the cord (as in ascending necrotic myelopathy associated with cancer) or as polyneuropathy. Brief clonic or myoclonic movements of the limbs often precede paralysis in acute transverse lesions, particularly those due to cord infarction.

PATTERNS OF SPINAL CORD DISEASE The location of the major ascending and descending pathways of the spinal cord are shown in Fig. 368-1. Most fiber tracts -- including the posterior columns and the spinocerebellar and pyramidal tracts -- travel ipsilateral to the side of the body they innervate. As noted above, afferent fibers mediating pain and temperature sensation are unusual in that they ascend contralaterally as the spinothalamic tract. The anatomic relationships of these various fiber tracts and nuclei produce distinctive clinical syndromes that are pathognomonic of spinal cord disease and that often provide clues to the underlying disease process.

Brown-Sequard hemicord syndrome This syndrome consists of ipsilateral weakness (pyramidal tract) and loss of joint position and vibratory sense (posterior column), with contralateral loss of pain and temperature sense (spinothalamic tract) below the lesion. The sensory level for pain and temperature is one or two levels below the lesion. Segmental signs, such as radicular pain, muscle atrophy, or loss of a deep tendon reflex, when they occur, are unilateral. Pure examples of hemicord syndromes are rare; partial or bilateral forms are more common. Partial syndromes may involve the dorsal (posterior) quadrant, producing ipsilateral loss of vibration and position sense, or ventral (anterior) quadrant with ipsilateral paralysis and contralateral loss of pain and temperature sense.

Central Cord Syndrome The central cord syndrome results from disorders of gray matter nerve cells and crossing spinothalamic tracts near the central canal. In the cervical cord, the central cord syndrome produces arm weakness out of proportion to leg weakness and a "dissociated" sensory loss consisting of loss of pain and temperature sense in a cape distribution over the shoulders, lower neck, and upper trunk with intact light touch,

joint position, and vibration sense. Trauma, syringomyelia, tumors, and anterior spinal artery ischemia are common causes of the central cord syndrome.

Anterior two-thirds syndrome This syndrome results from extensive bilateral disease of the spinal cord that spares the posterior columns. All spinal cord functions -- motor, sensory and autonomic -- are lost below the level of the lesion, with the striking exception of intact vibration and position sensation. The etiology is vascular, either thromboembolism of the anterior spinal artery or compression of this vessel by mass lesions within the spinal canal.

Intramedullary and Extramedullary Syndromes The diagnosis of spinal cord disorders frequently requires that intramedullary processes, which arise within the substance of the cord, be distinguished from extramedullary processes that compress the spinal cord or its vascular supply. Distinguishing features are relative and serve only as rough guides to clinical decision making. With extramedullary lesions, radicular pain is often prominent, and there is early sacral sensory loss (lateral spinothalamic tract) and spastic weakness in the legs (corticospinal tract) due to the superficial location of these fibers in the lateral spinal cord, which renders them susceptible to external compression. Intramedullary lesions tend to produce poorly localized burning pain rather than radicular pain and spare sensation in the perineal and sacral areas; corticospinal tract signs may appear late. With extramedullary lesions, the distinction between extradural and intradural masses is important, as the former are generally malignant and the latter benign; a long duration of symptoms favors an intradural origin.

SPECIFIC LOCALIZING SIGNS

Cervical cord High cervical cord lesions are frequently life-threatening, producing quadriplegia and weakness of respiratory muscles innervated by the phrenic nerve (C3-C5). There is diaphragmatic paralysis, and breathing is possible only by use of accessory muscles of respiration. Extensive lesions near the junction of the cervical cord and medulla are usually fatal owing to involvement of adjacent medullary centers, which results in vasomotor and respiratory collapse. Partial lesions in this area, generally due to trauma, may interrupt decussating pyramidal tract fibers destined for the legs, which cross below those of the arms, resulting in a "crural paresis" of the lower limbs. Compressive lesions near the foramen magnum may produce weakness of the ipsilateral shoulder and arm followed by weakness of the ipsilateral leg, then the contralateral leg, and finally the contralateral arm; the patient may complain of suboccipital pain spreading to the neck and shoulders. Lesions at C4-C5 produce quadriplegia with preserved respiratory function. At the midcervical (C5-C6) level, there is relative sparing of shoulder muscles and loss of biceps and brachioradialis reflexes. Lesions at C7 spare the biceps but produce weakness of finger and wrist extensors and loss of the triceps reflex. Lesions at C8 paralyze finger and wrist flexion, and the finger flexor reflex is lost. In general, cervical cord disorders are best localized by the pattern of weakness that ensues, whereas sensory deficits have less localizing value. A Horner's syndrome (miosis, ptosis, and facial hypohidrosis) may also occur ipsilateral to cervical cord lesions at any level.

Thoracic cord Lesions of the thoracic cord are best localized by identification of a sensory level on the trunk. Sensory dermatomes of the body are shown inFig. 23-2;

useful markers are at the nipples (T4) and umbilicus (T10). Weakness of the legs and disturbances of bladder, bowel, or sexual function may also accompany damage to the thoracic cord. The abdominal wall musculature, supplied by the lower thoracic cord, is observed during movements of respiration or coughing or by asking the patient to interlock the fingers behind the head in the supine position and attempt to sit up. Lesions at T9-T10 paralyze the lower, but spare the upper, abdominal muscles, resulting in upward movement of the umbilicus when the abdominal wall contracts (Beevor's sign) and in loss of lower, but not upper, superficial abdominal reflexes (Chap. 356). With unilateral lesions, attempts to contract the abdominal wall produce movement of the umbilicus to the normal side; superficial abdominal reflexes are absent on the involved side. Midline back pain is a useful localizing sign in the thoracic region.

Lumbar cord The lumbar and sacral cord segments progressively decrease in size, and focal lesions of these segments are less easily localized than in cervical and thoracic regions. Lesions at L2-L4 paralyze flexion and adduction of the thigh, weaken leg extension at the knee, and abolish the patellar reflex. Lesions at L5-S1 paralyze movements of the foot and ankle, flexion at the knee, and extension of the thigh, and abolish the ankle jerk (S1). A cutaneous reflex useful in localization of lumbar cord disease is the cremasteric reflex (Chap. 356), which is segmentally innervated at L1-L2.

Sacral Cord/Conus Medullaris The conus medullaris is the tapered caudal termination of the spinal cord, comprising the lower sacral and single coccygeal segments. Isolated lesions of the conus medullaris spare motor and reflex functions in the legs. The conus syndrome is distinctive, consisting of bilateral saddle anesthesia (S3-S5), prominent bladder and bowel dysfunction (urinary retention and incontinence with lax anal tone), and impotence. The bulbocavernosus (S2-S4) and anal (S4-S5) reflexes are absent (Chap. 356). Muscle strength is largely preserved. Lesions of the conus medullaris must be distinguished from those of the cauda equina, the cluster of nerve roots derived from the lower cord as they descend to their exits in the intervertebral foramina. Cauda equina lesions are characterized by severe low back or radicular pain, asymmetric leg weakness or sensory loss, variable areflexia in the lower extremities, and relative sparing of bowel and bladder function. Mass lesions in the lower spinal canal may produce a mixed clinical picture in which elements of both cauda equina and conus medullaris syndromes coexist.**Cauda equina syndromes are discussed in Chap. 16.*

ACUTE AND SUBACUTE SPINAL CORD DISEASES

Acute and subacute spinal cord disorders are commonly due to extramedullary compression (tumor, infection, spondylosis, or trauma), infarction or hemorrhage, or inflammation. In this category are some of the most dangerous -- and treatable -- disorders in clinical practice. Early recognition is the key to successful management. Epidural compression due to malignancy often presents with warning signs, generally neck or back pain, bladder disturbances, or sensory symptoms, that precede the development of paralysis. Infarction, hemorrhage, or spinal subluxation is more likely to produce sudden "strokelike" myelopathy without antecedent symptoms.

NEOPLASTIC SPINAL CORD COMPRESSION

Neoplasms of the spinal canal may be extramedullary (epidural or intradural) or

intramedullary. In adults, most neoplasms are epidural in origin, resulting from metastases to the adjacent vertebral body, spinous or transverse process, or pedicle. Vertebral metastases are essentially bone-marrow metastases, and the propensity of solid tumors to metastasize to the vertebral column probably reflects the high percentage of bone marrow located in the axial skeleton of older individuals. Retroperitoneal neoplasms (especially lymphomas or sarcomas) may enter the spinal canal through the intervertebral foramina; typically they produce radicular pain and other signs of root involvement prior to cord compression. Almost any malignant tumor can metastasize to the spinal canal, although breast, lung, prostate, kidney, lymphoma, and plasma cell dyscrasia are particularly frequent. The thoracic cord is most commonly involved; exceptions are metastases from prostate and ovarian cancer, which occur disproportionately in the sacral and lumbar vertebrae, perhaps resulting from spread through Batson's plexus, a network of veins along the anterior surface of the spinal cord in the epidural space.

Pain is the initial symptom; it may be either aching and localized or sharp and radiating in quality. Pain indicates displacement of pain-sensitive structures, especially periosteum and meninges. The pain worsens with movement, coughing, or sneezing and may awaken patients at night. The recent onset of back pain, particularly if in the thoracic spine (which is uncommonly involved by spondylosis), should prompt consideration of vertebral metastasis. Rarely, pain is mild or absent. Pain typically precedes signs of cord compression by weeks or even months, but once cord compression occurs, it is always progressive and may advance rapidly. Therapy is effective only if administered early, when signs of cord dysfunction are mild or absent; therapy will not reverse a complete paralysis that has been present for>48 h. These realities highlight the importance of prompt recognition and efficient management of these lesions.

Plain radiographs of the spine and radionuclide bone scans have only a limited role in diagnosis because they fail to identify 15 to 20% of metastatic vertebral lesions and may miss paravertebral masses that reach the epidural space by growth through the intervertebral foramina. Magnetic resonance imaging (MRI) provides excellent anatomic resolution of the site and extent of the tumor (Fig. 368-2); at most centers, MRI has largely replaced computed tomography (CT) and myelography in the diagnosis of epidural masses. MRI can often distinguish between malignant lesions and other masses -- epidural abscess, tuberculoma, or epidural hemorrhage, among others -- that present in a similar fashion. Vertebral metastases are usually hypointense relative to a normal bone marrow signal on T1-weighted MRI scans; after the administration of gadolinium, contrast enhancement may "normalize" the appearance of the tumor by increasing its intensity to that of normal bone marrow. In contrast to infection, vertebral metastases typically do not cross the disk space. Nonetheless, it can be difficult to distinguish between infection and malignancy by MRI.

Because imaging resources are scarce, and both cancer and back pain are common, it is important to convey to the radiologist an estimate of the urgency of the imaging procedure requested. If signs of spinal cord involvement are present, imaging should be obtained on an emergency basis. If there are radicular symptoms but no evidence of myelopathy, it is usually safe to defer imaging for 24 to 48 h. With back or neck pain only, imaging studies should be obtained within a few days. Finally, up to 40% of

patients who present with symptomatic disease at one level are found to have asymptomatic epidural disease elsewhere; thus, the entire spine should be imaged in all patients with epidural malignancy.

TREATMENT

Management includes glucocorticoids to reduce interstitial edema, local radiotherapy (initiated as early as possible) to the symptomatic lesion, and specific therapy for the underlying tumor type. Glucocorticoids (dexamethasone, 40 mg daily) can be administered before the imaging study if the clinical suspicion is strong and continued at a lower dose (20 mg daily in divided doses) until radiotherapy (a total of 3000 cGy administered in 15 daily fractions) is completed. Radiotherapy appears to be as effective as surgery, even for classically radioresistant metastases. Biopsy of the epidural mass is usually unnecessary in patients with known preexisting cancer, but biopsy is indicated if a history of underlying cancer is lacking. Surgery, either decompression or vertebral body resection, should be considered when signs of cord compression worsen despite radiotherapy, when the maximum tolerated dose of radiotherapy has been delivered previously to the site, or when a vertebral compression fracture contributes to cord compression. A good response to radiotherapy can be expected in individuals who are ambulatory at presentation; new weakness is prevented, and some recovery of motor function occurs in approximately half of treated patients. Fixed motor deficits -- paraplegia or quadriplegia -- do not usually respond to either radiotherapy or surgery.

In contrast to tumors of the epidural space, most intradural mass lesions are slow-growing and benign. Meningiomas and neurofibromas account for most of these lesions, with occasional cases representing chordoma, lipoma, dermoid, or sarcoma. Meningiomas (Fig. 368-3) are often located posterior to the thoracic cord or near the foramen magnum, although they can arise from the meninges anywhere along the spinal canal. Neurofibromas are benign tumors of the nerve sheath that typically arise near the posterior root; when multiple, neurofibromatosis (Chap. 370) is the likely etiology. Symptoms usually begin with radicular sensory symptoms followed by an asymmetric, progressive spinal cord syndrome. Therapy is surgical resection.

Primary intramedullary tumors of the spinal cord are uncommon. They typically present as central cord or hemicord syndromes, often in the cervical region; there may be poorly localized burning pain in the extremities and sparing of sacral sensation. In adults, most of these lesions are either ependymomas, hemangioblastomas, or low-grade astrocytomas (Fig. 368-4). Complete resection of an intramedullary ependymoma is often possible with microsurgical techniques. Debulking of an intramedullary astrocytoma can also be helpful, as these are often slowly growing lesions; the value of adjunctive radiotherapy is uncertain. Secondary (metastatic) intramedullary tumors are rare.

SPINAL CORD INFARCTION

The spinal cord is supplied by three arteries that course vertically over its surface, a single anterior spinal artery, and paired posterior spinal arteries. At each segment, paired penetrators branching from the anterior spinal artery supply the anterior two-thirds of the spinal cord; the posterior spinal arteries, which often become less

distinct below the midthoracic level, supply the posterior columns. Rostrally, the spinal arteries arise from the vertebral arteries. During embryogenesis, arterial feeders arise at each segmental level, but most involute before birth; generally, between three and eight major feeders remain, arising from the vertebral, subclavian, intercostal (off the aorta), iliac, and sacral arteries. In addition to the vertebral arteries, in adults, anterior spinal artery feeders often occur at C6, at an upper thoracic level, and at T11-L2 (artery of Adamkiewicz). Feeders from the aorta are more likely to arise from the left side.

Spinal cord ischemia can occur at any level. The signs are determined by the level of the lesion and by the individual vascular anatomy, including areas of watershed flow and potential for anastomosis. The anterior spinal artery is discontinuous in some individuals, increasing the importance of feeders to the lower cord. With systemic hypotension, cord infarction occurs at the level of greatest ischemic risk, often T3-T4, and also at boundary zones between the anterior and posterior spinal artery territories. The latter may result in an acute -- or more commonly progressive -- syndrome of weakness and spasticity with little sensory change resembling amyotrophic lateral sclerosis (ALS).

Acute infarction in the territory of the anterior spinal artery produces paraplegia or quadriplegia, dissociated sensory loss affecting pain and temperature sense but sparing vibration and position sense, and loss of sphincter control. Onset may be sudden and dramatic or progressive over minutes or hours. Sharp midline or radiating back pain localized to the area of ischemia is frequently noted. Partial infarction of one anterior hemicord (hemiplegia or monoplegia and crossed pain and temperature loss) may also occur. Areflexia due to spinal shock is often present initially; with time, hyperreflexia and spasticity appear.

The acute onset of pain, sparing of posterior column function, and sharply demarcated spinal cord level distinguish anterior spinal artery infarction from epidural spinal cord compression, in which pain is often chronic, posterior column sense is impaired, and a cord level is indistinct. An exception to this rule is when epidural tumors compress or invade vascular structures, resulting in an anterior spinal artery syndrome. Infarction in the territory of the posterior spinal arteries, resulting in loss of posterior column function, also occurs and may be underrecognized as a cause of loss of position and vibration sense.

Spinal cord infarction is associated with aortic atherosclerosis, dissecting aortic aneurysm (chest or back pain with diminished pulses in legs), or hypotension from any cause. Cardiogenic emboli, vasculitis related to collagen vascular disease, and surgical clipping of aortic aneurysms are other predisposing conditions. Occasional cases develop either during pregnancy or after acute back trauma or exercise that by an unknown mechanism leads to embolism of nucleus pulposus material into spinal vessels. In a substantial number of cases, no cause can be found, and thromboembolism in arterial feeders is suspected.

MRIis often normal but is useful to exclude other causes of acute myelopathy, in particular epidural compression, spinal cord hemorrhage (hematomyelia), infectious myelitis, or transverse myelitis. Lumbar puncture is indicated whenever the underlying cause has not been clarified by MRI. Other useful laboratory studies include a

sedimentation rate to search for an underlying vasculitis, Venereal Disease Research Laboratories test, and evaluation for aortic or cardiac disease or for a hypercoagulable state.

Therapy is directed at treatment of any predisposing condition. In cord infarction due to presumed thromboembolism, anticoagulation is probably not indicated, with the exception of the unusual transient ischemic attack or incomplete infarction with a stuttering or progressive course.

EPIDURAL HEMATOMA

Hemorrhage into the epidural (or subdural) space can compress the spinal cord or roots. Presenting symptoms are the acute onset of focal or radicular pain followed by variable signs of a spinal cord or conus medullaris disorder. Trauma, tumor, or blood dyscrasias are predisposing conditions. Rare cases complicate lumbar puncture or epidural anesthesia, sometimes in association with use of low-molecular-weight heparin. Epidural hematoma can also occur on an idiopathic basis.MRIconfirms the clinical suspicion and can delineate the extent of the bleed. Extrinsic spinal cord compression from any cause is a medical emergency, and appropriate treatment consists of prompt recognition, reversal of any underlying clotting disorder, and emergency surgical decompression. Surgery may be followed by substantial recovery, especially in patients with some preservation of motor function preoperatively. Because of the risk of hemorrhage, lumbar puncture should be avoided whenever possible in patients with thrombocytopenia or other coagulopathies (including those due to therapeutic anticoagulation) until the underlying bleeding disorder is reversed.

HEMATOMYELIA

Hemorrhage into the substance of the spinal cord is rare. It may result from trauma, an intraparenchymal vascular malformation (see below), vasculitis due to polyarteritis nodosa or lupus erythematosus, bleeding disorders, or spinal cord infection or neoplasm. Hematomyelia presents as an acute painful transverse myelopathy. With large lesions, extension into the subarachnoid space may occur, resulting in subarachnoid hemorrhage (Chap. 361). Diagnosis is best made byMRI. Therapy is supportive, and surgical intervention is generally not useful. An exception is hematomyelia due to an underlying vascular malformation; in such cases, selective spinal angiography may be indicated, followed by acute surgical intervention to evacuate the clot and remove the underlying vascular lesion.

EPIDURAL ABSCESS

Spinal epidural abscess presents as a clinical triad of pain, fever, and rapidly progressive weakness. Prompt recognition of this distinctive and treatable medical emergency will in most cases prevent severe and permanent sequelae. Epidural abscesses can form anywhere along the spinal canal. Pain is almost always present, either midline along the spine or radicular in type. The duration of pain prior to presentation is generally two weeks or less, but in some chronic cases it may be several months or longer. Fever is common, often accompanied by an elevated white blood cell count or sedimentation rate. As the abscess expands, spinal cord injury results from

venous congestion and thrombosis, thrombophlebitis of the epidural space, spinal artery disease, or cord compression. Once weakness and other signs of myelopathy appear, progression is often rapid, although it may be gradual.

Risk factors include impaired immune status (diabetes mellitus, renal failure, alcoholism, malignancy), intravenous drug abuse, and infections of the skin or other tissues. Two-thirds of epidural infections result from hematogenous spread from the skin (furunculosis), soft tissue (pharyngeal or dental abscesses), or deep viscera (bacterial endocarditis). One-third result from direct extension of a local infection to the subdural space; examples of local predisposing conditions are vertebral osteomyelitis, decubitus ulcers, or iatrogenic complications of lumbar puncture, epidural anesthesia, or spinal surgery.

Most cases are due to *Staphylococcus aureus*; gram-negative bacilli, *Streptococcus*, anaerobes, and fungi can also cause epidural abscesses. Tuberculosis from an adjacent vertebral source remains an important cause in the underdeveloped world. As the population ages and the number of immunosuppressed individuals increases, an increase in the incidence of spinal epidural abscess (currently 2 per 1000 hospital admissions) has been noted.

MRIscans (Fig. 368-5) localize the abscess and exclude a primary intraparenchymal lesion, for example, transverse myelitis or hematomyelia. Lumbar puncture is often not required but may be indicated if encephalopathy or other clinical signs raise the question of associated meningitis, which is present in fewer than 25% of cases. In such situations, the level of the tap should be planned carefully to minimize the risk of inducing either meningitis by passage of the needle through infected tissue or herniation from decompression below an area of obstruction to the flow of cerebrospinal fluid (CSF). A high cervical tap is often the safest approach. CSF abnormalities in subdural abscess consist of pleocytosis with a preponderance of polymorphonuclear cells, an elevated protein level, and a reduced glucose level. Blood cultures are positive in <25% of cases.

TREATMENT

Treatment is emergency decompressive laminectomy with debridement combined with long-term antibiotic treatment. Surgical evacuation prevents development of paralysis and may improve or reverse paralysis in evolution, but it is unlikely to improve deficits of more than several days duration. Antibiotics should be started empirically before surgery, modified on the basis of culture results, and usually continued for at least 4 weeks. If surgery is contraindicated or if there is a fixed paraplegia or quadriplegia that is unlikely to improve following surgery, long-term administration of systemic and oral antibiotics can be used; in such cases, coverage may be guided by results of positive blood cultures. However, paralysis may develop or progress during antibiotic therapy; thus, initial surgical management remains the treatment of choice.

TRANSVERSE MYELITIS

Transverse myelitis is an acute or subacute, generally monophasic, inflammatory disorder of the spinal cord. The initial symptom is focal neck or back pain, followed by

various combinations of paresthesias, sensory loss, motor weakness, and sphincter disturbance evolving within hours to several days. There may be mild sensory symptoms only, or a devastating functional transection of the cord. Partial forms may selectively involve posterior columns, anterior spinothalamic tracts, or one hemicord. Dysesthesias may begin in the feet and ascend either symmetrically or asymmetrically, earlier in one leg than in the other; these symptoms may initially raise a question of Guillain-Barre syndrome, but involvement of the trunk with a sharply demarcated spinal cord level indicates the myelopathic nature of the process. In severe cases, areflexia indicating spinal shock may be present, but hyperreflexia soon supervenes; persistent areflexic paralysis indicates necrosis over multiple segments of the spinal cord.

Up to 40% of cases are associated with an antecedent infection or recent vaccination. Many infectious agents have been implicated, including influenza, measles, varicella, rubeola, mumps, and Epstein-Barr virus and cytomegalovirus, as well as *Mycoplasma*. As in the related disorder acute disseminated encephalomyelitis (Chap. 371), transverse myelitis often begins as the patient appears to be recovering from the infection, and infectious agents have not been isolated from the nervous system of affected individuals. These features suggest that transverse myelitis results from an autoimmune response triggered by infection and not from direct infection of the spinal cord.

Multiple sclerosis (MS) (see below) may present initially as transverse myelitis. MS-associated transverse myelitis usually is not associated with an antecedent infection or vaccination. Devic's disease (Chap. 371) is a demyelinating disorder that presents as transverse myelitis associated with optic neuritis that is typically bilateral. Transverse myelitis, at times recurrent, has also been associated with systemic lupus erythematosus and other collagen-vascular diseases, Sjogren's syndrome, and Behcet's disease; sarcoidosis may produce a subacute transverse myelopathy with severe cord swelling.

MRIfindings consist of variable swelling of the cord and diffuse or multifocal areas of abnormal bright signal on T2-weighted sequences, often extending over several cord segments. Contrast enhancement, indicating disruption in the blood-brain barrier associated with perivenous inflammation, is present in acute cases. MRI is also useful to exclude cord compression. A brain MRI should be obtained in all cases to assess the likelihood that the transverse myelitis represents an initial attack ofMS. A normal scan indicates that the risk of evolution to MS is low -- approximately 5% over 3 to 5 years; by contrast, the finding of multiple periventricular T2-bright lesions indicates a risk of 50% or greater over the same time period.CSF may be normal, but more often there is pleocytosis, with up to several hundred mononuclear cells per microliter; in severe or rapidly evolving cases, polymorphonuclear cells may be present. CSF protein levels are normal or at most mildly elevated; oligoclonal banding is a variable finding but, when present, is associated with future evolution to MS.

There are no prospective trials of therapy. Intravenous methylprednisolone (500 mg qd for 3 days) followed by oral prednisone (1 mg/kg per day for several weeks, then gradual taper) is used for treatment of moderate to severe symptoms.

ACUTE INFECTIOUS MYELOPATHIES

These inflammatory disorders result from direct invasion of the spinal cord by infectious agents. Bacterial etiologies are rare; almost any pathogenic species may be responsible and in one recent review *Listeria monocytogenes* was most frequently identified. Poliomyelitis is the prototypic virus that produces acute infection of the spinal cord. Herpes zoster is currently the most common viral cause of acute myelitis; cytomegalovirus, herpes simplex virus type 1, Epstein-Barr virus, and rabies virus have been identified in occasional cases. Herpes simplex virus type 2 may produce a recurrent sacral myelitis, which could be mistaken forMS, in association with outbreaks of genital herpes.**Viral infections of the spinal cord are discussed in Chap. 373.*

Schistosomiasis (Chap. 222) is an important cause of parasitic myelitis worldwide. The myelitis is intensely inflammatory and granulomatous in nature, caused by a local response to tissue-digesting enzymes produced by ova from the parasite. Toxoplasmosis (Chap. 217) can cause a focal myelopathy, and this diagnosis should be considered in patients with AIDS owing to the high frequency of nervous system toxoplasmosis in this population.

CHRONIC MYELOPATHIES

SPONDYLITIC MYELOPATHY

Neck and shoulder pain with stiffness are early symptoms; pressure on nerve roots results in radicular arm pain, most often in a C5 or C6 distribution. Compression of the cervical cord produces a slowly progressive spastic paraparesis, at times asymmetric, and often accompanied by paresthesias in the feet and hands. Vibratory sense is frequently diminished in the legs, and occasionally there is a sensory level for vibration on the upper thorax. Coughing or straining often produces leg weakness or radiating arm or shoulder pain. Dermatomal sensory loss in the arms, atrophy of intrinsic hand muscles, increased deep tendon reflexes in the legs, and extensor plantar responses are common. Urinary urgency or incontinence occurs in advanced cases. Reflexes in the arms are often diminished at some level, often the biceps (C5-C6). In individual cases, radicular, myelopathic, or combined signs may predominate. The diagnosis should be considered in cases of progressive cervical myelopathy, paresthesias of the feet and hands, or wasting of the hands. Spondylitic myelopathy is also one of the most common causes of gait difficulty in the elderly.

Diagnosis is best made byMRI. Extrinsic compression is appreciated on axial views, and T2-weighted sequences may reveal abnormal areas of high signal intensity within the cord adjacent to the site of compression. Definitive therapy consists of surgical relief of the compression, generally by posterior laminectomy. When that is not feasible, an anterior approach with resection of the protruded disc material may be required.**Cervical spondylosis and related degenerative diseases of the spine are discussed in Chap. 16.*

VASCULAR MALFORMATIONS

Although uncommon, vascular malformations are important lesions because they represent a treatable cause of progressive myelopathy. Arteriovenous malformations (AVMs) are most often located posteriorly, within the dura or along the surface of the

cord, at or below the midthoracic level. The typical presentation is a middle-aged man with a progressive myelopathy. The myelopathy may worsen slowly or rapidly or may have periods of apparent remission with superimposed worsenings resemblingMS. Acute deterioration due to hemorrhage into the spinal cord or subarachnoid space may also occur. At presentation, most patients have sensory, motor, and bladder disturbances. The motor disorder may predominate and produce a mixture of upper and lower motoneuron signs, simulatingALS. Pain, either dysesthesias or radicular pain, is also common. Other symptoms suggestive of AVM include intermittent claudication (symptoms that appear with exercise and are relieved by rest), or an effect of posture, menses, or fever on symptoms. A rare AVM syndrome presents as a progressive thoracic myelopathy with paraparesis developing over weeks or several months, associated with abnormally thick, hyalinized vessels (Foix-Alajouanine syndrome).

AVMslocated at cervical or upper thoracic levels are distinctive; they occur equally in males and females, tend to be located anterior rather than posterior to the cord, often have an intramedullary component to the malformation, and may bleed (see "Hematomyelia," above).

Examination of the skin overlying the spine may reveal a vascular lesion, lipoma, or area of altered pigmentation, all clues to a spinal cordAVM. Bruits are rare but should be sought at rest or after exercise. High-resolutionMRI with contrast administration detects most AVMs (Fig. 368-6). A small number of AVMs not detected by MRI may be visualized byCTmyelography as enlarged vessels along the surface of the cord. Definitive diagnosis requires selective spinal angiography, which will also define the vascular feeders and extent of the malformation. Embolization with occlusion of the major feeding vessels may stabilize a progressive neurologic deficit or produce a gradual recovery.

RETROVIRUS-ASSOCIATED MYELOPATHIES

The myelopathy associated with the human T cell lymphotropic virus type I (HTLV-I) presents as a slowly progressive spastic paraparesis with variable sensory and bladder disturbance. The myelopathy is typically thoracic. Approximately half of patients have back or leg pain. Signs may be asymmetric, may lack a well-defined sensory level, and may spare upper extremity function, although hyperreflexia in the arms is common. Onset is generally insidious, and the tempo of progression is variable, but most patients are nonambulatory within 10 years of onset. This presentation may resemble primary progressiveMS or a thoracicAVM. Diagnosis is made by demonstration ofHTLV-I-specific antibody in serum by enzyme-linked immunosorbent assay (ELISA), confirmed by radioimmunoprecipitation or Western blot analysis of specific antibody directed against protein products of the viral *gag* and *env* genes. There is no effective treatment; symptomatic therapy for spasticity and bladder symptoms may be helpful.**HTLV-I infections of the nervous system are discussed in Chap. 373.*

A progressive myelopathy may also occur in AIDS, characterized by vacuolar degeneration of the posterior and lateral tracts resembling subacute combined degeneration (see below).

SYRINGOMYELIA

Syringomyelia is a cavitary expansion of the spinal cord that may produce a progressive myelopathy. Syrinxes commonly occur in the lower cervical/high thoracic region or in the high cervical region, where they may extend rostrally to the medulla or pons (syringobulbia); any region of the spinal cord may be involved. More than half of all cases are associated with Chiari malformations. In the Chiari type 1 malformation, the cerebellar tonsils protrude through the foramen magnum and into the cervical spinal canal; when this abnormality is associated with protrusion of meninges (meningocele) or meninges and cord (meningomyelocele) through a spinal canal that has incompletely closed, it is designated a Chiari type 2 (or Arnold-Chiari) malformation. Acquired cases are often associated with trauma, inflammatory spinal cord disorders such as transverse myelitis, chronic arachnoiditis due to tuberculosis or other etiologies, or spinal cord tumors. Occasional cases are idiopathic.

Syringomyelia has been proposed to result from interference with the normal outflow ofCSF from the fourth ventricle to the subarachnoid space due to obstruction of the foramina of Luschka and Magendie. This blockage leads to downward pressure on the cervical spinal cord and progressive syrinx formation. However, syringomyelia may occur without foraminal obstruction, indicating that other factors, for example interference with normal upward CSF flow in the spinal canal, may also be important. Syrinxes associated with Chiari type 1 malformations generally communicate freely with the subarachnoid space, and the syrinx fluid resembles normal CSF; by contrast, in many acquired cases the syrinx cavities do not communicate, and the fluid is proteinaceous.

The classic presentation is a central cord syndrome with dissociated sensory loss and areflexic weakness in the upper limbs. The sensory deficit consists of loss of pain and temperature sensation which is "suspended" over the nape of the neck, shoulders, and upper arms in a cape distribution or is in the hands; vibration and position sensation is largely preserved. Most cases begin asymmetrically with unilateral sensory loss. Muscle wasting in the lower neck, shoulders, arms, and hands with asymmetric or absent reflexes reflects extension of the cavity to the anterior horns. As the lesion enlarges, spasticity and weakness of the legs, bladder and bowel dysfunction, and, in some cases, a Horner's syndrome appear. Thoracic kyphoscoliosis is a frequent additional finding. Some patients develop numbness and sensory loss on the face from damage to the descending tract of the trigeminal nerve (C2 level or above). With Chiari malformations, cough headache, and neck, arm, or facial pain are common. Syringobulbia may present as palatal or vocal cord paralysis, dysarthria, horizontal or vertical nystagmus, episodic dizziness, and/or tongue weakness.

Symptoms typically begin insidiously in adolescence or early adulthood, progress irregularly, and may undergo spontaneous arrest for several years. Onset or sudden deterioration may follow trauma, neck manipulation or extension, or severe cough. Symptoms of syringobulbia may progress rapidly.

MRIscans accurately identify syrinx cavities and associated spinal cord enlargement (Fig. 368-7). In all cases, MRI scans of the brain and the entire spinal cord should be obtained to delineate the full extent of the syrinx, assess posterior fossa structures, and determine whether hydrocephalus is present. If a Chiari malformation is not found, a

contrast-enhanced MRI scan should be obtained to search for abnormal enhancement from an associated spinal cord tumor.

TREATMENT

Treatment is surgical. Syringomyelia associated with tonsillar herniation is treated with posterior fossa decompression, generally consisting of suboccipital craniectomy, upper cervical laminectomy, and placement of a dural graft. If obstruction of fourth ventricular outflow is present, flow is reestablished by enlargement of the opening. If the syrinx cavity is large, some surgeons recommend direct decompression of the fluid cavity, but the added benefit of this procedure is uncertain, and morbidity may occur. With Chiari malformations, shunting of hydrocephalus should generally precede any attempt to correct the syrinx. Surgical results are often excellent, with stabilization of the neurologic deficit in most cases; some patients have improvement postoperatively. Syringomyelia secondary to trauma or infection is treated with a decompression and drainage procedure in which a small shunt is inserted between the syrinx cavity and the subarachnoid space. Finally, syringomyelia due to an intramedullary spinal cord tumor is managed by resection of the tumor if feasible; decompression of the cyst cavity may produce temporary relief, but recurrence is common.

MULTIPLE SCLEROSIS

Spinal cord involvement is common in MS. It may develop acutely as an exacerbation in a patient with known MS or appear as the presenting manifestation of the disease (see "Transverse Myelitis," above). Chronic progressive myelopathy is the most frequent cause of disability in both primary progressive and secondary progressive forms of MS. Involvement is typically asymmetric, producing motor, sensory, and bladder/bowel disturbances. Diagnosis is facilitated by identification of earlier attacks that may not be initially recalled by the patient; byMRI,CSF and evoked response testing; and by exclusion of other conditions. The diagnosis may be particularly difficult to establish in patients with primary progressive MS. Therapy with interferon b or glatiramer acetate is indicated for many patients with MS-related myelopathy that is not due to primary progressive MS.**MS is discussed in Chap. 371.*

SUBACUTE COMBINED DEGENERATION (VITAMIN B_{12}DEFICIENCY)

This treatable myelopathy presents with parasthesias in the hands and feet, early loss of vibration and position sensation, and a progressive spastic and ataxic weakness. Loss of reflexes due to a superimposed peripheral neuropathy, present in many patients, is an important diagnostic clue. Optic atrophy and irritability and other mental changes may be prominent in advanced cases and on occasion are the presenting symptoms (megaloblastic madness). The myelopathy of subacute combined degeneration tends to be diffuse rather than focal; signs are generally symmetric and reflect predominant involvement of the posterior and lateral tracts. The diagnosis is confirmed by the finding of a low serum B_{12}concentration, elevated levels of homocysteine and methylmalonic acid in uncertain cases, and a positive Schilling test (Chap. 75).

TABES DORSALIS

Tabes dorsalis and meningovascular syphilis of the spinal cord are presently rare but must be considered in the differential diagnosis of spinal cord syndromes, in particular those that arise in individuals infected with HIV. The most common symptoms of tabes are characteristic fleeting and repetitive, lancinating pains, which occur mostly in the legs and less commonly in the back, thorax, abdomen, arms, and face. Ataxia of the legs and gait due to loss of position sense occurs in half of patients. Paresthesias, bladder disturbances, and acute abdominal pain with vomiting (visceral crisis) occur in 15 to 30% of patients. The cardinal signs of tabes are loss of reflexes in the legs, impaired position and vibratory sense, Romberg's sign, and bilateral Argyll Robertson pupils, which fail to constrict to light but react with accommodation.

FAMILIAL SPASTIC PARAPLEGIA

Occasional cases of progressive myelopathy occur on a familial basis. Most present with progressive spasticity and weakness in the legs. Sphincter disturbances and mild degrees of sensory loss may also be present. On examination, a sharply defined spinal cord level is not detected, in contrast to many focal spinal cord disorders. In some families, whose condition is referred to as "complicated" familial spastic paraplegia, additional neurologic signs, for example, nystagmus, ataxia, or optic atrophy, occur. Onset may be as early as the first year of life or as late as middle adulthood. The genetic basis of several forms of familial spastic paraplegia is now known (Table 368-3). No disease-modifying therapy exists.

ADRENOMYELONEUROPATHY

This X-linked disorder, a variant of adrenoleukodystrophy, most commonly presents as a progressive spastic paraparesis beginning in early adulthood; some patients also have a mild peripheral neuropathy. Affected males usually have a history of adrenal insufficiency beginning in childhood. Rare heterozygous females may also present with adult-onset myelopathy. Diagnosis is usually made by demonstration of elevated levels of very long chain fatty acids in plasma and in cultured fibroblasts. The responsible gene, located at Xq17-28, encodes a protein involved in peroxysomal transport. Steroid replacement is indicated if hypoadrenalism is present, and bone marrow transplantation has been attempted for this condition without clear evidence of efficacy.

OTHER CHRONIC MYELOPATHIES

Primary lateral sclerosis (Chap. 365) is characterized by progressive spasticity with weakness, often accompanied by dysarthria and dysphonia. Sensory function is spared. The disorder resemblesALS, but there is no evidence of a lower motor neuron disturbance. Toxic causes include (1) lathyrism due to ingestion of chick peas containing the excitotoxinb-*N*-oxalylaminoalanine (BOAA) and seen primarily in the undeveloped world, and (2) nitrous oxide inhalation producing a myelopathy identical to subacute combined degeneration. Systemic lupus erythematosus (Chap. 311) and Sjogren's syndrome (Chap. 314) have both been associated with progressive myelopathy. Cancer-related causes include chronic paraneoplastic myelopathy (Chap. 101) or radiation injury (Chap. 370). Finally, in some patients the etiology of a chronic myelopathy may not be determined initially. A cause can ultimately be identified in most

idiopathic cases and thus periodic reassessment is essential.

**Traumatic spinal cord lesions are discussed in Chap. 369.*

MEDICAL REHABILITATION OF SPINAL CORD DISORDERS

The prospects for significant recovery from an acute spinal cord lesion fade after approximately 4 months. There are currently no effective means to promote repair of injured spinal cord tissue; promising experimental approaches include the use of factors that influence reinnervation by axons of the corticospinal tract or nerve graft bridges that promote reinnervation across spinal cord lesions. The disability associated with irreversible spinal cord damage is determined primarily by the level of the lesion and by whether the disturbance in function is complete or incomplete (Table 368-4). Even a complete high cervical cord lesion may be compatible with a productive life. Development of a rehabilitation plan framed by realistic expectations, and attention to the neurologic, medical, and psychological complications that commonly arise, are primary goals of treatment.

The usual symptoms associated with medical illnesses may be lacking, because of the destruction of afferent pain pathways in the cord. Unexplained fever, worsening of spasticity, or deterioration in neurologic function should prompt search for an underlying cause such as infection, thrombophlebitis, or an intraabdominal pathology; these etiologies are far more likely to be responsible than primary neurologic events such as meningitis, secondary syringomyelia, or chronic arachnoiditis. The loss of normal thermoregulation and inability to maintain normal body temperature can produce recurrent fever (*quadriplegic fever*), although most episodes of fever are due to infection of the urinary tract, lung, skin, or bone.

Bladder dysfunction generally results from loss of supraspinal innervation of the detrusor muscle of the bladder wall and the sphincter musculature. Detrusor spasticity is treated with anticholinergic drugs (oxybutinin, 2.5 to 5 mg qid) or tricyclic antidepressants with anticholinergic properties (imipramine, 25 to 200 mg/d). Failure of the sphincter muscle to relax during bladder emptying (urinary dyssynergia) may be managed with the a-adrenergic blocking agent terazosin hydrochloride (1 to 2 mg tid or qid), with intermittent catheterization, or, if that is not feasible, by use of a condom catheter in men or a permanent indwelling catheter. Surgical options include the creation of an artificial bladder by isolating a segment of intestine that can be catheterized intermittently (enterocystoplasty) or can drain continuously to an external appliance (urinary conduit). Bladder areflexia due to acute spinal shock or conus lesions is best treated by catheterization.

Bladder dysfunction predisposes the patient to urinary tract infection. Bacteriuria due to asymptomatic colonization is extremely common and is generally not treated. Prophylaxis with antiseptics or antibiotics is of little value. Urinary tract infections may present only as foul-smelling urine or a change in voiding pattern; the development of high fever or other systemic signs often indicates pyelonephritis. Bowel regimens and disimpaction are necessary in most patients to ensure at least biweekly evacuation and avoid colonic distention or obstruction.

High cervical cord lesions cause various degrees of mechanical respiratory failure requiring artificial ventilation. In cases of incomplete respiratory failure, chest physical therapy is useful, and a negative-pressure cuirass may alleviate atelectasis, particularly if the major lesion is below C4. With severe respiratory failure, tracheal intubation, followed by tracheotomy, provides tracheal access for ventilation and suctioning. Phrenic nerve pacing may be useful in some patients with lesions at C5 or above.

Patients with acute cord injury are at high risk for venous thrombosis and pulmonary embolism. During the first two weeks, use of calf-compression devices and anticoagulation with heparin (5000 U subcutaneously every 12 h) or warfarin (INR, 2 to 3) are recommended. In cases of persistent paralysis, anticoagulation should probably be continued for 3 months.

Prophylaxis against decubitus ulcers should involve frequent changes in position in a chair or bed, the use of special mattresses, and cushioning of areas where pressure sores often develop, such as the sacral prominence and heels. Early treatment of ulcers with careful cleansing, surgical or enzyme debridement of necrotic tissue, and appropriate dressing and drainage may prevent infection of adjacent soft tissue or bone.

Spasticity (Chap. 22) is often a late manifestation of spinal cord disease, occurring weeks or even months after the initial insult. Stretching exercises are useful to maintain mobility of joints. Drug treatment is effective but may result in reduced function, as some patients use their spasticity as an aid to stand, transfer, or walk. Baclofen (15 to 240 mg/d in divided doses) is the most effective drug available; it acts by facilitating GABA-mediated inhibition of motor reflex arcs. Diazepam acts by a similar mechanism and is useful for leg spasms that interrupt sleep (2 to 4 mg at bedtime). For nonambulatory patients, the direct muscle inhibitor dantrolene (25 to 100 mg qid) may be used, but it is potentially hepatotoxic. In severe cases, intrathecal baclofen administered via an implanted pump, botulinum toxin injections, or dorsal rhizotomy may be required to control spasticity.

Paroxysmal autonomic hyperreflexia may occur following lesions above the major splanchnic sympathetic outflow at T6. Headache, flushing, and diaphoresis above the level of the lesion, and hypertension with bradycardia or tachycardia, are the major symptoms. The trigger is typically a noxious stimulus -- for example, bladder or bowel distention, a urinary tract infection, or a decubitus ulcer -- below the level of the cord lesion. Ascending sensory fibers are thought to activate, via interneurons, sympathetic neurons of the intermediolateral nuclei in the thoracic spinal cord, producing vasoconstriction, tachycardia, and systemic hypertension. Reflex pathways, activated by carotid and aortic baroreceptors and projecting to the central nervous system via the vagus and glossopharyngeal nerves, then inhibit sympathetic activity above the cord lesion, producing vasodilation, but below the lesion descending pathways are blocked and sympathetic hyperactivity continues. Treatment consists of removal of offending stimuli; ganglionic blocking agents (mecamylamine, 2.5 to 5 mg) or other short-acting antihypertensive drugs are useful in some patients (see review by Colachis).

369. TRAUMATIC INJURIES OF THE HEAD AND SPINE - *Allan H. Ropper*

Head injuries are frequent in industrialized countries and affect many individuals in the prime of life. Almost 10 million head injuries occur annually in the United States alone, about 20% of which are serious enough to cause brain damage. Among men under 35 years, accidents, usually motor vehicle collisions, are the chief cause of death, and >70% of these involve head injury. Minor head injuries are so common that almost all physicians encounter patients requiring immediate care or suffering from various sequelae. Traumatic spinal cord injuries often occur in conjunction with head injury. The two are best considered together in the context of trauma to the nervous system.

A recent decline in mortality from head and spinal cord injuries can be attributed mainly to the use of seat belts and motorcycle helmets and the development of ambulance systems with trained personnel. In addition, a systematic approach to the evaluation of patients with head and spine trauma, beginning at the scene of the accident, has contributed to the improvement in outcome. Also, the wide availability of computed tomography (CT) and magnetic resonance imaging (MRI) has contributed to advances in diagnosis and intensive care treatment and an understanding of the pathologic lesions that are produced by trauma.

TYPES OF HEAD INJURIES

SKULL FRACTURES

A blow to the skull causes a fracture if the elastic tolerance of the bone is exceeded. Intracranial lesions accompany two-thirds of skull fractures, and the presence of a skull fracture increases manyfold the chances of an underlying subdural or epidural hematoma. Consequently, fractures are important primarily as markers of the site and severity of injury. They are also the cause of cranial nerve injuries and the source of entry pathways to the cerebrospinal fluid (CSF) for bacteria (meningitis), air (pneumocephalus), and leakage of CSF.

Fractures are classified as *linear*, *basilar*, *compound*, or *depressed*. Linear fractures, which are most often associated with subdural or epidural hematomas, account for 80% of all skull fractures. They are usually oriented from the point of impact toward the base of the skull. Basilar skull fractures are often extensions of adjacent fractures over the convexity of the skull but may occur independently owing to stresses on the floor of the middle cranial fossa or occiput. They are usually located parallel to the petrous bone or along the sphenoid bone toward the sella turcica and ethmoidal groove. Although most are uncomplicated, basilar skull fractures can causeCSFleakage, pneumocephalus, and cavernous-carotid fistulas. Hemotympanum (blood behind the tympanic membrane), delayed ecchymosis over the mastoid process (Battle's sign), or periorbital ecchymosis ("racoon sign") all signify fracture of the basilar skull. Because routine x-ray examination may fail to disclose basilar fractures, they should be suspected if these clinical signs are present. CSF may leak through the cribriform plate or the adjacent sinus and manifest as a watery discharge from the nose (CSF rhinorrhea). Persistent rhinorrhea and recurrent meningitis are indications for surgical repair of torn dura underlying the fracture. The precise site of the leak is often difficult to determine, but useful diagnostic tests include the instillation of water-soluble contrast into the CSF followed byCT with

the patient in various positions, and injection of radionuclide compounds or fluorescein into the CSF with an assessment of uptake of these compounds by absorptive nasal pledgets. The site of an intermittent leak is rarely delineated, and most resolve spontaneously. Sellar fractures, even ones associated with serious neuroendocrine dysfunction, are sometimes radiologically occult. Fractures of the dorsum sella may cause sixth or seventh nerve palsies or optic nerve damage. An air-fluid level in the sphenoid sinus suggests a fracture of the sellar floor.

Petrous bone fractures, especially those oriented along the long axis of the bone, may be associated with facial palsy, disruption of ear ossicles, andCSFotorrhea. Transverse petrous fractures are less common; they almost always damage the cochlea or labyrinths and often the facial nerve. External bleeding from the ear is usually from local abrasion of the external canal but can also result from petrous fracture.

Fractures of the frontal bone are often depressed, involving the frontal and paranasal sinuses and the orbits; permanent anosmia results if the olfactory filaments in the cribriform plate are disrupted. Depressed skull fractures are typically compound, but they are often neurologically asymptomatic because the impact energy is dissipated in breaking the bone; however, some are associated with brain contusions and focal neurologic signs caused by damage to the underlying cortical area. Prompt debridement and exploration of compound fractures are required in order to avoid infection.

CRANIAL NERVE INJURIES

The cranial nerves likely to be injured with head trauma include the olfactory, optic, oculomotor, and trochlear nerves; the first and second branches of the trigeminal nerve; and the facial and auditory nerves. Anosmia and an apparent loss of taste (actually a loss of perception of aromatic flavors, with elementary tastes retained) occur in ~10% of persons with serious head injuries, particularly with falls on the back of the head. This sequela results from displacement of the brain and shearing of the olfactory nerve filaments and may occur in the absence of a fracture. Recovery is the rule, leaving residual hyposmia, but if bilateral anosmia persists for several months, the prognosis is poor. Fractures of the sphenoid bone may rarely bruise or transect the optic nerve, resulting in unilateral partial or complete blindness and an unreactive pupil, usually equal in size to that of the other side and with a preserved consensual light response. Partial optic nerve injuries from closed trauma result in blurring of vision, central or paracentral scotomas, or sector defects. Direct orbital injury may cause short-lived blurred vision for close objects and pupillary paralysis because of reversible iridoplegia. Diplopia limited to downward gaze, which suggests trochlear nerve damage, occurs as an isolated problem after minor injury and can develop after a delay of several days; it may also result from fracture of the lesser wing of the sphenoid bone. The diplopia is corrected if the head is tilted away from the affected eye. Direct facial nerve injury by a basal fracture is present immediately in 3% of severe injuries; it may also be delayed 5 to 7 days. Fractures through the petrous bone, particularly the less common transverse type, are liable to produce this injury. Delayed facial palsy, the mechanism of which is unknown, has a good prognosis. Injury to the eighth cranial nerve from a fracture of the petrous bone causes loss of hearing, vertigo, and nystagmus immediately after injury. Deafness from nerve injury must be distinguished from that due to rupture of the eardrum, blood in the middle ear, or disruption of the ossicles from fracture through the

middle ear. A high-tone hearing loss occurs with direct cochlear concussion.

SEIZURES

Convulsions are surprisingly uncommon immediately after a head injury, but a brief period of tonic extensor posturing or a few clonic movements of the limbs just after the moment of impact may occur. However, the superficial cortical scars that evolve from contusions are highly epileptogenic and may later manifest as seizures, even after many years (Chap. 360). The severity of injury determines the risk of future seizures. It has been estimated that 17% of individuals with brain contusion, subdural hematoma, or prolonged loss of consciousness will develop a seizure disorder and that this risk extends for an indefinite period of time, whereas the risk is only 2% after mild injury; the majority of convulsions in the latter group occur within 5 years of injury.

CONCUSSION

Concussion refers to an immediate but transient loss of consciousness that is associated with a short period of amnesia and described as the experience or appearance of being dazed or "star struck." It typically occurs after a blunt impact that creates a sudden deceleration of the cranium and a movement of the brain within the skull. Severe concussion may precipitate a brief convulsion or autonomic signs such as facial pallor, bradycardia, faintness with mild hypotension, or sluggish pupillary reaction, but most patients are neurologically normal. Higher primates are particularly susceptible to concussion; in contrast, billy goats, rams, and woodpeckers can tolerate impact velocity and deceleration 100-fold greater than that experienced by humans. The mechanism of loss of consciousness in concussion is believed to be a transient electrophysiologic dysfunction of the reticular activating system in the upper midbrain caused by rotation of the cerebral hemispheres on the relatively fixed brainstem (Chap. 24).

Gross and light-microscopic changes in the brain are usually absent following concussion, but biochemical and ultrastructural changes, such as mitochondrial ATP depletion and local disruption of the blood-brain barrier, suggest that complex abnormalities occur.CT andMRIscans are usually normal; however, approximately 3% of patients will be found to have an intracranial hemorrhage of some type.

The amnesia of concussion typically follows at least a few moments of unresponsiveness, but rarely there is no loss of consciousness. The memory loss spans the time of, and moments before, mild impact injuries but may encompass previous weeks (rarely months) in cases of more severe trauma. The extent of retrograde amnesia has been suggested as a rough measure of the severity of injury. Any anterograde amnesia is usually brief and disappears rapidly in alert patients. Memory is regained in an orderly way from the most distant to recent memories, with islands of amnesia occasionally remaining in severe cases. The mechanism of peritraumatic amnesia is not known. Hysterical posttraumatic amnesia is not uncommon and should be suspected when inexplicable abnormalities of behavior occur, such as recounting events that cannot be recalled on later testing, a bizarre affect that emulates the lay notion of amnesia or psychosis (Ganser syndrome), forgetting one's own name, or a persistent anterograde deficit that is excessive in comparison with the degree of injury.

A single, uncomplicated head injury only infrequently produces permanent neurobehavioral changes in patients who are free of preexisting psychiatric problems and substance abuse. However, there has been increasing attention to minor problems in memory and concentration that may have an anatomic correlate in small shearing or other microscopic lesions (see below).

CONTUSION, BRAIN HEMORRHAGE, AND SHEARING LESIONS

A surface bruise of the brain, or *contusion*, consists of varying degrees of petechial hemorrhage, edema, and tissue destruction. Contusions and deeper hemorrhages result from mechanical forces that displace the hemispheres forcefully relative to the skull by deceleration of the brain against the inner skull, either under a point of impact (coup lesion) or, as the brain swings back, in the antipolar area (contrecoup lesion). Trauma sufficient to cause prolonged unconsciousness usually produces some degree of contusion. Because the motion of the hemispheres brings them into contact with the prominences of the sphenoid and other frontal basal bones, blunt impact, as from an automobile dashboard or from falling forward while drunk, typically causes contusions on the orbital surfaces of the frontal lobes and the anterior and basal portions of the temporal lobes. With lateral forces, as from the doorframe of a car, the contusions are situated on the lateral convexity of the hemispheres. In both instances there may be obverse contrecoup contusions.

Contusions are visible onCT andMRIscans, appearing early as inhomogeneous hyperdensities on CT and as hyperintensities on MRI; the signal changes reflect small scattered areas of cortical and subcortical blood and localized brain edema (Fig. 369-1); there is also some degree of subarachnoid bleeding, which may be detected by scans or lumbar puncture. Confluent, roughly spherical contusions can be distinguished from cerebral hemorrhages by their involvement of the cortical surface. Contusions may acquire a surrounding ringlike contrast enhancement after a week that may be mistaken for tumor or abscess. Glial and macrophage reactions begin within 2 days and result years later in scarred, hemosiderin-stained depressions on the surface (*plaques jaunes*) that are one source of posttraumatic epilepsy.

The clinical signs produced by contusions vary with their location and size; a hemiparesis or gaze preference, similar to the signs of a middle cerebral artery stroke, is fairly typical. Large bilateral contusions produce coma with extensor posturing. Contusions limited to the frontal lobes produce an abulic-taciturn state and those in the temporal lobe may cause an aggressive, combative, or delirous syndrome, described below. The secondary effects of progressive edema are the most threatening aspect of contusion injury and lead to coma and signs of secondary brainstem compression (pupillary enlargement).

Deep hemorrhages in the central white matter may result from confluent contusions in the depths of a sulcus. However, ganglionic, diencephalic, and other deep hematomas due to torsion or shearing forces in the brain occur independently of surface damage. Large single hemorrhages after minor trauma may bring to attention a bleeding diathesis or cerebrovascular amyloidosis in the elderly. For unexplained reasons, deep cerebral hemorrhages may not develop until several days after severe injury. Sudden

neurologic deterioration in a comatose patient or an unexplained rise in intracranial pressure (ICP) should therefore prompt investigation with aCTscan.

Another type of deep white matter lesion consists of widespread acute disruption, or "shearing," of axons at the time of impact. Characteristically there are small areas of tissue disruption in the corpus callosum and dorsolateral pons, but these areas may not be appreciated in scans. The presence of widespread axonal damage of both hemispheres, a state called *diffuse axonal injury*, has been proposed as the explanation of persistent coma or vegetative state, but small ischemic-hemorrhagic lesions in the midbrain and low diencephalon are as often the cause. Only severe shearing lesions that contain blood are visualized byCT, usually in the corpus callosum and centrum semiovale (Fig. 369-2); however, within days of the injury,MRI scan demonstrates such lesions throughout the white matter, especially with the use of gradient echo MRI sequences.

On occasion, especially in children, cranial trauma causes diffuse brain swelling within a few hours after injury, even thoughCT may not reveal focal contusions or hemorrhages. The swelling creates a mass effect with disastrous consequences. Swelling is likely due to microvascular disruption and greatly increased cerebral blood flow. Episodes of moderate hypotension after the injury may play a role in this complication.

Residual symptoms and signs of primary or secondary compressive brainstem hemorrhages or ischemic lesions include cerebellar tremor, pupillary enlargement, eye movement abnormalities, and the "locked-in" syndrome (Chap. 24).

SUBDURAL AND EPIDURAL HEMATOMAS

Hemorrhages beneath the dura (subdural) or between the dura and skull (epidural) may be associated with contusions and other injuries, making it difficult to determine their relative contribution to the clinical state. However, subdural and epidural hematomas more often occur as the sole manifestation of injury, and each has characteristic clinical and radiologic features. Because the mass effect and the rise in ICP caused by these hemorrhages may be life threatening, it is imperative that they be identified immediately byCT orMRI scan and evacuated when appropriate.

Acute Subdural Hematoma These lesions become symptomatic minutes or hours after injury. Up to one-third of patients have a lucid interval before coma supervenes, but most are drowsy or comatose from the moment of injury. Direct cranial trauma is not required for acute subdural hemorrhage to occur; acceleration forces alone, as from whiplash, are adequate, especially in the elderly and those taking anticoagulant medications. A unilateral headache and slightly enlarged pupil on the same side are frequently but not invariably found. Stupor or coma, a hemiparesis, and unilateral pupillary enlargement are the typical signs of larger hematomas; pupillary dilation is contralateral to the hematoma in 5 to 10%. In an acutely deteriorating patient with diminished alertness and with pupillary enlargement, burr (drainage) holes or an emergency craniotomy are appropriate, at times even without prior radiographic confirmation of subdural hematoma. Small subdural hematomas may be asymptomatic and usually do not require therapy. A more subacute syndrome from subdural hematoma occurs days to weeks after injury with drowsiness, headache, confusion, or

mild hemiparesis; it is seen in alcoholics and in the elderly. Chronic subdural hematoma is described below.

Most subdural hematomas appear as crescentic collections over the convexity of the hemisphere and are located over the frontotemporal region, less often in the inferior middle fossa or over the occipital poles (Fig. 369-3). The degree of midline shift is disproportionately greater than the apparent size of the clot in any one axialCT scan, but the guidelines relating shift to the level of consciousness outlined inChap. 24remain useful. Less common instances of interhemispheric, posterior fossa, or bilateral convexity clots are difficult to diagnose clinically, although drowsiness and the signs expected for each region can be detected (Chap 25). Larger clots are thought to be primarily venous in origin, though additional arterial bleeding sites are often found; some large clots, when explored surgically, appear to be exclusively arterial.

Acute Epidural Hematoma Epidural hematomas evolve more rapidly than subdural hematomas and are therefore more treacherous. They occur in up to 10% of severe trauma cases and are less often associated with underlying cortical damage than are subdural hematomas. Most patients are unconscious when first seen. A "lucid interval" of several minutes to hours before coma supervenes is said to be most characteristic of epidural hemorrhage, although it is not common, and epidural hemorrhage by no means is the only cause of this temporal profile.

An epidural hematoma located over the convexity of either lateral temporal lobe is explained by its origin from a torn dural vessel, most commonly the middle meningeal artery, which is transected by a fracture of the squamous portion of the temporal bone. Frontal, inferior temporal, or occipitoparietal epidural hematomas are less frequent, occurring when fractures disrupt branches of the middle meningeal artery. The hematoma strips the tightly attached dura from the inner table of the skull, producing a characteristic lenticular shaped clot onCT(Fig. 369-4). Epidural hematomas may be less frequent in the elderly because of the tighter attachment of dura to skull that occurs with aging. Posterior fossa epidural hematomas are rare and difficult to detect clinically; most result from surgery in that region, such as resection of an acoustic schwannoma.

Chronic Subdural Hematoma A history of trauma may or may not be elicited; 20 to 30% of patients recall no head injury, particularly the elderly and those with a bleeding diathesis. The causative injury may be trivial (striking the head against the branch of a tree, a sudden stop in a car, or minor head contact during a fall or faint) and is often forgotten because it was remote. Headaches (common but not invariable), slowed thinking, change in personality, a seizure, or a mild hemiparesis emerges weeks or months afterwards. The headache may fluctuate in severity, sometimes with positional changes. Many chronic subdural hematomas are bilateral and produce perplexing clinical syndromes. The initial clinical impression is of a stroke, brain tumor, drug intoxication, depression, or a dementing illness because drowsiness, inattentiveness, and incoherence of thought are more prominent than focal signs such as hemiparesis. Patients with undetected small bilateral subdural hematomas seem to have a low tolerance for surgery, anesthesia, and drugs that depress the nervous system, remaining drowsy or confused for long periods postoperatively. Occasionally a chronic hematoma causes brief episodes of hemiparesis or aphasia that are indistinguishable from transient ischemic attacks.

Skull x-rays are usually normal except for a shift of the calcified pineal body to one side or an occasional unexpected fracture. In very long-standing cases the irregular calcification of membranes that surround the collection may be appreciated.CTperformed without contrast infusion shows a low-density mass over the convexity of the hemisphere (Fig. 369-5), but between 2 to 6 weeks after the initial bleeding the clot appears isodense compared to adjacent brain. Bilateral chronic hematomas may fail to be detected because of the absence of lateral tissue shifts; this circumstance is suggested by a "hypernormal" CT scan with fullness of the cortical sulci and small ventricles in an older patient. CT with contrast demonstrates the vascular fibrous capsule surrounding the clot;MRI can reliably identify either a subacute or chronic clot. Lumbar puncture is not recommended for diagnosis because of the risk of worsening tissue shifts but, if performed, shows xanthochromia of the spinal fluid and a variable number of red blood cells. Chronic subdural hematomas can expand gradually and clinically resemble tumors of the brain.

Clinical observation and serial imaging are reasonable in patients with few symptoms and small subdural collections. Treatment with glucocorticoids alone is sufficient in some cases, but surgical evacuation is more often successful. The fibrous membranes that grow from the dura and encapsulate the region require surgical resection to prevent recurrent fluid accumulation. Small hematomas are largely resorbed, leaving only the organizing membranes, which become calcified after many years.

PENETRATING INJURIES, COMPRESSIONS, AND LACERATIONS

Tangential scalp wounds from bullets are capable of producing neurologic signs or delayed seizures because small hemorrhages or contusions arise even in the absence of missile penetration. Bullets entering the brain cause considerable damage because of their tremendous kinetic energy. A cylindrical area of necrosis surrounds the bullet track, but the nature of injury differs for different projectiles. Soft civilian bullets typically shatter on impact and leave a track of metallic fragments with moderate parenchymal damage, whereas military bullets, because of their high velocity and energy, disrupt tissue at great distances from the track and produce massive brain destruction. All of these penetrating injuries cause a rapid increase inICP for several minutes, followed by a drop depending on the volume of secondary hemorrhage and the degree of developing edema. Infection is a risk mainly from shell fragments, shrapnel, grenades, and mines, because such small projectiles carry surface bacteria and dirt into the brain. Most neurosurgeons administer systemic antibiotics prophylactically and perform local debridement for all types of penetrating injuries. Aneurysms may form as a result of disruption of vessel walls from the shock wave of the passing projectile; facial-orbital entrance wounds have the highest incidence of this complication. The aneurysms have an unpredictable course, but most that rupture do so in the first month. The prognosis for survival after missile injuries is good if consciousness is preserved and poor if coma is present from the outset.

In civilian practice, intracranial foreign bodies such as knives, picks, studgun staples, or high-speed tool bits may be missed unless skull x-rays are taken after what are seemingly minor penetrating injuries. Surgical removal of the object, debridement, and extensive exploration for hemorrhage and necrotic tissue are required.

TRAUMATIC VASCULAR DISSECTION AND OCCLUSION

The kinetic energy of minor or more severe head or neck trauma can produce dissection of the internal carotid or vertebral arteries by stripping the intima or the media. Chiropractic neck manipulation accounts for some cases. Severe blunt impacts to the neck can initiate a dissection several centimeters above the origins of the internal carotid or vertebral arteries. There is usually local neck pain over the affected carotid artery, a Horner's syndrome, and headache over the ipsilateral anterior cranium. Some patients with carotid dissection subsequently have large middle cerebral artery strokes with hemiplegia after a period of fluctuating hemiparesis. In drowsy or comatose patients, evidence of dissection or subsequent stroke is difficult to determine, but its presence is suggested by unexplained hemiplegia, unilateral miosis, or appearance of cerebral infarction on CTscan.

Traumatic vertebral artery dissection causes vertigo, vomiting, suboccipital or supraorbital headache, and other signs of lateral medullary or cerebellar ischemia. These symptoms may be attributed erroneously to vestibular concussion. In comatose patients, the only indication may be inferior cerebellar infarction on imaging studies. Vasospasm from traumatic subarachnoid blood may also be involved in the development of infarction after head injury.

Cavernous sinus arteriovenous fistulas are rare but serious complications in patients who survive severe head injury. The problem is first evident as a self-audible bruit (many are also audible to the examiner), proptosis, conjunctival injection, or visual impairment. Angiography shows early filling of the cavernous sinus and its draining tributaries. The fistula enlarges, causing increasingly severe local changes around the eye and orbit and decreased chances of visual recovery. About 10%, mostly small fistulas, resolve spontaneously. Many surgical approaches have been tried, including ligation of the carotid artery and direct obliteration of the fistula or cavernous sinus, but a detachable balloon that is delivered by an intravascular catheter has proved most successful.

INTRACRANIAL PRESSURE AND CEREBRAL BLOOD FLOW

RaisedICParising from contusion, hematoma, and subsequent progressive edema accounts for at least 50% of deaths after head injury; outcome is inversely related to the level of ICP. Aggressive treatment of raised ICP in modern intensive care units is believed to contribute to improved survival after severe head injury, but many other factors pertain, and the role of direct monitoring of ICP to guide therapy, while favored in many centers, is still uncertain.

For several minutes to an hour after acute head injury, cerebral blood flow increases in most patients, although metabolic demands and oxygen consumption of the cerebrum are diminished. Autoregulation -- the ability of the cerebral vasculature to maintain a constant blood flow in response to decreased or increased perfusion pressure -- is impaired globally and even more so in damaged regions. The rise in cerebral blood volume caused by the failure of autoregulation is thought to account for approximately two-thirds of the rise inICPafter severe head injury. The blood-brain barrier also

becomes more permeable in contused regions, promoting edema formation. Resting ICP is spontaneously interrupted by rises in ICP, termed *plateau waves*, which arise as a result of a loss of cerebrovascular tone and a resultant increase in cerebral blood volume. Plateau waves may be precipitated by iatrogenic maneuvers such as suctioning, physical therapy, excess fluid administration, or pain but also by mild, often unnoticed hypotension that causes cerebrovascular dilation. Signs of clinical deterioration, such as pupillary enlargement, may occur after plateau waves; occasionally, brain death ensues. Other secondary systemic phenomena after severe head injury, particularly hypotension and hypoxia, cause brain damage and greatly alter outcome.**The regulation of ICP and its relationship to cerebral blood flow (CBF) are discussed in Chap. 376.*

CLINICAL SYNDROMES AND TREATMENT OF HEAD INJURY

MINOR INJURY

The patient who is fully alert and attentive after head injury but who has one or more symptoms of headache, faintness, nausea, a single episode of emesis, difficulty with concentration, or slight blurring of vision has a good prognosis with little risk of subsequent deterioration. Such patients have usually sustained a concussion and are expected to have a brief amnestic epoch. Children and young adults are particularly prone to drowsiness, vomiting, and irritability, which is sometimes delayed for several hours after apparently minor injuries. Occasionally, vasovagal syncope occurs several minutes to an hour after the injury and may cause undue concern. Constant generalized or frontal headache is common in the days following trauma; it may be migrainous (throbbing and hemicranial) in nature. After several hours of observation, patients with this category of injury may be accompanied home and observed by a family member or friend. Most patients with a minor syndrome do not have a skull fracture on skull x-ray or hemorrhage onCT. The decision to perform these tests depends largely on clinical signs suggesting that the impact was severe (e.g., prolonged concussion, periorbital or mastoid hematoma, repeated vomiting), on the seriousness of other bodily injuries, and on the degree of surveillance that can be expected at home. Persistent severe headache and repeated vomiting in the context of normal alertness and no focal neurologic signs are usually benign, but radiologic studies should be obtained and observation in the hospital is justified.

INJURY OF INTERMEDIATE SEVERITY

Patients who are not comatose but who have persistent confusion, behavioral changes, subnormal alertness, extreme dizziness, or focal neurologic signs such as hemiparesis should be admitted to the hospital and soon thereafter have aCT scan. Usually a contusion or hematoma is found. The clinical syndromes most common in this group, in addition to postconcussive headache, dizziness, and vomiting, include (1) delirium with a disinclination to be examined or moved, expletive speech, and resistance if disturbed (anterior temporal lobe contusions); (2) a quiet, disinterested, slowed mental state (abulia) with dull facial appearance and irascibility (inferior frontal and frontopolar contusions); (3) a focal deficit such as aphasia or mild hemiparesis (due to subdural hematoma or convexity contusion, or, less often, carotid artery dissection); (4) confusion with inattention, poor performance on simple mental tasks, and fluctuating or slightly

erroneous orientation (associated with several types of injuries, including the first two described above as well as medial frontal contusions and interhemispheric subdural hematoma); (5) repetitive vomiting, nystagmus, drowsiness, and unsteadiness (usually labyrinthine concussion, but occasionally due to a posterior fossa subdural hematoma or vertebral artery dissection); and (6) diabetes insipidus (damage to the median eminence or pituitary stalk). It needs to be emphasized that intermediate-grade injuries are often complicated by drug or alcohol intoxication.

Clinical observation is necessary to detect increasing drowsiness, change in respiratory pattern, or pupillary enlargement and to ensure restriction of free water (unless there is diabetes insipidus). Asymmetry in limb posture, limb movement, or gaze preference suggests a subdural or epidural hematoma or large contusion. Most patients in this category improve over several days. During the first week, the state of alertness, memory, and other cognitive performance often fluctuate, and irascibility or agitation is common. Behavioral changes are worst at night, as with most other encephalopathies, and may be treated with small doses of antipsychotic medications. Subtle abnormalities of attention, intellect, spontaneity, and memory tend to return to normal weeks or months after the injury, sometimes surprisingly abruptly; persistent losses in cognition are discussed below.

SEVERE INJURY

Patients who are comatose from the onset require immediate neurologic attention and often resuscitation. After intubation, with care taken to avoid deforming the cervical spine, the depth of coma, pupillary size and reactivity, limb movements, and Babinski responses are assessed. As soon as vital functions permit and cervical spine x-rays and aCT scan have been obtained, the patient should be transported to a critical care unit. The finding of an epidural or subdural hematoma or large intracerebral hemorrhage is an indication for prompt surgery and intracranial decompression in otherwise salvageable patients. Subsequent treatment is probably best guided by direct measurement ofICP but may proceed on a presumptive basis using clinical status and CT scan as guides. All potential exacerbating factors must be eliminated. Hypoxia, hyperthermia, hypercarbia, awkward head positions, and high mean airway pressures from mechanical ventilation all increase cerebral blood volume and ICP. Many, but not all, patients will have lower ICP when the head and trunk are elevated. Active management of raised ICP includes hyperosmolar dehydration with 20% mannitol (0.25 to 1 g/kg every 3 to 6 h), preferably using directly measured ICP as a guide. Otherwise, a serum osmolality of ~300 mosmol/L is desirable. It is customary to restrict free water administration in order to maintain high serum osmolarity, but there is no rationale for a reduction in the total volume of fluids administered if they are iso- or hyperosmolar, e.g., normal saline. Induced hypocarbia to an initial level of 28 to 33 mmHg P_{CO2} is rapidly effective in reducing ICP, but its duration of effect is limited and its use has fallen out of favor, perhaps excessively so.

Persistently raisedICPafter inception of this conservative therapy generally indicates a poor outcome. Although the addition of high-dose barbiturates may further lower ICP, there is no beneficial effect on overall outcome. In many instances, barbiturates cause a parallel reduction in ICP and BP without a net improvement in cerebral perfusion. Systolic BP should be maintained >100 mmHg by vasopressor agents, if necessary.

Mean BP levels>110 to 120 mmHg may exaggerate brain edema, but some neurosurgeons allow the BP to rise above normal on the basis that this may abort plateau waves. A conventional approach to extreme hypertension utilizes diuretics and b-adrenergic blocking agents, angiotensin-converting enzyme inhibitors, or intermittent doses of barbiturates. A number of other antihypertensive drugs, including some calcium channel blockers and nitrates, are said to be relatively contraindicated because they may raise ICP. Antacids administered by nasogastric tube or direct-acting drugs are utilized to keep gastric pH >3.5 and prevent gastrointestinal bleeding as described below. The use of large doses of glucocorticoids in severe head injury does not improve outcome. Several studies suggest that early nutritional support results in faster neurologic recovery from head injury. If the patient remains comatose, it is worthwhile to repeat the CTor MRIscan to exclude a delayed surface or intracerebral hemorrhage. Intensive care salvages some critically ill head-injured patients by concentrating efforts on simple treatments that avoid medical complications, particularly pneumonia and sepsis and preventable increases in ICP.

SYSTEMIC DERANGEMENTS RESULTING FROM SEVERE HEAD TRAUMA

Injuries outside the cranium should be searched for at the outset, because they are likely to be forgotten if not initially noted. In particular, associated spinal, long bone, and abdominal injuries may cause delayed difficulties in management. Over half of patients who persist in coma for 24 h after head injury develop *abnormalities of electrolytes or fluid balance*. Diabetes insipidus should be suspected if urine output increases and urine specific gravity is low (Chap. 329). Replacement of water losses suffices for mild cases, but vasopressin may be required. Secretion of aldosterone and antidiuretic hormone (vasopressin, AVP) in response to stress favor the retention of sodium and free water, respectively. The latter usually predominates, leading to mild hypervolemic hyponatremia, but this is obscured if osmotic dehydrating agents have been used.

Some patients with head injuries suffer *hypoxia* acutely after injury without obvious pulmonary infiltrates. Aspiration pneumonia presents a great risk; lung injury from aspirated gastric contents, infection, and atelectasis may combine to produce the adult respiratory distress syndrome (ARDS) and severe arteriovenous shunting (Chap. 265). ARDS also occurs owing to disseminated intravascular coagulopathy, fat embolism, or, rarely, "neurogenic" pulmonary edema (see below). The effect of positive end-expiratory pressure (PEEP) onICP is complex, but PEEP should not be withheld if necessary for oxygenation. *Atelectasis* is common in all poorly responsive patients and is treated with chest physical therapy and adequate ventilator tidal volumes. *Pulmonary embolism* is also a major threat to bedridden patients, and intermittent pneumatic calf compression or modest doses of subcutaneous heparin may be useful prophylaxis. The latter has not predisposed to intracerebral or gastrointestinal bleeding. Early recognition of deep leg vein thrombosis and aggressive treatment by occlusion of the inferior vena cava may prevent later emboli.

Patients with severe long bone injuries are subject to widespread *cerebral fat embolism*. For uncertain reasons, this complication is seen less often than previously, perhaps because of better fluid replacement. In the typical case, head injury is a minor part of the overall trauma; nonetheless, severe cranial injury masks the syndrome. Several days after the bone fractures occur, restlessness, delirium or drowsiness progressing to coma

in severe cases, seizures, generalized brain edema, and hypoxia develop. About half the patients have retinal and punctate conjunctival hemorrhages or fat that is visible in retinal vessels. A petechial rash (prominent in the anterior axillary folds and supraclavicular fossae), diffuse interstitial infiltrates on the chest x-ray, fat in the urine, and/or renal failure occur in some patients. Severe reduction in arterial oxygen content is common from widespread lung injury (ARDS). Cerebral fat embolism causes a cerebral purpura, mainly in the white matter, due to capillary occlusion by fat globules. There is evidence that patients in whom this complication is recognized and treated early have a better prognosis. Massive doses of glucocorticoids and administration of positive-pressure ventilation with high end-expiratory pressures have been claimed to be useful.

Most patients with severe head injuries develop gastric erosions, but only a few have clinically significant hemorrhages. *Gastrointestinal bleeding* usually occurs in the first days to 1 week after injury. Unlike the majority of patients in shock or with stress ulceration, head-trauma patients often have elevated gastric acidity. Prophylactic treatment with gastric coating agents as discussed above, with H_2receptor blockers, or with frequent antacid administration probably reduces gastric hemorrhage in other stress states and is commonly used in head trauma.

Acute head trauma may cause transient apnea and cardiac arrest. In the absence of overwhelming brain damage, recovery from the arrest is the rule. Subsequently, a sympathoadrenal discharge or raisedICPcauses *systemic hypertension*, either with the classically associated bradycardia of the Cushing response or, almost as frequently, with tachycardia. Cardiac arrhythmias are common, most notably sinus bradycardia, supraventricular tachycardias, nodal rhythm, and heart block. T-wave inversion and alterations in the ST segment may simulate subendocardial ischemia. In some instances these changes are due to cardiac muscle contusion.

Neurogenic pulmonary edema is a form of respiratory failure in which the alveoli fill with fluid, as in congestive heart failure, but left ventricular end-diastolic pressure is normal after the infiltrates are established. The nature of this pulmonary vascular leak is not settled, but it may be the result of a sudden shift of intravascular volume from the systemic to the pulmonary circulation or there may be a direct cerebral neurogenic influence on the pulmonary microvasculature. The alveolar capillary leak may continue despite a return of pulmonary vascular pressure to normal.

Many patients demonstrate a mild *coagulopathy*, and 5 to 10% have various degrees of disseminated intravascular coagulation, a harbinger of poor outcome. There is a correlation between the severity of injury and the level of increased fibrin degradation products in blood, and one cause of the coagulopathy may be the release of highly thromboplastic material from damaged brain tissue.

PROGNOSIS

Extensive work by Jennet's group in Glasgow and by the Traumatic Coma Data Bank has provided data on the outcome in severe head injury. Verbal output, eye opening, and the best motor response of the limbs have been found to be predictive of outcome and are summarized using the "Glasgow Coma Scale" (Table 369-1). Over 85% of

patients with aggregate scores of 3 or 4 die within 24 h. However, a number of patients with slightly higher scores but a poor initial prognosis, including absent pupillary light responses, survive, suggesting that an initially aggressive approach is justified in most patients. Patients <20 years, particularly children, may make remarkable recoveries after having grave early neurologic signs. In one large study of severe head injury, 55% of children had a good outcome at 1 year, compared with 21% of adults. Older age, increasedICP, hypoxia and hypotension, and CT scan evidence of compression of the cisterns surrounding the brainstem and shift of midline structures are all poor prognostic signs. Delayed evacuation of large intracerebral clots is also associated with a poor prognosis.

Evoked potentials have prognostic value in head injury, similar to their use in ischemic-hypoxic brain injury, and their accuracy in predicting a poor outcome probably exceeds that of purely clinical methods. The results obtained from somatosensory evoked potentials are clearest, with the bilateral absence of cortical potentials (more caudal potentials present) predicting death or a vegetative state in over 90% of patients. A normal or mildly abnormal test, however, does not reliably predict a good functional outcome.

NEUROPSYCHOLOGICAL OUTCOME AFTER HEAD INJURY

A structural basis has been sought for the posttraumatic nervous instability termed the *postconcussion syndrome*, which consists of fatigue, dizziness, headache, and difficulty in concentration after mild or moderate injury. Most instances are difficult to distinguish from asthenia and depression. However, with intermediate-grade injury there is probably a substantial incidence of difficulty with attention and memory as well as other subtle cognitive deficits. Based on experimental models, some investigators believe that subtle axonal shearing lesions or biochemical alterations account for these symptoms despite normal findings on brain imaging, evoked potentials, and electroencephalogram. In moderate and severe trauma, neuropsychological changes are found routinely, but some of these deficits identified in formal testing are not important in daily functioning. Test scores tend to improve rapidly during the first 6 months after injury, then more slowly for years.

SPINAL CORD TRAUMA

Approximately 10,000 patients a year in the United States, mostly young and otherwise healthy, become paraplegic or quadriplegic because of spinal cord injuries; there are an estimated 200,000 quadriplegics in the nation. Most spinal cord injuries in civilian life result from fracture or dislocation of the surrounding vertebral column. Vertical compression with flexion is the main mechanism of injury in the thoracic cord, and hyperextension or flexion is the main cause of injury in the cervical cord. Preexisting spondylosis, a congenitally narrowed spinal canal, hypertrophied ligamentum flavum (Chap. 16), and instability of the apophyseal joints from diseases such as rheumatoid arthritis predispose to severe spinal cord damage even after minor degrees of injury.

PATHOPHYSIOLOGY AND PATHOLOGY OF SPINAL CORD INJURY

Considerable spinal cord damage results from secondary phenomena that arise in the

minutes and hours following injury. Even when a complete transverse myelopathy is evident immediately after impact, some secondary changes and the resultant damage may be reversible. The immediate compression of the cord causes pericapillary hemorrhages that coalesce and enlarge, particularly in the gray matter. Infarction of gray matter and early white matter edema are evident within 4 hours of experimental blunt injury. Eight hours after injury, there is global infarction at the traumatized level, and only at this point does necrosis of white matter and paralysis below the level of the lesion become irreversible. The necrosis and central hemorrhages enlarge to occupy one or two levels above and below the point of primary impact. Gliosis progresses over several months, and the affected regions may cavitate, causing a syringomyelic syndrome.

A large number of interventions for acute spinal compression injury have been of uncertain benefit, but high doses of methylprednisolone (typically 30 mg/kg followed by 5.4 mg/kg hourly for 23 h) administered within 8 hours of injury is associated with a slightly improved outcome. The critical factor for recoverable function is the time from injury to the institution of any therapy.

MANAGEMENT OF SPINAL CORD INJURY SYNDROMES

Any patient with an injury that involves the spine or head potentially has an associated instability of the spinal column. The care of such patients begins at the scene of the accident: the neck should be immobilized, and care should be taken during transport and during the physical and radiologic examinations to prevent extension or rotation of the neck and torsion-rotation of the thoracic spine. Intubation, if necessary, can be accomplished by a blind nasotracheal technique or over an endoscope in order to avoid neck extension. High thoracic or cervical cord transection causes hypotension and bradycardia because of a functional sympathectomy (sometimes corroborated by bilateral ptosis and miosis -- Horner's syndrome), which responds to infusion of crystalloid or colloid.

The neurologic assessment in the awake patient with possible spinal injury focuses on neck or back pain, diminished limb power, a sensory level on the trunk, and on deep tendon reflexes, which are usually absent below the level of acute cord injury. The level of injury can be approximated from the upper dermatome of sensory loss. Injuries above C5 cause quadriplegia and respiratory failure. At C5 and C6 the biceps are weak, whereas the deltoid and the supra- and infraspinatus are spared. C7 injuries cause weakness of the triceps, wrist extensors, and forearm pronators. Injuries at T1 and below cause paraplegia. Compression in the lower thoracic and lumbar spine causes a conus medullaris or cauda equina syndrome. Cauda equina injuries are usually incomplete, involving peripheral nerves rather than spinal cord, and therefore are surgically remediable for longer periods after injury than spinal cord compression. In a comatose patient, absent reflexes, especially with small pupils or paradoxical breathing and hypotension, signify a high cervical cord injury.**The principles of spinal cord localization are considered in detail in Chap. 368.*

Reversible and preventable causes of spinal cord compression must be detected and surgically remedied. These include dislocation of a vertebral body, or an unstable vertebral fracture that can lead to misalignment and cord compression in the future.

Treatment of fractures through the pedicles, facets, or vertebral bodies varies; some fractures heal with immobilization and time, usually 2 to 3 months, while others require surgical fusion to ensure stability. Many traumatic myelopathies have no clearly associated fracture or dislocation, but there is generally rupture of the supporting ligaments that has produced transient cord compression during the impact. If x-rays suggest any aberration in the position of vertebrae, then realignment should generally be undertaken quickly.CT orMRI exam is the most useful for demonstrating spinal misalignment and fractures. The role of myelography is not as compelling as it was in the past, but many neurosurgeons choose to instill a few drops of water-soluble contrast medium into the spinal subarachnoid space to demonstrate a block to the flow ofCSF by CT or conventional myelography. Decompression within 2 hours of severe injury may lead to some recovery of spinal cord function. With incomplete myelopathies, especially if the limbs are becoming progressively weaker, early realignment is performed even many hours after injury. The surgical approaches to decompressing the spinal column depend on the specific nature of the injury. In complete transverse myelopathies beyond 6 to 12 hours after injury, decompressive laminectomies are usually unsuccessful in restoring function.

Atlantoaxial dislocation can cause immediate death from respiratory failure, an event that may occur unexpectedly even without other neurologic signs. Rheumatoid arthritis predisposes to this injury. Atlantooccipital dislocations occur predominantly in children and are almost always fatal. "Jefferson's fractures" are burst fractures of the ring of the atlas resulting from a force descending on the vertex of the skull, as in diving accidents; they are usually asymptomatic. "Hangman's fractures" are produced by hyperextension and longitudinal distraction of the upper cervical spine, as occurs with penal hanging or striking the chin on a steering wheel in a head-on collision. These are usually fractures through the pedicles of C2 with subluxation anteriorly of C2 on C3. Traction reduction and prolonged immobilization usually allow proper healing.

Hyperflexion dislocation of the cervical vertebrae commonly causes quadriplegia. Occasionally, a markedly displaced injury is unassociated with neurologic dysfunction, presenting only with neck pain. Any degree of subluxation must be considered as potentially unstable.

Compression fracture of the cervical spine can cause neurologic damage if a bone fragment is driven backward (burst fracture) into the spinal cord. "Teardrop fractures" with crushing of a vertebral body, leaving a fragment of bone anteriorly, are usually associated with ligamentous disruption and spinal instability. Single compression fractures of the thoracic spine are usually stable because the thoracic cage provides support, but they may be associated with anterior spinal cord compression and require decompression and stabilization with the insertion of metal rods.

Mild *cervical hyperextension* injuries may cause only disruption of supporting ligamentous structures and can be well tolerated. More severe injuries cause vertebral displacement and cord compression. The "central cord syndrome" is produced by brief compression of the cervical cord and disruption of the central gray matter. It usually occurs in patients with an already narrow spinal canal, either congenitally or from cervical spondylosis. There is weakness of the arms with pinprick loss over the arms and shoulders, and relative sparing of leg power and sensation on the trunk and legs.

Abnormality of bladder function is variable. The prognosis for recovery is good.

Thoracolumbar fracture is produced by impact in the high or middle back, usually while the patient is bent over. Impingement on the spinal canal results in a complex combination of cauda equina and conus medullaris dysfunction. Purely lumbar fractures with displacement of a vertebral body produce cauda equina compression. Surgical decompression is usually recommended, even with severe neurologic deficits, because there is considerable potential for recovery of the nerve roots of the cauda.

The subsequent care of patients with spinal cord injury is best undertaken in specialized centers.**General principles of medical and urologic management are discussed in Chap. 368.*

370. PRIMARY AND METASTATIC TUMORS OF THE NERVOUS SYSTEM - *Stephen M. Sagar*, *Mark A. Israel*

Malignant primary tumors of the central nervous system (CNS) occur in approximately 18,000 individuals and account for an estimated 13,300 deaths in the United States annually, a mortality rate of 5 per 100,000. An almost equal number of benign tumors of the CNS were diagnosed, with a much lower mortality rate. Glial tumors account for 50 to 60% of primary brain tumors, meningiomas account for about 25%, schwannomas for about 10%, and all other CNS tumors for the remainder. An increase in the frequency of diagnosis of malignant gliomas in the elderly has been reported in recent years. It is unclear if this change represents a true increased incidence or is the result of more frequent use of modern neuroimaging techniques.

Brain and vertebral metastases from systemic tumors are more prevalent than primaryCNStumors. About 15% of patients who die of cancer (80,000 individuals each year in the United States) have symptomatic brain metastases; an additional 5% suffer spinal cord involvement. These tumors, therefore, pose a major problem in the management of systemic cancer.

BRAIN TUMORS

Approach to the Patient

Clinical Features Brain tumors usually present with one of three syndromes: (1) subacute progression of a focal neurologic deficit; (2) seizure; or (3) nonfocal neurologic disorder such as headache, dementia, personality change, or gait disorder. The presence of systemic symptoms such as malaise, weight loss, anorexia, or fever suggests a metastatic rather than a primary brain tumor.

Progressive focal neurologic deficits result from compression of neurons and white matter tracts by expanding tumor and surrounding edema. Less commonly, a brain tumor may present with a stroke-like onset of focal neurologic deficit. Although this presentation may be caused by hemorrhage into the tumor, often no hemorrhage can be demonstrated and the mechanism is obscure. Tumors frequently associated with hemorrhage include high-grade astrocytomas and metastatic melanoma and choriocarcinoma.

Seizures may result from disruption of cortical circuits. Tumors that invade or compress the cerebral cortex, even small meningiomas, are more likely to be associated with seizures than subcortical neoplasms. Nonfocal neurologic dysfunction usually reflects increased intracranial pressure, hydrocephalus, or diffuse tumor spread. Tumors in some areas of the brain may produce subtle deficits; for example, frontal lobe tumors may present with personality change, dementia, or depression.

Headache may result from focal irritation or displacement of pain-sensitive structures (Chap. 15) or from a generalized increase in intracranial pressure. A headache that worsens rather than abates with recumbency is suggestive of a mass lesion. The headache of increased intracranial pressure has a characteristic pattern. Early on, these headaches are usually holocephalic and episodic, occurring more than once a day.

They typically develop rapidly over several minutes, persist for 20 to 40 min, and subside quickly. They may awaken the patient from a sound sleep, generally 60 to 90 min after retiring, or may be precipitated by coughing, sneezing, or straining. Vomiting may occur with severe headaches. As elevated intracranial pressure becomes sustained, the headache becomes continuous but varying in intensity. Elevated intracranial pressure may cause papilledema (Chap. 28), although it is often not present in patients over 55 years old.

Infrequent but characteristic brain tumor presentations include anosmia from a meningioma arising along the cribiform plates and olfactory tracts and unilateral hearing loss from schwannomas of the eighth cranial nerve. Asymptomatic brain tumors, most often meningiomas, are commonly discovered incidentally on imaging studies obtained for unrelated purposes.

The Karnofsky performance scale is useful in assessing and following patients with brain tumors (Chap. 79). A score ³70 indicates that the patient is ambulatory and independent in self-care activities; it has often been taken as a level of function justifying aggressive therapy.

Laboratory Examination Primary brain tumors typically do not produce serologic abnormalities such as an elevated sedimentation rate or tumor-specific antigens associated with systemic cancers. In contrast, metastases to the nervous system, depending on the type and extent of the primary tumor, may be associated with systemic signs of malignancy (Chap. 83). Lumbar puncture may precipitate brain herniation in patients with mass lesions, and should be performed only in patients with suspectedCNSinfection or meningeal metastasis. Findings in the cerebrospinal fluid (CSF) of patients with primary and metastatic nervous system tumors may include raised opening pressure, elevated protein level, and a mild lymphocytic pleocytosis. Astrocytomas that extend to the ventricular surface, or the rupture of an epidermoid cyst, can occasionally produce an intense CSF inflammatory reaction simulating infectious meningitis. The CSF rarely contains malignant cells, with the important exceptions of leptomeningeal metastases, primary CNS lymphoma and primitive neuroectodermal tumors, including medulloblastoma.

Neuroimaging Computed tomography (CT) and magnetic resonance imaging (MRI) reveal mass effect and contrast enhancement. Mass effect reflects the volume of neoplastic tissue as well as surrounding edema. Brain tumors typically produce a vasogenic pattern of edema, with accumulation of excess water in white matter. The normal blood-brain barrier results from tight junctions between endothelial cells that prevent entry of most charged molecules into the nervous system. Contrast enhancement reflects a breakdown of the blood-brain barrier within the tumor, permitting leakage of contrast agent. Low-grade gliomas typically do not exhibit contrast enhancement.

Positron emission tomography (PET) and single-photon emission tomography (SPECT) have ancillary roles in the imaging of brain tumors, primarily in distinguishing tumor recurrence from tissue necrosis that can occur after irradiation (see below). Electroencephalography (EEG) has a role in the evaluation of patients with possible seizures. Functional imaging with PET,MRI, or magnetoencephalography may be of use

in surgical or radiosurgical planning to define the anatomic relationship of the tumor to critical brain regions such as the primary motor cortex.

TREATMENT

Symptomatic Glucocorticoids decrease the volume of edema surrounding brain tumors and improve neurologic function; dexamethasone (12 to 20 mg/d in divided doses orally or intravenously) is used because it has relatively little mineralocorticoid activity.

Tumors that involve the cerebral cortex or hippocampus may produce epilepsy. Anticonvulsants are therefore used therapeutically and prophylactically; phenytoin, carbamazepine, and valproic acid are equally effective (Chap. 360). If the tumor is subcortical in location, prophylactic anticonvulsants are unnecessary.

Gliomas are associated with an increased risk for deep vein thrombosis and pulmonary embolism, probably because these tumors secrete procoagulant factors into the systemic circulation. Whether this risk extends to other brain tumors is unknown. Even though hemorrhage within gliomas is a frequent histopathologic finding, patients with gliomas appear to be at no increased risk for symptomatic intracranial bleeding following treatment with an anticoagulant. Prophylaxis with low-dose subcutaneous heparin should be considered for patients with gliomas who have lower limb immobility, which places them at risk for deep venous thrombosis.

PRIMARY BRAIN TUMORS

ETIOLOGY

Exposure to ionizing radiation is the only well-documented environmental risk factor for the development of brain tumors. A number of hereditary syndromes are associated with an increased risk of brain tumors (Table 370-1). Genes that contribute to the development of brain tumors, as well as other malignancies, fall into two general classes, *tumor-suppressor genes* and *proto-oncogenes* (Chap. 81). Whereas germ line mutations of tumor suppressor genes are rare, somatic mutations are almost invariably found in malignant tumors, including brain tumors. Likewise, the over-expression of proto-oncogenes is frequent in brain tumors as well as systemic malignancies. Moreover, cytogenetic analysis often reveals characteristic changes. In astrocytic tumors, DNA is commonly lost on chromosomes 10p, 17p, 13q, and 9. Oligodendrogliomas frequently have deletions of 1p and 19q. In meningiomas portions of 22q, which contains the gene for neurofibromatosis type 2, are often lost. Less frequently there is evidence of amplification of specific genes, for example *EGFR* in some astrocytomas.

The particular constellation of genetic alterations varies among individual gliomas, even those that are histologically indistinguishable. Moreover, gliomas are genetically unstable, genetic abnormalities tend to accumulate with time, and these changes correspond with increasingly aggressive malignant behavior. There appear to be at least two genetic routes for the development of malignant glioma (Fig. 370-1). One route involves the progression, generally over years, from a low grade astrocytoma with early deletions of chromosome 17 and inactivation of the p53 gene to a malignant glioma with

additional chromosomal deletions. The second route is characterized by the de novo appearance of a malignant glioma with amplification of the *EGFR* gene and an intact p53 gene. In both pathways, inactivation of the *PTEN* gene as a result of the loss of chromosome 10 occurs frequently.

ASTROCYTOMAS

Tumors derived from astrocytes are the most common primary intracranial neoplasms (Fig. 370-2). Their neuropathologic appearance is highly variable. The most widely used histologic grading system is the World Health Organization (WHO) four-tiered grading system. Grade I is reserved for special histologic variants of astrocytoma that have an excellent prognosis after surgical excision. These include *juvenile pilocytic astrocytoma*, *subependymal giant cell astrocytoma* (which occurs in patients with tuberous sclerosis), and *pleiomorphic xanthoastrocytoma*. At the other extreme is grade IV, *glioblastoma multiforme*, a clinically aggressive tumor. *Astrocytoma* (grade II) and *anaplastic astrocytoma* (grade III) are intermediate. The histologic features associated with higher grade are hypercellularity, nuclear and cytoplasmic atypia, endothelial proliferation, mitotic activity, and necrosis. Endothelial proliferation and necrosis are especially robust predictors of aggressive behavior.

A limitation of all grading schemes, especially when applied to a single biopsy, is that astrocytic tumors are histologically variable from region to region, and their histopathology may change with time. It is common for low-grade astrocytomas to progress over time to a higher histopathologic grade and a more aggressive clinical course.

Quantitative measures of mitotic activity also correlate with prognosis. The proliferation index can be determined by immunohistochemical staining with antibodies to the proliferating cell nuclear antigen (PCNA) or with a monoclonal antibody termed *Ki-67*, which recognizes a histone protein expressed in proliferating but not quiescent cells. These measures provide estimates of DNA synthesis and correlate with malignant clinical behavior of the tumor.

The overall prognosis is poor. In a representative Finnish population, the median survival was 93.5 months for patients with grade I or II astrocytomas, 12.4 months for patients with grade III (anaplastic astrocytoma), and 5.1 months for patients with grade IV (glioblastoma) tumors. In the United States, the median survival of patients with high-grade brain tumors is approximately 12 months. In addition to histopathology, features that correlate with poor prognosis include age over 65 and a poor functional status, as defined by the Karnofsky performance scale (see Table 79-2).

Low-Grade Astrocytoma Low-grade astrocytomas are more common in children than adults. Pilocytic astrocytoma, named for its characteristic spindle-shaped cells, is the most common childhood brain tumor. It frequently occurs in the cerebellum. Typically, this tumor is cystic and well demarcated from adjacent brain. Complete surgical excision usually produces long-term, disease-free survival.

The optimal management of other low-grade astrocytomas, termed fibrillary astrocytomas, is controversial. For patients who are symptomatic from mass effect or

poorly controlled epilepsy, surgical excision can relieve symptoms. For patients who are asymptomatic or minimally symptomatic at presentation, a diagnostic biopsy should be performed and, when surgically feasible, the tumor may be resected. The indications for postoperative radiation therapy are uncertain. In many centers, when only a biopsy or partial resection is possible, postoperative external beam radiation therapy is administered, whereas it is not used if a gross total tumor resection can be achieved. Other centers reserve radiation therapy for tumor recurrence or progression, at which time the tumor may display a more malignant phenotype. No role for chemotherapy in the management of low-grade astrocytoma has been defined.

High-Grade Astrocytoma The large majority of astrocytomas arising in adults are high grade, supratentorial, and do not have a clearly defined margin. Neoplastic cells migrate away from the main tumor mass and infiltrate adjacent brain, often tracking along white matter pathways. Imaging studies do not indicate the full extent of the tumor. These tumors are eventually fatal, although prolonged survival occurs in a few patients. Longer survival correlates with younger age, better performance status, and greater extent of surgical resection. Late in their course, gliomas, especially those located in the posterior fossa, can metastasize alongCSFpathways to the spine. Metastases outside theCNS are rare.

High-grade astrocytomas are managed with glucocorticoids, surgery, radiation therapy, and chemotherapy. Dexamethasone is generally administered at the time of diagnosis and continued for the duration of radiation therapy. After completion of radiotherapy, the dose of dexamethasone is tapered to the lowest tolerated dose.

Because astrocytomas infiltrate adjacent normal brain, total surgical excision is not possible. Surgery is indicated to obtain tissue for pathologic diagnosis and to control mass effect. Moreover, retrospective studies indicate that the extent of tumor resection correlates with survival, at least in younger patients. Therefore, accessible astrocytomas are resected aggressively in patients younger than 65 years old who are in good general medical condition.

Postoperative radiation therapy prolongs survival and improves quality of life, although the duration of benefit is only a few months. Treated with dexamethasone alone following surgery, the mean survival of patients under 65 years of age with glioblastoma is 7 to 9 months. Survival is prolonged to 11 to 13 months with radiation therapy. Focal brain irradiation is less toxic and is as effective as whole-brain radiation for the treatment of primary glial tumors. Radiation is generally administered to the tumor mass, as defined by contrast enhancement on a CT orMRIscan, plus a 3- to 4-cm margin. A total dose of 5000 to 7000 cGy is administered in 25 to 35 equal fractions, 5 days per week.

The roles of stereotaxic radiosurgery and interstitial brachytherapy in glioma treatment are uncertain. *Stereotaxic radiosurgery* is the administration of a focused high dose of radiation to a precisely defined volume of tissue in a single treatment, usually using the gamma knife. Stereotaxic radiosurgery can potentially achieve tumor ablation without surgery. A major limitation of stereotaxic radiosurgery is that it can be used for only relatively small tumors, generally less than 3 cm in maximum diameter. *Interstitial brachytherapy*, the implantation of radioactive beads into the tumor mass, is generally

reserved for tumor recurrence because of its associated toxicity -- in particular, necrosis of adjacent brain tissue.

Chemotherapy is marginally effective and is often used as an adjuvant following surgery and radiation therapy. Nitrosoureas, including carmustine (BCNU) and lomustine (CCNU), are the most effective available agents. Since a typical glioma infiltrates normal brain where the blood-brain barrier is relatively intact, lipid-soluble agents such as the nitrosoureas, which cross the blood-brain barrier, may reach more malignant cells than water-soluble agents. Experimental approaches include intraarterial infusion of chemotherapy, the implantation of chemotherapy-releasing wafers or injection of chemotherapeutic agents into the tumor resection cavity, administration of chemotherapy after disruption of the blood-brain barrier, and intensive chemotherapy regimens supported by autologous bone marrow transplantation.

Gliomatosis cerebri is a rare form of astrocytoma in which there is diffuse infiltration of the brain by malignant astrocytes without a focal enhancing mass. It generally presents as a multifocalCNSsyndrome or a more generalized disorder including dementia, personality change, or seizures. Neuroimaging studies are often nonspecific, and biopsy is required to establish the diagnosis. Gliomatosis is treated with whole-brain radiation therapy and, in selected patients, with systemic chemotherapy.

OLIGODENDROGLIOMAS

Oligodendrogliomas have a more benign course and are more responsive to cytotoxic treatment than astrocytomas. Five-year survival is greater than 50%, and 10-year survival is 25 to 34%.

Oligodendrogliomas occur chiefly in supratentorial locations; in adults about 30% contain areas of calcification (Fig. 370-3). Many gliomas contain mixtures of cells with astrocytic and oligodendroglial features. If this mixed histology is prominent, the tumor is termed a *mixed glioma* or an *oligoastrocytoma*. The greater the oligodendroglial component, the more benign the clinical course. As a rule, oligodendrogliomas are less infiltrative than astrocytomas, permitting more complete surgical excision. The histologic features of mitoses, necrosis, and nuclear atypia are associated with a more aggressive clinical course. If these features are prominent, the tumor is termed an *anaplastic oligodendroglioma*.

The optimal management of oligodendrogliomas has not been defined. Surgery, at minimum a stereotaxic biopsy, is necessary to establish a diagnosis. Many oligodendrogliomas are amenable to gross total surgical resection. In addition, oligodendrogliomas may respond dramatically to systemic combination chemotherapy with procarbazine, lomustine and vincristine (PCV). Oligodendrogliomas with deletions of chromosomes 1p and 19q typically respond to PCV, but only about 25% of oligodendrogliomas lacking these genetic markers respond to chemotherapy. Chemotherapy may be used as the initial treatment, and residual tumor can be surgically excised or treated with stereotaxic radiosurgery. An alternative approach is to first excise the accessible tumor mass, then administer systemic chemotherapy and finally, employ stereotaxic radiosurgery or external beam radiation for residual tumor.

EPENDYMOMAS

In adults ependymomas are typically located in the spinal canal, especially in the lumbosacral region, arising from the filum terminale of the spinal cord. These tumors often have a myxopapillary histology, with a papillary arrangement of cells and mucin production. In children, ependymomas occur within the ventricles, most often the fourth ventricle, and may exhibit diagnostic ependymal rosettes. Ependymomas with histologic signs of malignancy, including cellular atypia, frequent mitotic figures, or a high labeling index, virtually always recur after surgical resection. Imaging withCT orMRIscans reveals ependymomas as uniformly enhancing masses that are relatively well demarcated from adjacent neural tissue. Ependymomas may metastasize viaCSFpathways: brain tumor metastases that spread to the spinal cord by this means are termed *drop metastases*.

Following the gross total excision of an ependymoma, the prognosis is excellent. The 5-year disease-free survival is >80%. However, many ependymomas cannot be totally excised, and postoperative focal external beam radiation or stereotaxic radiosurgery is used. Whether focal radiation is adequate or whether the entire neuraxis needs to be irradiated is not resolved.

GERMINOMAS

These tumors most commonly present during the second decade of life, generally at sites within or adjacent to the third ventricle including the pineal region. Germinomas are the most frequent variety of *germ cell tumor*, a tumor type arising in midline structures and including *teratoma*, yolk sac tumor (*endodermal sinus tumor*), *embryonal carcinoma*, and *choriocarcinoma*. Germinomas of theCNS may be benign but are more often aggressive and invasive. Due to their location, patients frequently present with hypothalamic-pituitary dysfunction including diabetes insipidus, visual field deficits, disturbances of memory or mood, or hydrocephalus (Chap. 328). Neuroimaging demonstrates germinomas to be uniformly enhancing masses with or without well-defined borders. The treatment of choice is complete surgical resection. For unresectable tumors, a stereotaxic biopsy is performed for diagnosis, and focal radiation is the primary therapy. When the extent of disease or very young age precludes radiotherapy as primary treatment, platinum-based chemotherapy may decrease tumor size and facilitate subsequent radiation therapy of residual disease or recurrent tumor. Prognosis depends on the histology and surgical resectability of the tumor. Germinomas are generally radiosensitive and chemosensitive, and 5-year survival is>85%.

MEDULLOBLASTOMAS AND PRIMITIVE NEUROECTODERMAL TUMORS (PNET)

These highly cellular malignant tumors are thought to arise from neural precursor cells. Medulloblastomas of the posterior fossa are the most frequent malignant brain tumor of children. If the tumor is not disseminated at presentation, the prognosis is generally favorable; subsets of pediatric patients have >70% survival rates at 5 years, although <50% of all children with medulloblastoma survive to adulthood. PNET is a term applied to tumors histologically indistinguishable from medulloblastoma but occurring either in adults or supratentorially in children. In adults,>50% present in the posterior fossa, but these tumors frequently disseminate alongCSFpathways.

If possible, these tumors should be surgically excised, although outcome is not related to the extent of surgery. In adults, surgical excision of aPNETshould be followed by chemotherapy and irradiation of the entire neuraxis, with a boost in radiation dose to the primary tumor. Aggressive treatment can result in prolonged survival, although half of adult patients relapse within 5 years of treatment.

CNSLYMPHOMA

Primary CNS Lymphoma These are B cell malignancies of intermediate to high grade that present within the neuraxis without evidence of systemic lymphoma. They occur most frequently in immunocompromised individuals, specifically organ transplant recipients or patients with AIDS (Chap. 309), but the incidence of primary CNS lymphoma is increasing in both immunocompetent and immunocompromised patients. In immunocompromised patients, CNS lymphomas are invariably associated with Epstein-Barr virus (EBV) infection of the tumor cells. Chromosomal translocations involving the c-*myc* gene occur in EBV-associated lymphomas outside the CNS (Chap. 112) but not in primary CNS lymphoma.

In immunocompetent patients, neuroimaging studies most often reveal a uniformly enhancing mass lesion. In immunocompromised patients, primaryCNSlymphoma is likely to be multicentric and exhibit ring enhancement or to arise in the meninges (Fig. 370-4). Stereotaxic needle biopsy can be used to establish the diagnosis. Leptomeningeal involvement is present in approximately 15% of patients at presentation and in 50% at some time during the course of the illness. Moreover, the disease extends to the eyes in up to 15% of patients. Therefore, a slit-lamp examination and, if indicated, anterior chamber paracentesis or vitreous biopsy is necessary before radiation therapy to define radiation ports.

The prognosis of primaryCNSlymphoma is poor compared to histologically similar lymphoma occurring outside the CNS. Many patients experience a favorable clinical and radiographic response to glucocorticoids that may be dramatic; however, it is invariably transient and relapse occurs within weeks. Radiotherapy has been the mainstay of treatment, but systemic combination chemotherapy including high-dose methotrexate is also effective. Intrathecal chemotherapy with methotrexate should also be used if leptomeningeal disease is present. Despite aggressive therapy,>90% of patients develop recurrent CNS disease. Historically, the survival of immunocompetent patients with CNS lymphoma has been approximately 18 months, and may now be longer with the use of systemic chemotherapy. In organ transplant recipients, reversal of the immunosuppressed state can improve outcome. Survival with AIDS-related primary CNS lymphoma is very poor, generally £3 months; pretreatment performance status, the degree of immunosuppression, and the extent of CNS dissemination at diagnosis all appear to influence outcome.

Secondary CNS Lymphoma Secondary CNS lymphoma almost always occurs in association with progressive systemic disease in adults with B cell lymphoma or B cell leukemia who have tumor involvement of bone, bone marrow, testes, or the cranial sinuses. Leptomeningeal lymphoma is usually detectable with contrast-enhancedCT or gadolinium-enhancedMRI of the brain and spine or byCSFexamination. Treatment

consists of systemic chemotherapy, intrathecal chemotherapy, and CNS irradiation. It is usually possible to effectively suppress the leptomeningeal disease, although the overall prognosis is determined by the course of the systemic lymphoma.

PITUITARY ADENOMAS SeeChap. 328.

MENINGIOMAS

Meningiomas are derived from mesoderm, probably from cells giving rise to the arachnoid granulations. These tumors are usually benign and attached to the dura. They may invade the skull but only infrequently invade the brain. Meningiomas most often occur along the sagittal sinus, over the cerebral convexities, in the cerebellar-pontine angle, and along the dorsum of the spinal cord. They are more frequent in women than men, with a peak incidence in middle age.

Meningiomas may be found incidentally on aCT orMRI scan or may present with a focal seizure, a slowly progressive focal deficit, or symptoms of raised intracranial pressure. The radiologic image of a dural-based, extra-axial mass with dense, uniform contrast enhancement is essentially diagnostic, although a dural metastasis must also be considered (Fig. 370-5). A meningioma may have a "dural tail," a streak of dural enhancement flanking the main tumor mass; however, this finding may be present with other dural tumors.

Total surgical resection of benign meningiomas is curative. If a total resection cannot be achieved, local external beam radiotherapy reduces the recurrence rate to <10%. For meningiomas that are not surgically accessible, targeted radiosurgery with the gamma knife or heavy particle radiation should be considered. Small asymptomatic meningiomas incidentally discovered in older patients can safely be followed radiologically; these tumors grow at an average rate of approximately 0.24 cm in diameter per year and only rarely become symptomatic.

Rare meningiomas invade the brain or have histologic evidence of malignancy such as nuclear pleomorphism and cellular atypia. A high mitotic index is also predictive of aggressive behavior. *Hemangiopericytoma*, although not strictly a meningioma, is a meningeal tumor with an especially aggressive behavior. Meningiomas with features of aggressiveness and hemangiopericytomas, even if totally excised by gross inspection, frequently recur and should receive postoperative radiotherapy. Chemotherapy has no proven benefit.

SCHWANNOMAS

These tumors are also called *neuromas*, *neurinomas*, or *neurolemmomas*. They arise from Schwann cells of nerve roots, most frequently in the eighth cranial nerve (vestibular schwannoma, formerly termed acoustic schwannoma). The fifth cranial nerve is the second most frequent site; however, schwannomas may arise from any cranial or spinal root except the optic and olfactory nerves, which are myelinated by oligodendroglia rather than Schwann cells. Neurofibromatosis (NF) type 2 (see below) strongly predisposes to vestibular schwannoma. Schwannomas of spinal nerve roots are also seen in these patients as well as patients with NF type 1.

Eighth nerve schwannomas typically arise from the vestibular division of the nerve. Because the vestibular system adapts to slow destruction of the eighth nerve, vestibular schwannomas characteristically present as progressive unilateral hearing loss rather than with dizziness or other vestibular symptoms. Unexplained unilateral hearing loss always merits evaluation, including audiometry and either brainstem auditory evoked potentials or anMRI scan (Chap. 29). As a vestibular schwannoma grows, it can compress the cerebellum, pons, or facial nerve, producing associated symptoms. With rare exceptions schwannomas are histologically and clinically benign. They appear as dense and uniformly enhancing neoplasms on MRI (Fig. 370-6). Vestibular schwannomas enlarge the internal auditory canal, an imaging feature that helps distinguish them from other cerebellopontine angle masses.

Whenever possible, schwannomas should be surgically excised. When the tumors are small, it is usually possible to preserve hearing in the involved ear. In the case of large tumors, the patient is usually deaf at presentation; nonetheless, surgery is indicated to prevent further compression of posterior fossa structures. Gamma knife treatment is also effective for schwannoma but is equivalent in cost and complication rate to surgery. Moreover, the long-term consequences of stereotaxic radiosurgery, including the possibility of secondary radiation-induced neoplasms, are unknown.

OTHER BENIGN BRAIN TUMORS

Epidermoid tumors are cystic tumors with proliferative epidermal cells at the periphery and more mature epidermal cells towards the center of the cyst. The mature cells desquamate into the liquid center of the cyst. Epidermoid tumors are thought to arise from embryonic epidermal rests within the cranium. They occur extraaxially near the midline, in the middle cranial fossa, the suprasellar region, or the cerebellopontine angle. Epidermoid cysts are well-demarcated lesions that are amenable to complete surgical excision. Postoperative radiation therapy is unnecessary.

Dermoid cysts are thought to arise from embryonic rests of skin tissue trapped within theCNSduring closure of the neural tube. The most frequent locations are in the midline supratentorially or at the cerebellopontine angle. Histologically, they are composed of all elements of the dermis, including epidermis, hair follicles, and sweat glands; they frequently calcify. Treatment is surgical excision.

Craniopharyngiomas are thought to arise from remnants of Rathke's pouch, the mesodermal structure from which the anterior pituitary gland is derived (Chap. 328). Craniopharyngiomas typically present as suprasellar masses. Histologically, craniopharyngiomas resemble epidermoid tumors; they are usually cystic, and in adults 80% are calcified. Because of their location, they may present as growth failure in children, endocrine dysfunction in adults, or visual loss in either age group. Treatment is surgical excision; postoperative external beam radiation or stereotaxic radiosurgery is added if total surgical removal cannot be achieved.

Colloid cysts are benign tumors of unknown cellular origin that occur within the third ventricle and can obstructCSFflow. *Rare benign primary brain tumors* include neurocytomas, subependymomas, and pleomorphic xanthoastrocytomas. Surgical

excision of these neoplasms is the primary treatment and can be curative.

NEUROCUTANEOUS SYNDROMES

This group of genetic disorders, also known as the *phakomatoses*, produces a variety of developmental abnormalities of skin along with an increased risk of nervous system tumors (Table 370-1). These disorders are inherited as autosomal dominant conditions with variable penetrance.

NEUROFIBROMATOSIS TYPE 1 (VON RECKLINGHAUSEN'S DISEASE) (FIG. 370-CD1)

NF1 is characterized by cutaneous *neurofibromas*, pigmented lesions of the skin called *cafe au lait spots*, freckling in non-sun exposed areas such as the axilla, hamartomas of the iris termed Lisch nodules, and pseudoarthrosis of the tibia. Neurofibromas are benign peripheral nerve tumors composed of proliferating Schwann cells and fibroblasts. They present as multiple, palpable, rubbery, cutaneous tumors. They are generally asymptomatic; however, if they grow in an enclosed space, e.g., the intervertebral foramen, they may produce a compressive radiculopathy or neuropathy. Aqueductal stenosis with hydrocephalus, scoliosis, short stature, hypertension, epilepsy, and mental retardation may also occur.

Mutation of the *NF1* gene on chromosome 17 causes von Recklinghausen's disease. The *NF1* gene is a tumor suppressor gene; it encodes a protein, *neurofibromin*, which modulates signal transduction through the *ras* GTPase pathway. Patients with NF1 are at increased risk of developing nervous system neoplasms, including plexiform neurofibromas, optic gliomas, ependymomas, meningiomas, astrocytomas, and pheochromocytomas. Neurofibromas may undergo secondary malignant degeneration and become sarcomas.

NEUROFIBROMATOSIS TYPE 2

NF2 is characterized by the development of bilateral vestibular schwannomas in >90% of individuals who inherit the gene. Patients with NF2 also have a predisposition for the development of meningiomas, gliomas, and schwannomas of cranial and spinal nerves. In addition, a characteristic type of cataract, juvenile posterior subcapsular lenticular opacity, occurs in NF2. Multiple cafe au lait spots and peripheral neurofibromas occur rarely.

In patients with NF2, vestibular schwannomas usually present with progressive unilateral deafness early in the third decade of life. Bilateral vestibular schwannomas are generally detectable by MRIat that time (Fig. 370-6). Surgical management, designed to treat the underlying tumor and preserve hearing as long as possible, is difficult.

The *NF2* gene on chromosome 22q codes for a protein called *neurofibromin 2*, *schwannomin*, or *merlin*, with homology to a family of cytoskeletal proteins that includes moesin, ezrin, and radixin.

TUBEROUS SCLEROSIS (BOURNEVILLE'S DISEASE)

Tuberous sclerosis is characterized by cutaneous lesions, seizures, and mental retardation. The cutaneous lesions include adenoma sebaceum (facial angiofibromas, Fig. 370-CD2), ash leaf-shaped hypopigmented macules (best seen under ultraviolet illumination with a Wood's lamp) (Fig. 370-CD3), shagreen patches (yellowish thickenings of the skin over the lumbosacral region of the back), and depigmented nevi. On neuroimaging studies, the presence of subependymal nodules, which may be calcified, is characteristic. Patients inheriting the tuberous sclerosis gene are at increased risk of developing ependymomas and childhood astrocytomas, of which >90% are *subependymal giant cell astrocytomas*. These are benign neoplasms that may develop in the retina or along the border of the lateral ventricles. They may obstruct the foramen of Monro and produce hydrocephalus. Rhabdomyomas of the myocardium and angiomyomas of the kidney, liver, adrenals, and pancreas may also occur.

Treatment is symptomatic. Anticonvulsants for seizures, shunting for hydrocephalus, and behavioral and educational strategies for mental retardation are the mainstays of management. Severely affected individuals generally die before age 30.

Mutations at both 9q(TSC-1) and 16p(TSC-2) are associated with tuberous sclerosis. The mutated genes code for *tuberins*, proteins that modulate the GTPase activity of other cellular proteins.

VON HIPPEL-LINDAU SYNDROME

This syndrome consists of retinal, cerebellar, and spinal hemangioblastomas, which are slowly growing cystic tumors. Hypernephroma, renal cell carcinoma, pheochromocytoma, and cysts of the kidneys, pancreas, epididymis, or liver may also occur. Erythropoietin production by hemangioblastomas may result in polycythemia. The von Hippel-Lindau (VHL) tumor suppressor gene on chromosome 3p encodes a protein that appears to suppress transcription elongation by RNA polymerase II.

TUMORS METASTATIC TO BRAIN

MECHANISMS OF BRAIN METASTASES

The large majority of brain metastases disseminate by hematogenous spread. The anatomic distribution of brain metastases generally parallels regional cerebral blood flow, with a predilection for the gray matter-white matter junction and for the border zone between middle cerebral and posterior cerebral artery distributions. The lung is the most common origin of brain metastases; both primary lung cancer and cancers metastatic to the lung can metastasize to the brain. Breast cancer has a propensity to metastasize to the cerebellum and the posterior pituitary gland. This propensity could be explained by patterns of retrograde venous flow from the thorax into the skull or by an especially hospitable environment for breast cancer cells provided by the cerebellum and pituitary (the "seed and soil" hypothesis).

Lung cancer (adenocarcinoma and small cell lung cancer), breast cancer (especially ductal carcinoma), gastrointestinal malignancies, and melanoma are common tumors

that metastasize to brain (Table 370-2). Certain less common tumors have a special propensity to metastasize to brain, including germ cell tumors and thyroid cancer. By contrast, prostate cancer, ovarian cancer, and Hodgkin's disease rarely metastasize to the brain. Moreover, breast cancer that metastasizes to bone tends not to metastasize to the brain. Therefore, the cellular environment of the brain is hospitable to only a subset of systemic cancers. Parenchymal spinal cord metastases are rare.

EVALUATION OF METASTASES FROM KNOWN CANCER

OnMRIscans brain metastases typically appear as well-demarcated, approximately spherical lesions that are hypointense or isointense relative to brain on T1-weighted images and bright on T2-weighted images. They invariably enhance with gadolinium, reflecting extravasation of gadolinium through tumor vessels that lack a blood-tumor barrier (Fig. 370-7). Small metastases often enhance uniformly. Larger metastases typically produce ring enhancement surrounding a central mass of nonenhancing necrotic tissue that develops as the metastasis outgrows its blood supply. Metastases are surrounded by variable amounts of edema. Blood products may also be seen, reflecting hemorrhage of abnormal tumor vessels.

The radiologic appearance of a brain metastasis is not specific. The differential diagnosis of ring-enhancement lesions includes brain abscess, radiation necrosis, toxoplasmosis, granulomas (tuberculosis, sarcoidosis), demyelinating lesions, primary brain tumors, primaryCNSlymphoma, stroke, hemorrhage, and trauma. Contrast-enhanced CT scanning is less sensitive thanMRI for the detection of brain metastases. Cytologic examination of theCSF is not indicated, since intraparenchymal brain metastases almost never shed cells into CSF. Measuring CSF levels of tumor markers such as carcinoembryonic antigen (CEA) is rarely helpful in management.

BRAIN METASTASES WITHOUT A KNOWN PRIMARY TUMOR

In general hospital populations, up to one-third of patients presenting with brain metastases do not have a known underlying cancer. These patients generally present with either a seizure or a progressive neurologic deficit. Neuroimaging studies demonstrate one or multiple ring-enhancement lesions. In individuals who are not immunocompromised and not at risk for brain abscesses, this radiologic pattern is most likely due to brain metastasis.

Diagnostic evaluation begins with a search for the primary tumor. Blood tests should includeCEA and liver function tests. A careful examination of the skin for melanoma and the thyroid gland for masses should be carried out. ACT scan of the chest, abdomen, and pelvis should be obtained. If these are all negative, further imaging studies, including bone scan, other radionuclide scans, and upper and lower gastrointestinal barium studies, are unlikely to be productive. The search for a primary cancer most often discloses lung cancer, particularly small cell lung cancer, or melanoma. In 30% of patients no primary tumor can be identified even after extensive evaluation.

A tissue diagnosis is essential. If a primary tumor is found, it will usually be more accessible to biopsy than a brain lesion. If a single brain lesion is found in a surgically accessible location, if a primary tumor is not found, or if the primary tumor is in a

location difficult to biopsy, the brain metastasis should be biopsied or resected.

TREATMENT

Once a systemic cancer metastasizes to the brain it is, with rare exception, incurable. Therapy is therefore palliative, designed to prevent disability and suffering and, if possible, to prolong life. Published outcome studies have focused on survival as the primary end point, leaving questions regarding quality of life unanswered. There is, however, widespread agreement that glucocorticoids, anticonvulsants, and radiation therapy improve the quality of life for many patients. The roles of surgery and chemotherapy are less well established.

General Measures High-dose glucocorticoids frequently ameliorate symptoms of brain metastases. Improvement is often dramatic, occurs within 6 to 24 h, and is sustained with continued administration, although the toxicity of glucocorticoids is cumulative. Therefore, if possible, a more definitive therapy for metastases should be instituted to permit withdrawal of glucocorticoid therapy. One-third of patients with brain metastases have one or more seizures. Anticonvulsants are empirically used for seizure prophylaxis when supratentorial metastases are present.

Specific Measures

Radiation Therapy Radiation is the primary treatment for brain metastases. Since multiple microscopic deposits of tumor cells throughout the brain are likely to be present in addition to metastases visualized by neuroimaging studies, whole-brain irradiation is usually used. Its benefit has been established in controlled studies, but no clear dose response has been shown. Usually, 30-37.5 Gy is administered in 10 to 15 fractions; an additional dose ("boost") of focal irradiation to a single or large metastasis may also be administered.

Surgery Up to 40% of patients with brain metastases have only a single tumor mass identified byCT. Accessible single metastases are usually surgically excised as a palliative measure. If the systemic disease is under control, total resection of a single brain lesion has been demonstrated to improve survival and minimize disability. Survival appears to be improved if surgery is followed by whole-brain irradiation.

Chemotherapy Brain metastases of certain tumors, including breast cancer, small cell lung cancer, and germ cell tumors, are often responsive to systemic chemotherapy. Although metastases frequently do not respond as well as the primary tumor, dramatic responses to systemic chemotherapy or hormonal therapy may occur in some cases. In patients who are neurologically stable, two to four cycles of systemic chemotherapy may be administered initially to reduce tumor mass and render the residual tumor more amenable to radiation therapy. Even if a complete radiologic remission is achieved from chemotherapy, whole-brain irradiation should then be administered.

Experimental Therapies These include stereotaxic radiosurgery, gene therapy, immunotherapy, intraarterial chemotherapy, and chemotherapy administered following osmotic disruption of the blood-brain barrier.

LEPTOMENINGEAL METASTASES

Leptomeningeal metastases are also called *carcinomatous meningitis*, *meningeal carcinomatosis*, and, in the cases of specific tumors, *leukemic meningitis* or *lymphomatous meningitis*. Clinical evidence of leptomeningeal metastases is present in 8% of patients with metastatic solid tumors; at necropsy, the prevalence is as high as 19%. Among solid tumors, adenocarcinomas of the breast and lung and melanoma are most often responsible (Table 370-2). In one-quarter of patients the systemic cancer is under control; thus effective control of leptomeningeal disease can improve the quality and duration of life.

Pathologically, three patterns of tumor involvement may be seen: (1) a diffuse coating of the leptomeninges by a thin layer of tumor cells, (2) nodular growth of macroscopic tumor metastases in meninges and on nerve roots, or (3) plaque-like metastases in the leptomeninges with many cells shed into the subarachnoid space and extension of tumor into Virchow-Robin spaces. Leptomeningeal metastases may coexist with parenchymalCNSmetastases.

Cancer usually metastasizes to the meninges via the bloodstream. Alternatively, a superficially located parenchymal metastasis may shed cells directly into the subarachnoid space. Some tumors, including squamous cell carcinoma of the skin and some non-Hodgkin's lymphomas, have a propensity to grow along peripheral nerves and may seed the meninges by that route.

CLINICAL FEATURES

Leptomeningeal metastases present with signs and symptoms at multiple levels of the nervous system, most often in a setting of known systemic malignancy. Encephalopathy is frequent, and cranial neuropathy or spinal radiculopathy from nodular nerve root compression is characteristic. Hydrocephalus results from obstruction ofCSFoutflow in the posterior fossa. Focal neurologic deficits from coexisting intraparenchymal metastases may occur.

LABORATORY EVALUATION

Leptomeningeal metastases are diagnosed by cytologic demonstration of malignant cells in theCSF, byMRIdemonstration of nodular tumor deposits in the meninges or diffuse meningeal enhancement (Fig. 370-8), or by meningeal biopsy. CSF findings are usually those of an inflammatory meningitis, consisting of lymphocytic pleocytosis, elevated protein levels, and normal or low CSF glucose. A complete MRI examination of the neuraxis may demonstrate hydrocephalus due to obstruction of CSF pathways and identify nodular meningeal metastases.

TREATMENT

In selected patients, intrathecal chemotherapy and focal external beam radiotherapy to sites of leptomeningeal disease are the mainstays of management. Although the prognosis of leptomeningeal metastases is poor, approximately 20% of patients aggressively treated for leptomeningeal metastases can expect a sustained response of

approximately 6 months. Intrathecal therapy exposes meningeal tumor to high concentrations of chemotherapy with minimal systemic toxicity. Methotrexate can be safely administered intrathecally and is effective against leptomeningeal metastases from a variety of solid tumors and lymphoma; ara-C and thio-TEPA are alternative agents. Intrathecal chemotherapy may be administered either by repeated lumbar puncture or through an indwelling Ommaya reservoir, which consists of a catheter in one lateral ventricle attached to a reservoir implanted under the scalp. If there is a question of patency ofCSFpathways, a radionuclide flow study may be performed.

Large deposits of tumor on the meninges or along nerve roots are unlikely to respond to intrathecal chemotherapy, as the barrier to diffusion is too great. Therefore, external beam radiation is employed. Hydrocephalus is treated with a ventriculoperitoneal shunt, although seeding of the peritoneum by tumor is a risk.

MALIGNANT SPINAL CORD COMPRESSION

Spinal cord compression from solid tumor metastases usually results from expansion of a vertebral metastasis into the epidural space. Primary tumors that frequently metastasize to bone include lung, breast, and prostate cancer. Back pain is usually the first symptom and is prominent at presentation in 90% of patients. The pain is typically dull, aching, and may be associated with localized tenderness. If a nerve root is compressed, radicular pain is also present. The neurologic signs that accompany spinal cord compression are determined by the spinal level of the lesion; the thoracic cord is most often affected. Weakness, sensory loss, and autonomic dysfunction (urinary urgency and incontinence, fecal incontinence, and sexual impotence in men) are the hallmarks of spinal cord compression. Once signs of spinal cord compression appear, they tend to progress rapidly. It is thus essential to recognize and treat this devastating complication of malignancy at the earliest possible time in order to prevent irreversible neurologic deficits.**Diagnosis and management are discussed in Chap. 368.*

METASTASES TO THE PERIPHERAL NERVOUS SYSTEM

Systemic cancer may compress or invade peripheral nerves. Compression of the brachial plexus may occur by direct extension of Pancoast's tumors (cancer of the apex of the lung) or by extension of local lymph node metastases of breast or lung cancer or lymphoma. The lumbosacral plexus may be compressed by the retroperitoneal spread of prostate or ovarian cancer or lymphoma. Skull metastases may compress cranial nerve branches as they pass through the skull, and pituitary metastases may extend into the cavernous sinus. The epineurium generally provides an effective barrier to invasion of the peripheral nerves by solid tumors, but certain tumors characteristically invade and spread along peripheral nerves. Squamous cell carcinoma of the skin may spread along branches of the trigeminal nerve and extend intracranially. Non-Hodgkin's lymphoma may be neurotrophic and cause a syndrome resembling mononeuropathy multiplex. Focal external beam radiation may reduce pain, prevent irreversible loss of peripheral nerve function, and possibly restore function.

In patients with cancer who have brachial or lumbosacral plexopathy, it may be difficult to distinguish tumor invasion from radiation injury. High radiation dose or the presence of myokymia (rippling contractions of muscle) suggests radiation injury, whereas pain

suggests tumor. Radiographic imaging studies may be equivocal, and surgical exploration is sometimes required.

COMPLICATIONS OF THERAPY

RADIATION TOXICITY

The nervous system is vulnerable to delayed injury by therapeutic radiation. The mechanism of injury is unknown, but radiation-induced free radical production is probably contributory. Histologically, there is demyelination, hyaline degeneration of small arterioles, and eventually brain infarction and necrosis. However, radiation injury can occur without vasculopathy, suggesting that ischemia is a late manifestation and does not account entirely for the tissue damage.

Radiation injury to the brain is classified by the time of its occurrence. *Acute radiation injury* occurs during or immediately after therapy. It is rarely seen with current protocols of external beam radiation but may occur after stereotaxic radiosurgery. Manifestations include headache, sleepiness, and worsening of preexisting neurologic deficits. *Early delayed radiation injury* occurs within 4 months of therapy. It is associated with an increased white matter T2 signal onMRIscans. In children, the *somnolence syndrome* is a common form of early delayed radiation injury in which somnolence and ataxia develop after whole-brain irradiation. Irradiation of the cervical spine may cause Lhermitte's phenomenon, an electricity-like sensation evoked by neck flexion (Chap. 368). Acute and early delayed radiation injury are steroid-responsive and self-limited disorders and do not appear to increase the risk of late radiation injury.

Late delayed radiation injury produces permanent damage to the nervous system. It occurs more than 4 months (generally 8 to 24 months) after completion of therapy; onset 15 years after therapy has been described. After whole-brain irradiation, progressive dementia can occur, sometimes accompanied by gait apraxia. White matter signal abnormalities are present onMRIstudies (Fig. 370-9). Following focal brain irradiation, radiation necrosis occurs within the radiation field, producing a contrast-enhanced mass, frequently with ring enhancement. MRI orCT scans are often unable to distinguish radiation necrosis from recurrent tumor, butPET orSPECTscans may demonstrate that glucose metabolism is increased in tumor tissue but decreased in radiation necrosis. Biopsy is frequently required to establish the correct diagnosis. Peripheral nerves, including the brachial and lumbosacral plexuses, may also develop late delayed radiation injury over a time span similar to that observed in theCNS.

If untreated, radiation necrosis of theCNS may act as an expanding mass lesion, although it may resolve spontaneously or after steroid treatment. Progressive radiation necrosis is best treated with surgical resection if the patient has a life expectancy of at least 6 months and a good Karnofsky performance score. There are anecdotal reports that anticoagulation with heparin or coumadin may be beneficial. Radiation injury also accelerates the development of atherosclerosis in large arteries, but an increase in the risk of stroke becomes significant only years after radiation treatment.

Endocrine dysfunction frequently follows exposure of the hypothalamus or pituitary gland to therapeutic radiation. Growth hormone is the pituitary hormone most sensitive

to radiation therapy, and thyroid-stimulating hormone is the least sensitive; ACTH, prolactin, and the gonadotropins have an intermediate sensitivity.

Development of a second neoplasm is another risk of therapeutic radiation that generally occurs many years after radiation exposure. Depending on the irradiated field, the risk of gliomas, meningiomas, sarcomas, and thyroid cancer is increased.

COMPLICATIONS OF CHEMOTHERAPY

Chemotherapy regimens used to treat primary brain tumors have generally included a nitrosourea and are well tolerated. Infrequently, nitrosoureas and other drugs used to treatCNSneoplasms cause altered mental states (e.g., confusion, depression), ataxia, and seizures. Chemotherapy for systemic malignancy is a more frequent cause of nervous system toxicity. Cisplatin commonly produces tinnitus and high-frequency bilateral hearing loss, especially in younger patients. At cumulative doses>450 mg/m_2, cisplatin can produce a symmetric, large fiber axonal predominantly sensory neuropathy; paclitaxel (Taxol) produces a similar picture. Fluorouracil and high-dose cytosine arabinoside can cause cerebellar dysfunction that resolves after discontinuation of therapy. Vincristine, which is commonly used to treat lymphoma, may cause an acute ileus and is frequently associated with development of a progressive distal, symmetric sensory-motor neuropathy with foot drop and paresthesias.

371. MULTIPLE SCLEROSIS AND OTHER DEMYELINATING DISEASES - *Stephen L. Hauser*, *Donald E. Goodkin*

The demyelinating diseases occupy a unique place in neurology owing to their frequency; tendency to strike young adults; diversity of manifestations; and range of fundamental questions in neurobiology, immunology, virology, and genetics that arise regarding their pathogenesis. These disorders share features of inflammation and selective destruction of central nervous system (CNS) myelin; the peripheral nervous system (PNS) is spared. No specific tests for the demyelinating diseases exist, and diagnosis is based on recognition of the distinctive clinical patterns of CNS injury they produce.

MULTIPLE SCLEROSIS

Multiple sclerosis (MS) is characterized by (1) a relapsing-remitting or progressive course and (2) a pathologic triad ofCNSinflammation, demyelination, and gliosis (scarring). Lesions of MS are classically said to be *disseminated* in time and space. MS affects approximately 350,000 Americans and 1.1 million individuals worldwide. In Western societies, MS is second only to trauma as a cause of neurologic disability arising in early to middle adulthood. Current evidence indicates that MS is an autoimmune disease that develops in genetically susceptible individuals who have resided in certain permissive environments. Manifestations of MS vary from a benign illness to a rapidly evolving and incapacitating disease requiring profound adjustments in life-style and goals for patients and their families. Complications from MS affect multiple body systems; hence, a multidisciplinary approach is recommended to optimize clinical care.

PATHOGENESIS

AnatomyMSderives its name from the multiple scarred areas visible on macroscopic examination of the brain. These lesions, termed *plaques*, are sharply demarcated gray or pink areas easily distinguished from surrounding white matter. Plaques vary in size from 1 or 2 mm to several centimeters. The acute MS lesion, rarely found at autopsy, consists of perivenular cuffing by inflammatory mononuclear cells, predominantly T lymphocytes and macrophages, which also infiltrate white matter tissue and appear to orchestrate demyelination. At sites of inflammation, the blood-brain barrier is disrupted but the vessel wall itself is preserved, distinguishing the MS lesion from vasculitis. In some inflammatory lesions, a distinctive pattern of myelin damage, termed *vesicular demyelination*, can be appreciated. This change consists of dissolution of the multilamellated compact myelin sheaths that surround axon cylinders and their reconstitution as a lattice-like network of myelin membrane fragments. Myelin-specific autoantibodies (see "Immunology," below) are bound to the vesiculated myelin membranes, at least in some patients; these autoantibodies are thought to promote demyelination and stimulate macrophages and microglial cells (specializedCNSphagocytes of bone marrow origin) that scavenge the myelin debris. As lesions evolve, astrocytes proliferate extensively (gliosis). Oligodendrocytes, the myelin-producing cells, also proliferate initially in most MS lesions, but these cells are often destroyed as the infiltration and gliosis progress. Surviving oligodendrocytes or those that newly differentiate from a precurser pool may partially remyelinate naked

axons, resulting in *shadow plaques*. MS lesions may enlarge by gradual concentric outward growth; some chronic plaques display histologic gradations of increasing acuity from the center to the lesion edge.

The correspondence between number and size of plaques ("plaque burden") and the severity of clinical symptoms is imprecise. Hence, an extensive plaque burden may be associated with mild symptoms; or, conversely, seemingly minor pathologic changes may be present in some severely disabled individuals. Occasional cases either are clinically silent or produce "nonspecific" isolated symptoms such as facial pain, and evidence ofMS is found unexpectedly at autopsy.

Recent ultrastructural studies ofMSlesions suggest that different underlying pathologies may be present in different patients. Heterogeneity has been identified both in terms of the fate (i.e., death or survival) of oligodendrocytes in plaques and by the presence or absence of antibody and complement deposition. In primary progressive MS (PPMS; see below), a distinctive oligodendroglial cytopathy has been reported based on examination of a limited number of cases; if confirmed, this finding would suggest that PPMS is a unique disorder. Finally, although selective demyelination with sparing of axon cylinders is the hallmark of MS, partial or total axonal destruction, and in extreme cases cavitation, may also occur. The extent of axonal loss appears to correlate with irreversible neurologic disability. Axonal loss and cavitation are particularly prominent in the subtype of MS known as neuromyelitis optica or Devic's syndrome (see below).

Physiology Demyelination may have either negative or positive effects on axonal conduction. *Negative conduction abnormalities* consist of slowed axonal conduction, variable conduction block that occurs in the presence of high- but not low-frequency volleys of impulses, or complete conduction block. Conduction block in demyelinated fibers may also occur in response to raised temperature or metabolic derangements. The mechanism of conduction block appears to involve a hyperpolarization of the resting axon potential due to the exposure of voltage-dependent potassium channels that are normally buried underneath the myelin sheath. *Positive conduction abnormalities* include generation of ectopic impulses, spontaneously or after mechanical deformation, and abnormal "crosstalk" between demyelinated axons. Variable conduction block may explain the fluctuations in function that vary from hour to hour and from day to day in many patients and the characteristic worsening that is associated with fever or exercise. Ectopic impulse generation or "crosstalk" might give rise to Lhermitte's symptom, paroxysmal symptoms, or paresthesias (see below). Experimental therapies designed to alleviate conduction abnormalities inMS have included the use of calcium channel blockers to reduce the threshold for impulse generation and pharmacologic blockade (with 4-aminopyridine) of potassium channels.

Epidemiology MS is approximately twice as common in females as in males. In both sexes, the incidence rises steadily from adolescence to age 35 and declines gradually thereafter. The mean age of onset is slightly later in men than in women, due in part to a relative overrepresentation of males inPPMS, which has a later mean age of onset. MS beginning as early as age two years or as late as the eighth decade of life is rare but well documented. Various epidemiologic observations, summarized below, support of the role of an environmental exposure of some type in MS.

Location and Risk MS is primarily a disease of individuals living in temperate climates. The prevalence increases with increasing distance from the equator; this finding appears to be true in both the northern and southern hemispheres. Prevalence rates and north-south gradients are generally similar in North America and Europe. The highest known prevalence (250 per 100,000) occurs in the Orkney islands, located north of the mainland of Scotland, and MS is also common throughout Scandinavia and northern Europe. Numerous studies also suggest that location influences MS risk. For example, the prevalence of MS is low in Japan (2 per 100,000) but moderate (15 per 100,000) in Japanese Americans.

Changes in prevalence Studies from the United States, Europe, and Australia suggest that the prevalence ofMS may have increased during the twentieth century, however these findings could represent an artifact due to improved detection of cases in the modern era.

Reported clusters Several possible point epidemics ofMS have been described, the most convincing of which occurred in the Faeroe Islands off the coast of Denmark after the British occupation during World War II.

GENETIC CONSIDERATIONS

An inherent genetic susceptibility to MS exists, as summarized by the following observations:

Risk in Different Ethnic Groups The prevalence ofMSdiffers among ethnic groups that reside in the same environment. In the United States, the prevalence of MS is higher in Caucasians than in other racial groups, consistent with observations in other parts of the world.

Familial Aggregation First-, second-, and third-degree relatives of patients withMS are at increased risk for the disease. Siblings of affected individuals have a lifetime risk of ~5%, whereas the risk to parents or children of affected individuals is somewhat lower. Studies of adoptees, half-siblings, and spouses of patients with MS strongly indicate that familial aggregation is primarily determined by shared genetic, and not environmental, factors.

Twin Studies The most compelling evidence for a genetic effect onMS is derived from twin studies, which demonstrate concordance rates of ~30% in monozygotic twins and 5% in dizygotic twins (similar to the risk in nontwin siblings).

The inheritance of MS cannot be explained with a simple genetic model. A single-gene hypothesis is at odds with concordance estimates in twin and family studies and with the observed nonlinear decrease in disease risk as the genetic distance from the MS proband is increased. It is likely that susceptibility is determined by multiple independent genetic loci (polygenic inheritance), each with a relatively small contribution to the overall risk. It is also possible that different genetic causes of susceptibility to MS (genetic heterogeneity) may exist. Linkage and association studies have identified the major histocompatibility complex (MHC) on chromosome 6 as one genetic determinant for MS. This complex encodes the histocompatibility antigens (the HLA system) that

present peptide antigens to T cells. The class II (HLA-D) region of the MHC is most strongly associated with MS, and susceptibility appears to result from the presence of the DR2 allele and its corresponding haplotype, defined by molecular criteria as DRB1*1501, DQA1*0102, DQB1*0602. Other genetic regions implicated in MS susceptibility include loci on chromosomes 3, 5, 16, and 19.

Immunology MSappears to be an autoimmune disease mediated, at least in part, by T lymphocytes. Evidence in support of this concept is derived from analogy to the laboratory model experimental allergic encephalomyelitis (EAE) and from direct studies of the immune system of MS patients.

Autoreactive T Lymphocytes Myelin basic protein (MBP) is an important T cell antigen inEAE and probably also in humanMS. In patients with MS but not in unaffected individuals activated MBP-reactive T cells can be identified in the peripheral blood. In cerebrospinal fluid (CSF), the frequency of T cells reactive against MBP (and other myelin proteins) is also higher in patients with MS than in unaffected individuals. Direct evidence that MBP-reactive T cells are present in MS lesions has also been suggested by sequence analysis of the antigen-binding domain of T cell receptor molecules cloned from plaque tissue. The susceptibility gene DR2 may influence the immune response to MBP because it binds with high affinity to a fragment of MBP spanning amino acids 89 to 101; this region of MBP appears to be immunodominant for T cell responses in DR2-positive individuals.

Autoantibodies Increasing evidence suggests that autoantibodies play some role inMS, probably acting in concert with a pathogenic T cell response. InEAE, autoantibodies directed against myelin oligodendrocyte glycoprotein (MOG), a quantitatively minor myelin protein, were found to mediate MS-like demyelinating lesions; and recently anti-MOG antibodies were also detected in actively demyelinating MS lesions. MOG is thus a good candidate as a humoral autoantigen in MS. Evidence of an abnormal humoral immune response is present in theCSF of patients with MS. Membrane attack complexes can be detected in the CSF, suggesting a role for complement-mediated antibody damage. Elevated levels of immunoglobulin are easily measured and are characteristic of CSF in MS. Oligoclonal antibody -- derived from expansion of a small number of different molecules -- is also present in most cases. Oligoclonal immunoglobulin is also detected in other chronic inflammatory responses, including infections, and thus is not specific to MS. It is synthesized locally, and the specific pattern is unique to each patient. Attempts to identify an antigen against which most oligoclonal immunoglobulin is directed have been unsuccessful.

Cytokines Numerous cytokines and chemokines have been detected in brain,CSF, and peripheral blood of patients with MS, and it is probable that these molecules regulate many of the cellular interactions that operate in this disease (Chap. 305). By analogy toEAETH1 cytokines that regulate cellular immunity, including interleukin (IL) 2, tumor necrosis factor (TNF) a, and interferon (IFN)g have traditionally been thought to be central to MS pathogenesis. TNF-a or IFN-gmay contribute directly to tissue damage by injuring oligodendrocytes or the myelin membrane. Unfortunately, treatment strategies designed to blunt the TH1 response have thus far not been successful in treating MS. Furthermore, a recent clinical trial with a humanized antibody to TNF-aappeared to worsen MS. The identification of autoantibodies in MS suggests that TH2 cytokines

(including IL-4, IL-5, and IL-10) may play a pathogenic role in MS, and may explain why the results of T_H1-based approaches have been disappointing.

Triggers Magnetic resonance imaging (MRI) scans indicate that many patients with relapsing forms of MShave bursts of multifocal inflammation that occur approximately monthly, or 7 to 10 times more frequently than clinical attacks. This finding suggests the presence of a large reservoir of subclinical disease in MS. Bursts appear to be associated with the migration of activated T cells from the peripheral blood across the blood-brain barrier and into brain; the triggers responsible for these bursts are not known. Patients may experience relapses after nonspecific upper respiratory infections, suggesting that molecular mimicry between viruses and myelin antigens may trigger attacks, or that some viruses may function as superantigens capable of activating disease-inducing T cells in MS (Chap. 305).

Microbiology As noted above, epidemiologic evidence supports the role of an environmental exposure inMS. MS risk also correlates with high socioeconomic status, which may reflect improved sanitation and delayed initial exposures to infectious agents. Some viruses, e.g., poliomyelitis and measles viruses, produce neurologic sequelae more frequently when the age of initial infection is delayed. The most widely studied experimental model of virus-induced demyelinating disease is infection with Theiler virus, a murine coronavirus similar to measles virus and canine distemper virus. Infection with some Theiler strains produces a chronic infection of oligodendrocytes with multifocal perivascular lymphocytic infiltration and demyelination, closely resembling lesions of MS.

In patients withMS, high antibody titers have been reported in serum andCSFagainst many viruses, including measles, herpes simplex, varicella, rubella, Epstein-Barr, and influenza C and some parainfluenza strains. Furthermore, numerous viruses and bacteria (or their genomic sequences) have been recovered from MS tissues and fluids. The most recent claims have involved human herpes virus type 6 (HHV-6) and chlamydia pneumoniae. A causal role for any infectious agent in MS remains unproven.

CLINICAL MANIFESTATIONS

The onset ofMS may be abrupt or insidious. Symptoms may be severe or seem so trivial that a patient may not seek medical attention for months or years. Initial symptoms are commonly one or more of the following: weakness or diminished dexterity in one or more limbs, a disturbance of gait, optic neuritis, sensory disturbance, diplopia, and ataxia (Table 371-1).

Weakness of the limbs may manifest as fatigue, disturbance of gait, or loss of dexterity. Initially, weakness may be detected only after physical exertion. Weakness is frequently accompanied by pyramidal signs including increased motor tone (spasticity), hyperreflexia, an extensor plantar response, and an absent superficial abdominal reflex. Occasionally, a tendon reflex may be lost (simulating a peripheral nerve lesion) if afferent fibers of the motor reflex arc are disrupted by a lesion in the dorsal root entry zone.

Optic neuritis generally presents as diminished acuity, dimness, or color desaturation in

the central field of vision. These symptoms may be mild or progress over hours or days to severe visual loss, or rarely to complete loss of light perception. Visual symptoms are generally monocular but may occur bilaterally. Periorbital pain frequently precedes or accompanies diminished visual acuity and may be aggravated by eye movement. An afferent pupillary response (Fig. 28-2) may be detected by a swinging flashlight test. Funduscopic examination may be normal or reveal swelling of the optic disc (papillitis). Venous sheathing of retinal vessels, due to the transendothelial migration of lymphocytes, is occasionally present. Pallor of the optic disc (optic atrophy) commonly follows an episode of optic neuritis. Uveitis occurs rarely.

Visual blurring inMS may result from optic neuritis or diplopia. These two causes are distinguished by asking the patient to cover each eye sequentially and observing whether the visual difficulty clears. *Diplopia* may result from an internuclear ophthalmoplegia (INO) or extraocular muscle weakness of the sixth (or rarely the third or fourth) cranial nerves. An INO consists of impaired or slowed adduction of one eye from a lesion in the ipsilateral medial longitudinal fasciculus. This tract connects the sixth cranial nerve nucleus with the contralateral third nerve nucleus. Prominent nystagmus is often observed in the abducting eye, along with a small skew deviation. An INO can resemble an isolated medial rectus palsy. Convergence is often preserved in INO, helping to differentiate between these two entities. The finding of bilateral INO is highly suggestive of MS. Other common gaze disturbances in MS include a horizontal gaze palsy due to an ipsilateral lesion in the abducens nucleus or the paramediam pontine reticular formation, a "one and a half" syndrome from a horizontal gaze palsy plus an INO, and acquired pendular nystagmus.

Sensory symptoms commonly include paresthesias (tingling, "pins and needles," or painful burning) or hypesthesia (numbness or a "dead" feeling). Complaints of unpleasant feelings of "swollen," "wet,", "raw", or "tightly wrapped" body parts are common. Sensory symptoms often begin in a focal area of a limb, the torso, or the head and spread over hours or days to adjacent ipsilateral or contralateral areas of the body. Involvement of the trunk with a "cord level" is diagnostically helpful because it identifies the spinal cord and not thePNS as the origin of the sensory symptoms.

Ataxia of gait and limbs reflects demyelination in the cerebellum or cerebellar pathways. In advancedMScerebellar dysarthria (scanning speech) is common. The true extent of cerebellar involvement may be uncertain when motor and sensory deficits coexist.

Bladder dysfunction manifests as urgency or hesitancy in voiding, incomplete emptying, or incontinence. Constipation is also common. One or more of these symptoms occurs at some time in most patients withMS and may be present at onset. Fecal urgency or bowel incontinence occur less commonly.

Cognitive dysfunction may be recognized early or late in the course ofMS. Cognitive deficits most commonly include memory loss, impaired attention, problem-solving difficulties, slowed information processing, and difficulties in shifting between cognitive tasks. Impaired judgment and emotional liability may be evident. These symptoms impair activities of daily living in as many as 20% of patients.

Depression is experienced by ~60% of patients during the course of the illness. Suicide

is 7.5-fold more common than in age-matched controls.

Fatigue occurs in most patients withMS. It may be maximum during mid-afternoon or continuous throughout the day. Symptoms of fatigue include generalized motor weakness, limited ability to concentrate or read, lassitude, and sleepiness.

Heat sensitivity is experienced as the appearance of new symptoms or the worsening of preexisting symptoms on exposure to heat. For example, transient visual blurring may become apparent during a hot shower or with physical exercise. It is a common phenomenon for symptoms of MS to worsen transiently, sometimes in a dramatic fashion, during the course of a febrile illness (see pseudoexacerbation, below).

Ancillary Symptoms *Lhermitte's symptom* is the sensation of a momentary electric current or shock evoked by neck flexion, other neck movements, or cough. The symptom typically radiates down the spine into the legs, but it may radiate into the arms or be provoked by movements of the lumbar spine. Lhermitte's symptom is not specific toMS; it also occurs with other spinal cord disorders, including cervical spondylosis.

Paroxysmal symptoms are brief and stereotypic. Tonic spasms consist of an unpleasant tingling or other sensation association with tonic contraction of a limb, face, or trunk. Other paroxysmal symptoms include dysarthria and ataxia, diplopia, transient unilateral paralysis, hemifacial spasm, paresthesias, and pain. Attacks may be momentary or persist for ^{3}30 s. They generally begin in clusters, occurring many times throughout the day, and the patient may identify precipitating factors such as hyperventilation or particular movements.

Trigeminal neuralgia, a lancinating facial pain, may also occur; features that suggestMSrather than an idiopathic etiology (Chap. 367) include onset before 50 years of age, bilateral occurrence, objective facial sensory loss, and constant rather than paroxysmal pain.

Facial weakness may resemble idiopathic Bell's palsy; however, facial weakness due toMS is generally not associated with ipsilateral loss of taste sensation or retroauricular pain (Chap. 367).

Facial myokymia, or chronic flickering contractions of the facial musculature, are also common. The movements commonly involve the orbicularis oculus muscle and appear under the eye. Facial myokymia may arise from lesions of the corticobulbar tracts or brainstem course of the facial nerve.

Vertigo may appear suddenly and in dramatic fashion with gait unsteadiness and vomiting, resembling acute labyrinthitis. A brainstem rather than end-organ origin of vertigo is suggested by the presence of coexisting trigeminal or facial nerve involvement, vertical nystagmus, or nystagmus that is unaccompanied by latency of onset, direction reversal, or fatigue (Chap. 21). Hearing loss may also occur but is uncommon.

DISEASE COURSE

Approximately 85% of patients withMSexperience an abrupt onset of symptoms and signs at disease onset. Thereafter, the clinical course may be characterized by acute episodes of worsening (exacerbations or relapses), gradual progression of disability, or combinations of both. Four clinical patterns are recognized by international consensus. Patients with *relapsing-remitting MS* (RRMS) experience relapses with or without complete recovery and are clinically stable between these episodes (Fig. 371-1, A and B). Approximately 50% of patients with RRMS convert to *secondary progressive MS* (SPMS) within 10 years of disease onset. The secondary progressive phase is characterized by gradual progression of disability with or without superimposed relapses (Fig. 371-1, C and D). In contrast, patients with *primary progressive MS* (PPMS) experience gradual progression of disability from onset without superimposed relapses (Fig. 371-1, E and F). Approximately 10% of patients with MS experience this clinical pattern. Patients with *progressive relapsing MS* experience gradual progression of disability from disease onset later accompanied by one or more relapses; this clinical pattern affects ~5% of patients (Fig. 371-1G).

DIAGNOSIS

There is no definitive diagnostic test. Diagnostic criteria for clinically definiteMSrequire documentation of two or more episodes of symptoms and two or more signs that reflect pathology in anatomically noncontiguous white matter tracts of theCNS(Table 371-2). Symptoms must last more than one day and occur as distinct episodes that are separated by 28 or more days. At least one of the two required signs must be present on neurological examination. The second may be documented as an abnormal paraclinical test, either brain or spinal cordMRI, or visual, auditory, or somatosensory evoked electrical response. In patients who experience gradual progression of disability for 6 or more months without superimposed relapses, documentation of intrathecal IgG may be used to support the diagnosis.

DIAGNOSTIC TESTS

Magnetic Resonance Imaging Widespread availability of brain and spinal cordMRI has revolutionized the diagnosis and management ofMS. Disease-related changes are detected by MRI (Fig. 371-2) in >95% of patients who otherwise meet diagnostic criteria for definite MS (Table 371-2). An increase in vascular permeability, detected by leakage of the intravenous contrast agent gadolinium DPTA into the brain, appears to be a very early event in the formation of new MS lesions and perhaps is a marker of inflammation. Gadolinium enhancement persists for 2 to 8 weeks; and the residual mixture of edema, inflammation, demyelination, axonal loss, and gliosis in the MS plaque remains visible as a focal area of hyperintensity on spin-echo (T2-weighted) and proton-density images. Lesions often appear to extend outward from the ventricular surface, corresponding to a pattern of perivenous demyelination that is observed pathologically in MS (Dawson's fingers). Lesions are also commonly found within the brainstem, corpus callosum, cerebellum, and spinal cord. Lesions of the anterior corpus callosum are particularly useful diagnostically because this site is usually spared in cerebrovascular disease. Specific criteria for the use of MRI in support of a diagnosis of MS have been proposed (Table 371-2).

The correlation between the total volume of T2-weighted signal abnormality -- the

"lesion burden" -- and clinical measures of disability is poor. Approximately one-third of hyperintense T2-weighted lesions appear hypointense on T1-weighted imaging sequences. These "black holes" provide more specific imaging markers of irreversible demyelination and axonal loss that correlate more robustly with clinical measures of disability. The correlation between MRI measures and clinical status is even stronger with emerging imaging techniques, including magnetization transfer imaging and proton-magnetic resonance spectroscopic imaging, which can distinguish irreversible demyelination and axonal loss from reversible edema and inflammation.

Evoked Responses Evoked response testing may detect slowed or absent conduction in visual, auditory, somatosensory, or motor pathways (Chap. 357). These tests use computer averaging techniques to record the electrical response evoked in the nervous system after repetitive sensory stimuli. One or several evoked responses are abnormal in 80 to 90% of patients withMS. Abnormalities in evoked responses occur with a variety of neurologic disorders that disrupt pathways being measured; thus, they are not specific to MS. Testing is of diagnostic value when it provides evidence of a subclinical second lesion in a patient who manifests only one abnormality on neurologic examination (Table 371-2).

Cerebrospinal Fluid (CSF) CSF abnormalities consist of abnormally increased levels of intrathecally synthesized IgG, oligoclinal banding, and mononuclear cell pleocytosis. Various formulas are used to distinguish intrathecally synthesized IgG from serum IgG that may have entered theCNSpassively across a disrupted blood-brain barrier. One formula expresses the ratio of IgG to albumin in the CSF divided by the ratio in the serum ("the CSF IgG index"). Oligoclonal banding of CSF IgG is detected by agarose gel electrophoresis techniques. Two or more oligoclonal bands are found in 75 to 90% of patients withMS. Oligoclonal banding may be absent at the onset of MS, and in individual patients the number of bands present may increase with time. It is important that paired serum samples be studied to exclude a systemic origin of the oligoclonal bands.

OtherCSFabnormalities also occur but are less specific for MS. In one large series, CSF mononuclear pleocytosis (>5 cells/uL) was present in 25% of patients withMS. CSF cell counts are generally <20/uL in patients with MS, and counts >50/uL are unusual but may occur with acute myelopathy. Pleocytosis of >75 cells/uL or a finding of polymorphonuclear leukocytes in CSF makes the diagnosis of MS unlikely. Pleocytosis is more common in young patients with relapsing-remitting MS than in older patients with progressive forms of MS. The total CSF protein content is usually normal or only slightly increased. A protein elevation>100 mg/dL is rare and should prompt consideration of alternative diagnosis such as an infection or tumor.

DIFFERENTIAL DIAGNOSIS

Numerous diagnostic formulas have been proposed forMS(Table 371-2); although useful, they cannot replace sound clinical judgment. No single clinical sign or test is diagnostic of MS. The diagnosis is usually easily made in a young adult with relapsing and remitting symptoms referable to different areas ofCNSwhite matter. The possibility of an alternate diagnosis should be considered when (1) symptoms are localized exclusively to the posterior fossa, craniocervical junction, or spinal cord; (2) the patient

is younger than 15 or older than 60 years; (3) the clinical course is progressive from onset; and (4) the patient has never experienced visual, sensory or bladder symptoms. Diagnosis may also be difficult in patients with a rapid or even explosive onset suggesting a cerebrovascular accident, or mild symptoms only and a normal neurologic examination. In such situations, the patient should be questioned carefully for a history of prior attacks that may not be recalled initially. Rarely, a mass lesion resulting from intense inflammation and swelling may occur in MS and may mimic a primary or metastatic tumor.

Examination reveals evidence of neurologic disease in most patients. Abnormal signs are often more widespread than expected from the interview. For example, a patient withMS may present with symptoms in one leg and signs in both. This type of finding is helpful when it permits exclusion of a single focal lesion as the source of a patient's symptoms. Conversely, the presence of features that are uncommon or rare in MS should call the diagnosis into question. These include aphasia, extrapyramidal syndromes suggesting parkinsonism, chorea, isolated dementia, amyotrophy with fasciculations, peripheral neuropathy, fever, headache, seizures, or coma.

Systemic lupus erythematosus (SLE) rarely produces a relapsing or progressive disorder that mimicsMS; other manifestations of SLE are usually present (Chap. 311). Behcet's syndrome may produce a chronic illness with optic neuropathy and myelopathy but more often presents as an acute or subacute multifocalCNSdisorder (Fig. 371-CD1); characteristic oral and genital lesions, uveitis, and an elevated ESR are distinguishing features (Chap. 316). Relapsing-remitting CNS syndromes have also been described in Sjogren's syndrome. Sarcoidosis may produce cranial nerve palsies (especially of the seventh cranial nerve), progressive optic atrophy, or myelopathy (Chap. 318). Systemic involvement helps to distinguish these conditions from MS. Lyme borreliosis (Fig. 371-CD2) may involve the optic nerve, brainstem, or spinal cord in the absence of characteristic rash, fever, or meningoradiculitis (Chap. 176). Other chronic infections, including meningovascular syphilis and infection with HIV, may need to be considered. HTLV type I-associated myelopathy (HAM; tropical spastic paraparesis) is characterized by back pain, progressive spasticity affecting predominantly the lower limbs, and bladder symptoms (Chap. 373). Diagnosis is based on identification of specific antibody to HTLV-I in serum and CSF and by direct virus isolation. Infection with the HTLV-II retrovirus may cause a progressive myelopathy similar to that caused by HTLV-I.

As noted above, the acute onset of a focalCNSdisturbance in a previously healthy individual may suggest a stroke or migraine. Progressive focal deficits should always prompt consideration of a compressive lesion. Primary CNS lymphoma may produce single or multiple lesions that contrast-enhance onMRI and may resemble acute lesions ofMS. A progressive or relapsing brainstem disturbance may be due to a vascular malformation in the posterior fossa. Pontine glioma is distinguished from MS by its tendency to produce progressive deficits that involve contiguous structures. Chiari malformations presenting in adulthood may cause cerebellar ataxia, nystagmus, and spastic weakness of the limbs; headache, lower cranial nerve palsies, and a syringomyelic syndrome are useful distinguishing features. Progressive myelopathies may result from cervical spondylosis, spinal cord tumor, or arteriovenous malformation (Chap. 368).

A positive family history, neurologic signs suggesting diffuse symmetric demyelination, and lack of characteristicCSFchanges raise the possibility of a metabolic or genetic condition that may mimicMS. Subacute combined degeneration due to vitamin B_{12}deficiency may produce an MS-like syndrome in the absence of megaloblastic anemia (Chap. 368). Uncommon genetic disorders that may mimic MS include Krabbe's disease, metachromatic leukodystrophy, methylenetetrahydrofolate reductase deficiency, biotinidase deficiency, adrenomyeloneuropathy, familial spastic paraparesis, spinocerebellar ataxia, mitochondrial encephalopathy with lactic acidosis and stroke (MELAS), Leber's disease, and subacute necrotizing encephalomyelopathy (Leigh's disease).

PROGNOSIS

Most patients withMSexperience progressive disability. Fifteen years after diagnosis, fewer than 20% of patients with MS have no functional limitation, 50 to 60% require assistance when ambulating, 70% are limited or unable to perform major activities of daily living, and 75% are not employed. In 1998, it was estimated that the total annual economic burden of MS in the United States exceeded 6.8 billion. The following clinical and brainMRIfeatures may confer a more favorable prognosis: presentation with isolated optic neuritis or sensory symptoms, complete recovery from a first attack, age of onset younger than 40 years, female sex, relapsing-remitting clinical course, and fewer than two relapses in the first year of illness. In general, patients who experience minimal neurologic impairment 5 years after the first symptoms are least likely to be severely disabled 10 to 15 years later. By comparison, patients with persistent truncal ataxia, severe action tremor, or a disease course that is progressive from the onset are more likely to experience progression of disability.

In patients who experience an initial attack of monosymptomatic optic neuritis, brainstem signs, or myelopathy, brainMRIprovides useful prognostic information. If the brain MRI reveals multiple T2-weighted lesions, the risk of developing definiteMSwithin a 10-year period of follow-up is 70 to 80%. Conversely, if the brain MRI is normal, <10% of patients will experience a second episode of symptoms consistent with MS within 10 years.

TREATMENT

The treatment ofMS may be divided into two categories: (1) treatments designed to modify the disease process and (2) symptomatic management. Longitudinal scoring of the functional consequences of MS is essential for treatment decisions. The Kurtzke Expanded Disability Status Score (EDSS) is the most widely used measure of neurologic impairment in MS (Table 371-3).

Disease Modifying Therapies forRRMS(Fig. 371-3) Three treatment options for patients with RRMS are approved for use in the United States: (1)IFN-b1b (Betaseron), (2) IFN-b1a (Avonex), and (3) glatiramer acetate (Copaxone). Each of these treatments is also prescribed for patients withSPMS who experience frequent exacerbations because this clinical pattern cannot be distinguished reliably from RRMS with incomplete recovery from exacerbations. In Phase III clinical trials, recipients of IFN-b1b, IFN-b1a, and glatiramer acetate experienced ~30% fewer clinical

exacerbations and significantly fewer newMRIlesions compared to placebo recipients. IFN-b1b and IFN-b1a also convincingly delayed time to onset of sustained progression of disability. Furthermore, IFN-b1a was found to delay the development of clinically definite MS in patients who experience a single episode of demyelination and have MRI findings indicating prior subclinical disease.

Treatment effects withIFN-b1b and IFN-b1a may be mediated by down regulating (1) expression ofMHCmolecules on the surface of antigen-presenting cells, (2) actions of proinflammatory cytokines, and (3) expression of vascular endothelial adhesion molecules and matrix metalloproteinases that mediate trafficking of activated lymphocytes and macrophages into theCNS. Glatiramer acetate, a synthetic polypeptide designed to resembleMBP, may act by (1) inducing antigen-specific suppressor T cells as a result of shared determinants between copolymer 1 and MBP and (2) binding to MHC molecules on the surface of antigen-presenting cells.

IFN-b1b, 8.0 million international units (MIU), is administered by subcutaneous injection every other day. IFN-b1a, 6.0 MIU, is administered by intramuscular injection once every week. Glatiramer acetate, 20 mg, is administered by subcutaneous injection every day. IFN-b1b, IFN-b1a and glatiramer acetate are generally well tolerated. Erythematous reactions at the injection site are common with IFN-b1b and glatiramer acetate. Transient flu-like symptoms frequently occur at the beginning of IFN-b treatment; these symptoms, which usually resolve within several months, can be managed with ibuprofen, acetaminophen or other analgesic medications. Approximately 15% of glatiramer acetate recipients experience one or more episodes of flushing, chest tightness, dyspnea, palpitations, and anxiety after injection. This systemic reaction is unpredictable, self-limited, and generally lasts <1 h. Approximately 40% of IFN-b1b recipients and 5 to 25% of IFN-b1a recipients develop neutralizing antibodies within 12 months of initiating therapy. Data suggest that neutralizing antibodies may degrade clinical efficacy, but this relationship is not apparent in all patients. The clinical usefulness of commercially available tests for neutralizing antibodies is unclear.

In the United States, ~90% of treated patients withRRMSreceive one of the interferons as first-line therapy, and the remaining 10% receive glatiramer acetate. Irrespective of the agent chosen, treatment should probably be discontinued in patients who continue to experience frequent clinical exacerbations or gradual progression of disability for[3]6 months. It is unknown whether patients who fail to respond adequately to treatment with any one of these interventions will respond more favorably to another; thus, it is reasonable to try a second agent (Fig. 371-3). The value of combination therapy is also unknown at this time.

Disease Modifying Therapies for SPMSIFN-b1b (Betaferon) and mitoxantrone (novantrone) were each shown to reduce annual exacerbation rates andMRIactivity and delay time to onset of sustained progression of disability in patients with SPMS. Applications for approval of use of these drugs are filed in the United States. IFN-b1b is currently approved for treatment of SPMS in Canada and Europe. IFN-b1b, 8.0 MIU, is administered subcutaneously every other day. Mitoxantrone, 12 mg/m_2, is administered by intravenous infusion every third month. It may act as a T and B cell immunosuppressant and an enhancer of suppressor cell function. Mitoxantrone may cause mild nausea, slight hair thinning, leukopenia, thrombocytopenia and irreversible

amennorhea. Dose-related cardiac toxicity is of concern, and treatment with mitoxantrone should be considered only in patients with normal ventricular ejection fractions; periodic echocardiograms are advised if cumulative doses of mitoxantrone exceed 100 mg/m^2.

Other Off-Label Treatment Options for RRMS and SPMS *Azathioprine*, 2 to 3 mg/kg body weight, is administered orally each day. This drug modestly reduces annual exacerbation rates in patients with RRMS and SPMS. Its effect on sustained progression of disability is less convincing

Methotrexate, 7.5 mg, is administered orally once each week. This drug, when administered for up to 2 years, modestly reduces disease activity in patients with SPMS as assessed by MRI and standardized tests of manual dexterity. An important practical advantage of methotrexate is the simplicity of a weekly oral dosing schedule.

Cyclophosphamide (CTX) reduces progression of disability in patients with SPMS when compared to ACTH. However, this observation has not been convincingly demonstrated in a placebo-controlled trial. Some investigators advocate pulse CTX therapy for young adults with aggressive forms of MS who fail to respond to approved treatment options.

Intravenous immunoglobulin (IVIg), 0.15 to 0.20 g/kg body weight, administered monthly for up to 2 years convincingly reduced annual exacerbation rates, but its effects on disability and MRI activity were not investigated. At higher doses, 1g/kg body weight daily for 2 days every 6 months, IVIg significantly reduced new MRI activity. Use of this treatment will probably be limited because of its high cost, questions about optimal dose, and uncertainty about the effect of long-term treatment on disability.

Methylprednisolone administered in bimonthly cycles at high doses modestly delays time to onset of sustained progression of disability.

2-Chlorodeoxyadenosine (2-CDA, cladribine) significantly reduces MRI activity in patients with SPMS. However, significant clinical benefits were not observed during 12 months of therapy in a Phase III clinical trial. In the absence of convincing clinical benefit, it is unlikely that 2-CDA will be commonly prescribed.

Disease-Modifying Therapies for PPMS No approved therapies for PPMS exist at this time. The results of ongoing trials of IFN-b1a, glatiramer acetate, and mitoxantrone in PPMS are awaited.

Therapy for Exacerbations The severity and duration of acute exacerbations of MS are reduced by treatment with glucocorticoids. Although methylprednisolone (MePDN) is most commonly prescribed, there is no consensus for the optimal dose and route of administration. Clinical exacerbations that impair activities of daily living can be treated with MePDN, 1000 mg, administered intravenously each day for 3 days followed by oral prednisone, 60 mg daily for 5 days, then tapering by 10 mg each day thereafter. A similar approach is employed for treatment of initial attacks of demyelinating disease. With the exception of severe attacks that jeopardize patient safety, treatment can generally be administered in an outpatient setting. Physical and occupational therapy should be prescribed when impaired mobility or decreased manual dexterity impair

activities of daily living.

Common side effects of short-term glucocorticoid therapy include fluid retention, potassium loss, weight gain, gastric disturbances, acne, and emotional lability. Salt and fluid retention are managed with a low-salt, potassium-rich diet and avoidance of potassium-wasting diuretics. In patients who have heart disease or require concurrent diuretic therapy, oral potassium supplementation is advised. Lithium carbonate (300 mg orally bid) may provide effective prophylaxis for patients who experience emotional lability and insomnia associated with glucocorticoid therapy. For patients with a history of peptic ulcer disease, cimetidine (400 mg bid) or ranitidine (150 mg bid) is advised.

In one small controlled trial, plasma exchange (7 treatments given over 2 weeks) was effective in some patients with unusually fulminant attacks of demyelination unresponsive to glucocorticoids.

When patients experience an acute deterioration, it is important to consider whether this change reflects new disease activity or a "pseudoexacerbation" resulting from an adverse reaction to therapy, increased ambient temperature, fever, or an infection. In such instances treatment with glucocorticoids is contraindicated. Pseudoexacerbations generally resolve within 48 h after initiating appropriate treatment.

Other Therapeutic Claims Purported therapies of no proven value include megadose vitamins, calcium orotate, bee stings, cow colostrum, hyperbaric oxygen, procarin, and chelation. Patients should be discouraged from seeking out costly or potentially hazardous therapies carried out by well-meaning but naive practitioners. Although preliminary data suggest potential roles for HHV-6 and chlamydia pneumonia inMS, these reports are unconfirmed, and treatment with gancyclovir or antibiotics is not currently recommended. The National Multiple Sclerosis Society web site is the best source for information on therapeutic options for MS.

Symptomatic Therapy *Spasticity* with stiffness, flexor spasms, and clonus can be disabling and painful. Acute worsening of spasticity may occur with underlying infection (frequently of the urinary tract), obstipation, bedsores, other painful lesions, or injuries. Although the mechanisms are poorly understood, spasticity may also worsen followingIFN-btherapy. These potential precipitants should be considered and treated specifically. All medications for spasticity have limited efficacy and may produce symptomatic worsening in patients who rely upon spasticity to provide leg strength necessary for effective ambulation. Baclofen (15 to 80 mg/d in divided doses) is the most useful drug available. In refractory cases, baclofen administered orally in higher doses (up to 240 mg/d) or intrathecally via an indwelling catheter may be effective. Tizanidine (2 to 8 mg tid) and diazepam (1 to 2 mg bid or tid) are particularly effective for painful nocturnal spasms, but daytime use is often limited by excessive somnolence. Cyclobenzaprine hydrochloride (5 to 10 mg bid or tid), clonazepam (0.5 to 1.0 mg tid, including a bedtime dose), and clonidine hydrochloride (0.1 to 0.2 mg tid, including a bedtime dose) may be useful for patients who otherwise fail to respond. Dantrolene may produce unacceptable weakness, and its use is usually reserved for nonambulatory patients. A course of glucocorticoids may be given in exceptional cases where other agents have failed, but benefits seldom last more than 2 to 3 weeks.

Pain, including trigeminal neuralgia and painful dysesthesias, may respond to carbamazepine (100 to 1200 mg/d in divided, escalating doses), gabapentin (300-3600 mg/d), dilantin (300-400 mg/d), amitriptyline (25-150 mg/d), or baclofen (10-80 mg/d). In patients with unilateral leg pain, it may be difficult to distinguish dysesthesias due toMS from radiculopathy due to lumbar disk disease; nonsurgical therapy is justified in the absence of convincing signs of nerve root compression.

Paroxysmal symptoms respond to carbamazepine (up to 1200 mg in divided doses), gabapentin (100 to 600 mg tid), or acetazolamide (125 to 250 mg tid). Although no treatment for tremor is satisfactory, slight improvement is occasionally seen with clonazepam (0.5 to 1.0 mg bid or tid), primidone (125 to 250 mg bid or tid), ondansetron (4 to 8 mg bid or tid), and isoniazid (up to 1200 mg in divided doses). Stereotaxic thalamotomy may be considered in cases of disabling tremor in which a unilateral reduction in symptoms is required, but the general experience with this procedure has been disappointing.

Because specific symptoms of *bladder dysfunction* correlate poorly with physiologic findings, urodynamic evaluation is often required. The pathophysiology of abnormal micturition also may change over time inMS. Bladder hyperreflexia is treated with anticholinergics: oxybutynin (5 mg bid or tid), tolterodine (1 to 2 mg bid), or propantheline (7.5 to 15 mg qid). Urinary retention due to bladder hyporeflexia may respond to the cholinergic drug bethanecol (10 to 50 mg tid or qid). Dyssynergia between detrusor and external sphincter muscles may be treated effectively with a combination of anticholinergic medication to decrease bladder contractions and intermittent catheterization. Terazosin hydrochloride (1 to 5 mg at bedtime) ameliorates dyssynergia but may result in urinary incontinence. Supravesical urinary diversion or a chronic indwelling catheter may be required in cases of severe bladder disturbance. Ascorbic acid may reduce the risk of urinary tract infections.

Bowel dysfunction, including constipation and urge incontinence, can be ameliorated by regimentation of bowel function with laxatives and enemas. A low-fiber diet to decrease bulk may be advised for incontinence. *Erectile dysfunction* in males is often treated effectively with sildenafil citrate (50 to 100 mg po prn). Those who fail to respond may benefit from papaverine and phentolamine injections in the corpora cavernosa. Implantation of a penile prosthesis is generally undertaken only for those who fail to respond to other treatment options. Women may experience vaginismus, which may respond to antispasticity medications, or decreased vaginal lubrication leading to dyspareunia, which may be treated effectively with water soluble lubricants.

Afternoon *fatigue* may be reduced by a shift to an early work schedule or a regular afternoon nap. Amantadine (100 mg bid), pemoline (37.5 mg bid), or fluoxetine hydrochloride (20 mg qd or bid) may prove useful in some patients with disabling fatigue. *Emotional lability* often responds to amitriptyline (25 to 75 mg/d) or fluoxetine (20 mg/d). It is essential to be vigilant for clinical evidence of *depression*, since the risk of suicide is increased in patients withMS. Occupational counseling and other support services may assist patients and their families in coping with the effects of the disease. Health maintenance should be emphasized, including stress reduction, a balanced diet, avoidance of rapid change in weight, and adequate rest. Although there is little evidence linking vaccination with relapses of MS, it is prudent to avoid unnecessary

immunizations. Swimming is an ideal form of exercise for many patients because of the buoyant support and hypothermia that is achieved.

Pregnancy may affect the course ofMS. Compared with nonpregnant MS patients, pregnant patients experience fewer attacks during gestation but more attacks in the first 3 months after parturition. The two effects appear to be roughly similar in magnitude; thus, no effect of pregnancy on disability or on the overall disease course has been identified. Although it has been hypothesized that high levels of prolactin induced in the postpartum period and maintained by breast feeding result in immune stimulation that predisposes to relapses of MS, studies indicate no effect of breast feeding on attack frequency in the postpartum period. The advisability of childbearing should be determined primarily by the patient's physical state and available social support.

CLINICAL VARIANTS OF MS

Neuromyelitis optica (Devic's syndrome) is characterized by separate attacks of acute optic neuritis and myelitis. Optic neuritis may be unilateral or bilateral and precede or follow an attack of myelitis by days, months, or years. Respiratory failure may result from cervical cord lesions.CSFneutrophil counts >50/uL are reported to occur in as many as 20% of patients. In contrast to patients with MS, patients with Devic's syndrome do not experience brainstem, cerebellar, and cognitive involvement, and the brainMRI is normal. Characteristically, MRI demonstrates a transiently enhancing focal region of swelling and cavitation that extends over three or more spinal cord segments. In contrast to MS, histopathology of these lesions may reveal areas of necrosis and thickening of blood vessel walls. Thus, it remains uncertain whether Devic's syndrome is a variant of MS or a separate entity. The role of disease-modifying therapies for MS has not been rigorously studied in patients with Devic's syndrome. This syndrome is unusual in Caucasians but appears to be more common in Asians. The 5-year survival rate in the Mayo Clinic series was ~70%.

Acute MS (Marburg's variant) is a rare acute fulminant process that generally ends in death from brainstem involvement within one year. There are no remissions. Diagnosis can be established only at postmortem examination; widespread demyelination, axonal loss, edema, and macrophage infiltration are characteristic, and discrete plaques may also be seen. In contrast to postinfectious encephalomyelitis (see below), this disorder does not follow exanthematous infection or vaccination. It has been suggested that acuteMS may be associated with an immature form of myelin that is more susceptible to breakdown. As with Devic's syndrome, it is unclear whether this syndrome represents an extreme form of MS or another disease altogether.

ACUTE DISSEMINATED ENCEPHALOMYELITIS

In contrast toMS, acute disseminated encephalomyelitis (ADEM) is distinguished by a monophasic course and a frequent association with antecedent immunization (postvaccinal encephalomyelitis) or infection (postinfectious encephalomyelitis). The pathologic hallmark of ADEM is the presence of widely scattered small foci of perivenular inflammation and demyelination. In its most explosive form, acute hemorrhagic leukoencephalitis, lesions are vasculitic and hemorrhagic, and the clinical course is devastating.

Postvaccinal encephalomyelitis may follow the administration of smallpox and certain rabies vaccines. Postinfectious encephalomyelitis is most frequently associated with the viral exanthems of childhood. Natural infection with measles virus is the most common antecedent (1 in 1000 cases). Worldwide, measles encephalomyelitis remains a common illness, but in developed countries use of the live measles vaccine has dramatically reduced its incidence. AnADEM-like illness rarely follows vaccination with live measles vaccine (1 to 2 in 10^6immunizations). ADEM is now most frequently associated with varicella (chickenpox) infections (1 in 4000 to 10,000 cases). It also may follow infection with rubella, mumps, influenza, parainfluenza, and infectious mononucleosis viruses and with *Mycoplasma*. Some patients may have a nonspecific upper respiratory infection or no known antecedent illness.

An autoimmune response toMBP can be detected in theCSF from many patients withADEM. This response has been most clearly established after rabies vaccination and infection with measles virus. With measles infection, the induction of immune responses to a variety ofCNSantigens may occur, but only the response to MBP correlates with the development of ADEM. Many cases of postvaccinal encephalomyelitis may result from sensitization with brain material that contaminates the viral vaccines. Attempts to demonstrate direct viral invasion of the CNS have been unsuccessful. The molecular mechanism responsible for virus-induced triggering of an autoimmune response to MBP is not known but may include molecular mimicry due to antigens shared between the virus and host determinants or to virus-mediated CNS injury with secondary sensitization to MBP.

CLINICAL MANIFESTATIONS

The severity ofADEMvaries. In severe cases, the onset is abrupt, and progression is rapid (hours to days). In postinfectious ADEM, the neurologic syndrome generally begins late in the course of the viral illness as the exanthem is fading. Fever reappears, and headache, meningismus, and lethargy progressing to coma may develop. Seizures are common. Signs of disseminated neurologic disease are consistently present. Motor findings may include hemiparesis or quadriparesis and extensor plantar responses. Tendon reflexes may be lost initially, later to become hyperactive. Variable degrees of sensory loss and of brainstem involvement may occur. In ADEM due to complications from chickenpox, cerebellar involvement is often prominent.CSFprotein is modestly elevated (50 to 150 mg/dL). Lymphocytic pleocytosis, generally £200 cells per microliter, occurs in 80% of patients. Occasional patients have higher counts or a mixed polymorphonuclear-lymphocytic pattern during the initial days of the illness. Transient CSF oligoclonal banding has been reported.MRI may reveal extensive gadolinium enhancement of white matter in brain and spinal cord.

DIAGNOSIS

The diagnosis is easily established when there is a history of recent vaccination or exanthematous illness. In severe cases with predominantly cerebral involvement, acute encephalitis due to infection with herpes simplex or other viruses may be difficult to exclude. In the absence of a specific viral prodrome or of immunization, it may not be possible to distinguishADEMfrom acuteMS. The simultaneous onset of disseminated

symptoms and signs indicating optic nerve, brain, and spinal cord involvement is common in ADEM and rare in MS. Similarly, meningismus, drowsiness or coma, or seizures suggest ADEM. Optic nerve involvement is generally bilateral in ADEM and unilateral in MS, and transverse myelopathy is usually complete in the former and partial in the latter. TheCSFprotein level is normal in most patients with MS; lymphocyte counts are rarely>50 cells/uL, and polymorphonuclear leukocytes are not present.MRIfindings that may support a diagnosis of ADEM include extensive and relatively symmetric white matter abnormalities and diffuse gadolinium enhancement of all abnormal areas, indicating active disease and a monophasic course.

TREATMENT

Therapy consists of intravenous methylprednisolone as employed for exacerbations ofMS. Uncontrolled studies have found ACTH and plasmapheresis also to be of benefit. Occasional patients show evidence of relapse shortly after termination of therapy, and for them, reinstitution of therapy may be useful. The prognosis reflects the severity of the underlying acute illness. Measles encephalomyelitis is associated with a mortality rate of 5 to 20%, and most survivors have permanent neurologic sequelae. Children who recover may have persistent seizures and behavioral and learning disorders.

372. BACTERIAL MENINGITIS AND OTHER SUPPURATIVE INFECTIONS - *Karen L. Roos*, *Kenneth L. Tyler*

ACUTE BACTERIAL MENINGITIS

DEFINITION

Bacterial meningitis is an acute purulent infection within the subarachnoid space. It is associated with a central nervous system (CNS) inflammatory reaction that may result in decreased consciousness, seizures, raised intracranial pressure, and stroke. The meninges, the subarachnoid space, and the brain parenchyma are all involved in the inflammatory reaction; as such, *meningoencephalitis* is the more accurate descriptive term.

EPIDEMIOLOGY

Bacterial meningitis is the most common form of suppurative intracranial infection, with an annual incidence >2.5 cases/100,000 population. The epidemiology of bacterial meningitis has changed in recent years. Currently, the organisms most commonly responsible for community-acquired bacterial meningitis are *Streptococcus pneumoniae* (~50%), *Neisseria meningitidis* (~25%), group B streptococci (~10%), and *Listeria monocytogenes* (~10%). *Haemophilus influenzae* was once the most common cause of bacterial meningitis in the United States. The incidence of *H. influenzae* meningitis declined precipitously following the introduction of the *H. influenzae* type b (Hib) vaccine in 1987, and *H. influenzae* now accounts for <10% of bacterial meningitis cases. There have also been major changes in the epidemiology of pneumococcal disease, with the global emergence and increasing prevalence of penicillin- and cephalosporin-resistant strains of *S. pneumoniae*. As of 1998, ~44% of clinical isolates of *S. pneumoniae* in the United States had intermediate or high levels of resistance to penicillin. In the past several years, there has been an increase in the incidence of meningococcal infections on college campuses and an increase in the incidence of meningococcal disease in North America and Europe due to the emergence of a virulent strain of serogroup C, serotype 2a *N. meningitidis*. An increasing incidence of *N. meningitidis* strains with moderate or relative resistance to penicillin and a decreased susceptibility to ampicillin has been reported worldwide, but the clinical significance of these strains is still unknown. Annual meningitis epidemics, caused primarily by the serogroup A meningococcus, continue to occur in the meningitis belt of sub-Saharan Africa. Epidemics due to the serogroup B meningococcus continue to occur in Europe, Latin America, and New Zealand. Group B streptococcus or *S. agalactiae* was previously responsible for meningitis predominantly in neonates, but it has been reported with increasing frequency in individuals >50 years, particularly those with underlying diseases. *L. monocytogenes* has emerged as an important cause of bacterial meningitis in the elderly and in individuals with impaired cell-mediated immunity.

ETIOLOGY

S. pneumoniae (Chap. 140) is the most common cause of meningitis in adults >20 years. There are a number of predisposing conditions that increase the risk of pneumococcal meningitis, the most important of which is pneumococcal pneumonia.

Additional risk factors include coexisting acute or chronic otitis media, alcoholism, diabetes, splenectomy, hypogammaglobulinemia, complement deficiency, and head trauma with basilar skull fracture and cerebrospinal fluid (CSF) rhinorrhea.

N. meningitidis (Chap. 146) accounts for nearly 60% of bacterial meningitis cases in children and young adults between the ages of 2 and 20. The nasopharynx is initially colonized by this organism, resulting in either an asymptomatic carrier state or invasive meningococcal disease. The risk of invasive disease following nasopharyngeal colonization depends on both bacterial virulence factors and host immune defense mechanisms, including the host's capacity to produce antimeningococcal antibodies and to lyse meningococci by both the classic and alternative complement pathways. Individuals with deficiencies of any of the complement components, including properdin, are highly susceptible to meningococcal infections.

Enteric gram-negative bacilli are the causative organisms of meningitis that is associated with chronic and debilitating diseases such as diabetes, cirrhosis or alcoholism, and chronic urinary tract infections and following neurosurgical procedures, particularly craniotomy or craniectomy.

Resistance to infection with *L. monocytogenes* requires effective cell-mediated immunity. As a result, elderly individuals and those with impaired cell-mediated immunity due to organ transplantation, pregnancy, malignancy, chronic illness, or immunosuppressive therapy are all at increased risk for listerial meningitis. Infection is acquired by ingesting foods contaminated by this organism. Foodborne human listerial infection has been reported from contaminated coleslaw, milk, deli meat, and soft cheeses.

The frequency of *H. influenzae* type b meningitis in children has declined dramatically since the introduction of theHibconjugate vaccine, although rare cases of Hib meningitis in vaccinated children have been reported. More frequently, *H. influenzae* causes meningitis in unvaccinated children and adults.

Staphylococcus aureus and coagulase-negative staphylococci are predominant organisms causing meningitis that follows invasive neurosurgical procedures, particularly shunting procedures for hydrocephalus, or occurs as a complication of the use of subcutaneous Ommaya reservoirs for the administration of intrathecal chemotherapy.

PATHOPHYSIOLOGY

The most common bacteria that cause meningitis, *S. pneumoniae* and *N. meningitidis*, initially colonize the nasopharynx by attaching to nasopharyngeal epithelial cells. Bacteria are transported across epithelial cells in membrane-bound vacuoles to the intravascular space or invade the intravascular space by creating separations in the apical tight junctions of columnar epithelial cells. Once the bacteria gain access to the bloodstream, they are able to avoid phagocytosis by neutrophils and classic complement-mediated bactericidal activity because of the presence of a polysaccharide capsule. Once in the bloodstream, bacteria can reach the intraventricular choroid plexus. Infection of choroid plexus epithelial cells allows bacteria direct access to

theCSF. Some bacteria, such as *S. pneumoniae*, can adhere directly to cerebral capillary endothelial cells and subsequently migrate through or between these cells to reach the CSF. Bacteria are able to multiply rapidly within CSF because of the absence of effective host immune defenses. Normal CSF contains few white blood cells (WBCs) and relatively small amounts of complement proteins and immunoglobulins. The paucity of the latter two prevents effective opsonization of bacteria, an essential prerequisite for bacterial phagocytosis by neutrophils. Phagocytosis of bacteria is further impaired by the fluid nature of CSF, which is less conducive to phagocytosis than a solid tissue substrate.

A critical event in the pathogenesis of bacterial meningitis is the inflammatory reaction induced by the invading bacteria. Many of the neurologic manifestations and complications of bacterial meningitis result from the immune response to the invading pathogen rather than from direct bacteria-induced tissue injury. As a result, neurologic injury can progress even after the CSF has been sterilized by antibiotic therapy.

The lysis of bacteria with the subsequent release of cell-wall components into the subarachnoid space is the initial step in the induction of the inflammatory response and the formation of a purulent exudate in the subarachnoid space (Fig. 372-1). Bacterial cell-wall components, such as the lipopolysaccharide (LPS) molecules of gram-negative bacteria and teichoic acid and peptidoglycans of *S. pneumoniae*, induce meningeal inflammation by stimulating the production of inflammatory cytokines and chemokines by microglia, astrocytes, monocytes, microvascular endothelial cells, andCSFleukocytes. In experimental models of meningitis, cytokines including tumor necrosis factor (TNF) and interleukin (IL) 1 are present in CSF within 1 to 2 h of intracisternal inoculation of LPS. This cytokine response is quickly followed by an increase in CSF protein concentration and leukocytosis. Chemokines (cytokines that induce chemotactic migration in leukocytes) and a variety of other proinflammatory cytokines are also produced and secreted by leukocytes and tissue cells that are stimulated by IL-1 and TNF. In addition, bacteremia and the inflammatory cytokines induce the production of excitatory amino acids, reactive oxygen and nitrogen species (free oxygen radicals, nitric oxide, and peroxynitrite), and other mediators that can induce death of brain cells.

Much of the pathophysiology of bacterial meningitis is a direct consequence of elevated levels ofCSFcytokines and chemokines.TNF andIL-1 act synergistically to increase the permeability of the blood-brain barrier, resulting in induction of vasogenic edema and the leakage of serum proteins into the subarachnoid space (Fig. 372-1). The subarachnoid exudate of proteinaceous material and leukocytes obstructs the flow of CSF through the ventricular system and diminishes the resorptive capacity of the arachnoid granulations in the dural sinuses, leading to obstructive and communicating hydrocephalus and concomitant interstitial edema.

Inflammatory cytokines upregulate the expression of selectins on cerebral capillary endothelial cells and leukocytes, which allows for leukocytes to adhere to vascular endothelial cells and to subsequently migrate into theCSF. The adherence of leukocytes to capillary endothelial cells increases the permeability of blood vessels, allowing for the leakage of plasma proteins into the CSF, which adds to the inflammatory exudate. Neutrophil degranulation results in the release of toxic metabolites that contribute to

cytotoxic edema, cell injury, and death. Contrary to previous beliefs, CSF leukocytes probably do little to contribute to the clearance of CSF bacterial infection.

During the very early stages of meningitis there is an increase in cerebral blood flow, soon followed by a decrease in cerebral blood flow and a loss of cerebrovascular autoregulation. Cerebral perfusion pressure (CPP) is defined as the difference between the mean arterial pressure (MAP) and the intracranial pressure (ICP), i.e., CPP= MAP - ICP. CPP is protected by cerebrovascular autoregulation, which dilates or constricts cerebral resistance vessels in response to alterations in CPP, due to changes in either the MAP or the ICP. Loss of cerebrovascular autoregulation means that any increase in systemic blood pressure leads to an increase in cerebral blood flow and ICP. Conversely, a decrease in mean systemic arterial pressure, for example, associated with septic shock, results in a decrease in cerebral blood flow and subsequent cerebral ischemia and infarction. The cerebrovascular complications of bacterial meningitis include not only a loss of autoregulation but also narrowing of the large arteries at the base of the brain due to encroachment on the vessel by the purulent exudate in the subarachnoid space and infiltration of the arterial wall by inflammatory cells with intimal thickening (vasculitis); this may result in ischemia and infarction, obstruction of branches of the middle cerebral artery by thrombosis, thrombosis of the major cerebral venous sinuses, and thrombophlebitis of the cerebral cortical veins. The combination of interstitial, vasogenic, and cytotoxic edema leads to raised ICP and coma. Cerebral edema, either focal or generalized, can lead to cerebral herniation (see below). Focal or diffuse cerebral edema is the most likely cause of meningitis-associated brain herniation; however, hydrocephalus and dural sinus or cortical vein thrombosis may also play a role.

CLINICAL PRESENTATION

Meningitis can present as either an acute fulminant illness that progresses rapidly in a few hours or as a subacute infection that progressively worsens over several days. The classic clinical triad of meningitis is fever, headache, and nuchal rigidity ("stiff neck"). Each of these signs and symptoms occurs in>90% of cases. Alteration in mental status occurs in >75% of patients and can vary from lethargy to coma. Nausea, vomiting, and photophobia are also common complaints. Nuchal rigidity is the pathognomonic sign of meningeal irritation and is present when the neck resists passive flexion. Kernig's and Brudzinski's signs are also classic signs of meningeal irritation. Kernig's sign is elicited with the patient in the supine position. The thigh is flexed on the abdomen, with the knee flexed; attempts to passively extend the leg elicit pain when meningeal irritation is present. Brudzinski's sign is elicited with the patient in the supine position and is positive when passive flexion of the neck results in spontaneous flexion of the hips and knees.

Seizures occur as part of the initial presentation of bacterial meningitis or during the course of the illness in up to 40% of patients. Focal seizures are usually due to focal arterial ischemia or infarction, cortical venous thrombosis with hemorrhage, or focal edema. Generalized seizure activity and status epilepticus are due to fever, hyponatremia, or cerebral anoxia or, less commonly, as a result of toxicity from antimicrobial agents.

The rash of meningococcemia begins as a diffuse erythematous maculopapular rash

resembling a viral exanthem, but the skin lesions of meningococcemia rapidly become petechial. Petechiae are found on the trunk and lower extremities, in the mucous membranes and conjunctiva, and occasionally on the palms and soles.

RaisedICP is an expected complication of bacterial meningitis and is the major cause of obtundation and coma in this disease. More than 90% of patients will have aCSFopening pressure >180 mmH_2O, and 20% have opening pressures >400 mmH_2O. Signs of increased ICP include a deteriorating or reduced level of consciousness, papilledema, dilated poorly reactive pupils, sixth nerve palsies, decerebrate posturing, and the Cushing reflex (bradycardia, hypertension, and irregular respirations). The most disastrous complication of increased ICP is cerebral herniation. The incidence of herniation in patients with bacterial meningitis has been reported to occur in as few as 1% to as many as 8% of cases.

DIAGNOSIS

When the clinical presentation is suggestive of bacterial meningitis, blood cultures should be immediately obtained and empirical antimicrobial therapy initiated without delay. The diagnosis of bacterial meningitis is made by examination of the CSF(Table 372-1). The need for cranial magnetic resonance imaging (MRI) or computed tomography (CT) prior to lumbar puncture remains a controversial issue and must be dealt with on a case-by-case basis. In a patient with a normal level of consciousness and a neurologic examination with no evidence of papilledema or focal deficits, it is safe to perform lumbar puncture without prior neuroimaging studies. If lumbar puncture is delayed in order to obtain neuroimaging studies, empirical antibiotic therapy should be initiated after blood cultures are obtained. Antibiotic therapy for several hours prior to lumbar puncture will not significantly alter the CSF white blood cell count or glucose concentration, nor is it likely to sterilize the CSF so that the organism cannot be identified on Gram's stain. IncreasedICPshould be treated in patients with clinical signs of increased pressure, and lumbar puncture performed with a 22- or 25-gauge needle. Only a minimum amount of CSF need be removed for analysis; ~3.5 mL of CSF is sufficient to obtain a cell count (1.0 mL), glucose and protein concentrations (1.0 mL), latex particle agglutination (LA) tests (0.5 mL), and Gram's stain and bacterial cultures (1.0 mL). If possible, an additional 0.5 to 1.0 mL should be saved. Preadministration of mannitol and hyperventilation further decrease the risk of herniation in patients with elevated ICP.

The classicCSFabnormalities in bacterial meningitis are: (1) polymorphonuclear leukocytosis (>100 cells per microliter in 90%), (2) decreased glucose concentration [<2.2 mmol/L (<40 mg/dL) and/or CSF/serum glucose ratio of<0.4 in ~60%], (3) increased protein concentration [>0.45 g/L (>45 mg/dL) in 90%], and (4) increased opening pressure (>180 mmH_2O in 90%). CSF bacterial cultures are positive in >80% of patients, and CSF Gram's stain demonstrates organisms in>60%.

Opening pressure should be measured with the patient in the lateral recumbent position. In adults, the normal opening pressure is <180 mmH_2O, and the normal white blood cell count is <5 mononuclear cells (lymphocytes and monocytes) per microliter. Polymorphonuclear neutrophils (PMNs) are not found in cell counts of normalCSF; however, rare PMNs can be found in concentrated CSF specimens, such as those

analyzed for cytology. CSF glucose concentrations<2.2 mmol/L (<40 mg/dL) are abnormal, and a CSF glucose concentration of zero can be seen in bacterial meningitis. Use of the CSF/serum glucose ratio corrects for hyperglycemia that may mask a relative decrease in the CSF glucose concentration. The CSF glucose concentration is low when the CSF/serum glucose ratio is <0.6. A CSF/serum glucose ratio<0.40 is highly suggestive of bacterial meningitis but may also be seen in other conditions, including carcinomatous meningitis and rare cases of viral meningitis. It takes at least 30 min, and more likely several hours, for CSF glucose concentration to reach equilibrium with blood glucose concentrations; therefore, administration of 50 mL of 50% glucose (D50) prior to lumbar puncture, as commonly occurs in emergency room settings, is unlikely to alter CSF glucose concentration significantly unless more than a few hours have elapsed between glucose administration and lumbar puncture.

TheLA test for the detection of bacterial antigens of *S. pneumoniae*, *N. meningitidis*, *H. influenzae* type b, group B streptococcus, and *Escherichia coli* K1 strains in theCSF is very useful for making a rapid diagnosis of bacterial meningitis, especially in patients who have been pretreated with antibiotics and in whom CSF Gram's stain and culture are negative. The CSF LA test has a *specificity* of 95 to 100% for *S. pneumoniae* and *N. meningitidis*, so a positive test is virtually diagnostic of bacterial meningitis by these organisms. However, the *sensitivity* of the CSF LA test is only 70 to 100% for detection of *S. pneumoniae* and 33 to 70% for detection of *N. meningitidis* antigens, so a negative test does not exclude infection by these organisms. The Limulus amebocyte lysate assay is a rapid diagnostic test for the detection of gram-negative endotoxin in CSF, and thus for making a diagnosis of gram-negative bacterial meningitis. The test has a specificity of 85 to 100% and a sensitivity approaching 100%. Thus, a positive Limulus amebocyte lysate assay occurs in virtually all patients with gram-negative bacterial meningitis, but false-positives may occur. CSF polymerase chain reaction (PCR) tests are not as useful in the diagnosis of bacterial meningitis as they are in the diagnosis of viral CNS infections. A CSF PCR test has been developed for detecting DNA from bacteria in CSF, but its sensitivity and specificity need to be better characterized before its role in diagnosis can be defined.

Almost all patients with bacterial meningitis will ultimately have neuroimaging studies performed.MRI is preferred overCTbecause of its superiority in demonstrating areas of cerebral edema and ischemia. In patients with bacterial meningitis, diffuse meningeal enhancement is often seen after the administration of gadolinium. Meningeal enhancement is not diagnostic of meningitis but occurs in anyCNSdisease associated with increased blood-brain barrier permeability.

Petechial skin lesions, if present, should be biopsied. The rash of meningococcemia results from the dermal seeding of organisms with vascular endothelial damage, and biopsy may reveal the organism on Gram's stain.

DIFFERENTIAL DIAGNOSIS

Foremost in the differential diagnosis of bacterial meningitis is viral meningoencephalitis, specifically herpes simplex virus (HSV) encephalitis (Chaps. 182,373). The clinical presentation of HSV encephalitis includes headache, fever, altered consciousness, focal neurologic deficits (e.g., dysphasia, hemiparesis), and

focal or generalized seizures. Features that distinguish herpes encephalitis from bacterial meningitis include the findings onCSFstudies, neuroimaging, and electroencephalogram (EEG). The classic CSF profile in patients with viralCNSinfections is a lymphocytic pleocytosis with a normal glucose concentration, as contrasted with thePMNpleocytosis and hypoglycorrhachia characteristic of bacterial meningitis.MRIabnormalities other than meningeal enhancement are not seen in uncomplicated bacterial meningitis. Patients with HSV encephalitis frequently have MRI abnormalities, including increased signal within the orbitofrontal and medial temporal lobes and insular cortex on T2-weighted and FLAIR images. There is a distinctive EEG pattern in HSV encephalitis consisting of periodic, stereotyped, sharp-and-slow wave complexes originating in one or both temporal lobes and repeating at regular intervals of 2 to 3 s. The periodic complexes are typically noted between the second and the fifteenth day of the illness and are present in two-thirds of pathologically proven cases of HSV encephalitis.

The clinical presentation of encephalitis caused by arthropod-borne viruses (Chap. 198) can also resemble that of bacterial meningitis. Another consideration is rickettsial disease (Chap. 177). Rocky Mountain spotted fever (RMSF) is transmitted by a tick bite and caused by the bacteria *Rickettsia rickettsii*. The disease may resemble bacterial meningitis because of its common presentation with high fever, prostration, myalgia, headache, and nausea and vomiting. Most patients develop a characteristic rash within 96 h of the onset of symptoms. The rash is initially a diffuse erythematous maculopapular rash that may be difficult to distinguish from that of meningococcemia. It progresses to a petechial rash, then to a purpuric rash, and, if untreated, to skin necrosis or gangrene. The color of the lesions changes from bright red to very dark red, then yellowish-green to black. The rash typically begins in the wrist and ankles, and then spreads distally and proximally within a matter of a few hours and involves the palms and soles. Diagnosis is made by immunofluorescent staining of skin biopsy specimens.

Focal suppurativeCNSinfections (see below), including subdural and epidural empyema and brain abscess, should also be considered. The presence of focal features in a patient with suspected bacterial meningitis should prompt immediate neuroimaging studies;MRI is preferable toCT and is extremely sensitive and specific for diagnosis.

Among noninfectiousCNSprocesses, subarachnoid hemorrhage (SAH;Chap. 361) is generally the major consideration. A classic presentation of SAH is the explosive onset of a severe headache or a sudden transient loss of consciousness followed by a severe headache. Nuchal rigidity and vomiting are frequently present and contribute to the resemblance between SAH and meningitis.CT scan is a sensitive indicator of the presence of SAH and usually allows for prompt diagnosis, although occasional patients with suspected SAH have a normal CT scan. In these patients a lumbar puncture is indicated, and the presence of grossly bloodyCSFallows SAH to be immediately distinguished from bacterial meningitis.

TREATMENT

Empirical antimicrobial therapy (Table 372-2) Bacterial meningitis is a medical emergency. The goal is to begin antibiotic therapy within 60 min of a patient's arrival in

the emergency room. Empirical antimicrobial therapy is initiated in patients with suspected bacterial meningitis before the results ofCSFGram's stain and culture are known. *S. pneumoniae* (Chap. 140) and *N. meningitidis* (Chap. 146) are the most common etiologic organisms of community-acquired bacterial meningitis. Due to the emergence of penicillin- and cephalosporin-resistant *S. pneumoniae*, empirical therapy of community-acquired bacterial meningitis in children and adults should include a third-generation cephalosporin (e.g., ceftriaxone or cefotaxime) and vancomycin. Ceftriaxone or cefotaxime provide good coverage for susceptible *S. pneumoniae*, group B streptococci, and *H. influenzae* and adequate coverage for *N. meningitidis*. Ampicillin should be added to the empirical regimen for coverage of *L. monocytogenes* in individuals under three months of age, those over age 55, or those with suspected impaired cell-mediated immunity because of chronic illness, organ transplantation, pregnancy, malignancies, or immunosuppressive therapy. In hospital-acquired meningitis, and particularly meningitis following neurosurgical procedures, staphylococci and gram-negative organisms including *Pseudomonas aeruginosa* are the most common etiologic organisms. In these patients, empirical therapy should include a combination of vancomycin and ceftazidime. Ceftazidime should be substituted for ceftriaxone or cefotaxime in neurosurgical patients and in neutropenic patients, as *P. aeruginosa* may be the meningeal pathogen, and ceftazidime is the only cephalosporin with adequate activity against *P. aeruginosa* in theCNS.

Specific antimicrobial therapy (Table 372-3)

Meningococcal meningitis Although ceftriaxone and cefotaxime provide adequate empirical coverage for *N. meningitidis*, penicillin G remains the antibiotic of choice for meningococcal meningitis caused by susceptible strains. Isolates of *N. meningitidis* with moderate resistance to penicillin have been identified, but patients infected with these strains have still been successfully treated with penicillin.CSFisolates of *N. meningitidis* should be tested for penicillin and ampicillin susceptibility, and if resistance is found, cefotaxime or ceftriaxone should be substituted for penicillin. A 7-day course of intravenous antibiotic therapy is adequate for uncomplicated meningococcal meningitis. The index case and all close contacts should receive chemoprophylaxis with a 2-day regimen of rifampin (600 mg every 12 h for 2 days in adults and 10 mg/kg every 12 h for 2 days in children >1 year). Rifampin is not recommended in pregnant women. Alternatively, adults can be treated with one dose of ciprofloxacin (750 mg), one dose of azithromycin (500 mg), or one IM dose of ceftriaxone (250 mg). Close contacts are defined as those individuals who have had contact with oropharyngeal secretions either through kissing or by sharing toys, beverages, or cigarettes.

Pneumococcal meningitis Antimicrobial therapy of pneumococcal meningitis is initiated with a third-generation cephalosporin (ceftriaxone or cefotaxime) and vancomycin (Tables 372-2 and372-3). All CSFisolates of *S. pneumoniae* should be tested for sensitivity to penicillin and the third-generation cephalosporins. Once the results of antimicrobial susceptibility tests are known, therapy can be modified accordingly. For *S. pneumoniae* meningitis, an isolate of *S. pneumoniae* is considered to be susceptible to penicillin with a minimal inhibitory concentration (MIC)< 0.06 ug/mL, to have intermediate resistance when the MIC is 0.1 to 1.0 ug/mL, and to be highly resistant when the MIC> 1.0 ug/mL. Isolates of *S. pneumoniae* that have cephalosporin MICs £ 0.5 ug/mL are considered sensitive to the cephalosporins (cefotaxime,

ceftriaxone, cefepime). Those with MICs of 1 ug/mL are considered to have intermediate resistance, and those with MICs ³ 2 ug/mL are considered resistant. Penicillin-resistant strains of *S. pneumoniae* are more common than cephalosporin-resistant strains of *S. pneumoniae*. For meningitis due to pneumococci with cefotaxime or ceftriaxone MICs£ 0.5 ug/mL, treatment with cefotaxime or ceftriaxone is usually adequate. If the MIC is ³1 ug/mL, vancomycin is the antibiotic of choice. Rifampin can be added to vancomycin for its synergistic effect but is inadequate as monotherapy because resistance develops rapidly when it is used alone.

Patients with *S. pneumoniae* meningitis should have a repeat lumbar puncture performed 24 to 36 h after the initiation of antimicrobial therapy to document sterilization of theCSF. Failure to sterilize the CSF after 24 to 36 h of antibiotic therapy should be considered presumptive evidence of antibiotic resistance. Patients with penicillin- and cephalosporin-resistant strains of *S. pneumoniae* who do not respond to intravenous vancomycin alone may benefit from the addition of intraventricular vancomycin. The intraventricular route of administration is preferred over the intrathecal route because adequate concentrations of vancomycin in the cerebral ventricles are not always achieved with intrathecal administration. A 2-week course of intravenous antimicrobial therapy is recommended for pneumococcal meningitis.

***L. monocytogenes* meningitis** Meningitis due to this organism is treated with ampicillin for at least 3 weeks (Table 372-3). Gentamicin is often added (2 mg/kg loading dose then 5.1 mg/kg per day given every 8 h and adjusted for serum levels and renal function). The combination of trimethoprim [10 to 20 (mg/kg)/d] and sulfamethoxazole [50 to 100 (mg/kg)/d] given every 6 h may provide an alternative in penicillin-allergic patients.

Staphylococcal meningitis Meningitis due to susceptible strains of *S. aureus* or coagulase-negative staphylococci is treated with nafcillin (Table 372-3). Vancomycin is the drug of choice for methicillin-resistant staphylococci and for patients allergic to penicillin. In these patients, theCSFshould be monitored during therapy. If the CSF is not sterilized after 48 h of intravenous vancomycin therapy, then either intrathecal or intraventricular vancomycin, 20 mg once daily, can be added.

Gram-negative bacillary meningitis The third-generation cephalosporins, cefotaxime, ceftriaxone, and ceftazidime, are equally efficacious for the treatment of gram-negative bacillary meningitis, with the exception of meningitis due to *P. aeruginosa*, which should be treated with ceftazidime (Table 372-3). A 3-week course of intravenous antibiotic therapy is recommended for meningitis due to gram-negative bacilli.

Newer antibiotics Cefepime is a broad-spectrum fourth-generation cephalosporin with in vitro activity similar to that of cefotaxime or ceftriaxone against *S. pneumoniae* and *N. meningitidis* and greater activity against *Enterobacter* spp. and *P. aeruginosa*. The dose of cefepime is 2 g intravenously every 12 h in adults. In clinical trials, cefepime has been demonstrated to be equivalent to cefotaxime in the treatment of pneumococcal and meningococcal meningitis, but its efficacy in bacterial meningitis caused by penicillin- and cephalosporin-resistant pneumococcal organisms, *Enterobacter* spp., and *P. aeruginosa* has not been established. Meropenem is a carbapenem antibiotic structurally related to imipenem, but reportedly with less seizure proclivity than

imipenem. Meropenem is highly active in vitro against *L. monocytogenes*, has been demonstrated to be effective in cases of meningitis caused by *P. aeruginosa*, and shows good activity against penicillin-resistant pneumococci. In experimental pneumococcal meningitis, meropenem was comparable to ceftriaxone and inferior to vancomycin in sterilizingCSFcultures. The dose of meropenem is 1 to 2 g intravenously every 8 h for adults. The number of patients with bacterial meningitis enrolled in clinical trials of meropenem has not been sufficient to definitively assess the epileptogenic potential of this antibiotic. Firm recommendations regarding the use of cefepime and meropenem in bacterial meningitis await more clinical experience.

Adjunctive therapy The release of bacterial cell-wall components by bactericidal antibiotics leads to the production of the inflammatory cytokinesIL-1 andTNF in the subarachnoid space (Fig. 372-1). Dexamethasone exerts its beneficial effect by inhibiting the synthesis of IL-1 and TNF at the level of mRNA, decreasingCSFoutflow resistance, and stabilizing the blood-brain barrier. The rationale for giving dexamethasone 20 min before antibiotic therapy is that dexamethasone inhibits the production of TNF by macrophages and microglia only if it is administered before these cells are activated by endotoxin. Dexamethasone does not alter TNF production once it has been induced. The results of clinical trials of dexamethasone therapy in children, predominantly with meningitis due to *H. influenzae* and *S. pneumoniae*, have demonstrated its efficacy in decreasing meningeal inflammation and neurologic sequelae such as the incidence of sensorineural hearing loss. Evidence for efficacy of dexamethasone in other types of bacterial meningitis remains much more limited. The American Academy of Pediatrics recommends the consideration of dexamethasone for bacterial meningitis in infants and children ³2 months. The recommended dose is 0.6 mg/kg per day in four divided doses given intravenously for the first 2 days of antibiotic therapy or 0.8 mg/kg per day in two divided doses given for 2 days. The first dose of dexamethasone should be administered before or at least with the first dose of antibiotic.

The role of dexamethasone in the treatment of bacterial meningitis in adults remains uncertain. In a single clinical trial, dexamethasone was demonstrated to reduce the incidence of mortality in adults from pneumococcal meningitis. Other clinical trials of dexamethasone therapy in adults with bacterial meningitis are in progress. The suggested dose of dexamethasone is 0.6 mg/kg per day in four divided doses for the first 2 to 4 days of antimicrobial therapy. For the reasons cited earlier, dexamethasone should ideally be given 20 min before, or not later than simultaneous with, the first dose of antibiotics. It is unlikely to be of significant benefit if started ³6h after antimicrobial therapy has been initiated. Dexamethasone may decrease the penetration of vancomycin intoCSF, and it delays the sterilization of CSF in experimental models of *S. pneumoniae* meningitis. As a result, its potential benefit should be carefully weighed when vancomycin is the antibiotic of choice. The third-generation cephalosporins and rifampin penetrate the CSF extremely well, even in the presence of dexamethasone, and may provide an alternative when adjunctive dexamethasone is being used to treat *S. pneumoniae* meningitis.

Increased Intracranial Pressure Emergency treatment of increasedICPincludes elevation of the patient's head to 30 to 45°, intubation and hyperventilation (Pa_{CO_2}25 to 30 mmHg), and mannitol. Patients with increased ICP should be managed in an

intensive care unit. In these patients, accurate ICP measurements are best obtained with an ICP monitoring device.*Increased intracranial pressure is discussed in detail in Chap. 376.

PROGNOSIS

Mortality is 3 to 7% for meningitis caused by *H. influenzae*, *N. meningitidis*, or group B streptococci; 15% for that due to *L. monocytogenes*; and 20% for *S. pneumoniae*. In general, the risk of death from bacterial meningitis is significantly associated with (1) decreased level of consciousness on admission, (2) onset of seizures within 24 h of admission, (3) signs of increasedICP, (4) young age (infancy) and age >50, (5) the presence of comorbid conditions including shock and/or the need for mechanical ventilation, and (6) delay in the initiation of treatment. DecreasedCSFglucose concentration [<2.2 mmol/L (<40 mg/dL)] and markedly increased CSF protein concentration [>3 g/L (>300 mg/dL)] have been predictive of increased mortality and poorer outcomes in some series. Moderate or severe sequelae occur in ~25% of survivors of bacterial meningitis, although the exact incidence varies with the infecting organism. Common sequelae include decreased intellectual function, memory impairment, seizures, hearing loss and dizziness, and gait disturbances.

BRAIN ABSCESS

DEFINITION

A brain abscess is a focal, suppurative process within the brain parenchyma; it begins in an area of devitalized brain tissue as a localized area of cerebritis and develops into a collection of pus surrounded by a well-vascularized capsule.

EPIDEMIOLOGY

A bacterial brain abscess is a relatively uncommon intracranial infection, with an incidence of approximately 1 in 100,000 persons per year. Predisposing conditions include paranasal sinusitis, otitis media, and dental infections. Brain abscess is an extremely uncommon complication of these common infections, reflecting the efficiency with which they are treated with oral antimicrobial therapy, thereby minimizing the risk of subsequent intracranial spread of infection. In most modern series, a significant percentage of brain abscesses are not caused by classic pyogenic bacteria, but rather by *Toxoplasmi gondii*, *Aspergillus* spp., *Nocardia* spp., *Mycobacteria* spp., and fungi such as *Cryptococcus neoformans*. This distribution reflects the importance of brain abscesses in hosts whose immune systems are compromised, whether from HIV infection, organ transplantation, cancer, or immunosuppressive therapy. In Latin America and in immigrants from Latin America, the most common cause of brain abscess is *Taenia solium* (neurocysticercosis). The discussion that follows is limited to bacterial brain abscess; the other etiologies are discussed elsewhere.

ETIOLOGY

A brain abscess may develop (1) by direct spread from a contiguous cranial site of infection, such as paranasal sinusitis, otitis media, mastoiditis, or dental infection; (2)

following head trauma or a neurosurgical procedure; or (3) as a result of hematogenous spread from a remote site of infection. In 20 to 30% of cases no obvious primary source of infection is apparent (cryptogenic brain abscess).

Abscesses that develop as a result of direct spread of infection from the frontal, ethmoidal, or sphenoidal sinuses and those that occur due to dental infections are usually located in the frontal lobes. The most common pathogens in brain abscesses associated with paranasal sinusitis are microaerophilic and anaerobic streptococci, *Haemophilus* spp., *Bacteroides* spp. (non-*fragilis*), and *Fusobacterium* spp. The most common pathogens in brain abscess from dental infections are streptococci and *Prevotella* and *Porphyromonas* (formerly *Bacteroides*) spp.

The majority of brain abscesses associated with otitits media and mastoiditis occur in the temporal lobe and cerebellum and are caused by streptococci, *Bacteroides* spp. (including *B. fragilis*), *P. aeruginosa*, and Enterobacteriaceae. A brain abscess that is the result of hematogenous spread of infection from a site elsewhere in the body can occur anywhere in the brain but tends to form primarily in areas supplied by the middle cerebral artery (i.e., posterior frontal or parietal lobes). Metastatic abscesses are usually located at the interface of the gray-white matter and are often multiple. The microbiology of these brain abscesses is dependent on the primary source of infection. For example, brain abscesses that develop as a complication of infective endocarditis are often due to viridans streptococci or *S. aureus*; those that follow pyogenic lung infection are often due to *Streptococcus*, *Actinomyces*, or *Fusobacterium* species; those resulting from urinary sepsis are often caused by Enterobacteriaceae or *Pseudomonas aeruginosa*; and those associated with an intraabdominal source are frequently caused by *Streptococcus* spp., Enterobacteriaceae, or anaerobes. Abscesses that follow penetrating head trauma are frequently due to *S. aureus*, *Clostridium* spp., or Enterobacteriaceae, and those following a neurosurgical procedure are usually due to staphylococci, Enterobacteriaceae, or *P. aeruginosa*. Congenital cardiac malformations that produce a right-to-left shunt, such as tetralogy of Fallot, and atrial and ventricular septal defects allow bloodborne bacteria to bypass the pulmonary capillary bed and reach the brain. The decreased arterial oxygenation and saturation from the right-to-left shunt and polycythemia may cause focal areas of cerebral ischemia, thus providing a nidus for microorganisms that bypassed the pulmonary circulation to multiply and form an abscess. Streptococci are the most common pathogens in this setting.

PATHOGENESIS AND HISTOPATHOLOGY

Results of experimental models of brain abscess formation suggest that for bacterial invasion of brain parenchyma to occur, there must be preexisting or concomitant areas of ischemia, necrosis, or hypoxia in brain tissue. The intact brain parenchyma is relatively resistant to infection. Once bacteria have established infection, brain abscess formation evolves through four stages, regardless of the infecting organism. The early cerebritis stage (days 1 to 3) is characterized by a perivascular infiltration of inflammatory cells, which surround a central core of coagulative necrosis. Marked edema surrounds the lesion at this stage. In the late cerebritis stage (days 4 to 9), pus formation leads to enlargement of the necrotic center, which is surrounded at its border by an inflammatory infiltrate of macrophages and fibroblasts. A thin capsule of fibroblasts and reticular fibers gradually develops, and the surrounding area of cerebral

edema becomes more distinct than in the previous stage. The third stage, early capsule formation (days 10 to 13), is characterized by the formation of a capsule that is better developed on the cortical than on the ventricular side of the lesion. This stage correlates with the appearance of a ring-enhancing capsule on neuroimaging studies. The final stage, late capsule formation (day 14 and beyond), is defined by a well-formed necrotic center surrounded by a dense collagenous capsule. The surrounding area of cerebral edema has regressed, but marked gliosis with large numbers of reactive astrocytes has developed outside the capsule. This gliotic process may contribute to the development of seizures as a sequelae of brain abscess.

CLINICAL PRESENTATION

A brain abscess presents as an expanding intracranial mass lesion, rather than as an infectious process. The most common symptom is headache, occurring in >75% of patients. The headache is often characterized as a constant, dull, aching sensation, either hemicranial or generalized, and it becomes progressively more severe and refractory to therapy. Fever is present in only 50% of patients at the time of diagnosis and is typically low-grade. Thus the absence of fever should not exclude the diagnosis. The new onset of focal or generalized seizure activity is a presenting sign in 25 to 30% of patients. In most large series, a focal neurologic deficit is part of the initial presentation in>60% of patients.

The clinical presentation of a brain abscess depends on its location and on the presence of raisedICP, which develops as edema surrounds the evolving abscess. Hemiparesis is the most common localizing sign of a frontal lobe abscess. A temporal lobe abscess may present with a disturbance of language (dysphasia) or an upper homonymous quadrantanopia. Nystagmus and ataxia are signs of a cerebellar abscess. The earliest signs of increased ICP in a patient with a brain abscess are papilledema, nausea and vomiting, and drowsiness or confusion. Meningismus is not present unless the abscess has ruptured into the ventricle or the infection has spread to the subarachnoid space.

DIAGNOSIS

The diagnosis of a brain abscess is made by neuroimaging studies.CT has the advantage of greater feasibility in acutely ill patients, butMRI is better for demonstrating abscesses in the early (cerebritis) stages and is superior to CT for identifying abscesses in the posterior fossa. Cerebritis appears on MRI as an area of low-signal intensity on T1-weighted images with irregular postgadolinium enhancement and as an area of increased signal intensity on T2-weighted images. Cerebritis is often not visualized by CT scan. As the abscess matures, the appearance of the lesion changes. On a contrast-enhanced CT scan, a mature brain abscess appears as a focal area of hypodensity surrounded by ring enhancement. On T1-weighted MRI, a mature brain abscess has the characteristics demonstrated inFig. 372-2. On T2-weighted MRI, there is a hyperintense central area of pus surrounded by a well-defined hypointense capsule and a hyperintense area of edema.

The microbiologic diagnosis is made by Gram's stain and culture of abscess material obtained by stereotactic needle aspiration. Lumbar puncture should not be performed in

patients with known or suspected focal intracranial infections such as abscess or empyema;CSFanalysis contributes nothing to diagnosis or therapy, and lumbar puncture increases the risk of herniation.

Additional laboratory studies that may provide clues to the diagnosis of brain abscess in patients with aCNS mass lesion include the peripheral white blood cell count and erythrocyte sedimentation rate; the latter will be elevated in about 60% of patients, and about 50% will have a peripheral leukocytosis.

DIFFERENTIAL DIAGNOSIS

Conditions that can cause headache, fever, focal neurologic signs, and seizure activity include brain abscess, subdural empyema, bacterial meningitis, viral meningoencephalitis, superior sagittal sinus thrombosis, and acute disseminated encephalomyelitis. In unusual cases, tumors and, more rarely, cerebral infarction or hematoma can have an MRIor CTappearance resembling brain abscess.

TREATMENT

Empirical therapy of a brain abscess depends on the source of infection (Table 372-4) and typically includes a third-generation cephalosporin (e.g., cefotaxime) and metronidazole (Table 372-3 for antibiotic dosages). Patients with multiple abscesses, which suggest the possibility of hematogenous spread, or those who develop abscesses following head trauma should have nafcillin added to this regimen for coverage of staphylococci. Patients who develop abscesses following neurosurgical procedures should be treated with vancomycin plus ceftazidime (in place of cefotaxime) for coverage of both staphylococci and *P. aeruginosa*.

Aspiration and drainage of the abscess under stereotactic guidance are beneficial for both diagnosis and therapy. Empirical antibiotic coverage can be modified based on the results of Gram's stain and culture of the abscess contents (Table 372-4). Complete excision of a bacterial abscess via craniotomy or craniectomy is generally reserved for multiloculated abscesses or those in which stereotactic aspiration is unsuccessful. Antibiotic therapy alone is generally not optimal for treatment of brain abscess and should be reserved for patients whose abscesses cannot be surgically aspirated or otherwise drained, for selected patients with multiple abscesses, and in patients whose condition is too tenuous to allow performance of a neurosurgical procedure. All patients should receive a minimum of 6 to 8 weeks of parenteral antibiotic therapy. The role, if any, of supplemental oral antibiotic therapy following completion of a standard course of parenteral therapy has never been adequately studied.

In addition to surgical drainage and antibiotic therapy, patients should receive prophylactic anticonvulsant therapy because of the high risk of focal or generalized seizures. Anticonvulsant therapy is continued for at least 3 months after resolution of the abscess, and decisions regarding withdrawal are then based on the EEG. If the EEG is abnormal, anticonvulsant therapy should be continued. If the EEG is normal, anticonvulsant therapy can be slowly withdrawn, with close follow-up and repeat EEG after the medication has been discontinued.

Glucocorticoids should not be given routinely to patients with brain abscesses. Intravenous dexamethasone therapy (10 mg every 6 h) is usually reserved for patients with substantial periabscess edema and associated mass effect and increasedICP. Dexamethasone should be tapered as rapidly as possible to avoid delaying the natural process of encapsulation of the abscess.

SerialCT orMRIscans should be obtained on a monthly or twice-monthly basis to document resolution of the abscess. More frequent studies (e.g., weekly) are probably warranted in the subset of patients who are receiving antibiotic therapy alone. A small amount of enhancement may remain for months after the abscess has been successfully treated.

PROGNOSIS

Bacterial abscess can be successfully treated in the majority of patients. Seizures, however, are a common complication and occur in as many as 70% of patients.

SUBDURAL EMPYEMA

DEFINITION

A subdural empyema (SDE) is a collection of pus between the dura and arachnoid membranes (Fig. 372-3).

EPIDEMIOLOGY

SDEis a rare intracranial infection. Sinusitis is the most common predisposing condition and typically involves the frontal sinuses, either alone or in combination with the ethmoid and maxillary sinuses. Sinusitis-associated empyema has a striking predilection for young males, possibly reflecting sex-related differences in sinus anatomy and development. SDE may also develop as a complication of head trauma or following neurosurgical drainage of a subdural hematoma. Secondary infection of a subdural effusion may also result in empyema, although secondary infection of hematomas, in the absence of a prior neurosurgical procedure, is rare.

ETIOLOGY

Aerobic and microaerophilic streptococci and anaerobic bacteria are the most common causative organisms of sinusitis-associatedSDE. Staphylococci and gram-negative bacilli are often the etiologic organisms when SDE follows neurosurgical procedures or head trauma. SDE should be distinguished from subdural effusions that, especially in infants and children, may complicate bacterial meningitis. Subdural effusions are sterile collections of protein-rich fluid that result from increased permeability of the thin-walled capillaries and veins in the inner layer of the dura.

PATHOPHYSIOLOGY

Sinusitis-associatedSDEdevelops as a result of either retrograde spread of infection from septic thrombophlebitis of the mucosal veins draining the sinuses or contiguous

spread of infection to the brain from osteomyelitis in the posterior wall of the frontal or other sinuses. SDE may also develop from direct introduction of bacteria into the subdural space as a complication of a neurosurgical procedure. The evolution of SDE can be extremely rapid because the subdural space is a large compartment that offers few mechanical barriers to the spread of infection. In patients with sinusitis-associated SDE, suppuration typically begins in the upper and anterior portions of one cerebral hemisphere and then extends posteriorly. SDE is often associated with other intracranial infections including epidural empyema (40%), cortical thrombophlebitis (35%), and intracranial abscess or cerebritis (>25%). Cortical venous infarction produces necrosis of underlying cerebral cortex and subcortical white matter, with focal neurological deficits and seizures (see below).

CLINICAL PRESENTATION

A patient withSDEtypically presents with fever and a progressively worsening headache. Patients may also have signs and symptoms related to sinusitis or other primary sites of intracranial infection. As the infection progresses, focal neurologic deficits, seizures, and signs of increasedICPcommonly occur. Headache is the most common complaint at the time of presentation; initially it is localized to the side of the subdural infection but then becomes more severe and generalized. Contralateral hemiparesis or hemiplegia is the most common focal neurologic deficit and can occur from the direct effects of the SDE on the cortex or as a consequence of venous infarction. Seizures begin as partial motor seizures that then become secondarily generalized. Seizures may be due to the direct irritative effect of the SDE on the underlying cortex or result from cortical venous infarction (see above). In untreated SDE, the increasing mass effect and increase in ICP cause progressive deterioration in consciousness, leading ultimately to coma.

DIAGNOSIS

Neuroimaging has greatly facilitated the diagnosis ofSDE.MRI(Fig. 372-4) is superior toCT in identifying SDE and any associated intracranial infections. The administration of gadolinium greatly improves diagnosis by enhancing the rim of the empyema and allowing the empyema to be clearly delineated from the underlying brain parenchyma. Cranial MRI is also extremely valuable in identifying sinusitis, other focal CNS infections, cortical venous infarction, cerebral edema, and cerebritis.

CSFexamination should be avoided in all patients withSDE as it adds no useful information and is associated with the risk of cerebral herniation.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of the combination of headache, fever, focal neurologic signs, and seizure activity that progresses rapidly to an altered level of consciousness includesSDE, bacterial meningitis, viral encephalitis, brain abscess, superior sagittal sinus thrombosis, and acute disseminated encephalomyelitis.

TREATMENT

Emergent neurosurgical evacuation of the empyema, either through burr-hole drainage

or craniotomy, is the definitive step in the management of this infection. Empirical antimicrobial therapy should include a combination of a third-generation cephalosporin (e.g., cefotaxime or ceftriaxone), vancomycin, and metronidazole (Tables 372-3 and372-4for dosages). Parenteral antibiotic therapy should be continued for a minimum of 4 weeks. Specific diagnosis of the etiologic organisms is made based on Gram's stain and culture of fluid obtained via either burr holes or craniotomy; the initial empirical antibiotic coverage should be modified accordingly.

PROGNOSIS

Prognosis is influenced by the level of consciousness of the patient at the time of hospital presentation, the size of the empyema, and the speed with which therapy is instituted. Long-term neurologic sequelae, which include seizures and hemiparesis, occur in up to 50% of cases.

EPIDURAL ABSCESS

DEFINITION

Cranial epidural abscess is a suppurative infection occurring in the potential space between the inner skull table and the dura (Fig. 372-5).

ETIOLOGY AND PATHOPHYSIOLOGY

A cranial epidural abscess develops as a complication of a craniotomy or compound skull fracture or as a result of spread of infection from the frontal sinuses, middle ear, mastoid, or orbit. An epidural abscess may develop contiguous to an area of osteomyelitis, when craniotomy is complicated by infection of the wound or bone flap, or as a result of direct infection of the epidural space. Infection in the frontal sinus, middle ear, mastoid, or orbit can reach the epidural space through retrograde spread of infection from septic thrombophlebitis in the emissary veins that drain these areas or by way of direct spread of infection through areas of osteomyelitis. Unlike the subdural space, the epidural space is really a potential rather than an actual compartment. The dura is normally tightly adherent to the inner skull table, and infection must dissect the dura away from the skull table as it spreads. As a result, epidural abscesses are often smaller thanSDEs. Cranial epidural abscesses, unlike brain abscesses, only rarely result from hematogenous spread of infection from extracranial primary sites. The bacteriology of a cranial epidural abscess is similar to that of SDE (see above). The etiologic organisms of an epidural abscess that arises from frontal sinusitis, middle ear infections, or mastoiditis are usually streptococci or anaerobic organisms. Staphylococci or gram-negative organisms are the usual cause of an epidural abscess that develops as a complication of craniotomy or compound skull fracture.

CLINICAL PRESENTATION

Patients typically present with severe hemicranial headache and persistent fever. The diagnosis should always be suspected when these symptoms occur following recent head trauma or neurosurgery or in the setting of frontal sinusitis, mastoiditis, or otitis media.

DIAGNOSIS

CranialMRI is the procedure of choice to demonstrate a cranial epidural abscess. The sensitivity ofCT is limited by the presence of signal artifacts arising from the bone of the inner skull table. On MRI, an epidural abscess appears as a lentiform or crescent-shaped fluid collection that is hyperintense compared toCSF on T2-weighted images. On T1-weighted images, the fluid collection has a signal intensity that is intermediate between that of brain tissue and CSF. Following the administration of gadolinium, a significant enhancement of the dura is seen on T1-weighted images.

TREATMENT

Immediate neurosurgical drainage is indicated. Empirical antimicrobial therapy, pending the results of Gram's stain and culture of the purulent material obtained at surgery, should include a combination of penicillin, a third-generation cephalosporin, nafcillin or vancomycin, and metronidazole (Tables 372-2 and372-3). When the organism has been identified, antimicrobial therapy can be modified accordingly. Antibiotics should be continued for at least 3 weeks after surgical drainage.

SUPPURATIVE THROMBOPHLEBITIS

DEFINITION

Suppurative intracranial thrombophlebitis is septic venous thrombosis of cortical veins and sinuses. This may occur as a complication of bacterial meningitis,SDE, epidural abscess, or infection in the skin of the face, paranasal sinuses, middle ear, or mastoid.

ANATOMY AND PATHOPHYSIOLOGY

The cerebral veins and venous sinuses have no valves; therefore, blood within them can flow in either direction. The superior sagittal sinus is the largest of the venous sinuses (Fig. 372-6). It receives blood from the frontal, parietal, and occipital superior cerebral veins and the diploic veins, which communicate with the meningeal veins. Bacterial meningitis is a common predisposing condition for septic thrombosis of the superior sagittal sinus. The diploic veins, which drain into the superior sagittal sinus, provide a route for the spread of infection from the meninges, especially in cases where there is purulent exudate near areas of the superior sagittal sinus. Infection can also spread to the superior sagittal sinus from nearbySDE or epidural abscess. Dehydration from vomiting, hypercoagulable states, and immunologic abnormalities, including the presence of circulating antiphospholipid antibodies, also contribute to cerebral venous sinus thrombosis. Thrombosis may extend from one sinus to another, and often at autopsy thrombi of different histologic ages can be detected in several sinuses. Thrombosis of the superior sagittal sinus is often associated with thrombosis of superior cortical veins and small parenchymal hemorrhages.

The superior sagittal sinus drains into the transverse sinuses (Fig. 372-6). The transverse sinuses also receive venous drainage from small veins from both the middle ear and mastoid cells. The transverse sinus becomes the sigmoid sinus before draining

into the internal jugular vein. Septic transverse/sigmoid sinus thrombosis can be a complication of acute and chronic otitis media or mastoiditis. Infection spreads from the mastoid air cells to the transverse sinus via the emissary veins or by direct invasion. The cavernous sinuses are inferior to the superior sagittal sinus at the base of the skull. The cavernous sinuses receive blood from the facial veins via the superior and inferior ophthalmic veins. Bacteria in the facial veins enter the cavernous sinus via these veins. Bacteria in the sphenoid and ethmoid sinuses can spread to the cavernous sinuses via the small emissary veins. The sphenoid and ethmoid sinuses are the most common sites of primary infection resulting in septic cavernous sinus thrombosis.

CLINICAL MANIFESTATIONS

Septic thrombosis of the superior sagittal sinus presents as headache, nausea and vomiting, confusion, and focal or generalized seizures. There may be a rapid development of stupor and coma. Weakness of the lower extremities with bilateral Babinski signs or hemiparesis is often present. When superior sagittal sinus thrombosis occurs as a complication of bacterial meningitis, nuchal rigidity and Kernig's and Brudzinski's signs may be present.

The oculomotor nerve, the trochlear nerve, the abducens nerve, the ophthalmic and maxillary branches of the trigeminal nerve, and the internal carotid artery all pass through the cavernous sinus. The symptoms of *septic cavernous sinus thrombosis* are fever, headache, frontal and retroorbital pain, and diplopia. The classic signs are ptosis, proptosis, chemosis, and extraocular dysmotility due to deficits of cranial nerves III, IV, and VI. Hypo- or hyperesthesia of the ophthalmic and maxillary divisions of the fifth cranial nerve and a decreased corneal reflex may be detected. There may be evidence of dilated, tortuous retinal veins and papilledema.

Headache and earache are the most frequent symptoms of *transverse sinus thrombosis*. A transverse sinus thrombosis may also present with Gradinego's syndrome characterized by otitis media, sixth nerve palsy, and retroorbital or facial pain. Sigmoid sinus and internal jugular vein thrombosis may present with neck pain.

DIAGNOSIS

The diagnosis of septic venous sinus thrombosis is suggested by an absent flow void within the affected venous sinus onMRI and confirmed by magnetic resonance venography or the venous phase of cerebral angiography. The diagnosis of thrombophlebitis of intracerebral and meningeal veins is suggested by the presence of intracerebral hemorrhage but requires cerebral angiography for definitive diagnosis.

TREATMENT

Septic venous sinus thrombosis is usually treated with antibiotics and hydration. The choice of antimicrobial therapy is based on the bacteria responsible for the predisposing or associated condition. Anticoagulation with dose-adjusted heparin has been reported to be beneficial in patients with aseptic venous sinus thrombosis; it is also used in the treatment of septic venous sinus thrombosis complicating bacterial meningitis in patients who are worsening despite antimicrobial therapy and intravenous fluids. The presence

of a small intracerebral hemorrhage from septic thrombophlebitis is not an absolute contraindication to heparin therapy. Successful management of aseptic venous sinus thrombosis has been reported with urokinase therapy and with a combination of intrathrombus recombinant tissue plasminogen activator (rtPA) and intravenous heparin, but there is yet no reported experience with these therapies in septic venous sinus thrombosis.

(Bibliography omitted in Palm version)

373. VIRAL MENINGITIS AND ENCEPHALITIS - *Kenneth L. Tyler*

Hundreds of viruses have been reported to produce acute infection and injury to the central or peripheral nervous systems. Many aspects of the clinical characteristics of these diseases are determined by whether the infection is limited primarily to the meninges (*meningitis*) or extends to involve the parenchyma of the brain (*encephalitis*), spinal cord (*myelitis*), or nerve roots (*radiculitis*). In some cases more than one of these areas can be involved simultaneously (meningoencephalitis, myeloradiculitis, etc.). Viruses can also produce chronic or persistent infections of the central nervous system (CNS).**Infections caused by HIV are discussed in Chap. 309, human T cell leukemia virus (HTLV) types I and II in Chap. 368, and prions in Chap. 375.*

ACUTE VIRAL INFECTIONS

VIRAL MENINGITIS

Clinical Manifestations The syndrome of viral meningitis consists of fever, headache, and meningeal irritation coupled with an inflammatory cerebrospinal fluid (CSF) profile (see below). Fever may be accompanied by malaise, myalgia, anorexia, nausea and vomiting, abdominal pain, and/or diarrhea. It is not uncommon to see a mild degree of lethargy or drowsiness. The presence of more profound alterations in consciousness, such as stupor, coma, or marked confusion, should prompt consideration of alternative diagnoses. Similarly, seizures, cranial nerve palsies, or other focal neurologic signs or symptoms suggests parenchymal involvement and is not typical of uncomplicated viral meningitis. The headache associated with viral meningitis is usually frontal or retroorbital and often associated with photophobia and pain on moving the eyes. Nuchal rigidity is present in most cases but may be mild and present only near the limit of neck anteflexion. Evidence of severe meningeal irritation, such as Kernig's and Brudzinski's signs (Chap. 372), is generally absent.

Etiology Enteroviruses account for 75 to 90% of aseptic meningitis cases in most series (Table 373-1). Viruses belonging to the *Enterovirus* genus are members of the family Picornaviridae and include the coxsackieviruses, echoviruses, polioviruses, and human enteroviruses 68 to 71. Using a variety of diagnostic techniques includingCSFpolymerase chain reaction (PCR) tests, culture, and serology, a specific viral cause can be found in 75 to 90% of cases of viral meningitis. CSF cultures are positive in 30 to 70% of patients, the frequency of isolation depending on the specific viral agent. Approximately two-thirds of culture-negative cases of aseptic meningitis have a specific viral etiology identified by CSF PCR testing (see below).

Epidemiology The exact incidence of viral meningitis in the United States is impossible to determine since most cases go unreported to public health authorities. In temperate climates, there is a substantial increase in cases during the summer and early fall months, reflecting the seasonal predominance of enterovirus and arthropod-borne encephalitis virus ("arbovirus") infections, with a peak monthly incidence of about 1 reported case per 100,000 population. The dramatic seasonal predilections of some viruses causing meningitis provide a valuable but not always infallible clue to diagnosis (Table 373-2).

Laboratory Diagnosis

CSF examination The most important laboratory test in the diagnosis of meningitis is examination of the CSF. The typical profile in cases of viral meningitis is a lymphocytic pleocytosis (25 to 500 cells per microliter), a normal or slightly elevated protein level [0.2 to 0.8 g/L (20 to 80 mg/dL)], a normal glucose level, and a normal or mildly elevated opening pressure (100 to 350 mm H_2O). Organisms *are not* seen on Gram's or acid-fast stained smears or india ink wet mounts of CSF. Rarely, polymorphonuclear neutrophils (PMNs) may predominate in the first 48 h of illness, especially in patients with infections due to echovirus 9 or Eastern equine virus. However, the presence of a persisting PMN pleocytosis should always prompt consideration of bacterial meningitis or parameningeal infections. The total CSF cell count in viral meningitis is typically 25 to 500/uL, although cell counts of several thousand per microliter are occasionally seen, especially with infections due to lymphocytic choriomeningitis virus (LCMV) and mumps virus. The CSF glucose level is typically normal in viral infections, although it may be decreased in 10 to 30% of cases due to mumps as well as in cases due to LCMV. Rare instances of decreased CSF glucose concentration occur in cases of meningitis due to echoviruses and other enteroviruses, herpes simplex virus (HSV) type 2, and varicella-zoster virus (VZV). As a rule, a lymphocytic pleocytosis with a low glucose level should suggest fungal, listerial, or tuberculous meningitis or noninfectious disorders (e.g., sarcoid, neoplastic meningitis).

A number of tests measuring levels of various CSF proteins, enzymes, and mediators, including C-reactive protein, lactic acid, lactate dehydrogenase, neopterin, quinolinate, interleukin (IL) 1b, IL-6, soluble IL-2 receptor, b_2-microglobulin, and tumor necrosis factor (TNF), have been proposed as potential discriminators between viral and bacterial meningitis or as markers of specific types of viral infection (e.g., infection with HIV), but are of limited general use.

Polymerase Chain Reaction Amplification of Viral Nucleic Acid Amplification of viral-specific DNA or RNA from CSF using PCR amplification has become the single most important method for diagnosing CNS viral infections. HSV DNA is frequently amplified from the CSF of patients with herpes simplex encephalitis (HSV-1) and recurrent lymphocytic meningitis (HSV-2), even when standard culture techniques are negative. PCR is also used routinely to diagnose CNS viral infections caused by enteroviruses, cytomegalovirus (CMV), Epstein-Barr virus (EBV), and VZV. Genomic amplification and detection of enteroviral (coxsackie-, polio-, echo-, enterovirus) RNA in the CSF of patients with meningitis is now the diagnostic procedure of choice for this group of viruses.

CSF culture The overall results of CSF culture for the diagnosis of viral infection are disappointing (Table 373-3), presumably because of the generally low concentration of infectious virus present and the need to customize isolation procedures for individual viruses. For viral isolation, 2 mL of CSF should be brought promptly to the microbiology laboratory, where it should be refrigerated and processed as speedily as possible. CSF specimens for viral isolation should never be stored in a-20°C freezer since viruses are often unstable at this temperature, and most freezers have "frostfree" warm-up cycles that are detrimental to viral stability. Storage for>24 h is probably best done in a-70°C freezer.

Other Sources for Viral Isolation Viruses may also be isolated from sites and body fluids other thanCSF, including throat swabs, stool, blood, and urine. Enteroviruses and adenoviruses may be found in feces; arboviruses, some enteroviruses, andLCMV, in blood; mumps andCMV, in urine; and enteroviruses, mumps, and adenoviruses, in throat washings. During enteroviral infections, viral shedding in stool may persist for several weeks. The presence of enterovirus in stool is not diagnostic and may result from residual shedding from a previous enteroviral infection; it also occurs in some asymptomatic individuals during enteroviral epidemics.

Serologic Studies For some viruses, such as the arboviruses, serologic studies remain an important diagnostic tool but are less useful for viruses such asHSV,VZV,CMV, andEBV for which the prevalence of antibody seropositivity in the general population is high. Diagnosis of viral infection can be made by documenting seroconversion between acute-phase and convalescent sera (typically obtained after 2 to 4 weeks), or by demonstrating the presence of virus-specific IgM antibodies. Antiviral antibodies may be measured inCSF (see below). The timing of the antibody response often means that serologic data are useful mainly for the retrospective establishment of a specific diagnosis, and their value in initial diagnosis and management is limited. Most viral infections of theCNS are associated with intrathecal synthesis of antiviral antibody. This results in an elevation in the ratio of antibody in CSF compared to serum (CSF/serum antibody index).

Agarose electrophoresis or isoelectric focusing ofCSFg-globulins may reveal the presence of oligoclonal bands. These bands have been found in association with a number of viral infections, including infections with HIV,HTLVtype I,VZV, mumps, subacute sclerosing panencephalitis (SSPE), and progressive rubella panencephalitis. The associated antibodies are often directed against viral proteins. The finding of oligoclonal bands may be of some diagnostic utility, since typically they are not seen with arbovirus, enterovirus, orHSVinfections. Oligoclonal bands are also encountered in certain noninfectious neurologic diseases (e.g., multiple sclerosis) and may be found in nonviral infections (e.g., syphilis, Lyme borreliosis).

Other Laboratory Studies All patients with suspected viral meningitis should have a complete blood count and differential; liver function tests; and measurement of the erythrocyte sedimentation rate (ESR), blood urea nitrogen (BUN), and plasma levels of electrolytes, glucose, creatinine, creatine kinase, aldolase, amylase, and lipase. Abnormalities in specific test results may suggest particular etiologic diagnoses. Magnetic resonance imaging (MRI), computed tomography (CT), electroencephalography (EEG), evoked response studies, electromyography (EMG), and nerve conduction studies are not necessary in most cases. They are best used selectively when atypical presentations or unusual features present diagnostic problems.

Differential Diagnosis The most important issue in the differential diagnosis is the exclusion of nonviral causes that can mimic viral meningitis. The major categories of disease that should always be considered and excluded are (1) bacterial meningitis and other infectious meningidities (e.g., *Mycoplasma*, *Listeria*, *Brucella*, *Coxiella*, and *Rickettsia*); (2) parameningeal infections or partially treated bacterial meningitis; (3)

nonviral infectious meningitides where cultures may be negative (e.g., fungal, tuberculous, parasitic, or syphilitic disease); (4) neoplastic meningitis; and (5) meningitis secondary to noninfectious inflammatory diseases such as sarcoid, Behcet's disease, and the uveomeningitic syndromes.

Specific Viral Etiologies Enteroviruses (Chap. 193) are the most common cause of viral meningitis (>75% of cases with etiology identified) and should be considered the leading candidates when a typical case occurs in the summer months, especially in a child (<15 years) (Table 373-4). However, despite their summer prevalence, sporadic cases of enteroviralCNSinfection are seen year-round. The physical examination should include a careful search for exanthemata, hand-foot-mouth disease, herpangina, pleurodynia, myopericarditis, and hemorrhagic conjunctivitis, which may be stigmata of enterovirus infections.PCRamplification of enteroviral RNA fromCSF has become the diagnostic procedure of choice for these infections.

Arbovirus infections typically occur in the summer months, have clear geographic localization, and occur in epidemics, all factors reflecting the ecology of their transmission through infected insect vectors (Fig. 373-1);Table 373-6;Chap. 198). Arboviral meningitis should be considered when clusters of meningitis cases occur in a restricted geographic region during the summer or early fall. A history of tick exposure or travel or residence in the appropriate geographic area should suggest the possibility of Colorado tick fever virus or Powassan virus infection, although nonviral diseases producing meningitis (e.g., Lyme disease) or headache with meningismus (e.g., Rocky Mountain spotted fever) may also present this way.

HSV-2 meningitis (Chap. 182) occurs in approximately 25% of women and 11% of men at the time of an initial (primary) episode of genital herpes. Of these patients, 20% go on to have recurrent attacks of meningitis. In some series, HSV-2 has been the most important cause of aseptic meningitis in adults, especially women, and overall it is probably second only to enteroviruses as a cause of viral meningitis. Although HSV-2 can be cultured fromCSFduring a first episode of meningitis, cultures are invariably negative during recurrent episodes of HSV-2 meningitis. Diagnosis depends on amplification of HSV-2 DNA from CSF byPCR. Almost all cases of recurrent HSV meningitis are due to HSV-2, although rare cases due to HSV-1 have been reported. Most cases of benign recurrent lymphocytic meningitis, including those meeting accepted diagnostic criteria for Mollaret's meningitis, appear to be due to HSV. Genital lesions may not be present, and most patients give no history of genital herpes. CSF cultures are negative, although HSV DNA can be amplified from CSF by PCR during attacks of meningitis but not during symptom-free intervals.

VZV meningitis should be suspected in the presence of concurrent chickenpox or shingles. However, it is important to recognize that in some series up to 40% ofVZVmeningitis cases have been reported to occur in the absence of rash. The frequency of VZV as a cause of meningitis is extremely variable, ranging from as low as 3% to as high as 20% in different series. The frequency would be expected to decline with the increasing utilization of the live attenuated varicella vaccine (Varivax) in children. In addition to meningitis, encephalitis (see below), and shingles (see below), VZV can also produce acute cerebellar ataxia. This typically occurs in children and presents with the abrupt onset of limb and truncal ataxia. A similar syndrome occurs

less commonly in association withEBV and enteroviral infection.PCR has rapidly become a major tool in the diagnosis of VZVCNSinfections. In patients with negativeCSF PCR results, the diagnosis of VZV CNS infection can be made by the demonstration of VZV-specific intrathecal antibody synthesis and/or the presence of VZV CSF IgM antibodies, or by positive CSF cultures.

EBV infections may also produce aseptic meningitis, with or without accompanying evidence of the infectious mononucleosis syndrome. The diagnosis may be suggested by the finding of atypical lymphocytes in theCSF or an atypical lymphocytosis in peripheral blood. The demonstration of IgM antibody to viral capsid antigen (VCA), antibody to the diffuse (D) component of early antigen (EA), or subsequently a rising titer of antibody to nuclear antigen (EBNA) are indicative of acuteEBVinfection. EBV is almost never cultured from CSF, but EBV DNA can be amplified from CSF in many patients with EBV-associatedCNSinfections. HIV-infected patients with primary CNS lymphoma may have a positive CSF PCRfor EBV DNA even in the absence of meningoencephalitis.

HIV meningitis should be suspected in any patient with known or identified risk factors for HIV infection. Aseptic meningitis is a common manifestation of primary exposure to HIV and occurs in 5 to 10% of cases. In some patients, seroconversion may be delayed for several months; however, detection of the presence of HIV genome byPCR or p24 protein establishes the diagnosis. HIV can be cultured fromCSF in some patients. Cranial nerve palsies, most commonly involving cranial nerves V, VII, or VIII, are more common in HIV meningitis than in other viral infections.*For further discussion of HIV infection see Chap. 309.*

Mumps (Chap. 196) should be considered when meningitis occurs in the late winter or early spring, especially in males (male/female ratio 3:1). With the widespread use of the live attenuated mumps vaccine in the United States since 1967, the incidence of mumps meningitis has fallen by>95%. Rare cases of mumps vaccine-associated meningitis have been reported, but they are not usually seen after vaccination with the attenuated Jeryl-Lynn strain of virus used in the United States. The presence of orchitis, oophoritis, parotitis, pancreatitis, or elevations in serum lipase and amylase are suggestive but can be found with other viruses, and their absence does not exclude the diagnosis. Clinical meningitis occurs in 5% of patients with parotitis, but only 50% of patients with meningitis have associated parotitis. Mumps infection confers lifelong immunity, so a documented history of previous infection excludes this diagnosis. The presence of hypoglycorrhachia (10 to 30%) may be an additional diagnostic clue, once other causes have been excluded (see above). Up to 25% of patients may have aPMN-predominantCSFpleocytosis, and CSF abnormalities may persist for months. Diagnosis is typically made by isolation of virus from CSF and/or demonstration of seroconversion between acute-phase and convalescent sera.

LCMV infection (Chap. 198) should be considered when aseptic meningitis occurs in the late fall or winter, and in individuals with a history of exposure to house mice (*Mus musculus*), pet or laboratory rodents (e.g., hamsters), or their excreta. Some patients have an associated rash, pulmonary infiltrates, alopecia, parotitis, orchitis, or myopericarditis. Laboratory clues to the diagnosis ofLCMV, in addition to the clinical findings noted above, may include the presence of leukopenia, thrombocytopenia, or

abnormal liver function tests. Some cases present with a markedCSFpleocytosis (>1000 cells per microliter) and hypoglycorrachia (<30%).

TREATMENT

In the usual case of viral meningitis, treatment is symptomatic, and hospitalization is not required. Exceptions include patients with deficient humoral immunity, neonates with overwhelming infection, and patients in whom the clinical orCSFprofile suggests the possibility of a bacterial or other nonviral cause of infection. Patients with suspected bacterial meningitis should receive appropriate empirical therapy pending culture results (Chap. 372). Patients usually prefer to rest undisturbed in a quiet, darkened room. Analgesics can be used to relieve headache, which is often reduced by the initial diagnostic lumbar puncture. Antipyretics may help to reduce fever, which rarely exceeds 40°C. Hyponatremia may develop as a result of inappropriate vasopressin secretion (SIADH), so fluid and electrolyte status should be monitored. Repeat lumbar puncture is indicated only in patients whose fever and symptoms fail to resolve after a few days or if there is doubt about the initial diagnosis.

Oral or intravenous acyclovir may be of benefit in patients with meningitis caused byHSV-1 or -2 and in cases of severeEBVorVZVinfection. Data concerning treatment of HSV, EBV, and VZV meningitis are extremely limited. Seriously ill patients should probably receive intravenous acyclovir (30 mg/kg per day in three divided doses) for 7 days. Oral acyclovir (800 mg, five times daily), famciclovir (500 mg, tid), or valacyclovir (1000 mg, tid) for a week may be tried in less severely ill patients, although data on efficacy are lacking. Patients with HIV meningitis should receive highly active antiretroviral therapy (Chap. 309).

Patients with viral meningitis who are known to have deficient humoral immunity (e.g. X-linked agammaglobulinemia), and who are not already receiving either intramuscular g-globulin or intravenous immunoglobulin (IVIG), should be treated with these agents. Intraventricular administration of immunoglobulin through an Ommaya reservoir has been tried in some patients with chronic enteroviral meningitis who have not responded to intramuscular or intravenous immunoglobulin.

An experimental drug, pleconaril (Viropharma Inc., VP 63843), has shown efficacy against a variety of enteroviral infections and has good oral bioavailability and excellentCNSpenetration. Ongoing clinical trials in patients with enteroviral meningitis suggest that pleconaril decreases the duration of symptoms compared to placebo. Since most cases of enteroviral CNS infection are benign and self-limited, the indications for pleconaril therapy need to be better defined. Antiviral treatment might benefit patients with chronic CNS enteroviral infections in the setting of agammaglobulinemia or those who develop poliomyelitis as a complication of polio vaccine administration.

Vaccination is an effective method of preventing the development of meningitis and other neurologic complications associated with poliovirus, mumps, and measles infection. A live attenuatedVZVvaccine (Varivax) is available in the United States. Clinical studies indicate an effectiveness rate of 70 to 90% for this vaccine. Reduction in primary VZV infection would be expected to reduce the frequency and/or severity both

of primary neurologic complications of varicella and of the consequences of later reactivation (e.g., shingles).

Prognosis In adults, the prognosis for full recovery from viral meningitis is excellent. Rare patients complain of persisting headache, mild mental impairment, incoordination, or generalized asthenia for weeks to months. The outcome in infants and neonates (<1 year) is less certain; intellectual impairment, learning disabilities, hearing loss, and other lasting sequelae have been reported in some studies.

VIRAL ENCEPHALITIS

Definition In distinction to meningitis, where the infectious process and associated inflammatory response is limited largely to the meninges, in encephalitis the brain parenchyma is also involved. Many patients with encephalitis also have evidence of associated meningitis (meningoencephalitis) and, in some cases, involvement of the spinal cord or nerve roots (encephalomyelitis, encephalomyeloradiculitis).

Clinical Manifestations In addition to the acute febrile illness with evidence of meningeal involvement characteristic of meningitis, the patient with encephalitis commonly has an altered level of consciousness, an abnormal mental state, and evidence of either focal or diffuse neurologic signs and symptoms. Any degree of altered consciousness may occur, ranging from mild lethargy to deep coma. Patients with encephalitis are frequently confused, delirious, and disoriented. Mental aberrations may include hallucinations, agitation, personality change, behavioral disorders, and, at times, a frankly psychotic state. Focal or generalized seizures occur in >50% of patients with severe encephalitis. Virtually every possible type of focal neurologic disturbance has been reported in viral encephalitis; the signs and symptoms reflect the sites of infection and inflammation. The most commonly encountered focal findings are aphasia, ataxia, hemiparesis (with hyperactive tendon reflexes and extensor plantar responses), involuntary movements (e.g., myoclonic jerks), and cranial nerve deficits (e.g., ocular palsies, facial weakness). Involvement of the hypothalamic-pituitary axis may result in temperature dysregulation, diabetes insipidus, or the development ofSIADH. Despite the clear neuropathologic evidence that viruses differ in the regions of the CNSthey injure, it is often impossible to distinguish reliably on clinical grounds alone one type of viral encephalitis (e.g., that caused byHSV) from others (see "Differential Diagnosis," below).

Etiology The number of viruses reported to cause encephalitis is legion. In the United States, there are approximately 20,000 reported cases per year. The same organisms responsible for aseptic meningitis are also responsible for encephalitis, although their relative frequencies differ (Table 373-5;Fig. 373-1). The most important viruses causing sporadic cases of encephalitis in immunocompetent adults areHSV-1,VZV, and, less commonly, enteroviruses. Epidemics of encephalitis are caused by arboviruses, which belong to several different viral taxonomic groups including *Alphavirus* of the family Togaviridae (e.g. Eastern equine encephalitis virus, Western equine encephalitis virus), *Flavivirus* of the family Flaviviridae (e.g., St. Louis encephalitis virus, Powassan virus), and *Bunyavirus* of the family Bunyaviridae (e.g., California encephalitis virus serogroup, LaCrosse virus). In most years, the largest number of cases of arbovirus encephalitis are generally due to St. Louis encephalitis virus and the California encephalitis virus serogroup. New causes of viral encephalitis are constantly appearing, as evidenced by

the recent outbreak of ~300 cases of encephalitis with a 40% mortality rate in Malaysia caused by Nipah virus, a new member of the Paramyxovirus family. Similarly, well-known viruses may suddenly appear in unexpected locations, as illustrated by a recent outbreak of encephalitis in New York City due to West Nile virus.

Laboratory Diagnosis

CSF examination CSF examination should be performed in all patients with suspected viral encephalitis unless contraindicated by the presence of severely increased intracranial pressure (ICP). The characteristic CSF profile is indistinguishable from that of viral meningitis and consists of a lymphocytic pleocytosis, a mildly elevated protein level, and a normal glucose level. A CSF pleocytosis (>5 cells per microliter) occurs in>95% of patients with documented viral encephalitis, and its absence should prompt a careful search for other causes of an encephalopathy. In rare cases, a pleocytosis may be absent on the initial lumbar puncture but present subsequently. Patients who are severely immunocompromised by HIV infection, steroid or other immunosupressant drugs, chemotherapy, or certain lymphoreticular malignancies may fail to mount a CSF inflammatory response. CSF cell counts exceed 500/uL in only about 10% of patients with encephalitis. Infections with certain arboviruses (e.g., Eastern equine encephalitis or California encephalitis viruses), mumps, andLCMV may occasionally result in cell counts >1000/uL, but this degree of pleocytosis should suggest the possibility of nonviral infections or other inflammatory processes. Atypical lymphocytes in the CSF may be seen inEBVinfection and less commonly with other viruses, includingCMV,HSV, and enteroviruses. The presence of substantial numbers ofPMNsafter the first 48 h should prompt consideration of bacterial infection, leptospirosis, amebic infection, and noninfectious processes such as acute hemorrhagic leukoencephalitis. Large numbers of CSF PMNs may be present in patients with viral encephalitis due to Eastern equine encephalitis virus, echovirus 9, and, more rarely, other enteroviruses. About 20% of patients with encephalitis will have a significant number of red blood cells (>500/uL) in the CSF in a nontraumatic tap. The pathologic correlate of this may be the presence of a hemorrhagic encephalitis of the type seen with HSV, Colorado tick fever virus, and occasionally California encephalitis virus. A decreased CSF glucose level is distinctly unusual in viral encephalitis and should suggest the possibility of fungal, tuberculous, parasitic, leptospiral, syphilitic, sarcoid, or neoplastic meningitis. Rare patients with mumps, LCMV, or advanced HSV encephalitis may have low CSF glucose concentrations.

CSF PCR PCRamplification of viral nucleic acid has become the diagnostic procedure of choice for many types of viral encephalitis. Recent studies withHSVencephalitis indicate that the sensitivity (~98%) and specificity (~94%) of CSF PCR equal or exceed those of brain biopsy. Although less detailed specificity and sensitivity data are available for most other viruses, PCR has become the primary diagnostic test forCNSinfections caused byCMV,EBV,VZV, and enteroviruses (see "Viral Meningitis," above). Studies of HSV encephalitis indicate that the incidence of positive CSF PCR gradually declines after the second week of illness. PCR results are generally not affected by£1 week of antiviral therapy. In one study 98% of CSF specimens remained PCR-positive during the first week of initiation of antiviral therapy, but the numbers fell to ~50% 8 to 14 days, and to ~21% by³15 days after initiation of therapy.

Patients suspected of havingHSVencephalitis should be started on acyclovir (see below), and theirCSFshould be assayed for the presence of HSV DNA byPCR. A positive CSF PCR in the appropriate clinical setting is diagnostic of HSV encephalitis. A negative PCR test effectively excludes the diagnosis, unless the test is performed late in the course of illness or following prolonged antiviral therapy (see above). Blood or blood breakdown products may inhibit PCR reactions and generate false-negative results. Nonetheless the negative predictive value of a negative CSF PCR is ~98% and provides sufficient basis to discontinue acyclovir therapy unless mitigating circumstances likely to generate a false-negative PCR are present.

CSF culture Attempts to culture viruses from the CSF in cases of encephalitis are often disappointing (Table 373-3). Cultures are invariably negative in cases of HSV-1 encephalitis.

Serologic Studies and Antigen Detection The basic approach to the serodiagnosis of viral encephalitis is identical to that discussed earlier for viral meningitis. In patients withHSVencephalitis, both antibodies to HSV-1 glycoproteins and glycoprotein antigens have been detected in theCSF. Optimal detection of both HSV antibodies and antigen typically occurs after the first week of illness, limiting the utility of these tests in acute diagnosis. Nonetheless, CSF HSV antibody testing may be of value in selected patients whose illness is >1 week's duration and who are CSFPCR-negative for HSV.

MRI,*CT*,*EEG*Patients with suspected encephalitis almost invariably undergo neuroimaging studies and often EEG. These tests help identify or exclude alternative diagnoses and assist in the differentiation between a focal, as opposed to diffuse, encephalitic process. Focal findings in a patient with encephalitis should always raise the possibility ofHSVencephalitis. Examples of focal findings include: (1) areas of increased signal intensity in the frontotemporal, cingulate, or insular regions of the brain on T2-weighted spin-echo MRI images (Fig. 373-2); (2) temporoparietal areas of low absorption, mass effect, and contrast enhancement on CT; or (3) periodic focal temporal lobe spikes on a background of slow or low-amplitude ("flattened") activity on EEG. Approximately 10% of patients withPCR-documented HSV encephalitis will have a normal MRI, although nearly 90% will have abnormalities in the temporal lobe. CT is less sensitive than MRI and is normal in up to 33% of patients. EEG abnormalities occur in>90% of PCR-documented cases of HSV encephalitis; they typically involve the temporal lobes but are often nonspecific.

Brain Biopsy Brain biopsy is now generally reserved for patients in whomCSFPCRstudies fail to lead to a specific diagnosis, who have focal abnormalities onMRI, and who continue to show progressive clinical deterioration despite treatment with acyclovir and supportive therapy. The isolation ofHSV from brain tissue obtained at biopsy was once considered the "gold standard" for the diagnosis of HSV encephalitis, although with the advent of CSF PCR tests for HSV it is no longer necessary to perform brain biopsy for this purpose. The need for brain biopsy to diagnose other forms of viral encephalitis has also declined greatly with the widespread availability of CSF PCR diagnostic tests forEBV,CMV,VZV, and enteroviruses. When biopsy is performed, the tissue is cultured for virus and examined histopathologically and ultrastructurally. The biopsy is typically carried out under general anesthesia through a craniectomy. Tissue should be taken from a site that appears to be significantly involved on the basis of

clinical and laboratory criteria. Although brain biopsy is not an innocuous procedure, the mortality rate is low (<0.2%). Potential morbidity, in addition to that related to general anesthesia, includes local bleeding and edema, the development of a seizure focus, and wound dehiscence or infection. From a practical viewpoint, the incidence of serious morbidity appears to be between 0.5 and 2%.

Differential Diagnosis The differential diagnosis includes both infectious and noninfectious causes of encephalitis. Some of the most common illnesses masquerading as viral encephalitis, as identified in multicenter clinical trials using brain biopsy as a diagnostic standard, were vascular diseases; abscess and empyema; fungal, parasitic, rickettsial, and tuberculous infections; tumors; Reye's syndrome; toxic encephalopathy; subdural hematoma; and systemic lupus erythematosus. Of the nonviral infections, particular attention should be paid to *Listeria, Mycoplasma, Leptospira*, *Cryptococcus*, and *Mucor* infections, as well as to toxoplasmosis and tuberculosis.

Once nonviral causes of encephalitis have been excluded, the major diagnostic impetus is to distinguishHSV from other viruses that cause encephalitis. This distinction is particularly important because in virtually every other instance the therapy is supportive, whereas specific and effective antiviral therapy is available for HSV, and its efficacy is enhanced when it is instituted early in the course of infection. HSV encephalitis should be considered when clinical features suggesting involvement of the inferomedial frontotemporal regions of the brain are present, including prominent olfactory or gustatory hallucinations, anosmia, unusual or bizarre behavior or personality alterations, or memory disturbance. HSV encephalitis should always be suspected in patients with focal findings on clinical examination, neuroimaging studies, orEEG. The diagnostic procedure of choice in these patients isCSFPCRanalysis for HSV. A positive CSF PCR establishes the diagnosis, and a negative test dramatically reduces the likelihood of HSV encephalitis (see above).

Epidemiologic factors may provide important clues. Particular attention should be paid to the season of the year (Table 373-2), the age of the patient (Table 373-6), the geographic location and travel history (Fig. 373-1;Table 373-6), and possible exposure to animal bites, rodents, and ticks. *Morbidity and Mortality Weekly Reports* provides regular information about the prevalence of particular viruses causing encephalitis by season and region of the country. State public health authorities provide another valuable resource concerning isolation of particular agents in individual regions.

TREATMENT

Specific antiviral therapy should be initiated when appropriate. Vital functions, including respiration and blood pressure, should be monitored continuously and supported as required. In the initial stages of encephalitis, many patients will require care in an intensive care unit. Basic management and supportive therapy should include careful monitoring ofICP, fluid restriction and avoidance of hypotonic intravenous solutions, and suppression of fever. Seizures should be treated with standard anticonvulsant regimens, and prophylactic therapy should be considered in view of the high frequency of seizures in severe cases of encephalitis (>50%). As with all seriously ill, immobilized patients with altered levels of consciousness, encephalitis patients are at risk for aspiration

pneumonia, stasis ulcers and decubiti, contractures, deep venous thrombosis and its complications, and infections of indwelling lines and catheters.

Acyclovir is of benefit in the treatment ofHSV and should be started empirically in all patients with suspected viral encephalitis. Treatment should be discontinued in patients found not to have HSV encephalitis, with the possible exception of patients with severe encephalitis due toVZV orEBV. HSV, VZV, and EBV all encode an enzyme, deoxypyrimidine (thymidine) kinase, that phosphorylates acyclovir to produce acyclovir-5¢-monophosphate. Host cell enzymes then phosphorylate this compound to form a triphosphate derivative. It is the triphosphate that acts as an antiviral agent by inhibiting viral DNA polymerase and by causing premature termination of nascent viral DNA chains. The specificity of action depends on the fact that uninfected cells do not phosphorylate significant amounts of acyclovir to acyclovir-5¢-monophosphate. A second level of specificity is provided by the fact that the acyclovir triphosphate is a more potent inhibitor of viral DNA polymerase than of the analogous host cell enzymes.

Adults should receive a dose of 10 mg/kg of acyclovir intravenously every 8 h (30 mg/kg per day total dose) for a minimum of 14 days. Although no studies directly addressing this issue are yet available, we suggest repeating theCSFPCRafter completion of 14 days of acyclovir therapy, and discontinuing the acyclovir in PCR-negative patients. Patients with a persisting positive CSF PCR for HSVshould be treated for an additional 7 days, and the PCR repeated. Neonatal HSVCNSinfection is less responsive to acyclovir therapy than HSV encephalitis in adults; it is recommended that neonates with HSV encephalitis receive 20 mg/kg of acyclovir every 8 h (60 mg/kg per day total dose) for a minimum of 21 days.

Prior to intravenous administration, acyclovir should be diluted to a concentration £7 mg/mL. (A 70-kg person would receive a dose of 700 mg, which would be diluted in a volume of 100 mL.) Each dose should be infused slowly over 1 h rather than by rapid or bolus infusion, to minimize the risk of renal dysfunction. Care should be taken to avoid extravasation or intramuscular or subcutaneous administration. The alkaline pH of acyclovir can cause local inflammation and phlebitis (9%). Dose adjustment is required in patients with impaired renal glomerular filtration. Penetration intoCSF is excellent, with average drug levels approximately 50% of serum levels. Complications of therapy include elevations inBUN and creatinine levels (5%), thrombocytopenia (6%), gastrointestinal toxicity (nausea, vomiting, diarrhea) (7%), and neurotoxicity (lethargy or obtundation, disorientation, confusion, agitation, hallucinations, tremors, seizures) (1%). Acyclovir resistance may be mediated by changes in either the viral deoxypyrimidine kinase or DNA polymerase. To date, acyclovir-resistant isolates have not been a significant clinical problem in immunocompetent individuals. However, there have been reports of clinically virulent acyclovir-resistantHSVisolates from sites outside theCNS in immunocompromised individuals, including those with AIDS.

Oral antiviral drugs with efficacy againstHSV,VZV, andEBV, including acyclovir, famciclovir, and valacyclovir, have not been evaluated in the treatment of encephalitis either as primary therapy or as supplemental therapy following completion of a course of parenteral acyclovir. An NIAID/NINDS-sponsored phase III trial of supplemental oral valacyclovir therapy (2 g, tid for 3 months) following the initial 14- to 21-day course of therapy with parenteral acyclovir has recently been initiated in patients with HSV

encephalitis; it may help clarify the role of extended oral antiviral therapy.

Both ganciclovir and foscarnet have been shown to be effective in the treatment ofCMV-relatedCNSinfections. These drugs are often used in combination. Cidofovir (see below) may provide an alternative in patients who fail to respond to ganciclovir and foscarnet, although data concerning its use in CMV CNS infections are extremely limited.

Ganciclovir is a synthetic nucleoside analogue of 2¢-deoxyguanosine. The drug is preferentially phosphorylated by virus-induced cellular kinases. Ganciclovir triphosphate acts as a competitive inhibitor of theCMV DNA polymerase, and its incorporation into nascent viral DNA results in premature chain termination. Following intravenous administration,CSFconcentrations of ganciclovir are 25 to 70% of coincident plasma levels. The usual dose for treatment of severe neurologic illnesses is 5 mg/kg every 12 h given intravenously at a constant rate over 1 h. Induction therapy is followed by maintenance therapy of 5 mg/kg every day for an indefinite period. Induction therapy should be continued until patients show a decline in CSF pleocytosis and a reduction in CSF CMV DNA copy number on quantitativePCRtesting (where available). Doses should be adjusted in patients with renal insufficiency. Treatment is often limited by the development of granulocytopenia and thrombocytopenia (20 to 25%), which may require reduction in or discontinuation of therapy. Gastrointestinal side effects including nausea, vomiting, diarrhea, and abdominal pain occur in ~20% of patients. Some patients treated with ganciclovir for CMV retinitis have developed retinal detachment, but the causal relationship to ganciclovir treatment is unclear.

Foscarnet is a pyrophosphate analogue that inhibits viral DNA polymerases by binding to the pyrophosphate-binding site. Following intravenous infusion,CSFconcentrations range from 15 to 100% of coincident plasma levels. The usual dose for seriousCMV-related neurologic illness is 60 mg/kg every 8 h administered by constant infusion over 1 h. Induction therapy for 14 to 21 days is followed by maintenance therapy (60 to 120 mg/kg per day). Induction therapy may need to be extended in patients who fail to show a decline in CSF pleocytosis and a reduction in CSF CMV DNA copy number on quantitativePCRtests (where available). Approximately one-third of patients develop renal impairment during treatment, which is reversible following discontinuation of therapy in most, but not all, cases. This is often associated with elevations in serum creatinine and proteinuria and is less frequent in patients who are adequately hydrated. Many patients experience fatigue and nausea. Reduction in serum calcium, magnesium, and potassium occur in approximately 15% of patients and may be associated with tetany, cardiac rhythm disturbances, or seizures.

Cidofovir is a nucleotide analogue that is effective in treatingCMVretinitis and equivalent or better than ganciclovir in some experimental models of murine CMV encephalitis, although data concerning its efficacy in human CMVCNSdisease are limited. The usual dose is 5 mg/kg intravenously once weekly for 2 weeks, then biweekly for 2 or more additional doses, depending on clinical response. Patients must be prehydrated with normal saline (e.g., 1 L over 1 to 2 h) prior to each dose, and treated with probenecid (e.g., 1 g 3 h before cidofovir and 1 g 2 and 8 h after cidofovir). Nephrotoxicity is common; the dose should be reduced if renal function deteriorates.

Intravenous ribavarin (15 to 25 mg/kg per day in divided doses given every 8 h) has been reported to be of benefit in isolated cases of severe encephalitis due to California encephalitis (LaCrosse) virus. Ribavarin might be of benefit for the rare patients, typically infants or young children, with severe adenovirus or rotavirus encephalitis, and in patients with encephalitis due toLCMV or other arenaviruses. However, clinical trials are lacking. Hemolysis, with resulting anemia, has been the major side effect limiting therapy.

Sequelae There is considerable variation in the incidence and severity of sequelae in patients surviving viral encephalitis. In the case of Eastern equine encephalitis virus infection, nearly 80% of survivors have severe neurologic sequelae. At the other extreme are infections due toEBV, California encephalitis virus, and Venezuelan equine encephalitis virus, where severe sequelae are unusual. For example, approximately 5 to 15% of children infected with LaCrosse virus have a residual seizure disorder, and 1% have persistent hemiparesis. Detailed information about sequelae in patients withHSVencephalitis treated with acyclovir are available from the NIAID-CASG trials. Of 32 acyclovir-treated patients, 26 survived (81%). Of the 26 survivors, 12 (46%) had no or only minor sequelae, 3 (12%) were moderately impaired (gainfully employed but not functioning at their previous level), and 11 (42%) were severely impaired (requiring continuous supportive care). The incidence and severity of sequelae were directly related to the age of the patient and the level of consciousness at the time of initiation of therapy. Patients with severe neurologic impairment (Glasgow coma score 6) at initiation of therapy either died or survived with severe sequelae. Young patients (<30 years) with good neurologic function at initiation of therapy did substantially better (100% survival, 62% with no or mild sequelae) compared with their older counterparts (>30 years); (64% survival, 57% no or mild sequelae). Recent studies using quantitativeCSFPCRtests for HSV indicate that clinical outcome following treatment also correlates with the amount of HSV DNA present in CSF at the time of presentation.

ACUTE MYELITIS AND RADICULITIS

Myelitis is a viral infection of the spinal cord, which may occur as an isolated syndrome or in association with encephalitis (encephalomyelitis) or infection involving the nerve roots (myeloradiculitis). Viral infection involving sensory ganglia and nerve roots may also occur as an isolated syndrome, most commonly in the form of shingles.

MYELITIS

Clinical Features and Epidemiology The prototypical viral myelitis is the syndrome of acute anterior poliomyelitis caused by polioviruses. Paralytic polio (Chap. 193) is a rarity in the United States (four to eight cases per year), although it remains a major problem in some regions of the world. Most cases of paralytic polio in the United States occur as a result of the exceedingly rare reversion of vaccine strains to virulence. The cases are divided among those recently vaccinated and unvaccinated nonimmune adults exposed to recently vaccinated children. Occasional outbreaks have occurred in nonimmunized populations such as the Amish in Pennsylvania. Illness typically begins with prodromal symptoms, including fever, headache, myalgia, pharyngitis, nausea and vomiting, and meningeal signs. These are associated with the typicalCSFprofile of aseptic meningitis. In some patients these symptoms are followed by the development of muscle weakness

resulting from viral injury to the motor neurons in the anterior horn of the spinal cord or in brainstem motor nuclei. The incidence, severity, and pattern of weakness are age-dependent, with more severe disease being seen with increasing age. Young children often develop weakness of one leg, older children weakness of both legs, and adults asymmetric quadriparesis, often with associated urinary retention. Weakness is associated with fasciculations, loss of deep and superficial reflexes, and the development of atrophy. Involvement of the brainstem (bulbar polio) can result in dysphagia, dysarthria, respiratory impairment, and vasomotor disturbances. Although some patients complain of paresthesia, objective sensory loss is not present.

A distinctive polio-like syndrome is produced by enterovirus 70. Patients develop acute hemorrhagic conjunctivitis, followed days to weeks later by a poliomyelitis-like weakness.

Viruses may also affect both the anterior and posterior portions of the spinal cord over a considerable longitudinal extent, producing "transverse" myelitis. The clinical syndrome is one of acute muscle weakness, which may be of the flaccid hyporeflexic type initially but usually develops into spastic paralysis with hyperreflexia and extensor plantar responses. Sensory loss is almost invariably present and typically involves both pain-temperature and position-vibration modalities, producing a sensory level. Urinary symptoms (retention, overflow incontinence, or, in milder cases, hesitancy or decreased voiding sensation) and constipation or even fecal incontinence are present in virtually all patients. Although this syndrome can be caused by a variety of viruses, most cases in immunocompetent patients are due toHSV-2,VZV, orEBV.CMV is an important cause of myelitis in immunocompromised patients, notably those with HIV infection.

A mild form of myelitis predominantly affecting the sacral spinal cord occurs in association with genitalHSV-2 infection. At the time of the first episode of genital herpes, about 25% of women, and a smaller percentage of men, develop an aseptic meningitis syndrome. In some individuals this may be associated with urinary retention, dysesthesia, paresthesia, or neuralgia in the legs, buttocks, or genital area, and weakness in one or both legs.

Chronic viral myelitis is associated with advanced HIV infection (vacuolar myelopathy) and with infection due toHTLV-1 (tropical spastic paraparesis and HTLV-I-associated myelopathy).**For further discussion of these infections see Chap. 309.*

Diagnosis Almost all patients with viral myelitis will have inflammatory changes in theCSFincluding a lymphocytic pleocytosis and elevated protein; glucose is normal. An exception to this pattern occurs in HIV-associatedCMVmyeloradiculopathy in which a polymorphonuclear pleocytosis and low CSF glucose are characteristic. For myelitis caused byHSV,EBV, CMV, andVZV, CSFPCRstudies may be diagnostic. Some patients show evidence of intrathecal synthesis of antibody or the presence of CSF IgM antibodies, and these studies may be helpful in PCR-negative patients. Viral cultures are frequently positive in patients with CMV myelitis and may be positive in some cases of myelitis due to HSV-2. Neuroimaging studies may be helpful in identifying the site and extent of the myelitis. The usual findings are areas of increased T2 signal within the spinal cord parenchyma. Patients with HIV-associated CMV radiculomyelopathy may show increased signal and enhancement of the nerve roots. Perhaps the most important

role ofMRI is to exclude compressive lesions and other causes of acute myelopathy.

TREATMENT

Reports of treatment of viral myelitis are usually isolated case reports or small series. Patients with myelitis due toHSV,EBV, orVZVshould be treated with intravenous acyclovir (10 mg/kg, tid) for 10 to 14 days. Patients with HIV-associated CMV radiculomyelopathy should receive ganciclovir plus foscarnet (see above under CMV encephalitis for dose), although the results of treatment are frequently disappointing.

GANGLIONITIS AND RADICULITIS

Herpes Zoster (See alsoChap. 183)

Clinical Features Reactivation ofVZVlatent in neurons within the trigeminal or spinal sensory ganglia produces zoster (*shingles*). Zoster is a distinctive clinical syndrome consisting of paresthesia or dysesthesia in a dermatomal distribution followed by a localized cutaneous eruption. Zoster occurs in patients previously infected with chickenpox (varicella). During the initial varicella infection, virus in the skin travels up the sensory nerves to become latent within neurons in the trigeminal and spinal sensory ganglia. Reactivation results in active viral replication in sensory ganglia followed by spread of virus through nerves to the skin, where a dermatomal vesicular eruption occurs. The incidence of zoster increases with age and is higher in patients with compromised cellular immunity. The typical history is one of several days of itching, tingling, burning, or pain in a dermatomal distribution that is followed by a vesicular eruption consisting of clear vesicles on an erythematous base (Fig. 373-CD1). The vesicles become cloudy, dry, and crust over after 1 to 2 weeks. The lesions are most commonly found in the thoracic dermatomes, with T5-T10 accounting for approximately two-thirds of cases. Most patients will have hypalgesia and hypesthesia in the affected dermatome. About 5% of patients develop motor weakness and atrophy (zoster paresis) in the associated myotome. Rare patients can have zoster-like neuralgic pain in the absence of a cutaneous eruption (*zoster sine herpete*). Diagnosis in these patients depends on serologic studies in serum orCSF or the identification of VZV DNA in CSF byPCR.

Characteristic syndromes result from zoster eruptions involving the trigeminal and geniculate distribution. In 10 to 15% of cases, reactivation of virus in the trigeminal ganglia results in a rash in the distribution of the ophthalmic division of the trigeminal nerve (*ophthalmic zoster*). Vesicular eruption may be conjoined with conjunctivitis, keratitis, ocular muscle palsies, ptosis, and mydriasis. In rare cases, an attack is followed by the development of cerebral angiitis involving the ipsilateral carotid and/or middle cerebral arteries. Vascular compromise may lead to hemiplegia, aphasia, or other focal deficits contralateral to the side of the facial eruption. Reactivation of virus from the geniculate ganglion produces the *Ramsay Hunt syndrome*, consisting of facial palsy often associated with loss of taste in the anterior tongue, tinnitus, hearing loss, and vertigo. Zoster eruptions are found in the external auditory meatus.

Some 45% of patients over age 50 who develop shingles will experience pain persisting for>6 weeks after disappearance of the rash (*postherpetic neuralgia*). Postherpetic

neuralgia is almost never seen in children who develop zoster and is rare (6%) in adults younger than 50. (See "Treatment" below, and Chap. 183).

Diagnosis The diagnosis of shingles is generally made on clinical grounds. RecurrentHSVinfection may produce a similar syndrome of a cutaneous eruption in a dermatomal distribution associated with paresthesia. Unlike shingles, in which more than two or three recurrences in a lifetime would be virtually unknown, multiple recurrences are characteristic of HSV infection. The presence ofVZV can be confirmed by culture orPCR of material obtained from the vesicular lesions. Direct detection of varicella zoster virus antigens in vesicle scrapings by immunocytochemistry or fluorescent microscopy is more sensitive and specific than the traditional Tzanck preparation and more sensitive than culture. A Tzanck preparation is made by smearing material obtained from the base of a vesicle onto a slide, which is then stained with Wright or Giemsa stain. The presence of syncytial giant cells with intranuclear inclusions is typical of a herpesvirus infection but does not distinguish between VZV and HSV.

TREATMENT

Shingles in Immunocompetent Adults Three antiviral drugs, acyclovir, famciclovir, and valacyclovir, are available for treatment of herpes zoster (shingles). Famciclovir is the diacetyl prodrug form of the nucleoside penciclovir. Following oral administration famciclovir is enzymatically converted to penciclovir (which is not absorbed well orally). Penciclovir acts intracellularly like acyclovir, but its active triphosphate metabolite has an extended half-life compared to acyclovir triphosphate in infected cells. Valacyclovir is the 6-valine ester of acyclovir and is enzymatically converted to acyclovir in the liver. Valacyclovir is better absorbed than acyclovir and allows for significantly (~fourfold) higher serum andCSFacyclovir levels than can be achieved with equimolar doses of oral acyclovir.

Acyclovir, valacyclovir, and famciclovir all produce more rapid resolution of cutaneous lesions and decreased duration of viral shedding compared to placebo if therapy is started within 72 h of rash onset, and decrease the duration of pain. These effects are generally modest, and supportive therapy alone is probably sufficient in immunocompetent patients <50 years who do not have significant pain and whose lesions do not involve the trigeminal dermatome. Immunocompetent patients with trigeminal zoster should be treated with antiviral drugs to reduce the risk of developing keratitis or other ophthalmologic complications of zoster. Patients >50 years should be treated with antiviral drugs in an effort to reduce the risk or duration of postherpetic neuralgia (see below). Typical doses in immunocompetent adults are acyclovir, 800 mg five times per day for 7 to 10 days; famciclovir, 500 mg tid for 7 days; and valacyclovir 1000 mg tid for 7 days.

The role of adjunctive glucocorticoid therapy has not been definitively established. Its use is not recommended in patients <50 or in immunocompromised individuals. In immunocompetent individuals>50, glucocorticoids do not appear to increase complications when used in conjunction with antiviral agents and may reduce the incidence of postherpetic neuralgia. A typical regimen, which should only be used in patients also receiving antiviral therapy, is prednisone, 30 mg bid for 1 week, then 15 mg bid for a second week, and 7.5 mg bid for a final week.

Shingles in Immunocompromised Patients Immunocompromised patients, including those with HIV infection, who have evidence of disease involving more than one dermatome or in the trigeminal distribution should be treated with intravenous acyclovir (10 mg/kg tid for 10 to 14 days). Immunocompromised patients with mild disease limited to a single dermatome (other than the trigeminal) can be treated initially with oral agents. These patients should be closely monitored and switched to intravenous acyclovir if they show any signs of disease progression while receiving oral therapy. Adverse effects of famciclovir, valacyclovir, and acyclovir are generally minor, with headache and nausea being reported in about 8 to 20% of recipients. Patients with renal insufficiency require reduction in dosing.

Postherpetic Neuralgia Controlled trials of both amitriptyline and desipramine have shown these drugs to be of benefit in the treatment of postherpetic neuralgia. Amitriptyline should be started at low dose (12.5 to 25 mg/d) and gradually increased until pain is controlled or side effects prevent further dose increases; the optimal dose is usually in the range of 75 to 150 mg/d. Desipramine is probably equally efficacious; however, selective serotonin reuptake inhibitors appear to be of limited utility. In a controlled study, carbamazepine was shown to be effective in reducing neuropathic lancinating pain but not continuous aching or burning pain. Treatment should be started at 200 mg/d and gradually increased until pain is controlled or side effects limit further therapy. The usual effective dose is ~600 mg/d, but some patients may require up to 1200 mg/d. Gabapentin has also been shown to be effective in a randomized controlled trial. Patients should be started on 300 mg tid, with a gradual increase to a maximum of 1200 mg tid. Phenytoin and valproate sodium may also be effective for neuropathic zoster pain. Topical agents such as 2.5% lidocaine-2.5% prilocaine cream or 5% lidocaine gel may benefit some patients with milder symptoms.

VIRAL INFECTION OF THE PERIPHERAL NERVOUS SYSTEM

The distinction between ganglionitis, radiculitis, and neuritis are somewhat arbitrary and depend largely on the whether the brunt of injury involves the ganglia, nerve roots (radiculitis), or peripheral nerves (neuritis). Direct viral infection of peripheral nerves is unusual and should be distinguished from postviral immune-mediated injury to nerves. Many viruses, includingCMV,HSV,EBV,VZV, mumps virus, and hepatitis B virus (HBV) have been associated, based predominantly on seroepidemiologic studies, with Guillain-Barre syndrome. It is presumed that the antecedent viral infection triggers an immunologic reaction that subsequently results in damage to peripheral nerve myelin (Chap. 378). A Guillain-Barre-like syndrome can also be seen in association with HIV infection, although these patients typically have aCSFpleocytosis rather than the classic albuminocytologic dissociation (elevated protein, zero or few cells).

Patients with HIV infection may developCMVinfection of peripheral nerves, either alone or in combination with involvement of nerve roots and spinal cord. Patients present with back and leg pain, flaccid paraparesis with areflexia, multimodal sensory loss, and impairment of bowel and bladder function. TheCSFshows a polymorphonuclear pleocytosis with an elevated protein and, in some patients, a decreased glucose. As noted earlier, this CSF profile is extremely unusual in viral infections and should suggest the diagnosis of CMV polyradiculopathy in the appropriate clinical setting. CMV

inclusions and antigen can be detected in Schwann cells of affected nerves, and CSF cultures orPCR are frequently positive for CMV. Rare cases of CMV-associated multiple mononeuropathy have also been reported. Patients present with radial, peroneal, or sural neuropathies alone or in combination. CMV antigen can be detected in Schwann cells of involved nerves, indicating that the neuropathies are caused by direct viral infection. Evidence of demyelination may be present, and immune mechanisms may contribute to the pathogenesis of the nerve injury.

Viral spread from the site of initial inoculation to theCNSthrough nerves is integral to the pathogenesis of rabies virus infection (Chap. 197). Rabies virus particles have been detected by electron microscopy and rabies virus antigen by immunocytochemistry in nerves innervating the site of initial viral inoculation. Neural spread of virus is also a central feature of the pathogenesis of shingles (see above) and of recurrent herpes labialis and genitalis (Chap. 182).

Isolated cranial nerve palsies, especially of the facial nerve (Bell's palsy), have been attributed toHSV,VZV(Ramsay Hunt syndrome), HIV,EBV, enteroviruses, and mumps virus, although in many cases the etiologic relationship appears rather tenuous. Pathologic specimens are almost never available from acute cases of Bell's palsy because of the generally benign and self-limited nature of the illness. Virus has never been cultured from the facial nerve, nor have viral antigens or nucleic acid been detected. However, in a study of patients with peripheral facial palsy undergoing decompressive facial nerve surgery, HSV DNA was found byPCR in endoneurial fluid from the facial nerve in ~80% of 14 patients with Bell's palsy, and VZV DNA was found in ~90% of those with Ramsay Hunt syndrome. This represents the strongest evidence to date for the direct role of these viruses in facial palsy.

Auditory and/or vestibular syndromes may also result from viral injury to the eighth cranial nerve. Mumps, measles, andVZV have been associated with cases of unilateral or bilateral nerve deafness. Seroepidemiologic studies also suggest a possible role for parainfluenza viruses, adenoviruses, andHSV in acute hearing loss. HSV has also been suggested to have a role in the pathogenesis of some cases of vestibular neuritis, based on detection of HSV DNA by PCRin vestibular ganglia.

CHRONIC AND PERSISTENT VIRAL CNS DISEASE

PROGRESSIVE MULTIFOCAL LEUKOENCEPHALOPATHY

Clinical Features and Pathology Progressive multifocal leukoencephalopathy (PML) is a progressive disorder characterized pathologically by multifocal areas of demyelination of varying size distributed throughout theCNS. In addition to demyelination, there are characteristic cytologic alterations in both astrocytes and oligodendrocytes. Astrocytes are tremendously enlarged and contain hyperchromatic, deformed, and bizarre nuclei and frequent mitotic figures. Oligodendrocytes have enlarged, densely staining nuclei that contain viral inclusions formed by crystalline arrays of JC virus particles. Patients often present with visual deficits (45%), typically a homonymous hemianopia, and mental impairment (38%) (dementia, confusion, personality change). Motor weakness may not be present early but eventually occurs in 75% of cases.

Almost all patients (>95%) have an underlying immunosuppressive disorder. Prior to the HIV epidemic, common associated diseases included lymphoproliferative disorders, immune deficiency states, myeloproliferative disease, and chronic infectious or granulomatous diseases. Since 1984, the importance of these associated disorders inPML has been dwarfed by that of AIDS; >60% of currently diagnosed PML cases occur in patients with AIDS. Conversely, it has been estimated that nearly 1% of AIDS patients will develop PML. Early indications suggest that the basic features of AIDS-associated PML do not differ significantly from those of non-AIDS-associated PML.

Diagnostic Studies The diagnosis of PMLis frequently suggested byMRI or less commonlyCT. MRI is more sensitive than CT and reveals multifocal asymmetric, coalescing white matter lesions located periventricularly, in the centrum semiovale, in the parietal-occipital region, and in the cerebellum. These lesions have increased T2 and decreased T1 signal. The lesions of PML are generally nonenhancing or show only minimal peripheral enhancement and are not associated with edema or mass effect. CT shows hypodense nonenhancing white matter lesions without edema or mass effect.

TheCSF is typically normal, although mild elevation in protein and/or IgG may be found. Pleocytosis occurs in <25% of cases, is predominantly mononuclear, and rarely exceeds 25 cells/uL.PCRamplification of JC virus DNA from CSF has become an important diagnostic tool. CSF PCR for JC virus DNA has high specificity, but sensitivity has varied among studies. Rare cases of positive CSF PCR for JC virus DNA in the absence of clinical or radiographic evidence ofPML have been described in HIV-infected patients. It remains to be established whether these results are false positives or are indicative of preclinical PML.

The presence of a positiveCSFPCR for JC virus DNA in association with typicalMRIlesions in the appropriate clinical setting is diagnostic ofPML. Patients with negative CSF PCR studies may require brain biopsy for definitive diagnosis. In biopsy or necropsy specimens of brain, JC virus antigen and nucleic acid can be detected by immunocytochemistry, in situ hybridization, or PCR amplification. Detection of JC virus antigen or genomic material should only be considered diagnostic of PML if accompanied by characteristic pathologic changes, since both antigen and genomic material have been found in the brains of normal patients.

TREATMENT

No effective therapy forPML is available. Intravenous and/or intrathecal cytarabine were not shown to be of benefit in a recent randomized controlled trial. Based on isolated case reports of benefit in some patients, a randomized controlled trial of cidofovir is currently under way. Some patients with HIV-associated PML have shown dramatic clinical improvement associated with improvement in their immune status following institution of highly active antiretroviral therapy.

SUBACUTE SCLEROSING PANENCEPHALITIS

Clinical Features and Epidemiology SSPE is a rare chronic progressive demyelinating disease of theCNSassociated with a chronic nonpermissive infection of

brain tissue with measles virus. Fewer than 10 cases per year are reported in the United States. The incidence has declined substantially since the introduction of a measles vaccine. Most patients give a history of primary measles infection at an early age (2 years), which is followed after a latent interval of 6 to 8 years by the development of a progressive neurologic disorder. Some 85% of patients are between 5 and 15 years old at diagnosis. Initial manifestations include poor school performance and mood and personality changes. Typical signs of a CNS viral infection, including fever and headache, do not occur. As the disease progresses, patients develop progressive intellectual deterioration, focal and/or generalized seizures, myoclonus, ataxia, and visual disturbances. In the late stage of the illness, patients are unresponsive, quadriparetic, and spastic, with hyperactive tendon reflexes and extensor plantar responses.

Diagnostic Studies TheEEGshows a characteristic periodic pattern with bursts every 3 to 8 s of high-voltage, sharp slow waves, followed by periods of attenuated ("flat") background. TheCSF is acellular with a normal or mildly elevated protein level and a markedly elevatedg-globulin level (>20% of total CSF protein). CSF antimeasles antibody levels are invariably elevated, and oligoclonal antimeasles antibodies are often present.CT andMRI show evidence of multifocal white matter lesions, cortical atrophy, and ex vacuo ventricular enlargement. Measles virus can be cultured from brain tissue using special cocultivation techniques. Viral antigen can be identified immunocytochemically, and viral genome can be detected by in situ hybridization or PCRamplification.

TREATMENT

No definitive therapy forSSPE is available. Treatment with Inosiplex (isoprinosine) (100 mg/kg per day), alone or in combination with intrathecal or intraventricular interferon, has been reported to prolong survival and produce clinical improvement in some patients but has never been subjected to a controlled clinical trial.

PROGRESSIVE RUBELLA PANENCEPHALITIS

Clinical Features and Epidemiology This is an extremely rare disorder that primarily affects children with congenital rubella syndrome, although isolated cases have been reported following childhood rubella. All the approximately 20 cases reported to date have been in male children. After a latent period of 8 to 19 years, patients develop progressive neurologic deterioration. The initial manifestations are similar to those seen inSSPE and include decline in school performance, behavioral alterations, and seizures, followed by severe progressive dementia, prominent ataxia, pyramidal signs (spasticity, hyperreflexia, extensor plantar responses), and visual deterioration. In the terminal stages of the illness, patients are globally demented, mute, and quadriparetic, often with associated ophthalmoplegia.

Diagnostic Studies CSFshows a mild lymphocytic pleocytosis, slightly elevated protein level, markedly increased g-globulin, and rubella virus-specific oligoclonal bands.CT scan may show enlarged ventricles, cortical and cerebellar atrophy, and hypodensity in the white matter. Rubella virus has been isolated from explant and cocultivation cultures of brain biopsy material in one reported case.

TREATMENT

No therapy is currently available. Isoprinosine and amantadine are of no benefit. Universal prevention of both congenital and childhood rubella through the use of the available live attenuated rubella vaccine would be expected to eliminate the disease.

(Bibliography omitted in Palm version)

374. CHRONIC AND RECURRENT MENINGITIS - *Walter J. Koroshetz*, *Morton N. Swartz*

Chronic inflammation of the meninges (pia, arachnoid, and dura) can produce profound neurologic disability and may be fatal if not successfully treated. The condition is most commonly diagnosed when a characteristic neurologic syndrome exists for >4 weeks and is associated with a persistent inflammatory response in the cerebrospinal fluid (CSF) (white blood cell count >5/uL). The causes are varied, and appropriate treatment depends on identification of the etiology. Five categories of disease account for most cases of chronic meningitis: (1) meningeal infections, (2) malignancy, (3) noninfectious inflammatory disorders, (4) chemical meningitis, and (5) parameningeal infections.

CLINICAL PATHOPHYSIOLOGY

Neurologic manifestations of chronic meningitis (Table 374-1) are determined by the anatomic location of the inflammation and its consequences. Persistent headache with or without stiff neck and hydrocephalus, cranial neuropathies, radiculopathies, and cognitive or personality changes are the cardinal features. These can occur alone or in combination. When they appear in combination, widespread dissemination of the inflammatory process alongCSFpathways has occurred. In some cases, the presence of an underlying systemic illness points to a specific agent or class of agents as the probable cause. The diagnosis of chronic meningitis is usually made when the clinical presentation prompts the astute physician to examine the CSF for signs of inflammation.

CSFis produced by the choroid plexus of the cerebral ventricles, exits through narrow foramina into the subarachnoid space surrounding the brain and spinal cord, circulates around the base of the brain and over the cerebral hemispheres, and is resorbed by arachnoid villi projecting into the superior sagittal sinus. CSF flow provides a pathway for rapid spread of infectious and malignant processes over the brain, spinal cord, and cranial and spinal nerve roots. Spread from the subarachnoid space into brain parenchyma may occur via the arachnoid cuffs that surround blood vessels that penetrate brain tissue (Virchow-Robin spaces).

Intracranial Meningitis Nociceptive fibers of the meninges (Chap. 15) are stimulated by the inflammatory process, resulting in headache or neck or back pain. Obstruction ofCSFpathways at foramina or arachnoid villi may produce *hydrocephalus* and symptoms of raised intracranial pressure, including headache, vomiting, apathy or drowsiness, gait instability, papilledema, visual loss, impaired upgaze, or palsy of the seventh cranial nerve (CN) (Chap. 376). Cognitive and behavioral changes during the course of chronic meningitis may also result from vascular damage, which may similarly produce seizures, stroke, or myelopathy.

Inflammatory deposits seeded via the CSFcirculation are often prominent around the brainstem and cranial nerves and along the undersurface of the frontal and temporal lobes. Such cases, termed *basal meningitis*, often present as multiple cranial neuropathies, with visual loss (CN II), facial weakness (CN VII), hearing loss (CN VIII), diplopia (CNs III, IV, and VI), sensory or motor abnormalities of the oropharynx (CNs IX, X, and XII), decreased olfaction (CN I), or facial sensory loss and masseter weakness (CN V).

Spinal Meningitis Injury may occur to motor and sensory roots as they traverse the subarachnoid space and penetrate the meninges. These cases present as multiple radiculopathies with combinations of radicular pain, sensory loss, motor weakness, and sphincter dysfunction. Meningeal inflammation can encircle the cord, resulting in myelopathy. Patients with slowly progressive involvement of multiple cranial nerves and/or spinal nerve roots are likely to have chronic meningitis. Electrophysiologic testing (electromyography, nerve conduction studies, and evoked response testing) may be helpful in determining whether there is involvement of cranial and spinal nerve roots.

Systemic Manifestations In some patients, evidence of systemic disease provides clues to the underlying cause of chronic meningitis. A careful history and physical examination are essential before embarking on a diagnostic workup, which may be costly, prolonged, and associated with risk from invasive procedures. A complete history of travel, sexual practice, and exposure to infectious agents should be sought. Infectious causes are often associated with fever, malaise, anorexia, and signs of localized or disseminated infection outside the nervous system. Infectious causes are of major concern in the immunosuppressed patient, especially in patients with AIDS, in whom chronic meningitis may present without headache or fever. Noninfectious inflammatory disorders often produce systemic manifestations, but meningitis may be the initial manifestation. Carcinomatous meningitis may or may not be accompanied by clinical evidence of the primary neoplasm.

Approach to the Patient

The occurrence of chronic headache, hydrocephalus, cranial neuropathy, radiculopathy, and/or cognitive decline in a patient should prompt consideration of a lumbar puncture for evidence of meningeal inflammation. On occasion the diagnosis is made when an imaging study [computed tomography (CT) or magnetic resonance imaging (MRI)] shows contrast enhancement of the meninges, always an abnormal finding except after a recent neurosurgical procedure. Once chronic meningitis is confirmed byCSFexamination, effort is focused on identifying the cause (Tables 374-2 and374-3) by (1) further analysis of the CSF, (2) diagnosis of an underlying systemic infection or noninfectious inflammatory condition, or (3) pathologic examination of meningeal biopsy specimens.

Two clinical forms of chronic meningitis exist. In the first, the symptoms are chronic and persistent, whereas in the second there are recurrent, discrete episodes of illness. In the latter group, all symptoms, signs, andCSFparameters of meningeal inflammation resolve completely between episodes without specific therapy. In such patients, the likely etiologies include infection with herpes simplex virus (HSV) type 2; chemical meningitis due to leakage into CSF of contents from an epidermoid tumor, craniopharyngioma, or cholesteatoma; primary inflammatory conditions, including Vogt-Koyanagi-Harada syndrome, Behcet's syndrome (Chap. 316), Mollaret's meningitis, and systemic lupus erythematosus (SLE; Chap. 311); and drug hypersensitivity with repeated administration of the offending agent. The duration of chronic meningitis may also be of value in diagnosis; for example, an untreated patient with tuberculous meningitis is unlikely to survive beyond 4 to 6 weeks.

The epidemiologic history is of considerable importance and may provide direction for selection of laboratory studies. Pertinent features include a history of tuberculosis or exposure to a likely case; past travel to areas endemic for fungal infections (the San Joaquin Valley in California and southwestern states for coccidioidomycosis; midwestern states for histoplasmosis, southeastern states for blastomycosis); travel to the Mediterranean region or ingestion of imported unpasteurized dairy products (*Brucella*); time spent in areas endemic for Lyme disease (e.g., Connecticut, New York, Massachusetts); exposure to sexually transmitted disease (syphilis); exposure of an immunocompromised host to pigeons and their droppings (*Cryptococcus*); gardening (*Sporothrix schenkii*); ingestion of poorly cooked meat or contact with a household cat (*Toxoplasma gondii*); residence in Thailand or Japan (*Gnathostoma spinigerum*) or the South Pacific (*Angiostrongylus cantonensis*); rural residence and raccoon exposure (*Baylisascaris procyonis*); and residence in Latin America, the Philippines, or Southeast Asia when eosinophilic meningitis is present (*Taenia solium*).

The presence of focal cerebral signs in a patient with chronic meningitis suggests the possibility of a brain abscess or other parameningeal infection; identification of a potential source of infection (chronic draining ear, sinusitis, right-to-left cardiac or pulmonary shunt, chronic pleuropulmonary infection) supports this diagnosis. In some cases, diagnosis may be established by recognition and biopsy of unusual skin lesions (Behcet's syndrome, cryptococcosis, blastomycosis,SLE, Lyme disease, intravenous drug use, sporotrichosis, trypanosomiasis) or enlarged lymph nodes (lymphoma, tuberculosis, sarcoid, infection with HIV, secondary syphilis, or Whipple's disease). A careful ophthalmologic examination may reveal uveitis [Vogt-Koyanagi-Harada syndrome, sarcoid, or central nervous system (CNS) lymphoma], keratoconjunctivitis sicca (Sjogren's syndrome), or iridocyclitis (Behcet's syndrome) and is essential to assess visual loss from hydrocephalus. Aphthous oral lesions, genital ulcers, and hypopyon suggest Behcet's syndrome. Hepatosplenomegaly suggests lymphoma, sarcoid, tuberculosis, or brucellosis. Herpetic lesions in the genital area or on the thighs suggestsHSV-2 infection. A breast nodule, a suspicious pigmented skin lesion, or an abdominal mass directs attention to possible carcinomatous meningitis.

Imaging Once the clinical syndrome is recognized as a potential manifestation of chronic meningitis, proper analysis of theCSF is essential. However, if the possibility of raised intracranial pressure exists, a brain imaging study should be performed before lumbar puncture. In patients with communicating hydrocephalus caused by impaired resorption of CSF, lumbar puncture is safe and may lead to temporary improvement. However, if intracranial pressure is elevated because of a mass lesion, brain swelling, or a block in ventricular CSF outflow (obstructive hydrocephalus), then lumbar puncture carries the potential risk of brain herniation (Fig. 374-1). Obstructive hydrocephalus usually requires direct ventricular drainage of CSF.

Contrast-enhancedMRI orCTstudies of the brain and spinal cord can identify meningeal enhancement, parameningeal infections (including brain abscess), encasement of the spinal cord (malignancy or inflammation and infection), or nodular deposits on the meninges or nerve roots (malignancy or sarcoidosis). Imaging studies are also useful to localize areas of meningeal disease prior to meningeal biopsy.

Cerebral angiography may be indicated in patients with chronic meningitis and stroke to

identify cerebral arteritis (granulomatous angiitis, infectious arteritis).

Cerebrospinal Fluid Analysis TheCSFpressure should be measured and samples sent for bacterial culture, cell count and differential, Gram's stain, and measurement of glucose and protein. In cases without a known cause, CSF should be sent for the Venereal Disease Research Laboratories (VDRL) test, acid-fast bacillus (AFB) stain and culture, fungal wet mount and India ink preparation and culture, culture for fastidious bacteria and fungi, assays for cryptococcal antigen and oligoclonal immunoglobulin bands, and cytology. Other specific CSF tests (Tables 374-2 and374-3) or blood tests and cultures should be ordered as indicated on the basis of the history, physical examination, or preliminary CSF results (i.e., eosinophilic, mononuclear, or polymorphonuclear meningitis). Rapid diagnosis may be facilitated by polymerase chain reaction (PCR) testing to identify DNA sequences in the CSF that are specific for the suspected pathogenic organism.

In most categories of chronic (not recurrent) meningitis, mononuclear cells predominate in theCSF. When neutrophils predominate after 3 weeks of illness, the principal etiologic considerations are *Nocardia asteroides*, *Actinomyces israelii*, *Brucella*, *Mycobacterium tuberculosis* (5 to 10% of early cases only), various fungi (*Blastomyces dermatitidis*, *Candida albicans*, *Histoplasma capsulatum*, *Aspergillus* species, *Pseudallescheria boydii*, *Cladophialophora bantiana*) and noninfectious causes (SLE, exogenous chemical meningitis). When eosinophils predominate or are present in limited numbers in a primarily mononuclear cell response in the CSF, the differential diagnosis includes parasitic diseases (*A. cantonensis*, *G. spinigerum*, *B. procyonis*, or *Toxocara canis* infection, cysticercosis, schistosomiasis, echinococcal disease, *T. gondii* infection), fungal infections (6 to 20% eosinophils along with a predominantly lymphocyte pleocytosis, particularly with coccidioidal meningitis), neoplastic disease (lymphoma, leukemia, metastatic carcinoma), or other inflammatory processes (sarcoidosis, hypereosinophilic syndrome).

It is often necessary to broaden the number of diagnostic tests if the initial workup does not reveal the cause. In addition, repeated samples of large volumes ofCSF may be required to diagnose certain infectious and malignant causes of chronic meningitis. For instance, lymphomatous or carcinomatous meningitis may be diagnosed by examination of sections cut from a cell block formed by spinning down the sediment from a large volume of CSF. The diagnosis of fungal meningitis may require large volumes of CSF for culture of sediment. If standard lumbar puncture is unrewarding, a cervical cisternal tap to sample CSF near to the basal meninges may be fruitful.

Laboratory Investigation In addition to theCSFexamination, an attempt should be made to uncover pertinent underlying illnesses. Tuberculin skin test, chest radiograph, urine analysis and culture, blood count and differential, renal and liver function tests, and measurement of electrolytes (including calcium and phosphate), sedimentation rate, antinuclear antibody, and serum angiotensin-converting enzyme level are often indicated. Liver or bone marrow biopsy may be diagnostic in some cases of miliary tuberculosis, disseminated fungal infection, sarcoidosis, or metastatic malignancy. Abnormalities discovered on chest radiograph or chestCT can be pursued by bronchoscopy or transthoracic needle biopsy.

Meningeal Biopsy A diagnostic meningeal biopsy should be strongly considered in patients who are severely disabled, who need chronic ventricular decompression, or whose illness is progressing rapidly. The activities of the surgeon, pathologist, microbiologist, and cytologist should be coordinated so that a large enough sample is obtained and the appropriate cultures and histologic and molecular studies, including electron microscopic andPCRstudies, are performed. The diagnostic yield of meningeal biopsy can be increased by targeting regions that enhance with contrast onMRI orCT. With current microsurgical techniques, most areas of the basal meninges can be accessed for biopsy via a limited craniotomy. In a series from the Mayo Clinic reported by Cheng et al., MRI demonstrated meningeal enhancement in 47% of patients undergoing meningeal biopsy. Biopsy of an enhancing region was diagnostic in 80% of cases; biopsy of nonenhancing regions was diagnostic in only 9%; sarcoid (31%) and metastatic adenocarcinoma (25%) were the most common conditions identified.

Approach to the Enigmatic Case In approximately one-third of cases, the diagnosis is not known despite careful evaluation ofCSF and potential extraneural sites of disease. A number of the organisms that cause chronic meningitis may take weeks to be identified by cultures. In enigmatic cases several options are available, determined by the extent of the clinical deficits and rate of progression. It is prudent to wait until cultures are finalized if the patient is asymptomatic or symptoms are mild and not progressive. Unfortunately, in many cases progressive neurologic deterioration occurs, and rapid treatment is required. Ventricular-peritoneal shunts may be placed to relieve hydrocephalus, but the risk of disseminating the undiagnosed inflammatory process into the abdomen must be considered.

Empirical Treatment Diagnosis of the causative agent is essential because effective therapies exist for many etiologies of chronic meningitis, but if the condition is left untreated, progressive damage to theCNS and cranial nerves and roots is likely to occur. Occasionally, empirical therapy must be initiated when all attempts at diagnosis fail. In general, empirical therapy in the United States consists of antimycobacterial agents, amphotericin for fungal infection, or glucocorticoids for noninfectious inflammatory causes. It is important to direct empirical therapy of lymphocytic meningitis at tuberculosis, particularly if the condition is associated with hypoglycorrhachia and sixth and otherCNpalsies, since untreated disease is fatal in 4 to 8 weeks. In the Mayo Clinic series, the most useful empirical therapy was administration of glucocorticoids rather than antituberculous therapy. Carcinomatous or lymphomatous meningitis may be difficult to diagnose initially, but the diagnosis becomes evident with time.

THE IMMUNOSUPPRESSED PATIENT

Chronic meningitis is not uncommon in the course ofHIVinfection. Pleocytosis and mild meningeal signs often occur at the onset of HIV infection, and occasionally low-grade meningitis persists. Toxoplasmosis commonly presents as intracranial abscesses and may also be associated with meningitis. Other important causes of chronic meningitis in AIDS include infection with *Cryptococcus*, *Nocardia*, *Candida*, or other fungi; syphilis; and lymphoma. Toxoplasmosis, cryptococcosis, nocardiosis, and other fungal infections are important etiologic considerations in individuals with immunodeficiency states other than AIDS, including those due to immunosuppressive medications. Because of the increased risk of chronic meningitis and the attenuation of clinical signs of meningeal

irritation in immunosuppressed individuals,CSFexamination should be performed for any persistent headache or unexplained change in mental state.

375. PRION DISEASES - *Stanley B. Prusiner*, *Patrick Bosque*

Creutzfeldt-Jakob disease (CJD) is a degenerative disease of the central nervous system (CNS) that is caused by infectious proteins called *prions*. CJD typically presents with dementia and myoclonus, is relentlessly progressive, and usually results in death within a year of onset. Most patients with CJD are between 50 and 75 years of age; however, patients as young as 17 years and as old as 83 years have been recorded.

In mammals, prions reproduce by binding to the normal, *c*ellular isoform of the *pr*ion *p*rotein (PrP^C) and stimulating its conversion into the disease-*c*ausing isoform (PrP^{Sc}). PrP^C is rich in a-helix and has littleb-sheet, while PrP^{Sc}has less a-helix and a highb-sheet content (Fig. 375-1). This a tob transition in prion protein (PrP) structure is the fundamental event underlying prion diseases, which are disorders of protein conformation (Table 375-1).

Four new concepts have emerged from studies of prions. First, prions are the only known infectious pathogens that are devoid of nucleic acid. All other infectious agents possess genomes composed of either RNA or DNA that direct the synthesis of their progeny. Second, prion diseases may be manifest as infectious, genetic, and sporadic disorders. No other group of illnesses with a single etiology presents with such a wide spectrum of clinical manifestations. Third, prion diseases result from the accumulation ofPrP^{Sc}, the conformation of which differs substantially from that of its precursorPrP^C. Fourth, PrP^{Sc}can exist in a variety of different conformations, each of which seems to specify a specific disease phenotype. How a specific conformation of a PrP^{Sc}molecule is imparted to PrP^Cduring prion replication to produce nascent $PrP^{Sc}$with the same conformation is unknown. Additionally, it is unclear what factors determine where in theCNS a particular PrP^{Sc}molecule will be deposited.

SPECTRUM OF PRION DISEASES

The sporadic form ofCJD is the most common prion disorder in humans. Sporadic CJD (sCJD) accounts for ~85% of all cases of human prion disease, while inherited prion diseases account for 10 to 15% of all cases (Table 375-2). Familial CJD (fCJD), Gerstmann-Straussler-Scheinker disease (GSS), and fatal familial insomnia (FFI) are all dominantly inherited prion diseases that are caused by mutations in thePrPgene.

Although infectious prion diseases account for <1% of all cases and infection does not seem to play an important role in the natural history of these illnesses, the transmissibility of prions is an important biologic feature. Kuru of the Fore people of New Guinea is thought to have resulted from the consumption of brains from dead relatives during ritualistic cannibalism. With the cessation of ritualistic cannibalism in the late 1950s, kuru has nearly disappeared with the exception of a few recent patients exhibiting incubation periods of almost 40 years. Iatrogenic CJD (iCJD) seems to be the result of the accidental inoculation of patients with prions. New variant CJD (nvCJD) in teenagers and young adults in Europe is the result of exposure to tainted beef from cattle with bovine spongiform encepalopathy (BSE).

Six diseases of animals are caused by prions (Table 375-2). Scrapie of sheep and goats is the prototypic prion disease. Mink encephalopathy,BSE, feline spongiform

encephalopathy, and exotic ungulate encephalopathy are all thought to occur after the consumption of prion-infected foodstuffs. The origin of chronic wasting disease, a prion disease endemic in deer and elk in regions of North America, is uncertain.

EPIDEMIOLOGY

CJDis found throughout the world. The incidence ofsCJD is approximately one case per million population. Although many geographic clusters of CJD have been reported, each has been shown to segregate with aPrP gene mutation that results in a nonconservative substitution. Attempts to identify common exposure to some etiologic agent have been unsuccessful for both the sporadic and familial cases. Ingestion of scrapie-infected sheep or goat meat as a cause of CJD in humans has not been demonstrated by epidemiologic studies although speculation about this potential route of inoculation continues. Studies with Syrian hamsters demonstrate that oral infection with prions can occur, but the process is inefficient compared to intracerebral inoculation.

PATHOGENESIS

The human prion diseases were initially classified as neurodegenerative disorders of unknown etiology on the basis of pathologic changes being confined to theCNS. With the transmission of kuru andCJD to apes, investigators began to view these diseases as CNS infectious illnesses caused by slow viruses. Even though the familial nature of a subset of CJD cases was well described, the significance of this observation became more obscure with the transmission of CJD to animals. Eventually, the meaning of heritable CJD became clear with the discovery of mutations in the*PrP*gene of these patients. The prion concept explains how a disease can manifest as a heritable as well as an infectious illness. Moreover, the hallmark common to all of the prion diseases, whether sporadic, dominantly inherited, or acquired by infection, is that they involve the aberrant metabolism of the prion protein.

A major feature that distinguishes prions from viruses is the finding that both PrP isoforms are encoded by a chromosomal gene. In humans, the*PrP*gene is designated *PRNP* and is located on the short arm of chromosome 20. Limited proteolysis ofPrP^{Sc}produces a smaller, protease-resistant molecule of ~142 amino acids designated PrP 27-30; under the same conditions,$PrP^{C}$is completely hydrolyzed (Fig. 375-2). In the presence of detergent, PrP 27-30 polymerizes into amyloid. Prion amyloid formed by limited proteolysis and detergent extraction is indistinguishable from the filaments that aggregate to form PrP amyloid plaques in theCNS. Both the rods and the PrP amyloid filaments found in brain tissue exhibit similar ultrastructural morphology and green-gold birefringence after staining with Congo red dye.

Species Barrier Studies on the role of the primary and tertiary structures ofPrP in the transmission of prion disease have given new insights into the pathogenesis of these maladies. The amino acid sequence of PrP encodes the species of the prion, and the prion derives itsPrP^{Sc}sequence from the last mammal in which it was passaged. While the primary structure of PrP is likely to be the most important or even sole determinant of the tertiary structure ofPrP^{C}, PrP^{Sc}seems to function as a template in determining the tertiary structure of nascent PrP^{Sc}molecules as they are formed from PrP^{C}. In turn, prion diversity appears to be enciphered in the conformation of PrP^{Sc}, and thus, prion strains

seem to represent different conformers of PrP^{Sc}.

In general, transmission of prion disease from one species to another is inefficient, in that not all intracerebrally inoculated animals develop disease, and those that fall ill do so only after long incubation times that can approach the natural lifespan of the animal. This "species barrier" to transmission is correlated with the degree of homology between the amino acid sequence of PrP^{C} in the inoculated host and of PrP^{Sc} in the prion inoculum. The importance of sequence homology between the host and donor PrP argues that PrP^{C} directly interacts with PrP^{Sc} in the prion conversion process.

Prion Strains The existence of prion strains raised the question of how heritable biologic information can be enciphered in a molecule other than nucleic acid. Strains or varieties of prions have been defined by incubation times and the distribution of neuronal vacuolation. Subsequently, the patterns of PrP^{Sc} deposition were found to correlate with vacuolation profiles, and these patterns were also used to characterize strains of prions.

Persuasive evidence that strain-specific information is enciphered in the tertiary structure of PrP^{Sc} comes from transmission of two different inherited human prion diseases to mice expressing a chimeric human-mouse PrP transgene. In FFI, the protease-resistant fragment of PrP^{Sc} after deglycosylation has a molecular mass of 19 kDa, whereas in fCJD and most sporadic prion diseases, it is 21 kDa (Table 375-3). This difference in molecular mass was shown to be due to different sites of proteolytic cleavage at the NH_2 termini of the two human PrP^{Sc} molecules, reflecting different tertiary structures. These distinct conformations were not unexpected because the amino acid sequences of the PrPs differ.

Extracts from the brains of patients with FFI transmitted disease into mice expressing a chimeric human-mouse PrP transgene and induced formation of the 19-kDa PrP^{Sc}, whereas fCJD and sCJD produced the 21-kDa PrP^{Sc} in mice expressing the same transgene. On second passage, these differences were maintained, demonstrating that chimeric PrP^{Sc} can exist in two different conformations based on the sizes of the protease-resistant fragments even though the amino acid sequence of PrP^{Sc} is invariant.

This analysis was extended when patients with sporadic fatal insomnia (sFI) were identified. Although they did not carry a *PrP* gene mutation, the clinical and pathologic phenotype was indistinguishable from that of patients with FFI. Furthermore, 19-kDa PrP^{Sc} was found in their brains, and on passage of prion disease to mice expressing a chimeric human-mouse PrP transgene, PrP^{Sc} was also found. These findings indicate that the disease phenotype is dictated by the conformation of PrP^{Sc} and not the amino acid sequence. PrP^{Sc} acts as a template for the conversion of PrP^{C} into nascent PrP^{Sc}.

SPORADIC AND INHERITED PRION DISEASES

Initiation of sporadic disease may hypothetically follow from a somatic mutation and thus follow a path similar to that for germline mutations in inherited disease. In this situation, the mutant PrP^{Sc} must be capable of targeting wild type PrP^{C}, a process known to be

possible for some mutations but less likely for others. Alternatively, the activation barrier separating wild type PrP^{C} from PrP^{Sc} could be crossed on rare occasions when viewed in the context of a population. Most individuals would be spared, while presentations in the elderly with an incidence of ~1 per million would be seen.

Twenty different mutations resulting in nonconservative substitutions in the human *PrP* gene have, to date, been found to segregate with inherited human prion diseases. Missense mutations and expansions in the octapeptide repeat region of the gene are responsible for familial forms of prion disease. Five different mutations of the *PrP* gene have been linked genetically to heritable prion disease.

Although phenotypes may vary dramatically within families, specific phenotypes tend to associate with certain mutations. A clinical phenotype indistinguishable from typical sporadic CJD is usually seen with substitutions at codons 180, 183, 200, 208, 210, and 232. Substitutions at codons 102, 105, 117, 198, and 217 are associated with the GSS variant of prion disease. The normal human PrP sequence contains five repeats of an eight or nine peptide sequence. Insertions from two to nine extra octapeptide repeats are frequently associated with variable phenotypes ranging from a condition indistinguishable from sporadic CJD to a slowly progressive dementing illness of many years duration. A mutation at codon 178 resulting in substitution of asparagine for aspartate produces FFI if a methionine is encoded at the polymorphic 129 residue on the same allele. Typical CJD is seen if a valine is encoded at position 129 of the same allele.

Human *PrP* Gene Polymorphisms Polymorphisms influence the susceptibility to sporadic, inherited, and infectious forms of prion disease. The methionine/valine polymorphism at position 129 not only modulates the age of onset of some inherited prion diseases but also determines the clinical phenotype. The influence of the codon 129 polymorphism iatrogenic and sporadic forms of prion disease has also been documented. The finding that homozygosity at codon 129 predisposes to sCJD supports a model of prion production that favors PrP interactions between homologous proteins.

Substitution of the basic residue lysine at position 219 produced dominant negative inhibition of prion replication in neuroblastoma cells. A lysine at 219 has been found in 12% of the Japanese population, and this group seems to be resistant to prion disease. Dominant negative inhibition of prion replication was also found with substitution of the basic residue arginine at position 171; sheep with arginine are resistant to scrapie.

INFECTIOUS PRION DISEASES

IATROGENIC CJD

Accidental transmission of CJD to humans appears to have occurred with corneal transplantation, contaminated electroencephalogram (EEG) electrode implantation, and surgical procedures. Corneas from donors with inapparent CJD have been transplanted to apparently healthy recipients who developed CJD after prolonged incubation periods. The same improperly decontaminated EEG electrodes that caused CJD in two young patients with intractable epilepsy caused CJD in a chimpanzee 18 months after their experimental implantation.

Surgical procedures may have resulted in accidental inoculation of patients with prions during their operations, presumably because some instrument or apparatus in the operating theater became contaminated when a CJD patient underwent surgery. Although the epidemiology of these studies is highly suggestive, no proof for such episodes exists.

Dura Mater Grafts More than 70 cases ofCJDafter implantation of dura mater grafts have been recorded. All of the grafts were thought to have been acquired from a single manufacturer whose preparative procedures were inadequate to inactivate human prions. One case of CJD occurred after repair of an eardrum perforation with a pericardium graft.

Human Growth Hormone and Pituitary Gonadotropin Therapy The possibility of transmission ofCJD from contaminated human growth hormone (hGH) preparations derived from human pituitaries has been raised by the occurrence of fatal cerebellar disorders with dementia in >100 patients ranging in age from 10 to 41 years. These patients received injections of hGH every 2 to 4 days for 4 to 12 years. If it is assumed that these patients developed CJD from injections of prion-contaminated hGH preparations, the possible incubation periods range from 4 to 30 years. Even though several investigations argue for the efficacy of inactivating prions in hGH fractions prepared from human pituitaries with 6 *M* urea, it seems doubtful that such protocols will be used for purifying hGH because recombinant hGH is available. Four cases of CJD have occurred in women receiving human pituitary gonadotropin.

NEW VARIANT CJD

The restricted geographic occurrence and chronology ofnvCJDhave raised the possibility thatBSEprions have been transmitted to humans. Approximately 70 cases of nvCJD have been recorded, and the fact that the incidence has remained relatively constant has made establishing the origin of nvCJD difficult. No set of dietary habits distinguishes patients with nvCJD from apparently healthy individuals. Moreover, there is no explanation for the predilection of nvCJD for teenagers and young adults. Epidemiologic studies over the past three decades have failed to find evidence for transmission of sheep prions to humans. Attempts to predict the future number of cases of nvCJD on the basis of possible exposure to bovine prions before the offal ban in 1998 that prevented further feeding of meat and bone meal (MBM) to cattle have been uninformative because so few cases of nvCJD have occurred. Are we at the beginning of a human prion disease epidemic in Great Britain similar to those seen for BSE and kuru, or will the number of nvCJD cases remain small as seen withiCJDcaused by cadaverichGH?

It is possible that a particular conformation of bovine$PrP_{Sc}$was selected for heat resistance during the rendering process and was then reselected multiple times as cattle infected by ingesting prion-contaminated MBM were slaughtered and their offal rendered into more MBM. Recent studies of $PrP_{Sc}$from brains of patients who died ofnvCJDshow a pattern ofPrPglycoforms different from those found forsCJD oriCJD. But the usefulness of measuring PrP glycoforms is questionable when trying to relateBSE to nvCJD because PrP_{Sc} is formed after the protein is glycosylated and enzymatic

deglycosylation of PrP^{Sc} requires denaturation.

The most compelling evidence that nvCJD comes from BSE prions was obtained from experiments in mice expressing the bovine PrP transgene. Both BSE and nvCJD prions were efficiently transmitted to these transgenic mice. In contrast to sporadic CJD prions, nvCJD did not transmit disease efficiently to mice expressing a chimeric human-mouse PrP transgene. Earlier studies with nontransgenic mice suggested that nvCJD and BSE might be derived from the same source because both sources of inocula transmitted disease with similar but very long incubation periods.

NEUROPATHOLOGY

Frequently, the brains of patients with CJD have no recognizable abnormalities on gross examination. Patients who survive for several years have variable degrees of cerebral atrophy.

On light microscopy, the pathologic hallmarks of CJD are spongiform degeneration and astrogliosis. The lack of an inflammatory response in CJD and other prion diseases is an important pathologic feature of these degenerative disorders. Spongiform degeneration is characterized by many 1- to 5-um vacuoles in the neuropil between nerve cell bodies. Generally, the spongiform changes occur in the cerebral cortex, putamen, caudate nucleus, thalamus, and molecular layer of the cerebellum. Astrocytic gliosis is a constant but nonspecific feature of prion diseases. Widespread proliferation of fibrous astrocytes is found throughout the gray matter of brains infected with CJD prions. Astrocytic processes filled with glial filaments form extensive networks.

Amyloid plaques have been found in ~10% of CJD cases. Purified CJD prions from humans and animals exhibit the ultrastructural and histochemical characteristics of amyloid when treated with detergents during limited proteolysis. In first passage from some human Japanese CJD cases, amyloid plaques have been found in mouse brains. These plaques stain with antisera raised against PrP.

The amyloid plaques of GSS are morphologically distinct from those seen in kuru or scrapie. GSS plaques consist of a central dense core of amyloid surrounded by smaller globules of amyloid. Ultrastructurally, they consist of a radiating fibrillar network of amyloid fibrils with scant or no neuritic degeneration. The plaques can be distributed throughout the brain but are most frequently found in the cerebellum. They are often located adjacent to blood vessels. Congophilic angiopathy has been noted in some cases of GSS.

In nvCJD, a characteristic feature is the presence of "florid plaques." These are composed of a central core of PrP amyloid surrounded by vacuoles in a pattern suggesting petals on a flower.

CLINICAL FEATURES

Nonspecific prodromal symptoms occur in about a third of patients with CJD and may include fatigue, sleep disturbance, weight loss, headache, malaise, and ill-defined pain. Most patients with CJD present with deficits in higher cortical function. These deficits

virtually always progress over weeks or months to a state of profound dementia characterized by memory loss, impaired judgment, and a decline in virtually all aspects of intellectual function. A few patients present with either visual impairment or cerebellar gait and coordination deficits. Frequently, the cerebellar deficits are rapidly followed by progressive dementia. Visual problems often begin with blurred vision and diminished acuity, rapidly followed by dementia.

Other symptoms and signs include extrapyramidal dysfunction manifested as rigidity, masklike facies, or choreoathetoid movements; pyramidal signs (usually mild); seizures (usually major motor) and, less commonly, hypesthesia; supranuclear gaze palsy; optic atrophy; and vegetative signs such as changes in weight, temperature, sweating, or menstruation.

Myoclonus Most patients (~90%) withCJDexhibit myoclonus that appears at various times throughout the illness. Unlike other involuntary movements, myoclonus persists during sleep. Startle myoclonus elicited by loud sounds or bright lights is frequent. It is important to stress that myoclonus is neither specific nor confined to CJD. Dementia with myoclonus can also be due to Alzheimer's disease (AD) (Chap. 362), to cryptococcal encephalitis (Chap. 204), or to the myoclonic epilepsy disorder Unverricht-Lundborg disease (Chap. 360).

Clinical Course In documented cases of accidental transmission ofCJD to humans, an incubation period of 1.5 to 2.0 years preceded the development of clinical disease. In other cases, incubation periods of up to 30 years have been suggested. Most patients with CJD live 6 to 12 months after the onset of clinical signs and symptoms, whereas some live for up to 5 years.

DIAGNOSIS

The constellation of dementia, myoclonus, and periodic electrical bursts in an afebrile 60-year-old patient generally indicatesCJD. Clinical abnormalities in CJD are confined to theCNS. Fever, elevated sedimentation rate, leukocytosis in blood, or a pleocytosis in cerebrospinal fluid (CSF) should alert the physician to another etiology to explain the patient's CNS dysfunction.

Important variations in the typical course ofCJDappear in certain inherited and transmitted forms of the disease.fCJD has an earlier mean age of onset thansCJD. InGSS, ataxia is usually a prominent and presenting feature, with dementia occurring late in the disease course. GSS may present earlier than CJD (mean age, 43 years; range, 24 to 66 years) and is typically more slowly progressive than CJD; death usually occurs within 5 years of onset.FFI is characterized by insomnia and dysautonomia; dementia occurs only in the terminal phase of the illness. Rare sporadic cases have been identified.nvCJDhas an unusual clinical course, with a prominent psychiatric prodrome that may include visual hallucinations and early ataxia, while frank dementia usually is a late sign of nvCJD (see below).

DIFFERENTIAL DIAGNOSIS

Many conditions may mimicCJDsuperficially.AD is occasionally accompanied by

myoclonus but is usually distinguished by its protracted course and lack of motor and visual dysfunction.

Intracranial vasculitides (Chap. 317) may produce nearly all of the symptoms and signs associated with CJD, sometimes without systemic abnormalities. Myoclonus is exceptional with cerebral vasculitis, but focal seizures may confuse the picture; furthermore, myoclonus is often absent in the early stages of CJD. Stepwise change in deficits, prominent headache, abnormal cerebrospinal fluid, and focal magnetic resonance imaging (MRI) or angiographic abnormalities all favor vasculitis.

Neurosyphilis (Chap. 172) may present with dementia and myoclonus that progresses in a relatively rapid fashion but is easily distinguished fromCJD byCSFfindings, as is cryptococcal meningoencephalitis. A diffuse intracranial tumor (gliomatosis cerebri; Chap. 370) may occasionally be confused with CJD. In rare cases ofCNSneoplasia, neuroimaging studies are normal and there are no signs of increased intracranial pressure; however, CSF protein is usually elevated. Adult onset leukodystrophies (ceroid lipofuscinosis or Kuf's disease) and myoclonic epilepsy with Lafora bodies (Chap. 360) may be responsible for dementia, myoclonus, and ataxia; but the less acute courses and prominent seizures distinguish them from CJD. A number of diseases that may simulate CJD are easily distinguished by noting the clinical setting in which they occur. These diseases include anoxic encephalopathy, subacute sclerosing panencephalitis, progressive rubella panencephalitis, herpes simplex encephalitis (in immunoincompetent hosts), dialysis dementia, uremia, and portasystemic shunt encephalopathy.

WhenCJDbegins atypically, it may for a short time resemble other disorders such as Parkinson's disease, progressive supranuclear palsy (Chap. 363), or progressive multifocal leukoencephalopathy (Chap. 373). However, this resemblance usually fades early in the course of CJD.

Certain drug intoxications, particularly lithium and bismuth, may produce a syndrome with encephalopathy and myoclonus. The rare condition known as Hashimoto's encephalopathy, which presents with a subacutely progressive encephalopathy and myoclonus with periodic triphasic complexes on theEEGshould be excluded in every case of suspectedCJD. It is diagnosed by the finding of high titers of antithyroglobulin or antithyroid perioxidase (antimicrosomal) antibodies in the blood, and improves with glucocorticoid therapy. Unlike CJD, fluctuations in severity typically occur in Hashimoto's encephalopathy.

The AIDS dementia complex (Chap. 309) may occasionally imitateCJD in onset, early course, physical signs, computed tomography (CT) findings, and lack of abnormalities on routineCSFstudies. The few such patients without manifestations of systemic immunodeficiency (<10%) should be questioned about risk factors and should have serum antibodies to HIV determined. Additionally, more specific CSF tests are likely to be abnormal; in one study, CSF oligoclonal bands were present in six of nine patients, and intra-blood-brain barrier synthesis of IgG specific for HIV was elevated in eight of nine.

LABORATORY TESTS

With the exception of brain biopsy, there are no specific tests forCJD. If the constellation of pathologic changes frequently found in CJD is seen in a brain biopsy, then the diagnosis is reasonably secure (see Neuropathology, above). The rapid and reliable diagnosis of CJD postmortem can be accomplished with antisera toPrP. Numerous western blotting studies have consistently demonstrated PrP immunoreactive proteins that are proteinase K-resistant in the brains of patients with CJD. BecausePrP^{Sc}is not uniformly distributed throughout the CNS, the apparent absence of PrP^{Sc} in a limited sample such as a biopsy does not rule out prion disease. A highly sensitive and quantitative immunoassay was developed based on epitopes that are exposed inPrP^{C}but buried in PrP^{Sc}. Unlike all other immunoassays for PrP^{Sc}, this conformation-dependent immunoassay (CDI) does not require limited proteolysis to hydrolyze PrP^{C}before measurement of the protease-resistant core of PrP^{Sc}(PrP 27-30).

If the patient has a family history suggestive of inheritedCJD, sequencing the*PrP*gene may facilitate the diagnosis. Sometimes, the PrP sequence is helpful for even seemingly nonfamilial cases.

CTmay be normal or show cortical atrophy. TheMRI scan may show a subtle increased intensity in the basal ganglia with T2 or diffusion weighted imaging, but this finding is neither sensitive nor specific enough to make a diagnosis.CSF is nearly always normal but may show a minimal protein elevation. Although the stress protein 14-3-3 is elevated in the CSF of most patients withCJD, similar elevations of 14-3-3 are found in herpes simplex virus encephalitis, multi-infarct dementia, and stroke. InAD, 14-3-3 is generally not elevated. In the serum of some patients with CJD, the S-100 protein is elevated; but like 14-3-3, this elevation is not specific.

TheEEG is often useful in the diagnosis ofCJD. During the early phase of CJD, the EEG is usually normal or shows only scattered theta activity. In most advanced cases, repetitive, high voltage, triphasic, and polyphasic sharp discharges are seen, but in many cases their presence is transient. The presence of these stereotyped periodic bursts of<200 ms duration, occurring every 1 to 2 s, makes the diagnosis of CJD very likely. These discharges are frequently but not always symmetric; there may be a one-sided predominance in amplitude. As CJD progresses, normal background rhythms become fragmentary and slower.

CARE OF CJD PATIENTS

It is important to stress that CJD is neither a contagious nor a communicable disease, but it is transmissible. Although the risk of accidental inoculation by aerosols is very small, procedures producing aerosols should be performed in certified biosafety cabinets. Biosafety level 2 practices, containment equipment, and facilities are recommended by the Centers for Disease Control and Prevention and the National Institutes of Health. The primary problem in caring for patients with CJD is the inadvertent infection of healthcare workers by needle and stab wounds, whereas the possible transmission of a contagion through the air has never been documented. Electroencephalographic and electromyographic needles should not be reused after studies on patients with CJD have been performed.

There is no reason for pathologists or morgue dieners to resist performing autopsies on patients whose clinical diagnosis wasCJD. Standard microbiologic practices outlined here, along with specific recommendations for decontamination, seem to be adequate precautions for the care of patients with CJD and the handling of infected specimens.

DECONTAMINATION OF CJD PRIONS

Prions are extremely resistant to common inactivation procedures, and there is some disagreement about the optimal conditions for sterilization. Some investigators recommend treating CJD-contaminated materials once with 1 *N* NaOH at room temperature, but we believe this procedure may be inadequate for sterilization. Autoclaving at 132°C for 5 h or treatment with 2 *N* NaOH for several hours is recommended for sterilization of prions. The term "sterilization" implies complete destruction of prions; any residual infectivity can be hazardous.

PREVENTION AND THERAPEUTICS

There is no known effective therapy for treating or preventingCJD. With one possible exception, there are no well-documented cases of patients with CJD showing recovery either spontaneously or after therapy.

Several compounds have been demonstrated to eliminate prions from prion-infected cultured cells. A class of compounds known as "dendrimers" seems particularly efficacious in this regard. Several drugs delay the onset of disease in animals inoculated with prions if the drugs are given around the time of the inoculation. The most common scenarios in which one would want to treat humans are either patients showing signs of disease or presymptomatic patients carrying mutations predisposing them to develop prion disease. No treatment has shown any efficacy in animal models of these two scenarios.

Structure-based drug design predicated on dominant negative inhibition of prion formation has produced several promising compounds. Whether this approach or that of enhanced clearance of misfolded proteins will provide general methods for developing novel therapeutics for Alzheimer's disease and Parkinson's disease, as well as amyotrophic lateral sclerosis (ALS), remains to be established.

376. CRITICAL CARE NEUROLOGY - *J. Claude Hemphill*, *M. Flint Beal*, *Daryl R. Gress*

Advances in the understanding of the pathophysiology of acute nervous system injury and the development of treatments that target these injury mechanisms have led to the growth of critical care neurology as a discipline. Life-threatening neurologic illness may be caused by a primary disorder affecting any region of the neuroaxis or may occur as a consequence of a systemic disorder such as hepatic failure, multisystem organ failure (MSOF), or cardiac arrest (Table 376-1). Critical care neurology focuses on preservation of neurologic tissue and prevention of secondary brain injury caused by ischemia, edema, and elevated intracranial pressure (ICP).

PATHOPHYSIOLOGY

Brain Edema Swelling, or edema, of brain tissue occurs with many types of brain injury. The two principal types of edema are vasogenic and cytotoxic. *Vasogenic edema* refers to the influx of fluid and solutes into the brain through an incompetent blood-brain barrier (BBB). In the normal cerebral vasculature, endothelial tight junctions associated with astrocytes create an impermeable barrier (the BBB), through which access into the brain interstitium is dependent upon specific transport mechanisms (Chap. 355). The BBB may be compromised in ischemia, trauma, infection, and metabolic derangements. Typically, vasogenic edema develops rapidly following injury. *Cytotoxic edema* refers to cellular swelling. Originally described as a response to exogenous toxins, cellular swelling occurs in a variety of settings including brain ischemia and trauma. Early astrocytic swelling is a hallmark of ischemia.

Brain edema that is clinically significant usually represents a combination of vasogenic and cellular components. Edema can lead to increasedICP as well as tissue shifts and brain displacement from focal processes. These tissue shifts can cause injury by mechanical distraction and compression in addition to the ischemia of impaired perfusion consequent to the elevated ICP.

Cerebral Perfusion and Autoregulation Brain tissue requires constant perfusion in order to ensure adequate delivery of substrate, principally oxygen and glucose. The hemodynamic response of the brain has the capacity to preserve perfusion across a wide range of systemic blood pressures. Cerebral perfusion pressure (CPP), defined as the mean systemic arterial pressure (MAP) minus theICP, provides the driving force for circulation across the capillary beds of the brain. *Autoregulation* refers to the physiologic response whereby cerebral blood flow (CBF) remains relatively constant over a wide range of blood pressures as a consequence of alterations of cerebrovascular resistance (Fig. 376-1). If systemic blood pressure drops, cerebral perfusion is preserved through vasodilatation of arterioles in the brain; likewise, arteriolar vasoconstriction occurs at high systemic pressures to prevent hyperperfusion. At the extreme limits of MAP or CPP (high or low), flow becomes directly related to perfusion pressure. These autoregulatory changes occur in the microcirculation and are mediated by vessels below the resolution of those seen on angiography. CBF is also strongly influenced by pH and P_{CO2}. CBF increases with hypercapnia and acidosis and decreases with hypocapnia and alkalosis. This forms the basis for the use of hyperventilation to lower ICP, and this effect on ICP is mediated through a decrease in intracranial blood volume. Cerebral autoregulation is

critical to the normal homeostatic functioning of the brain, and this process may be disordered focally and unpredictably in disease states such as traumatic brain injury and severe focal cerebral ischemia.

Cerebrospinal Fluid and Intracranial Pressure The cranial contents consist essentially of brain, cerebrospinal fluid (CSF), and blood. CSF is produced principally in the choroid plexus of each lateral ventricle, exits the brain via the foramina of Luschka and Magendi, and flows over the cortex to be absorbed into the venous system along the superior sagittal sinus. Approximately 150 mL of CSF are contained within the ventricles and surrounding the brain and spinal cord; the cerebral blood volume is also ~150 mL. The bony skull offers excellent protection for the brain but allows little tolerance for additional volume. Significant increases in volume eventually result in increasedICP. Obstruction of CSF outflow, edema of cerebral tissue, or increases in volume from tumor or hematoma may increase ICP. Elevated ICP diminishes cerebral perfusion and can lead to tissue ischemia. Ischemia in turn may lead to vasodilatation via autoregulatory mechanisms designed to restore cerebral perfusion. However, vasodilatation also increases cerebral blood volume, which in turn then increases ICP, lowersCPP, and provokes further ischemia (Fig. 376-2). This vicious cycle is commonly seen in traumatic brain injury, massive intracerebral hemorrhage, and large hemispheric infarcts with significant tissue shift.**Excitotoxicity and mechanisms of cell death are discussed in Chap. 355.*

Approach to the Patient

Critically ill patients with severe central nervous system dysfunction require rapid evaluation and intervention in order to limit primary and secondary brain injury. Initial neurologic evaluation should be performed concurrent with stabilization of basic respiratory, cardiac, and hemodynamic parameters. Significant barriers may exist to neurologic assessment in the critical care unit. Endotracheal intubation and the use of sedative or paralytic agents to facilitate critical care procedures can make clinical assessment challenging.

An impaired level of consciousness is frequent in critically ill patients. The essential first task in assessment is to determine whether the cause of dysfunction is related to a diffuse, usually metabolic, process or whether a focal, usually structural, process is implicated. Examples of diffuse processes include metabolic encephalopathies related to organ failure, drug overdose, or hypoxia-ischemia. Focal processes include ischemic and hemorrhagic stroke and traumatic brain injury, especially with intracranial hematomas. Since these two categories of disorders have fundamentally different causes, treatments, and prognoses, the initial focus is on making this distinction rapidly and accurately.**The approach to the confused or comatose patient is discussed in Chap. 24; etiologies are listed in Table 24-1.*

Minor focal deficits may be present on the neurologic examination in patients with metabolic encephalopathies. However, the finding of prominent focal signs such as pupillary asymmetry, hemiparesis, gaze palsy, or paraplegia should alert the examiner to the possibility of a structural lesion. All patients with a decreased level of consciousness associated with focal findings should undergo an urgent neuroimaging procedure, as should all patients with coma of unknown etiology. Computed

tomographic (CT) scanning is usually the most appropriate initial study because it can be performed quickly in critically ill patients and demonstrates hemorrhage, hydrocephalus, and intracranial tissue shifts well. Magnetic resonance imaging (MRI) may provide more specific information in some situations, such as acute ischemic stroke (diffusion-weighted imaging, DWI) and cerebral venous sinus thrombosis (magnetic resonance venography, MRV). Any suggestion of trauma from the history or examination should alert the examiner to the possibility of cervical spine injury and prompt an imaging evaluation using plain x-rays, MRI, or CT.

Other diagnostic studies are best utilized in specific circumstances, usually when neuroimaging studies fail to reveal a structural lesion and the etiology of the altered mental state remains uncertain. Electroencephalography (EEG) can be important in the evaluation of critically ill patients with severe brain dysfunction. The EEG of encephalopathy typically reveals generalized slowing. One of the most important uses of EEG is to help exclude inapparent seizures, especially nonconvulsive status epilepticus. Untreated continuous or frequently recurrent seizures may cause neuronal injury, making the diagnosis and treatment of seizure crucial in this patient group. Lumbar puncture (LP) may be necessary to exclude infectious processes, and an elevated opening pressure may be an important clue to cerebral venous sinus thrombosis. In patients with coma or profound encephalopathy, it is preferable to perform a neuroimaging study prior to LP. If bacterial meningitis is suspected, an LP may be performed first or antibiotics may be empirically administered before the diagnostic studies are completed. Standard laboratory evaluation of critically ill patients should include assessment of serum electrolytes (especially sodium and calcium), glucose, renal and hepatic function, complete blood counts, and coagulation. Serum or urine toxicology screens should be performed in patients with encephalopathy of unknown cause. EEG, LP, and other specific laboratory tests are most useful when the mechanism of the altered level of consciousness is uncertain; they are not routinely performed in clear-cut cases of stroke or traumatic brain injury.

Monitoring ofICP can be an important tool in selected patients. Indications for ICP monitoring, as well as specific types of monitors, vary. In general, patients who should be considered for ICP monitoring are those with primary neurologic disorders, such as stroke or traumatic brain injury, who are not moribund and who are at significant risk for secondary brain injury due to elevated ICP and decreasedCPP. Such patients include those with severe traumatic brain injury resulting in coma [Glasgow Coma Scale (GCS) score of £8 (Table 369-1)]; those with large tissue shifts from supratentorial ischemic or hemorrhagic stroke resulting in decreased consciousness; and those with (or at risk for) hydrocephalus from subarachnoid hemorrhage, intraventricular hemorrhage, or posterior fossa stroke. An additional disorder in which ICP monitoring can add important information is fulminant hepatic failure, in which elevated ICP may be treated with barbiturates or, eventually, liver transplantation. In general, ventriculostomy is preferable to ICP monitoring devices that are placed in brain parenchyma, because ventriculostomy allowsCSFdrainage as a method of treating elevated ICP. However, parenchymal ICP monitoring is most appropriate for patients with diffuse edema and small ventricles (which may make ventriculostomy placement more difficult) or any degree of coagulopathy (in which ventriculostomy carries a higher risk of hemorrhagic complications).

Treatment of Elevated ICP ElevatedICP may occur in a wide range of disorders including head trauma, intracerebral hemorrhage, subarachnoid hemorrhage with hydrocephalus, and fulminant hepatic failure. BecauseCSF and blood volume can be redistributed initially, by the time elevated ICP occurs intracranial compliance is severely impaired. At this point, small changes in the volume of CSF, intravascular blood, edema, or a mass lesion may result in significant changes in ICP. Elevated ICP then diminishes cerebral perfusion. This is a fundamental mechanism of secondary ischemic brain injury and constitutes an emergency that requires immediate attention. Specific thresholds of ICP vary, but in general, ICP should be maintained at<20 mmHg andCPPshould be maintained at ³70 mmHg.

A number of different interventions may lowerICP, and ideally the selection of treatment will be based on the underlying mechanism responsible for the elevated ICP (Table 376-2). For example, in hydrocephalus from subarachnoid hemorrhage, the principal cause of elevated ICP is impairment ofCSFdrainage. In this setting, ventricular drainage of CSF is likely to be sufficient and most appropriate. In head trauma and stroke, cytotoxic edema may be most responsible, and the use of osmotic diuretics such as mannitol becomes an appropriate early step. As described above, elevated ICP may cause tissue ischemia, and, if cerebral autoregulation is intact, the resulting vasodilatation can lead to a cycle of worsening ischemia. Paradoxically, administration of vasopressor agents to increase mean arterial pressure may actually lower ICP by improving perfusion, thereby allowing autoregulatory vasoconstriction as ischemia is relieved and ultimately decreasing intracranial blood volume.

Early signs of elevatedICPinclude drowsiness and a diminished level of consciousness. Neuroimaging studies may reveal evidence of edema and mass effect. Hypotonic intravenous fluids should be avoided, and elevation of the head of the bed is recommended. Patients must be carefully observed for risk of aspiration and compromise of the airway as the level of alertness declines. Coma and unilateral pupillary changes are late signs and require immediate intervention. Emergent treatment of elevated ICP is most quickly achieved by intubation and hyperventilation, which causes vasoconstriction and reduces cerebral blood volume. Because of the concern of provoking or worsening cerebral ischemia, hyperventilation is best used for short periods of time until a more definitive treatment can be instituted. Furthermore, the effects of continued hyperventilation on ICP are short-lived, often only for several hours because of the buffering capacity of the cerebral interstitium, and rebound elevated ICP may accompany abrupt discontinuation of hyperventilation. As the level of consciousness declines to coma, the ability to follow the neurologic status of the patient by examination deteriorates and measurement of ICP must be considered. If a ventriculostomy device is in place, direct drainage ofCSF to reduce ICP is possible. Finally, high-dose barbiturates or hypothermia are sometimes used for refractory elevated ICP, although these have significant side effects and have not been shown to improve outcome.

CRITICAL CARE DISORDERS OF THE CENTRAL NERVOUS SYSTEM ASSOCIATED WITH SYSTEMIC DISEASE

HYPOXIC-ISCHEMIC ENCEPHALOPATHY

Hypoxic-ischemic encephalopathy occurs from lack of delivery of oxygen to the brain because of hypotension or respiratory failure. The most common causes are myocardial infarction, cardiac arrest, shock, asphyxiation, paralysis of respiration, and carbon monoxide or cyanide poisoning. In some circumstances, hypoxia may predominate. Carbon monoxide and cyanide poisoning are termed *histotoxic hypoxia* since they cause a direct impairment of the respiratory chain.

Clinical Manifestations Mild degrees of pure hypoxia, such as occur at high altitudes, cause impaired judgment, inattentiveness, motor incoordination, and, at times, euphoria. However, with hypoxia-ischemia, such as occurs with circulatory arrest, consciousness is lost within seconds. If circulation is restored within 3 to 5 min, full recovery may occur, but if hypoxia-ischemia lasts beyond 3 to 5 min, some degree of permanent cerebral damage is the rule. Except in extreme cases, it may be difficult to judge the precise degree of hypoxia-ischemia, and some patients make a relatively full recovery after even 8 to 10 min of global cerebral ischemia. The distinction between pure hypoxia and hypoxia-ischemia is important, since a Pa_{O2} as low as 20 mmHg (2.7 kPa) can be well tolerated if it develops gradually and normal blood pressure is maintained, but short durations of very low or absent cerebral circulation may result in permanent impairment.

Clinical examination at different time points after a hypoxic-ischemic insult (especially cardiac arrest) is useful in assessing prognosis for long-term neurologic outcome (Fig. 376-3). The prognosis is better for patients with intact brainstem function, as indicated by normal pupillary light responses, intact oculocephalic (doll's-eyes), oculovestibular (caloric), and corneal reflexes. Absence of these reflexes and the presence of persistently dilated pupils that do not react to light are grave prognostic signs. A uniformly dismal prognosis from hypoxic-ischemic coma is conveyed by the clinical findings of absence of pupillary light reflex or absence of a motor response to pain on day 3 following the injury. Electrophysiologically, the finding of bilateral absence of the early cortical somatosensory evoked response (SSEPs) in the first week also conveys a poor prognosis. Long-term consequences of hypoxic-ischemic encephalopathy include persistent coma or vegetative state (Chap. 24), dementia, visual agnosia (Chap. 25), parkinsonism, choreoathetosis, cerebellar ataxia, myoclonus, seizures, and an amnestic state, which may be a consequence of selective damage to the hippocampus (Chap. 26).

Pathologic Findings Principal histologic findings are extensive multifocal or diffuse laminar cortical necrosis (Fig. 376-4), with almost invariable involvement of the hippocampus. The hippocampal CA1 neurons are vulnerable to even brief episodes of hypoxia-ischemia, perhaps explaining why selective persistent memory deficits may occur after brief cardiac arrest. Scattered small areas of infarction or neuronal loss may be present in the basal ganglia, hypothalamus, or brainstem. In some cases, extensive bilateral thalamic scarring may affect thalamic and extrathalamic pathways that mediate arousal, and this has been suggested as one pathologic explanation for the persistent vegetative state. A specific form of hypoxic-ischemic encephalopathy, so-called watershed infarcts, occurs at the distal territories between the major cerebral arteries and can cause cognitive deficits, including visual agnosia, and weakness that is greater in proximal than in distal muscle groups.

Diagnosis Diagnosis is based upon the history of a hypoxic-ischemic event such as

cardiac arrest. Blood pressure <70 mmHg systolic or Pa_{O2}< 40 mmHg is usually necessary, although both absolute levels as well as duration of exposure are important determinants of cellular injury. Occasionally the clinical and radiographic features of a hypoxic-ischemic syndrome are seen without documented profound hypotension or hypoxia. Carbon monoxide intoxication can be confirmed by measurement of carboxyhemoglobin and is suggested by a cherry red color of the skin.

TREATMENT

Treatment should be directed at restoration of normal cardiorespiratory function. This includes securing a clear airway, ensuring adequate oxygenation and ventilation, and restoring cerebral perfusion, whether by cardiopulmonary resuscitation, fluid, pressors, or cardiac pacing. Hypothermia and neuroprotective agents that target different aspects of the cell injury cascade are experimental approaches that have not yet been shown to have clinical value.

Severe carbon monoxide intoxication may be treated with hyperbaric oxygen. Anticonvulsants may be needed to control seizures, although these are not usually given prophylactically. Posthypoxic myoclonus may respond to oral administration of clonazepam at doses of 1.5 to 10 mg daily or valproate at doses of 300 mg to 1200 mg daily in divided doses. Myoclonic status epilepticus after a severe hypoxic-ischemic insult portends a universally poor prognosis, even if seizures are controlled.

DELAYED POSTANOXIC ENCEPHALOPATHY

Delayed postanoxic encephalopathy is an uncommon phenomenon in which patients appear to make an initial recovery from hypoxic-ischemic insult but then develop a relapse characterized by apathy, confusion, and agitation. Progressive neurologic deficits may include shuffling gait, diffuse rigidity and spasticity, persistent parkinsonism or myoclonus, and, on occasion, coma and death after 1 to 2 weeks. Widespread cerebral demyelination may be present.

Carbon monoxide and cyanide intoxication can also cause a delayed encephalopathy. Little clinical impairment is evident when the patient first regains consciousness, but a parkinsonian syndrome characterized by akinesia and rigidity without tremor may develop. Symptoms can worsen over months, accompanied by increasing evidence of damage in the basal ganglia as seen on bothCT andMRI.

METABOLIC ENCEPHALOPATHIES

Altered mental states, variously described as confusion, delirium, disorientation, and encephalopathy, are present in many patients with severe illness in an intensive care unit (ICU). Older patients are particularly vulnerable to delirium, a confusional state characterized by disordered perception, frequent hallucinations, delusions, and sleep disturbance. This is often attributed to medication effects, sleep deprivation, pain, and anxiety. The term *ICU psychosis* has been used to describe a mental state with profound agitation occurring in this setting. The presence of family members in the ICU may help to calm and orient agitated patients, and in severe cases, low doses of neuroleptics (e.g., haloperidol 0.5 to 1 mg) can be useful. Ultimately, the psychosis

resolves with improvement in the underlying illness and a return to familiar surroundings.

In the ICU setting, several metabolic causes of an altered level of consciousness predominate. Hypercarbic encephalopathy can present with headache, confusion, stupor, or coma. Hypoventilation syndrome occurs most frequently in patients with a history of chronic CO_2 retention who are receiving oxygen therapy for emphysema or chronic pulmonary disease (Chap. 263). The elevated Pa_{CO_2} leading to CO_2 narcosis may have a direct anesthetic effect, and cerebral vasodilatation from increased Pa_{CO_2} can lead to increased ICP. Hepatic encephalopathy is suggested by asterixis and can occur in chronic liver failure or acute fulminant hepatic failure. Both hyperglycemia and hypoglycemia can cause encephalopathy, as can hypernatremia and hyponatremia. Confusion, impairment of eye movements, and gait ataxia are the hallmarks of acute Wernicke's disease (see below).

SEPTIC ENCEPHALOPATHY

Pathogenesis In patients with sepsis, the systemic response to infectious agents leads to the release of circulating inflammatory mediators that appear to contribute to encephalopathy. Critical illness, in association with the systemic inflammatory response syndrome (SIRS), can lead to MSOF. This syndrome can occur in the setting of apparent sepsis, severe burns, or trauma, even without clear identification of an infectious agent. Many patients with critical illness, sepsis, or SIRS develop encephalopathy without obvious explanation. This condition is broadly termed *septic encephalopathy*. While the specific mediators leading to neurologic dysfunction remain uncertain, it is clear that the encephalopathy is not simply the result of metabolic derangements of multiorgan failure. The cytokines tumor necrosis factora, interleukin (IL) 1, IL-2, and IL-6 are thought to play a role in this syndrome.

Diagnosis Septic encephalopathy presents clinically as a diffuse dysfunction of the brain without prominent focal findings. Confusion, disorientation, agitation, and fluctuations in level of alertness are typical. In more profound cases, especially with hemodynamic compromise, the decrease in level of alertness can be more prominent, at times resulting in coma. Hyperreflexia and frontal release signs such as a grasp or snout reflex (Chap. 356) can be seen. Abnormal movements such as myoclonus, tremor, or asterixis can occur. Septic encephalopathy is quite common, occurring in the majority of patients with sepsis and MSOF. Diagnosis is often difficult because of the multiple potential causes of neurologic dysfunction in critically ill patients, and requires exclusion of structural, metabolic, toxic, and infectious (e.g., meningitis or encephalitis) causes. Although the mortality of patients with septic encephalopathy severe enough to produce coma approaches 50%, this reflects the severity of the underlying critical illness and is not a direct result of the septic encephalopathy. Neurologically, successful treatment of the underlying critical illness almost always results in complete resolution of the encephalopathy, without significant residua.

CENTRAL PONTINE MYELINOLYSIS

This disorder typically presents in a devastating fashion as quadriplegia and pseudobulbar palsy. Predisposing factors include severe underlying medical illness or

nutritional deficiency; most cases are associated with rapid correction of hyponatremia or with hyperosmolar states. The pathology consists of demyelination without inflammation in the base of the pons, with relative sparing of axons and nerve cells.MRI is useful in establishing the diagnosis (Fig. 376-5) and may also identify partial forms that present as confusion, dysarthria, and/or disturbances of conjugate gaze without quadriplegia. Therapeutic guidelines for the restoration of severe hyponatremia should aim for gradual correction, i.e., by £10 mmol/L (10 meq/L) within 24 h and 20 mmol/L (20 meq/L) within 48 h.

WERNICKE'S DISEASE

Wernicke's disease is a common and preventable disorder due to a deficiency of thiamine (Chap. 75). In the United States, alcoholics account for most cases, but patients with malnutrition due to hyperemesis, starvation, renal dialysis, cancer, or AIDS are also at risk. The characteristic clinical triad is that of ophthalmoplegia, ataxia, and global confusion. However, only one-third of patients with acute Wernicke's disease present with the classic clinical triad. Most patients are profoundly disoriented, indifferent, and inattentive, although rarely they have an agitated delirium related to ethanol withdrawal. If the disease is not treated, stupor, coma, and death may ensue. Ocular motor abnormalities include horizontal nystagmus on lateral gaze, lateral rectus palsy (usually bilateral), conjugate gaze palsies, and rarely ptosis. Gait ataxia probably results from a combination of polyneuropathy, cerebellar involvement, and vestibular paresis. The pupils are usually spared, but they may become miotic with advanced disease.

Wernicke's disease is usually associated with other manifestations of nutritional disease, such as polyneuropathy. Rarely, amblyopia or spinal spastic ataxia occurs. Tachycardia and postural hypotension may be related to impaired function of the autonomic nervous system or to the coexistence of cardiovascular beriberi. Patients who recover show improvement in ocular palsies within hours after the administration of thiamine, but horizontal nystagmus may persist. Ataxia improves more slowly than the ocular motor abnormalities. Approximately half recover incompletely and are left with a slow, shuffling, wide-based gait and an inability to tandem walk. Apathy, drowsiness, and confusion improve more gradually. As these symptoms recede, an amnestic state with impairment in recent memory and learning may become more apparent (*Korsakoff's psychosis*). Korsakoff's psychosis is frequently persistent; the residual mental state is characterized by gaps in memory, confabulation, and disordered temporal sequencing.

Pathology Lesions in the periventricular regions of the diencephalon, midbrain, and brainstem as well as the superior vermis of the cerebellum consist of symmetric discoloration of structures surrounding the third ventricle, aqueduct, and fourth ventricle, with petechial hemorrhages in occasional acute cases and atrophy of the mamillary bodies in most chronic cases. There is frequently endothelial proliferation, demyelination, and some neuronal loss. These changes may be detected byMRIscanning (Fig. 376-6). The amnestic defect is related to lesions in the dorsal medial nuclei of the thalamus.

Pathogenesis Thiamine is a cofactor of several enzymes, including transketolase,

pyruvate dehydrogenase, and a-ketoglutarate dehydrogenase. Thiamine deficiency produces a diffuse decrease in cerebral glucose utilization and results in mitochondrial damage. Glutamate accumulates owing to impairment ofa-ketoglutarate dehydrogenase activity and, in combination with the energy deficiency, may result in excitotoxic cell damage.

TREATMENT

Wernicke's disease is a medical emergency and requires immediate administration of thiamine, in a dose of 50 mg either intravenously or intramuscularly. The dose should be given daily until the patient resumes a normal diet and should be begun prior to treatment with intravenous glucose solutions. Glucose infusions may precipitate Wernicke's disease in a previously unaffected patient or cause a rapid worsening of an early form of the disease. For this reason, thiamine should be administered to all alcoholic patients requiring parenteral glucose.

CRITICAL CARE DISORDERS OF THE PERIPHERAL NERVOUS SYSTEM ASSOCIATED WITH SYSTEMIC DISEASE

Critical illness with disorders of the peripheral nervous system (PNS) arises in two contexts: (1) primary neurologic diseases that require critical care interventions such as intubation and mechanical ventilation, and (2) secondary PNS manifestations of systemic critical illness, often involvingMSOF. The former include acute polyneuropathies such as Guillain-Barre syndrome (Chap. 378), neuromuscular junction disorders including myasthenia gravis (Chap. 380) and botulism (Chap. 144), and primary muscle disorders such as polymyositis (Chap. 382). The latter result either from the systemic disease itself or as a consequence of interventions.

General principles of respiratory evaluation in patients withPNSinvolvement, regardless of cause, include assessment of pulmonary mechanics, such as maximal inspiratory force (MIF) and vital capacity (VC), and evaluation of strength of bulbar muscles. Regardless of the cause of weakness, endotracheal intubation should be considered when the MIF falls to<-25 cmH_2O or the VC is <1 L. Also, patients with severe palatal weakness may require endotracheal intubation in order to prevent acute upper airway obstruction or recurrent aspiration. Arterial blood gases and percutaneous oxygen saturation are used to follow patients with potential respiratory compromise from PNS dysfunction; however, intubation and mechanical ventilation should be undertaken long before oxygen saturation drops or CO_2retention develops from hypoventilation.**Principles of mechanical ventilation are discussed in Chap. 266.*

NEUROPATHY

While encephalopathy may be the most obvious neurologic dysfunction in critically ill patients, dysfunction of thePNS is also quite common. It is typically present in patients with prolonged critical illnesses lasting several weeks and involving sepsis; clinical suspicion is aroused when there is failure to wean from mechanical ventilation despite improvement of the underlying sepsis and critical illness. *Critical illness polyneuropathy* refers to the most common PNS complication related to critical illness; it is seen in the setting of prolonged critical illness, sepsis, andMSOF. Neurologic findings include

diffuse weakness, decreased reflexes, and distal sensory loss. Electrophysiologic studies demonstrate a diffuse, symmetric, distal axonal sensorimotor neuropathy, and pathologic studies have confirmed axonal degeneration. The precise mechanism of critical illness polyneuropathy remains unclear, but circulating factors such as cytokines, which are associated with sepsis andSIRS, are thought to play a role. It has been reported that up to 70% of patients with the sepsis syndrome have some degree of neuropathy, although far fewer have a clinical syndrome profound enough to cause severe respiratory muscle weakness requiring prolonged mechanical ventilation or resulting in failure to wean. Treatment is supportive, with specific intervention directed at treating the underlying illness. While spontaneous recovery is usually seen, the time course may extend over weeks to months and necessitate long-term ventilatory support and care even after the underlying critical illness has resolved.

DISORDERS OF NEUROMUSCULAR TRANSMISSION

A defect in neuromuscular transmission may be a source of weakness in critically ill patients. Myasthenia gravis (Chap. 380) may be a consideration; however, persistent weakness secondary to impaired neuromuscular junction transmission is almost always due to administration of drugs. A number of medications impair neuromuscular transmission; these include antibiotics, especially aminoglycosides, and beta-blocking agents. In theICU, the nondepolarizing neuromuscular blocking agents (nd-NMBAs), also known as muscle relaxants, are most commonly responsible. Included in this group of drugs are such agents as pancuronium, vecuronium, rocuronium, and atracurium. They are often used to facilitate mechanical ventilation or other critical care procedures, but with prolonged use persistent neuromuscular blockade may result in weakness even after discontinuation of these agents hours or days earlier. Risk factors for this prolonged action of neuromuscular blocking agents include female sex, metabolic acidosis, and renal failure.

Prolonged neuromuscular blockade does not appear to produce permanent damage to thePNS. Once the offending medications are discontinued, full strength is restored, although this may take days. In general, the lowest dose of neuromuscular blocking agent should be used to achieve the desired result, and, when these agents are used in theICU, a peripheral nerve stimulator should be used to monitor neuromuscular junction function.

MYOPATHY

Critically ill patients, especially those with sepsis, frequently develop muscle wasting, often in the face of seemingly adequate nutritional support. The assumption has been that this represents a catabolic myopathy brought about as a result of multiple factors, including elevated cortisol and catecholamine release and other circulating factors induced by theSIRS. In this syndrome, known as *cachectic myopathy*, serum creatine kinase levels and electromyography (EMG) are normal. Muscle biopsy shows type II fiber atrophy. Panfascicular muscle fiber necrosis may also occur in the setting of profound sepsis. This so-called *septic myopathy* is characterized clinically by weakness progressing to a profound level over just a few days. There may be associated elevations in serum creatine kinase and urine myoglobin. Both EMG and muscle biopsy may be normal initially but eventually show abnormal spontaneous activity and

panfascicular necrosis with an accompanying inflammatory reaction.

Acute quadriplegic myopathy describes a clinical syndrome of severe weakness seen in the setting of glucocorticoid andnd-NMBAuse. The most frequent scenario in which this is encountered is the asthmatic patient who requires high-dose glucocorticoids and nd-NMBA to facilitate mechanical ventilation. This muscle disorder is not due to prolonged action of nd-NMBAs at the neuromuscular junction but, rather, is an actual myopathy with muscle damage; it has occasionally been described with high-dose glucocorticoid use alone. Clinically this syndrome is most often recognized when a patient fails to wean from mechanical ventilation despite resolution of the primary pulmonary process. Pathologically, there may be vacuolar changes in both type I and type II muscle fibers with evidence of regeneration. Acute quadriplegic myopathy has a good prognosis. If patients survive their underlying critical illness, the myopathy invariably improves and patients usually return to normal. However, because this syndrome is a result of true muscle damage, not just prolonged blockade at the neuromuscular junction, this process may take weeks or months, and tracheostomy with prolonged ventilatory support may be necessary. At present, it is unclear how to prevent this myopathic complication, except by avoiding use of nd-NMBAs, a strategy not always possible. Monitoring with a peripheral nerve stimulator can help to avoid the overuse of these agents. However, this is more likely to prevent the complication of prolonged neuromuscular junction blockade than it is to prevent this myopathy.

SECTION 3 -DISORDERS OF NERVE AND MUSCLE

377. APPROACH TO THE PATIENT WITH PERIPHERAL NEUROPATHY - *Arthur K. Asbury*

Peripheral neuropathy is a general term indicating peripheral nerve disorders of any cause; the manifestations of neuropathy may be so diverse that it is difficult for the physician to know where to begin and how to proceed.

The clinical and electrodiagnostic (EDX) approach to evaluation and management of a neuropathic disorder is summarized in Fig. 377-1. The EDX approach consists of electrophysiologic examination of nerve and muscle, including nerve conduction studies and electromyography. It is part of the evaluation of any neuropathy and is considered to be an extension of the neurologic examination. Using this scheme, the examiner determines for each patient the tempo, distribution, and severity of the neuropathy and makes a judgment as to whether the problem represents a mononeuropathy, a mononeuropathy multiplex, or a polyneuropathy. Often this distinction is obvious. With the sum of clinical and EDX information in hand, the differential diagnostic possibilities and treatment options are usually narrowed to a manageable number.

MONONEUROPATHY

Mononeuropathy refers to focal involvement of a single nerve trunk and therefore implies a local cause. Direct trauma, compression, and entrapment are the usual ones. Ulnar neuropathies, due to lesions either at the ulnar groove or in the cubital tunnel, and median neuropathy due to compression in the carpal tunnel constitute the great majority of mononeuropathies encountered in clinical practice. These are described below, and other common mononeuropathies are listed inTable 377-1.EDXexamination is part of the evaluation of mononeuropathies, mainly to judge the nature of the focal lesion (demyelinating or axonal degeneration) and, in severe mononeuropathies, to determine whether any nerve fibers remain in continuity.

In the absence of a history of trauma to the nerve trunk, factors favoring conservative management of a mononeuropathy include sudden onset, no motor deficit, few or no sensory findings (even though pain and sensory symptoms may be present), and no evidence of axonal degeneration byEDXcriteria. Factors favoring active measures including surgical intervention are chronicity and worsening neurologic deficit on examination, particularly if motor and EDX evidence suggests that the lesion has produced a degree of wallerian degeneration.

Ulnar Neuropathy Complete ulnar paralysis results in a characteristic claw-hand deformity owing to wasting and weakness of many of the small hand muscles and hyperextension of the fingers at the metacarpophalangeal joints and flexion at the interphalangeal joints. The flexion deformity is most pronounced in the fourth and fifth fingers. Sensory loss occurs over the fifth finger, the ulnar aspect of the fourth finger, and the ulnar border of the palm. The superficial location of the nerve at the elbow makes it a common site of pressure palsy. The ulnar nerve may also become entrapped just distal to the elbow in the cubital tunnel formed by the aponeurotic arch linking the two heads of the flexor carpi ulnaris. Also, prolonged pressure on the base of the palm,

as occurs with use of hand tools or bicycle riding, may result in damage to the deep palmar branch of the ulnar nerve, causing weakness of the small hand muscles but no sensory loss (Table 377-1).

Carpal Tunnel Syndrome The median nerve in the carpal tunnel lies in close quarters with nine tendons. Entrapment of the nerve at the wrist (*carpal tunnel syndrome*) may be secondary to excessive use of the wrist, tenosynovitis with arthritis, or local infiltration, e.g., by a thickening of connective tissue as in acromegaly or by deposit of amyloid or by one of the mucopolysaccharidoses. Other systemic diseases associated with an increased incidence of carpal tunnel syndrome are hypothyroidism, rheumatoid arthritis, and diabetes mellitus, but underlying diseases account for only a small fraction of all cases. The main symptoms of carpal tunnel syndrome are nocturnal paresthesias of thumb, index, and middle fingers. With worsening, numbness occurs in that distribution, and is demonstrable by pin examination. Eventually weakness and atrophy of the abductor pollicis brevis (thenar eminence) becomes evident. The principal treatment of carpal tunnel syndrome is surgical section of the carpal ligament to relieve entrapment. Incomplete lesions of the median nerve between the axilla and wrist may result in *causalgia* (a particularly severe type of burning pain;Chap. 12;Table 377-1).

Tarsal Tunnel Syndrome The distal tibial nerve, along with several tendons and the posterior tibial artery, lies in the tarsal tunnel just posterior to the medial malleolus. Because of its superficial site, the distal tibial nerve is subject to compression or to direct trauma. Causes include sprain or fracture of the ankle, ill-fitting footwear, posttraumatic fibrosis, cysts, or ganglia adjacent to the nerve, arthritis, and tenosynovitis. Characteristic symptoms are pain in the ankle and the sole of the foot with paresthesias, particularly upon walking. On examination, the tibial nerve trunk in the tarsal tunnel is usually tender to palpation, sensory deficit should be demonstrable on the sole of the foot, and weakness of the toe plantar-flexor muscles may be noted.EDXexamination and also nerve block using local anesthetic are useful in establishing the diagnosis. Definitive treatment is extensive surgical decompression of the tibial nerve in the tarsal tunnel. Tarsal tunnel syndrome, in terms of its pathophysiology and management, is similar to carpal tunnel syndrome but is much less common (Table 377-1).

POLYNEUROPATHY

The prototypical picture of polyneuropathy occurs with acquired toxic or metabolic neuropathic states. The first symptoms tend to be sensory and consist of tingling, prickling, burning, or bandlike dysesthesias in the balls of the feet or tips of the toes, or in a general distribution over the soles (Chap. 23). Symptoms and findings are usually symmetric and graded distally. If the polyneuropathy remains mild, objective motor or sensory signs may not be detectable.

With progression, dysesthesias spread up the lower legs. Pansensory loss is usually found over both feet, ankle jerks are lost, and weakness of dorsiflexion of the toes, best demonstrated in the great toe, is present. In some instances, the process begins with weakness in the feet, without preceding sensory symptoms. As worsening occurs, sensory loss moves centripetally in a graded "stocking" fashion, and the patient may complain that the feet have a numb or "wooden" feeling or may say "I feel as though I'm

walking on stumps." Patients have difficulty walking on their heels during examination, and their feet may slap while walking. Later, the knee jerk reflex disappears and foot drop becomes more apparent. By the time sensory disturbance has reached the upper shin, dysesthesias are usually noticed in the tips of the fingers. The degree of spontaneous pain varies but is often considerable. Light stimuli to hypesthetic areas, once perceived, may be experienced as extremely uncomfortable (*hyperpathia*). Unsteadiness of gait may be out of proportion to muscle weakness because of proprioceptive loss.

Worsening is more severe in the legs than in the arms and proceeds in a centripetal, symmetrically graded manner with pansensory loss, areflexia, and muscle atrophy; motor weakness is usually greater in the extensor muscles than in corresponding flexor groups. When the sensory disturbance reaches the elbows and mid-thighs, a tent-shaped area of hypesthesia may often be demonstrated on the lower abdomen. This area will grow broader, and its apex will extend rostrally toward the sternum as the neuropathy worsens. By this time, patients generally cannot stand or walk or hold objects in their hands.

Overall, nerve fibers are affected according to axon length, without regard to root or nerve trunk distribution -- hence the aptness of the term *stocking-glove* to describe the pattern of sensory deficit. In general, the motor deficit is also graded, distal, and symmetric.

Although *polyneuropathy* connotes a widespread symmetric process, usually distal and graded, polyneuropathies are quite diverse because of the variability of tempo, severity, mix of sensory and motor features, and presence or absence of positive symptoms. For instance, a patient with a subacute, severely dysesthetic sensory polyneuropathy and alopecia who is in the early phases of thallium intoxication bears little similarity to the patient with a 40-year history of insidiously progressive clumsiness of gait whose findings are foot drop, lower leg atrophy, pes cavus, and minimal asymptomatic distal sensory deficit due to a hereditary polyneuropathy (Chap. 379). These two patients fall at opposite ends of the spectrum of polyneuropathy.

The classification of peripheral neuropathies has become increasingly complex as the capacity to discriminate new subgroups and identify new associations with toxins and systemic disorders improves. Further, our grasp of the pathophysiologic basis of the clinical phenomena observed in neuropathy has increased rapidly. But these advances are primarily descriptive; little progress has been made in understanding the fundamental pathogenic events in nervous tissue that eventuate in any of the polyneuropathies.

The important features of each major grouping of polyneuropathies are summarized inTable 377-2, and key aspects of specific polyneuropathies are given in 377-3, 377-4, 377-5, and 377-6.

MONONEUROPATHY MULTIPLEX (MULTIFOCAL NEUROPATHY)

Mononeuropathy multiplex refers to simultaneous or sequential involvement of individual noncontiguous nerve trunks, either partially or completely, evolving over days to years.

Since the disease process underlying mononeuropathy multiplex involves peripheral nerves in a multifocal and random fashion, progression of the disease involves a tendency for the neurologic deficit to become less patchy and multifocal and more confluent and symmetric. As a result, some patients present with a distal symmetric neuropathy. Attention to the pattern of early symptoms is therefore important in making the judgment that a particular neuropathy is indeed a mononeuropathy multiplex.

ASSESSMENT AND DIAGNOSIS OF POLYNEUROPATHY AND MONONEUROPATHY MULTIPLEX

Clues to the diagnosis of these neuropathies often lie in unnoticed or forgotten events occurring weeks or months prior to the onset of symptoms. Inquiry should be made about recent viral illnesses; other systemic symptoms; institution of new medications; exposures to solvents, pesticides, or heavy metals; the occurrence of similar symptoms in family members or coworkers; habits concerning alcohol; and the presence of preexisting medical disorders. Patients should be asked if they would feel well if free of their neuropathic symptoms; answers will suggest the presence or absence of an underlying systemic illness.

How did symptoms first appear? Even with distal polyneuropathies, symptoms may appear in the sole of one foot a few days or a week before the other, but usually the patient will describe a distal graded disturbance that moves evenly and symmetrically in centripetal fashion. Symptoms that first appear in the distribution of individual digital nerves, involving only half of a digit at a time, and then gradually spread and coalesce suggest a multifocal process (mononeuropathy multiplex), as might occur with a systemic vasculitis or cryoglobulinemia.

The evolution of neuropathy ranges from rapid worsening over a few days to an indolent process lasting many years. Polyneuropathies that progress slowly, over more than 5 years, are most likely to be genetically determined, particularly if the major manifestations are distal atrophy and weakness with few or no positive sensory symptoms. Diabetic polyneuropathy and paraproteinemic neuropathies also progress insidiously over 5 to 10 years. Axonal degenerations of toxic or metabolic origin tend to evolve over several weeks to a year or more, and the rate of progression of demyelinating neuropathies is highly variable, ranging from a few days in Guillain-Barre syndrome (GBS;Chap. 378) to many years in others.

Major fluctuations in the course of neuropathy raise two possibilities: (1) relapsing forms of neuropathy and (2) repeated toxic exposures. Slow fluctuation in symptoms taking place over weeks or months (reflecting changes in the activity of neuropathy) should not be confused with day-to-day variation or diurnal undulation of symptoms. The latter are common to all neuropathic disorders. An example is carpal tunnel syndrome, in which dysesthesias may be prominent at night but absent during the day.

Palpation of the nerve trunk to detect enlargement is a frequently forgotten part of the neurologic examination. In mononeuropathy or mononeuropathy multiplex, the entire course of the nerve trunk in question should be explored manually for focal thickening, for the presence of neurofibroma, point tenderness, or Tinel's phenomenon (generation of a tingling sensation in the sensory territory of the nerve by tapping along the course

of the nerve trunk); and for pain elicited by stretching of the nerve trunk. In leprous neuritis, fusiform thickening of nerve trunks is frequent, and beading of nerve trunks may be encountered in amyloid polyneuropathy. In genetically determined hypertrophic neuropathies, uniform thickening of all nerve trunks may occur, often to the caliber of a clothesline or larger.

Most neuropathies involve nerve fibers of all sizes, but damage is sometimes restricted to either large or small fibers. In a polyneuropathy affecting mainly small fibers, diminished pinprick and temperature sensation, often with painful, burning dysesthesias, will predominate, along with autonomic dysfunction but with relative sparing of motor power, balance, and tendon jerks. Some cases of amyloid and distal diabetic polyneuropathies fall into this category. In contrast, large-fiber polyneuropathy is characterized by areflexia, sensory ataxia, relatively minor cutaneous sensory deficit, and variable degrees of motor dysfunction, sometimes severe.

For patients with polyneuropathy or mononeuropathy multiplex, standard tests should include a complete blood count and measurement of erythrocyte sedimentation rate, urinalysis, chest x-ray, postprandial blood glucose determination, and serum protein electrophoresis. Further tests are dictated by the combined results of the history and the physical andEDXexamination (Fig. 377-1).

ElectrodiagnosisEDXexamination is a key procedure in all patients with suspected neuropathy. It is generally not possible to make the distinction between axonal and demyelinating disorders by clinical examination alone; here EDX analysis is particularly useful. EDX features of demyelination are slowing of nerve conduction velocity (NCV), dispersion of evoked compound action potentials, conduction block (major decrease in amplitude of muscle compound action potentials on proximal stimulation of the nerve, as compared to distal stimulation), and marked prolongation of distal latencies (Chap. 357). In contrast, axonal neuropathies are characterized by a reduction in amplitude of evoked compound action potentials with relative preservation of NCV. The distinction between a primarily demyelinating neuropathy and an axonal neuropathy is crucial because of the differing approaches to diagnosis and management.

EDXstudies also help to determine the presence or absence of a sensory involvement when that is not clear by clinical examination alone. It provides information about the distribution of subclinical findings, thus sharpening the diagnostic focus. Other issues that may be clarified by the electrodiagnostician include:

1. The distinction between disorders primary to nerve and to muscle (neuropathy versus myopathy)

2. The distinction between root or plexus involvement and more distal nerve trunk involvement

3. The distinction between generalized polyneuropathic processes and widespread multifocal nerve trunk involvement

4. The distinction between upper and lower motor neuron weakness

5. The distinction, in a given generalized polyneuropathic process, between primary demyelinating neuropathy and axonal degeneration

6. The assessment, in both primary axonal and demyelinating neuropathies, of features bearing on the nature, activity, and likely prognosis of the neuropathy

7. The assessment, in mononeuropathies, of the site of the lesion and its major effect on nerve fibers, especially the distinction between demyelinating conduction block and wallerian degeneration

8. The characterization of disorders of the neuromuscular junction

9. The identification, often in muscle of normal bulk and strength, of important features such as chronic partial denervation, fasciculations, and myotonia

10. The analysis of cramp, and its distinction from physiologic contracture

If in a particular instance of progressive polyneuropathy of subacute or chronic evolution theEDXfindings are those of an axonopathy, a long list of metabolic states and exogenous toxins comes under consideration (Tables 377-3 and377-4). If the course is protracted over several years, it raises the likelihood of a hereditary neuropathy (Chap. 379); family members must be examined and additional attention given to the family history. If the EDX findings indicate primary demyelination of nerve, the approach is entirely different. The possibilities then include acquired demyelinating neuropathy, thought to be immunologically mediated (Chap. 378), and genetically determined neuropathies, some of which are marked by uniform and drastic slowing of nerve conduction velocities (Chap. 379).

If the clinical features indicate mononeuropathy multiplex, theEDXquestion is whether the process is primarily axonal or demyelinating. Almost one-third of all adults with the clinical syndrome of mononeuropathy multiplex have a clear-cut picture of a demyelinating disorder, often with foci of persistent conduction block on EDX examination. Multifocal demyelinating neuropathy may represent part of the spectrum of chronic inflammatory demyelinating neuropathy (CIDP), or, if multifocal and only motor, would fit into the related category of multifocal motor neuropathy.**For further discussion of the management of multifocal motor neuropathy, see Chap. 378.*

The remaining two-thirds of patients with mononeuropathy multiplex have a picture of patchy axonal involvement byEDXexamination. Although ischemia should be suspected as the basis of neuropathy in these patients, only about one-half can be shown to have disease of the vasa nervorum, usually vasculitis. Management of those with proven vasculitis of vasa nervorum is often the same as treatment for systemic vasculitis (Chaps. 317 and378). If the cause of mononeuropathy multiplex remains undiagnosed even on follow-up, management should be conservative. In many patients the disease will stabilize or reverse, at least partially.

Mononeuropathy multiplex syndrome may also be seen as a manifestation of leprosy, sarcoidosis, certain types of amyloidosis, hypereosinophilia syndrome, cryoglobulinemia, neuroAIDs, and multifocal types of diabetic neuropathy.

Nerve Biopsy The sural nerve at the ankle is the preferred site for cutaneous nerve biopsy. There are few indications to employ this invasive technique. The main one is in asymmetric and multifocal neuropathic disorders producing a clinical picture of mononeuropathy multiplex, the basis of which is still unclear after other laboratory investigations are complete. Diagnostic considerations include vasculitis, multifocal demyelinating neuropathies, amyloidosis, leprosy, and occasionally sarcoidosis. Nerve biopsy is also helpful when one or more cutaneous nerves are palpably enlarged. Another clinical application is in establishing the diagnosis in some genetically determined childhood disorders such as metachromatic leukodystrophy, Krabbe's disease, giant axonal neuropathy, and infantile neuroaxonal dystrophy. In all of these recessively inherited diseases, both the central nervous system and the peripheral nervous system are affected.

There is a tendency to carry out sural nerve biopsy in distal symmetric polyneuropathies of subacute or chronic evolution. This practice is discouraged because its yield is low. Nerve biopsy in this situation may be useful as part of an approved research protocol when the biopsy will provide crucial information not otherwise obtainable.

SPECIAL CATEGORIES OF NEUROPATHY

Some neuropathies require individual description because of their importance or distinctiveness.

Diabetic Neuropathies The neuropathies of diabetes mellitus are classified inTable 377-5. A limitation of this classification is that most patients do not fit neatly into any single category but instead have overlapping clinical features of several. For instance, many diabetic patients with distal, primarily sensory polyneuropathy can also be shown to have autonomic dysfunction, usually in the form of vasomotor disturbance in the limbs and abnormalities of sweating. Similarly, patients who develop a proximal motor syndrome often have dysautonomic features (including sexual impotence in males) and some degree of distal sensory polyneuropathy. To compound matters, such patients appear at risk of developing a cranial mononeuropathy. Pain is a frequent feature of diabetic neuropathies (Table 377-5) but is variable in incidence and degree.

Diabetic neuropathies occur in the setting of long-standing hyperglycemia (decades), whether the diabetes is insulin-dependent or not. By far the most common neuropathies related to diabetes mellitus are the diffuse sensory and autonomic types (categories 1 and 2 under "Symmetric" in Table 377-5). Sensory and autonomic polyneuropathy, chronic and indolent in evolution, may first be noticed in the third to fifth decades in patients with juvenile-onset diabetes but tends to occur after age 50 in patients with adult-onset diabetes. Focal and multifocal types of neuropathy are less common but quite dramatic (categories 1, 2, and 3 under "Asymmetric" inTable 377-5). They rarely occur before the age of 45 and are usually subacute or acute in onset. Cranial mononeuropathies are isolated sixth or third nerve palsies. The latter spares the pupil in three-fourths of cases, and some local pain or headache occurs in one-half. Truncal (thoracoabdominal) neuropathy is painful, involves one or more intercostal or lumbar nerves unilaterally, and frequently coexists with the asymmetric proximal motor neuropathy. In asymmetric proximal motor neuropathy, the most evident features are

weakened muscles innervated by the femoral and obturator nerves (quadriceps femoris, iliopsoas, adductor magnus) and ipsilateral loss of the knee jerk reflex. Sensory deficit is minor, but pain in the hip and anterior thigh may be prominent. In all these multifocal and focal neuropathies, the pain usually subsides within weeks to a year, and function is usually partly or completely recovered. The same is true for symmetric proximal motor neuropathy (category 3 under "Symmetric" in Table 377-5).

Focal and multifocal diabetic neuropathies are considered to be ischemic in origin, and ischemia may also underlie symmetric polyneuropathies, which are also thought to involve abnormality of nerve metabolism.

Management of diabetic neuropathies is directed toward optimal glycemic control and symptomatic pain suppression. In the long-term Diabetes Control and Complications Trial, patients who controlled their diabetes meticulously showed significantly less neuropathy. The role of aldose reductase inhibitors in preventing or reversing diabetic complications, including neuropathy, remains unclear. Entrapment neuropathies are frequently amenable to surgical decompression.

Neuropathies with HIV Infection Neuropathies are common in infection with HIV, but different types of neuropathy are seen according to the stage of the disease.GBS orCIDP(Chap. 378) are the neuropathies likely to occur following conversion to seropositivity and during the asymptomatic phase of HIV infection. Treatment is the same as for HIV-negative patients. In later, symptomatic stages, mononeuritis multiplex, axonal in nature, can occur; the course is typically subacute or chronic. In some cases, vasculitis of the vasa nervorum has been demonstrated.

The most common neuropathy is a distal, symmetric, mainly sensory polyneuropathy, which evolves slowly in the late symptomatic stages of HIV infection and frequently coexists with symptomatic encephalopathy and myelopathy (Table 377-3;Chap. 309). Improvement of this polyneuropathy with zidovudine treatment has been claimed. Sensory polyneuropathy of late-stage HIV infection must be distinguished from toxic polyneuropathy that may result from the use of nucleoside analogue treatment (Table 377-4). Also in the late stages, a severe, destructive, subacute, asymmetric polyradiculopathy involving the cauda equina may be seen; it is caused by an opportunistic infection of the nerve roots with cytomegalovirus. Ganciclovir, started early, can arrest the disorder.

Neuropathies with Lyme Disease A focal or multifocal radiculoneuropathy may occur weeks, months, or even years after primary infection by the tick-borne spirochete *Borrelia burgdorferi*. Although usually sensory and either dysesthetic or painful, the neuropathy is variable in distribution, affecting cranial nerves and spinal roots or nerves in a patchy, asymmetric fashion. Neuropathy is often chronic and persistent; cerebrospinal fluid pleocytosis is the rule. In many, improvement occurs spontaneously, but the course is shortened by treatment with antibiotics, usually intravenous ceftriaxone (Chap. 176).

Herpes Zoster This is a sensory neuritis due to infection with varicella-zoster virus and is characterized by acute inflammation of one or more dorsal root ganglia. Lancinating pain and hyperalgesia over the skin surface supplied by the affected roots occur for 3 to

4 days, followed by the appearance in the same segment of a herpetic eruption characterized by painful raised blisters on reddened bases. Pain usually subsides in a few weeks. If the inflammatory process spreads to involve related motor roots, segmental motor weakness and wasting appear. Paralysis of the oculomotor nerves may occur in conjunction with involvement of the ophthalmic division of the trigeminal ganglion (ophthalmoplegic zoster). Facial paralysis may occur with involvement of the geniculate ganglion and herpetic eruption on the ipsilateral tympanic membrane or external ear canal (Ramsay Hunt syndrome).

In fewer than 5% of patients, neuropathic pain persists in the dermatomal distribution of the affected ganglia. This pain, known as *postherpetic neuralgia*, is intense, burning, hyperpathic, and unrelenting; it often dominates the lives of those affected. Advancing age is a risk factor for this outcome. In some patients, blunting of the pain to tolerable levels is achieved by use of carbamazepine or a tricyclic antidepressant such as desipramine (Chap. 12).

Leprous Neuritis This is a major worldwide cause of neuropathy. *Mycobacterium leprae* organisms readily invade Schwann cells in cutaneous nerve twigs, particularly those associated with unmyelinated nerve fibers. *M. leprae* thrives best in the coolest tissues in the body. Two major forms of leprous neuritis are recognized, tuberculoid and lepromatous, which actually represent the ends of a spectrum of disease, the middle of which is called borderline (dimorphous) leprosy (patchy and multifocal involvement of skin and nerve). The treatment of a given case depends on where it falls in this spectrum (Chap. 170). Tuberculoid (high-resistance) leprosy consists of a single patch of hypesthetic or anesthetic skin in any location. The skin patch is frequently thickened, reddened, or hypopigmented. Few or no *M. leprae* bacilli may be demonstrated. If a superficially placed nerve trunk, typically a cutaneous nerve, courses just beneath the area of affected skin, it may be engulfed in the inflammatory reaction, resulting in an associated mononeuropathy. Such a nerve may be palpably enlarged and beaded. Lepromatous (low-resistance) leprosy is marked by immunologic tolerance, numerous bacilli, and widespread skin thickening, cutaneous anesthesia, and anhidrosis, which spare only the warmest parts of the body, notably the axilla, the groin, and beneath the scalp hair. Motor signs (focal weakness and atrophy) result from damage to mixed nerves lying close to the skin, particularly the median, ulnar, peroneal, and facial nerves.

Bell's Palsy This seventh nerve palsy is due to inflammation of the facial nerve in the facial canal, the basis for which remains obscure. Edema may play a part in causing compression of nerve fibers, with resulting acute unilateral paralysis of facial muscles (Chap. 367).

Sarcoidosis This may involve single or multiple peripheral nerves, producing asymmetric mononeuritis or polyneuritis. Unilateral or bilateral facial paralysis is described in association with parotitis and uveitis (Heerfordt's syndrome).

Polyneuritis Cranialis This is a relapsing and remitting mononeuropathy multiplex restricted to cranial nerves (Chap. 367). It is usually associated with indolent tuberculous cervical adenitis (scrofula) or sarcoidosis. Treatment of the underlying condition will halt the cranial nerve palsies.

SPECIAL NEUROPATHIC PRESENTATIONS

Some disorders selectively affect the peripheral nervous system, limiting dysfunction to specific systems or sites, such as motor nerves, brachial plexus, or the autonomic nervous system.

Autonomic Neuropathy The autonomic nervous system regulates the visceral organs and vegetative functions (Chap. 366). Many pharmacologic agents modify specific autonomic functions, but autonomic neuropathy (dysautonomia) with structural changes in pre- and postganglionic neurons can also occur. Usually autonomic neuropathy is a manifestation of a more generalized polyneuropathy also affecting somatic peripheral nervous function, as in diabetic neuropathy,GBS, and alcoholic polyneuropathy, but occasionally syndromes of pure pandysautonomia are encountered. Symptoms of dysautonomia are mainly negative (i.e., loss of function) and include postural hypotension with faintness or syncope, anhidrosis, hypothermia, bladder atony, obstipation, dry mouth and dry eyes from failure of salivary and lacrimal glands to secrete, blurring of vision from lack of pupillary and ciliary regulation, and sexual impotence in males. Positive phenomena (hyperfunction) may also occur and include episodic hypertension, diarrhea, hyperhidrosis, and either tachycardia or bradycardia. Management is symptomatic and also directed at the underlying cause, if it can be identified.

Pure Motor Neuropathy Disorder affecting any level of the motor unit -- anterior horn cell, motor axon, or neuromuscular junction -- can result in a purely lower motor syndrome without sensory disturbance. Distinguishing anterior horn cell disorders (motor neuronopathies) from motor axonopathies may be difficult clinically because they share manifestations (weakness, muscle denervation atrophy, hypo- or areflexia, fasciculations).EDXexamination may also fail to localize the primary site of the lesion (neuropathic versus neuronopathic) unless the lesion is demyelinating in nature, in which case it is by definition neuropathic.

Examples of motor neuronopathies include the lower-motor form of amyotrophic lateral sclerosis, poliomyelitis, hereditary spinal muscular atrophies, and adult variant of hexosaminidase A deficiency. Motor neuropathies may be seen with lead or dapsone intoxication, occasionally with porphyria, and also with multifocal motor neuropathy. The latter is a chronic asymmetric disorder of mid-life associated with persistent conduction block onEDXexamination, and often high titers of antiganglioside antibodies (particularly anti-GM_1). Neuromuscular junction disorders (e.g., Lambert-Eaton myasthenic syndrome, tick bite paralysis, other types of toxic neuromuscular blockade) are purely motor and can be recognized and localized electrodiagnostically. Some motor-sensory polyneuropathies have predominant motor symptoms and signs, such as hereditary motor-sensory neuropathies,GBS, andCIDP, but the subclinical sensory component is readily demonstrated electrodiagnostically or by quantitative sensory testing.

Pure Sensory Neuropathy Clinical presentations involving primary sensation only (Table 377-6;Chap. 23) are not uncommon. Manifestations may (1) reflect mainly large afferent fiber involvement with deficits of vibratory and proprioceptive sense, areflexia, and sensory ataxia with or without tingling dysesthesias; (2) reflect mainly small afferent fiber involvement with numbness and cutaneous hypesthesia to pin-prick and

temperature stimuli, often with painful, burning dysesthesias; or (3) be pansensory, with both large and small fiber manifestations. The pattern of distribution, although variable, is often distal and symmetric, particularly for large-fiber neuropathies.

The most severe and widespread of these pure sensory syndromes exhibit poor or no recovery, suggesting irreversible lesions of nerve cell bodies in dorsal root and trigeminal ganglia. These are referred to as *sensory neuronopathies*. With sensory neurotoxins, moderate doses lead to potentially reversible neuropathy, but high doses appear to cause irreversible neuronopathy (Table 377-6).

Plexopathy This term refers to disorders of either the brachial or the lumbosacral plexus. Lesions of the brachial plexus are characterized by motor and sensory signs different from those expected in either mononeuropathies of the upper limb or polyneuropathies. The usual causes are direct trauma to the plexus, idiopathic brachial neuritis (also called *neuralgic amyotrophy*), cervical rib or band, infiltration by malignant tumor, or prior radiation therapy. When the upper parts of the brachial plexus, arising from cervical roots 5 through 7, are affected, weakness and atrophy of shoulder girdle and upper arm muscles occur. Injuries to the lower brachial plexus, arising from the eighth cervical and first thoracic roots, produce distal arm weakness, atrophy, and focal sensory deficit in the forearm and hand. In general, idiopathic brachial neuritis, irradiation with >60 Gy (6000 rad), and particular types of trauma (arm jerked downward) result in damage to the upper portions of the brachial plexus. In contrast, infiltration by malignant tumor, cervical rib or band, and certain other types of trauma (arm jerked upward) cause damage to the lower brachial plexus. Lumbosacral plexopathies are less common; they may be due to idiopathic lumbosacral plexitis, retroperitoneal hemorrhage, or malignant tumor infiltration or may occur in association with long-standing diabetes mellitus.

Cold Effects Cold exerts direct deleterious effects on peripheral nerve, independent of ischemia. Cold injury to nerve occurs after prolonged exposure, usually of a limb, to moderately low temperatures, as with immersion of the feet in seawater; actual freezing of tissue is not required. Axonal degeneration of myelinated fibers is the pathologic expression of cold injury. Frequently, limbs affected by cold injury to nerve show sensory deficit and dysesthesias, cutaneous vasomotor instability, pain, and marked sensitivity to minimal cold exposure, which persist for many years. The pathophysiology of these phenomena is uncertain.

Trophic Changes The array of observable changes in completely denervated muscle, bone, and skin, including hair and nails, is well known, if incompletely understood. It is unclear what portion of the changes is due purely to denervation versus that caused by disuse, immobility, lack of weight bearing, and particularly recurrent, unnoticed, painless trauma. Considerable evidence favors the view that ulceration of skin, poor healing, tissue resorption, neurogenic arthropathy, and mutilation are the result of repeated unheeded injury to insensitive parts. This sequence of events is avoidable with proper attention to and care of the insensitive parts by both patient and physician.

RECOVERY FROM NEUROPATHY

In contrast to axons in the central nervous system, peripheral nerve fibers have an

excellent ability to regenerate under proper circumstances. The process of regeneration following axonal degeneration may take from 2 months to more than a year, depending on the severity of the neuropathy and the length of regeneration required. Regeneration can take place when the cause of the neuropathy has been eliminated, such as removal from contact with a neurotoxic substance or correction of an abnormal metabolic state. A deficit secondary to demyelination may recover rapidly, since intact axons may remyelinate in just a few weeks. For example, a patient withGBS, in whom demyelination but no secondary axonal degeneration has occurred, may recover to normal strength from bedfastness and paralysis of arms and legs in as little as 3 to 4 weeks.

PERIPHERAL NERVE TUMORS

These tumors are mostly benign and can arise on any nerve trunk or twig. Although peripheral nerve tumors can occur anywhere in the body, including the spinal roots and cauda equina, many are subcutaneous in location and present as a soft swelling, sometimes with a purplish discoloration of the skin. Two major categories of peripheral nerve tumors are recognized: neurilemmoma (schwannoma) and neurofibroma. Neurilemmomas are usually solitary and grow in the nerve sheath, rendering the tumor relatively easy to dissect free. In contrast, neurofibromas tend to be multiple, grow in the endoneurial substance, which renders them difficult to dissect, may undergo malignant changes, and are the hallmark of von Recklinghausen's neurofibromatosis (NF1) (Chap. 370).

378. GUILLAIN-BARRE SYNDROME AND OTHER IMMUNE-MEDIATED NEUROPATHIES - *Arthur K. Asbury*, *Stephen L. Hauser*

GUILLAIN-BARRE SYNDROME

Guillain-Barre syndrome (GBS) is an acute, frequently severe, and fulminant polyradiculoneuropathy that is autoimmune in nature. It occurs year-round at a rate of about one case per million per month, or approximately 3500 cases per year in the United States and Canada. Males and females are equally at risk, and in western countries adults are more frequently affected than children.

CLINICAL MANIFESTATIONS

GBSmanifests as rapidly evolving areflexic motor paralysis with or without sensory disturbance. The usual pattern is an ascending paralysis that may be first noticed as rubbery legs. Weakness typically evolves over hours to a few days and is frequently accompanied by tingling dysesthesias in the extremities. The legs are usually more affected than the arms, and facial diparesis is present in 50% of affected individuals. The lower cranial nerves are also frequently involved, causing bulbar weakness and difficulty with handling secretions and maintaining an airway. Most patients require hospitalization, and almost 30% require ventilatory assistance at some time during the illness. Fever and constitutional symptoms are absent at the onset, and, if present, cast doubt on the diagnosis. Deep tendon reflexes usually disappear within the first few days of onset. Cutaneous sensory deficits, e.g., loss of pain and temperature sensation, are usually relatively mild; but functions subserved by large sensory fibers, such as deep tendon reflexes and proprioception, are more severely affected. Bladder dysfunction may occur in severe cases but is usually transient. If bladder dysfunction is a prominent feature and comes early in the course, possibilities other than GBS should be considered, particularly spinal cord disease. Once clinical worsening stops and the patient reaches a plateau, the crisis is usually past. Improvement may begin within days of the plateau.

Several subtypes ofGBS are now recognized, as determined primarily by electrodiagnostic and pathologic distinctions (Table 378-1). In severe cases of GBS requiring critical care management, autonomic involvement is common. Usual features are loss of vasomotor control with wide fluctuation in blood pressure, postural hypotension, and cardiac dysrhythmias. These features require close monitoring and management and can be fatal. Pain is another common feature of GBS; several types are encountered. Most common is deep aching pain in weakened muscles, which patients liken to having over-exercised the previous day. Other pains in GBS include back pain involving the entire spine and sometimes dysesthetic pain in the extremities as a manifestation of sensory nerve fiber involvement. These pains are self-limited and should be treated with standard analgesics.

A range of limited or regionalGBSsyndromes may be encountered, although uncommonly. These include (1) the M. Fisher syndrome (Table 378-1 and see "Immunopathogenesis," below); (2) pure sensory forms; (3) ophthalmoplegia with anti-GQ1b antibodies (see "Immunopathogenesis," below), as part of severe motor-sensory GBS; (4) GBS with severe bulbar and facial paralysis, sometimes

associated with antecedent cytomegalovirus infection and anti-GM2 antibodies; and (5) acute pandysautonomia.

ANTECEDENT EVENTS

Seventy-five percent of cases ofGBS are preceded 1 to 3 weeks by an acute infectious process, usually respiratory or gastrointestinal. Culture and seroepidemiologic techniques show that 20 to 30% of all cases occurring in North America, Europe, and Australia are preceded by infection or reinfection with *Campylobacter jejuni*. A similar proportion is preceded by a human herpes virus infection, often cytomegalovirus or Epstein-Barr virus. Other viruses and also Mycoplasma pneumoniae have been identified as agents involved in antecedent infections. Recent immunization has also been associated with GBS. The swine influenza vaccine, administered widely in the United States in 1976, is the most notable example; influenza vaccines in use from 1992 to 1994, however, resulted in only one additional case of GBS per million persons vaccinated. Older type rabies vaccine, prepared in nervous system tissue, is implicated as a trigger of GBS in developing countries where it is still used; the mechanism is presumably immunization against neural antigens. GBS also occurs more frequently than can be attributed to chance alone in patients with lymphoma, including Hodgkin's disease (Chap. 112), in HIV-seropositive individuals (Chap. 309), and in patients with systemic lupus erythematosus (Chap. 311).

IMMUNOPATHOGENESIS

Several lines of evidence support an autoimmune basis for acute inflammatory demyelinating polyneuropathy (AIDP), the most common and best studied type ofGBS; by analogy the concept extends to all of the subtypes of GBS (Table 378-1).

It is likely that both cellular and humoral immune mechanisms contribute to tissue damage inAIDP. T cell activation is suggested by the finding that elevated levels of cytokines and cytokine receptors are present in serum [interleukin (IL)2, soluble IL-2 receptor] and in cerebrospinal fluid (CSF) [IL-6, tumor necrosis factora, interferon-g]. AIDP is also closely analogous to an experimental T cell-mediated immunopathy designated experimental allergic neuritis (EAN); EAN is induced in laboratory animals by immune sensitization against protein fragments derived from peripheral nerve proteins, and in particular against the P2 protein. Based on analogy to EAN, it was initially thought that AIDP was likely to be primarily a T cell-mediated disorder, however, abundant data now suggest that autoantibodies directed against nonprotein determinants may be central to many cases.

Circumstantial evidence suggests that all GBSresults from immune responses to nonself antigens (infectious agents, vaccines) that misdirect to host nerve tissue through a resemblance-of-epitope (molecular mimicry) mechanism (Fig. 378-1) (Chap. 307). The neural targets are likely to be glycoconjugates, specifically gangliosides (Fig. 378-2). Gangliosides are complex glycosphingolipids that contain one or more sialic acid residues; various gangliosides participate in cell-cell interactions (including those between axons and glia), modulation of receptors, and regulation of growth. They are typically exposed on the plasma membrane of cells, rendering them susceptible to an antibody-mediated attack. Gangliosides and other glycoconjugates are present in large

quantity in human nervous tissues and in key sites, such as nodes of Ranvier. Antiganglioside antibodies, most frequently to GM1, are common in GBS (20 to 50% of cases), particularly in those preceded by *C. jejuni* infection. Furthermore, isolates of *C. jejuni* from stool cultures of patients with GBS have surface glycolipid structures that antigenically cross react with gangliosides, including GM1, concentrated in human nerves. Another line of evidence is derived from experience in Europe with parenteral use of purified bovine brain gangliosides for treatment of various neuropathic disorders. Five to 15 days after injection some recipients developed acute motor axonal GBS with high titers of anti-GM1 antibodies that recognized epitopes at nodes of Ranvier and motor endplates.

Particularly noteworthy is the M. Fisher syndrome (MFS), which presents as rapidly evolving ataxia and areflexia of limbs without weakness, and ophthalmoplegia often with pupillary paralysis. The MFS variant accounts for ~5% of allGBScases. Anti-GQ1b antibodies are found in >90% of patients with MFS (Table 378-1;Fig. 378-2), and titers of IgM and IgG are highest early in the course. Anti-GQ1b antibodies are not found in other forms of GBS unless there is extraocular motor nerve involvement. Of note, extraocular motor nerves are enriched in GQ1b gangliosides in comparison to limb nerves. Further, a monoclonal anti-GQ1b antibody raised against *C. jejuni* isolated from a patient with MFS blocked neuromuscular transmission experimentally.

Taken together, these observations provide strong but still inconclusive evidence that anti-ganglioside antibodies play an important pathogenic role inGBS. Definitive proof requires the passive transfer of GBS with specific antibodies; this procedure has not yet been accomplished, although a single case of apparent maternal-fetal transplacental transfer of GBS has been described.

PATHOPHYSIOLOGY

In the demyelinating forms ofGBS, the basis for flaccid paralysis and sensory disturbance is conduction block. This finding, demonstrable electrophysiologically, implies that the axonal connections remain intact. Hence, recovery can take place rapidly as remyelination occurs. In severe cases of demyelinating GBS, secondary axonal degeneration usually occurs; its extent can be estimated electrophysiologically. More secondary axonal degeneration correlates with a slower rate of recovery and a greater degree of residual disability. When a primary axonal pattern is encountered electrophysiologically, the implication is that axons have degenerated and become disconnected from their targets, specifically the neuromuscular junctions, and must therefore regenerate for recovery to take place. In motor axonal cases in which recovery is rapid, the lesion is thought to be localized to preterminal motor branches, allowing regeneration and reinnervation to take place quickly.

LABORATORY FEATURES

CSFfindings are distinctive, consisting of an elevated CSF protein level (100 to 1000 mg/dL) without accompanying pleocytosis. The CSF is often normal when symptoms have been present for £48 h; by the end of the first week the level of protein is usually elevated. An increased white cell count in the CSF (10 to 100/uL) in otherwise typical GBS raises the possibility of unrecognized HIV infection (Chap. 309). Electrodiagnostic

features are mild or absent in the early stages and lag behind the clinical evolution. In cases with demyelination (Table 378-1) prolonged distal latencies, conduction velocity slowing, evidence of conduction block, and temporal dispersion of compound action potential are the usual features. In cases with primary axonal pathology, the principal electrodiagnostic finding is reduced amplitude of compound action potentials without conduction slowing or prolongation of distal latencies.

DIAGNOSIS

GBSis a descriptive entity. The diagnosis is made by recognizing the pattern of rapidly evolving paralysis with areflexia, absence of fever or other systemic symptoms, and characteristic antecedent events (Table 378-2). In the early phases, laboratory tests are helpful only to exclude other disorders that can resemble GBS. Electrodiagnostic features may be minimal, and theCSFprotein level may not rise until the end of the first week. If the diagnosis is strongly suspected, treatment should be initiated without waiting for evolution of the characteristic electrodiagnostic and CSF findings to occur. GBS patients with risk factors for HIV or with CSF pleocytosis should have a serologic test for HIV.

TREATMENT

Treatment should be initiated as soon after diagnosis as possible. Each day counts; ~2 weeks after the first motor symptoms, immunotherapy is no longer effective. Either high-dose intravenous immune globulin (IVIg) or plasmapheresis can be initiated, as they are equally effective (Table 378-3). A combination of the two therapies is not significantly better than either alone. IVIg is usually administered as five daily infusions for a total dose of 2 g/kg body weight. A course of plasmapheresis, consisting of ~40 to 50 mL/kg plasma exchange (PE) daily for 4 to 5 days, is usually employed. In patients who are treated early in the course of GBSand improve, relapse may occur in the second or third week. Brief treatment with the original therapy is usually effective. Glucocorticoids have not been found to be effective in GBS.

In the worsening phase of GBS, most patients require monitoring in a critical care setting, with particular attention to vital capacity, cardiovascular status, and chest physiotherapy. As noted, ~30% of patients with GBS require ventilatory assistance, sometimes for prolonged periods of time (several weeks or longer). Frequent turning and assiduous skin care are important, as are daily range-of-motion exercises to avoid joint contractures.

PROGNOSIS AND RECOVERY

Approximately 85% of patients withGBSachieve a full functional recovery within several months to a year, although minor findings on examination (such as areflexia) may persist. The mortality rate is <5% in optimal settings; death usually results from secondary pulmonary complications. The outlook is worst in patients with severe proximal motor and sensory axonal damage. Such axonal damage may be either primary or secondary in nature (see "Pathophysiology," above), but in either case successful regeneration cannot occur. Other factors that worsen the outlook for recovery are advanced age, a fulminant or severe attack, and a delay in the onset of

treatment.

CHRONIC INFLAMMATORY DEMYELINATING POLYNEUROPATHY

Chronic inflammatory demyelinating polyneuropathy (CIDP) is distinguished fromGBS by its chronic course. In other respects, this neuropathy shares many features with GBS, including elevatedCSFprotein levels and the electrodiagnostic findings of acquired demyelination. Most cases occur in adults, and males are affected slightly more often than females. The incidence of CIDP is lower than that of GBS, but due to the protracted course the prevalence is greater.

CLINICAL MANIFESTATIONS

Onset is usually gradual, sometimes subacute; and, in a few, the initial attack is indistinguishable from that ofGBS. Symptoms are both motor and sensory in most cases. Weakness of the limbs is usually symmetric but can be strikingly asymmetric. There is considerable variability from case to case. Some patients have a chronic progressive course, whereas others, usually younger patients, have a relapsing and remitting course. Some have only motor findings, and a small proportion present with a relatively pure syndrome of sensory ataxia. Tremor occurs in ~10% and may become more prominent during periods of subacute worsening or improvement. A small proportion have cranial nerve findings, including external ophthalmoplegia.CIDPtends to ameliorate over time with treatment; the result is that many years after onset nearly 75% of patients have a reasonable functional recovery with only modest degrees of disability. Death from CIDP is uncommon.

DIAGNOSIS

The diagnosis rests on characteristic clinical,CSF, and electrophysiologic findings. The CSF is usually acellular with an elevated protein level, sometimes several times normal. Electrodiagnostically, variable degrees of conduction slowing, prolonged distal latencies, temporal dispersion of compound action potentials, and conduction block are the principal features. In particular, the presence of conduction block is a certain sign of an acquired demyelinating process. Evidence of axonal loss, presumably secondary to demyelination, is present in >50% of patients. In all patients withCIDP, serum protein electrophoresis with immunofixation is indicated to screen for monoclonal gammopathy and associated conditions (see "Monoclonal Gammopathy of Undetermined Significance," below).

PATHOGENESIS

Although there is evidence of immune activation inCIDP, the precise mechanisms of pathogenesis are unknown. Biopsy typically reveals little inflammation and onion-bulb thickening of nerves resulting from recurrent demyelination and remyelination. The response to therapy suggests that CIDP is immune-mediated; interestingly, CIDP responds to glucocorticoids (see below), whereasGBS does not. Approximately 25% of patients with clinical features of CIDP also have a monoclonal gammopathy of undetermined significance (MGUS). Cases associated with monoclonal IgA or IgG usually respond to treatment as favorably as cases without a monoclonal gammopathy.

Patients with IgM monoclonal gammopathy tend to have more sensory findings, a more protracted course and may have a less satisfactory response to treatment, although this is an area of controversy.

TREATMENT

Most authorities initiate treatment forCIDPwhen progression is rapid or walking is compromised. If the disorder is mild, management can be expectant, awaiting spontaneous remission. Controlled studies have shown that high dose IVIg, PE, and glucocorticoids are all more effective than placebo. Initial therapy is usually eitherIVIg orPE, which appear to be equally effective. IVIg is administered as 0.4 g/kg body weight daily for 5 days; most patients require periodic retreatment at approximately 6-week intervals. PE is initiated at 2 to 3 treatments per week for 6 weeks; periodic retreatment may also be required. Treatment with oral glucocorticoids is another option (60 to 80 mg prednisone daily for 1 to 2 months, followed by a gradual dose reduction of 10 mg per month as tolerated), but long-term adverse effects including bone demineralization, gastrointestinal bleeding, and cushingoid changes are problematic. Approximately one-half of patients with CIDP fail to adequately respond to the initial therapy chosen; a different treatment should then be tried. Patients who fail therapy with IVIg, PE, and glucocorticoids may benefit from treatment with immunosuppressive agents such as azathiaprine, methotrexate, cyclosporine, and cyclophosphamide, either alone or as adjunctive therapy. Use of these therapies requires periodic reassessment of their risks and benefits.

MULTIFOCAL MOTOR NEUROPATHY

Multifocal motor neuropathy (MMN) is a distinctive but uncommon neuropathy that presents as a slowly progressive motor weakness and atrophy evolving over years in the distribution of selected nerve trunks, associated with sites of persistent focal motor conduction block in the same nerve trunks. Sensory fibers are relatively spared. The arms are affected more frequently than the legs, and>75% of all patients are male. Some cases have been confused with lower motor neuron forms of amyotrophic lateral sclerosis (Chap. 365). Approximately 50% of patients present with high titers of polyclonal IgM antibody to the ganglioside GM1. It is uncertain how this finding relates to the discrete foci of persistent motor conduction block, but high concentrations of GM1 gangliosides are normal constituents of nodes of Ranvier in peripheral nerve fibers. Pathology reveals demyelination and mild inflammatory changes at the sites of conduction block.

Most patients withMMNrespond to high-doseIVIg(dosages as forCIDP, above) and some refractory patients have responded to cyclophosphamide. Glucocorticoids andPE are not effective.

NEUROPATHIES WITH MONOCLONAL GAMMOPATHY

MULTIPLE MYELOMA

Clinically overt polyneuropathy occurs in ~5% of patients with the commonly encountered type of multiple myeloma, which exhibits either lytic or diffuse osteoporotic

bone lesions. These neuropathies are sensorimotor, are usually mild but may be severe, and generally do not reverse with successful suppression of the myeloma. In most cases, electrodiagnostic and pathologic features are consistent with a process of axonal degeneration.

In contrast, myeloma with osteosclerotic features, although representing only 3% of all myelomas, is associated with polyneuropathy in one-half of cases. These neuropathies, which may also occur with solitary plasmacytoma, are distinct because they (1) are usually demyelinating in nature, (2) often respond to radiation therapy or removal of the primary lesion, (3) are associated with different monoclonal proteins and light chains (almost always lambda as opposed to primarily kappa in the lytic type of multiple myeloma), and (4) may occur in association with other systemic findings including thickening of the skin, hyperpigmentation, hypertrichosis, organomegaly, endocrinopathy, anasarca and clubbing of fingers. These are features of the POEMS syndrome (*p*olyneuropathy, *o*rganomegaly, *e*ndocrinopathy, M protein, and *s*kin changes). The pathogenesis of this uncommon syndrome and the explanation for its association with lambda light chains are unknown.

Neuropathies are also encountered in other systemic conditions with gammopathy including Waldenstrom's macroglobulinemia, primary systemic amyloidosis, and cryoglobulinemic states (mixed essential cryoglobulinemia, some cases of hepatitis C).

MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE

Chronic polyneuropathies occurring in association withMGUS are usually associated with the immunoglobulin isotypes IgG, IgA, and IgM. From a clinical standpoint, many of these patients are indistinguishable from patients withCIDPwithout monoclonal gammopathy (see Chronic Inflammatory Demyelinating Polyneuropathy, above), and their response to immunosuppressive agents is also similar. An exception is the syndrome of IgM kappa monoclonal gammopathy associated with an indolent, longstanding, sometimes static sensory neuropathy, frequently with tremor and sensory ataxia. Most patients are male and over age 50. In the majority, the monoclonal IgM immunoglobulin binds to a normal peripheral nerve constituent, myelin-associated glycoprotein (MAG), found in the paranodal regions of Schwann cells. Binding appears to be specific for a polysaccharide epitope that is also found in other normal peripheral nerve myelin glycoproteins, P0 and PMP22, and also in other normal nerve-related glycosphingolipids (Fig. 378-1). In the MAG-positive cases, IgM paraprotein is incorporated into the myelin sheaths of affected patients and widens the spacing of the myelin lamellae, thus producing a distinctive ultrastructural pattern. Demyelination and remyelination are the hallmarks of the lesions. The chronic demyelinating neuropathy appears to result from a destabilization of myelin metabolism rather than activation of an immune response. Therapy with chlorambucil or cyclophosphamide often results in improvement of the neuropathy associated with a prolonged reduction in the levels in the circulating paraprotein; chronic use of these alkylating agents is associated with significant risks (Chap. 84). In a small proportion of patients, MGUS will in time evolve into frankly malignant conditions, such as multiple myeloma (Chap. 113) or lymphoma (Chap. 112).

VASCULITIC NEUROPATHY

Peripheral nerve involvement is common in polyarteritis nodosa (PAN), appearing in half of all cases clinically and in 100% of cases at postmortem studies (Chap. 317). The most common pattern is multifocal (asymmetric) motor-sensory neuropathy (mononeuropathy multiplex) due to ischemic lesions of nerve trunks and roots; however, some cases of vasculitic neuropathy present as a distal, symmetric motor-sensory neuropathy. Symptoms of neuropathy are a common presenting complaint in patients with PAN. The electrodiagnostic findings are those of an axonal process. Small- to medium-sized arteries of the vasa nervorum, particularly the epineural vessels, are affected in PAN, resulting in a widespread ischemic neuropathy. A high frequency of neuropathy is also present in allergic angiitis and granulomatosis (Churg-Strauss syndrome).

Systemic vasculitis should always be considered when a subacute or chronically evolving mononeuropathy multiplex occurs in conjunction with constitutional symptoms (fever, anorexia, weight loss, loss of energy, malaise and nonspecific pains). Diagnosis of suspected vasculitic neuropathy is made by a combined nerve and muscle biopsy, with serial section or skip-serial techniques (Chap. 377).

Approximately one-third of biopsy-proven cases of vasculitic neuropathy are "nonsystemic" in that the vasculitis appears to affect only peripheral nerve. Constitutional symptoms are absent, and the course is more indolent than that ofPAN. The erythrocyte sedimentation rate may be elevated, but other tests for systemic disease are negative. Nevertheless, clinically silent involvement of other organs is likely, and vasculitis is frequently found in muscle biopsied at the same time as nerve.

Vasculitic neuropathy may also be seen as part of the vasculitis syndrome occurring in the course of other connective tissue disorders. The most frequent is rheumatoid arthritis, but ischemic neuropathy due to involvement of vasa nervorum may also occur in mixed cryoglobulinemia, Sjogren's syndrome, Wegener's granulomatosis, hypersensitivity angiitis (Chap. 317), and progressive systemic sclerosis (Chap. 313). Management of these neuropathies including the "nonsystemic" vasculitic neuropathy consists of treatment of the underlying condition as well as the aggressive use of glucocorticoids and other immunosuppressant drugs, usually cyclophosphamide.

ANTI-HU PARANEOPLASTIC NEUROPATHY

This uncommon immune-mediated disorder manifests as a sensory neuronopathy, i.e., selective damage to dorsal root ganglia. The onset is often asymmetric with dysesthesias and sensory loss in the limbs that soon progress to affect all limbs, the torso, and face. Marked sensory ataxia, pseudoathetosis, and inability to walk, stand, or even sit unsupported are frequent features and are secondary to the extensive deafferentation. Subacute sensory neuronopathy is often idiopathic, but ~25% of cases are paraneoplastic, primarily related to lung cancer, and most of those are small cell lung cancer (SCLC) (Chap. 101). The gene *HuD*, ordinarily expressed only in neurons, is expressed in SCLC cells; the gene product functions as an RNA binding protein. Host anti-Hu antibodies to this tumor gene product cross-react with the same epitope expressed in dorsal root ganglion neurons, which results in immune-mediated neuronal destruction. An encephalomyelitis may accompany the sensory neuronopathy and

presumably has the same pathogenesis. Neurologic symptoms usually precede, by 1 year on average, the identification of SCLC. The sensory neuronopathy runs its course in a few weeks or months and stabilizes, leaving the patient disabled. Most cases are unresponsive to treatment with glucocorticoids,IVIg,PE, or immunosuppressant drugs.

379. CHARCOT-MARIE-TOOTH DISEASE AND OTHER INHERITED NEUROPATHIES - *Phillip F. Chance*, *Thomas D. Bird*

CHARCOT-MARIE-TOOTH DISEASE

GENERAL CLINICAL FEATURES

Charcot-Marie-Tooth (CMT) neuropathy comprises a heterogeneous group of inherited peripheral nerve diseases (Table 379-1). Transmission is most frequently autosomal dominant but may also be autosomal recessive or X-linked. An estimated 1 in 2500 persons has a form of CMT, making it one of the most frequently encountered inherited neurologic syndromes.

The neuropathy of CMTaffects both motor and sensory nerves. Typical features consist of distal muscle weakness and atrophy, impaired sensation, and absent or hypoactive deep tendon reflexes. Common signs and symptoms are related to muscle loss and weakness, initially involving the feet and legs and later progressing to the hands and forearms. A history of an abnormal high-stepped (steppage) gait with frequent tripping and falling is frequently elicited. Complaints related to foot deformity (pes cavus, or high-arched feet) result from loss of intrinsic muscles of the feet. Despite the involvement of sensory nerves in CMT, complaints of limb pain or sensory disturbances are unusual.

Onset is most often during the first or second decade of life, although presentation in mid-adult life is not unusual. The variation in clinical presentation is exceptionally wide, ranging from individuals whose only clinical finding is pes cavus and minimal or no distal muscle weakness to those with severe distal atrophy and marked hand and foot deformity. However, it is unusual for patients withCMT to lose ambulation. There are no therapies that can prevent the onset or delay progression of disability associated with CMT. Patients frequently benefit from physical therapy, use of ankle-foot orthroses (AFOs) to alleviate foot drop, and, in some cases, surgical procedures to the foot. Surgery should be undertaken only when pain or difficulty walking due to severe foot deformity cannot be managed by more conservative means.

CLASSIFICATION BY PHENOTYPE

A widely accepted classification system distinguishes demyelinating forms ofCMT(also designated as CMT type 1, or CMT1) from those due to axonal degeneration (CMT type 2, or CMT2). Individuals with CMT1 have electrophysiologic findings of reduced motor and sensory nerve conduction velocities (NCVs; typically<38 to 40 m/s) and pathologic findings of hypertrophic demyelinating neuropathy ("onion bulbs"). By contrast, in CMT2 there is relative preservation of the myelin sheath and these individuals have normal or near-normal NCVs. CMT3 refers to Dejerine-Sottas disease (DSD; see below), CMT4 to autosomal recessive forms of CMT, and CMTX to X-linked varieties.

An alternative classification system designates these disorders as hereditary motor and sensory neuropathies (HMSN); HMSNI refers to CMT1, HMSNII to CMT2, HMSNIII to DSD, and HMSNIV to Refsum disease (see below).

Approach to the Patient

A clinical diagnosis of an inherited peripheral neuropathy consistent with a form ofCMT(CMT1 or CMT2) should be established prior to undertaking specific genetic tests. Other causes of peripheral neuropathy (e.g., diabetes mellitus, alcoholism, heavy metal poisoning, immune neuropathies) should also be considered and, if necessary, ruled out. An environmental exposure may affect multiple family members, thereby potentially mimicking a hereditary illness. CMT is usually a chronic, slowly progressive condition. One should be suspicious of cases that seem to have a rapid course of deterioration. As noted above, the neurologic findings show great variability in patients with CMT; mild pes cavus and depressed deep tendon reflexes may be the only signs of disease.

Although symptoms related to sensory disturbances are uncommon inCMT, a careful sensory examination is nonetheless essential. In patients who have no objective signs of sensory impairment and no evidence of sensory nerve dysfunction on electrophysiologic studies, alternative diagnoses including primary motor system disorders (e.g., distal spinal muscle atrophy, juvenile amyotrophic lateral sclerosis) should be considered.

The pedigree is of paramount importance in the diagnosis of CMT. Examination of multiple family members, particularly parents, for subtle signs of neuropathy may help to establish a diagnosis. If possible, it is also important to obtainNCVs and an electromyogram (EMG) from all at-risk family members.

GENETIC CONSIDERATIONS

CMT Neuropathy Type 1A (CMT1A) The overwhelming majority of autosomal dominantCMT1 pedigrees demonstrate linkage to chromosome 17p11.2-12 (CMT1A) and are most frequently associated with a tandem 1.5-megabase (Mb) DNA duplication in this chromosomal region. The DNA duplication is usually inherited as a stable Mendelian trait; however, it may also arise as a de novo event. The de novo duplication is responsible for most sporadic cases of CMT1 and may also account for some cases of CMT1 previously thought to occur on the basis of an autosomal recessive mode of inheritance. When present as a de novo event, the duplication results more commonly from an error in spermatogenesis; however, ~10% of de novo cases have been found to result from an error in oogenesis.

The critical gene forCMT1A is peripheral myelin protein-22 (PMP22), which is expressed in Schwann cells. The *PMP22* gene encodes a 160-amino-acid protein localized to the compact portion of peripheral nerve myelin; it contains four putative transmembrane domains and is highly conserved in evolution. The level of expression of PMP22 is crucial for proper myelination of peripheral nerves. The neuropathy in patients with the 17p11.2-12 duplication results from the presence of three copies of PMP22 leading to increased expression at this locus. In rare cases, patients homozygous for the CMT1A duplication have been identified, and in some cases these individuals exhibit a more severe phenotype than their heterozygous siblings or parents. As discussed below, monosomic underexpression of PMP22 results in hereditary neuropathy with liability to pressure palsies (HNPP).

RareCMT1 pedigrees that are linked to chromosome 17p11.2-12 yet lack the DNA duplication may harbor missense mutations within the *PMP22* gene.

Approximately three-quarters of patients with a clinical diagnosis ofCMT1 carry the 17p11.2-12 duplication. DNA testing for CMT1A (including the associated chromosome 17 duplication and sequencing to detect point mutations in PMP22) has become available and is now an accepted part of the evaluation of many patients with suspected hereditary neuropathies (see below).

CMT Neuropathy Type 1B (CMT1B) CMT1B is much less common than CMT1A; it results from mutations in the human myelin protein zero gene (*MPZ*, or P_0), which maps to chromosome 1q22-q23. P_0 is the major structural protein component of peripheral nervous system myelin (quantitatively 50% by weight) and represents ~10% of total Schwann cell mRNA. P_0 is a member of the immunoglobulin gene superfamily of cell adhesive molecules and localizes to the compact portion of peripheral nerve myelin. P_0protein consists of 248 amino acids and contains an intracellular and a glycosylated extracellular domain with a single transmembrane segment. Many different point mutations in the P_0 gene have been found in patients with CMT1B, and these mutations predominately map to the extracellular domain of its gene product.

At the clinical level it is not possible to differentiate patients withCMT1A from those with CMT1B. Molecular genetic testing is available.

Dejerine-Sottas Disease DSD(also called*HMSNIII*) is a severe, infantile or childhood onset, hypertrophic demyelinating polyneuropathy.NCVs are greatly prolonged (typically <10 m/s), and elevations in the cerebrospinal fluid (CSF) protein level are typically present. The clinical features of DSD overlap those of severeCMT1, and for this reason, the continued clinical separation of CMT1 and DSD is perhaps unwarranted. Many cases of DSD appear to be sporadic, occuring in the absence of a family history of neuropathy.

Molecular genetic studies indicate that DSDmay be associated with point mutations in the P_0or the *PMP22* genes, although pedigrees have been described that lack mutations in either the P_0, *PMP22*, or *Cx32* gene (see below). All DSD mutations identified to date appear to function as dominant genetic traits. Recently, a point mutation in the P_0 gene has been proposed as a mechanism for congenital hypomyelinating neuropathy (CHN), likely an even more severe form of DSD.

Hereditary Neuropathy with Liability to Pressure Palsies HNPP(also called *tomaculous neuropathy*) is an autosomal dominant disorder that produces an episodic, recurrent demyelinating neuropathy. HNPP typically develops during adolescence and may cause attacks of numbness, muscular weakness, and atrophy. Peroneal palsies, carpal tunnel syndrome, and other entrapment neuropathies are manifestations of HNPP. Motor and sensoryNCVs are mildly reduced in affected patients as well as in asymptomatic gene carriers. Pathologic changes observed in HNPP include segmental demyelination and tomaculous, or sausage-like, formations in peripheral nerves. Because of mild overlap of clinical features withCMT1, HNPP patients may on occasion be misdiagnosed as having CMT1.

TheHNPPlocus maps to chromosome 17p11.2-12 and is associated with a 1.5-Mb deletion. The duplicatedCMT1A chromosome (described earlier) and the deleted HNPP chromosome are the reciprocal products of unequal crossing-over during meiosis. In the case of HNPP, loss of a copy of the *PMP22* gene and underexpression of this critical myelin gene lead to demyelination. Most HNPP patients have the associated chromosome 17 deletion; however, rare patients with HNPP have been found to have point mutations in the *PMP22* gene. Molecular genetic testing is clinically available.

Treatment forHNPP is largely supportive. Surgical decompression of nerves has been proposed but is controversial. There is some evidence that surgical repair of carpal tunnel syndrome in HNPP is of little benefit and that transposition of the ulnar nerve at the elbow may produce poor results because the nerves are especially sensitive to manipulation and minor trauma.

CMT Neuropathy Type 2 CMT2 is less common than CMT1, and less progress has been made towards its molecular understanding. In general, CMT2 has a later age of onset, produces less involvement of the intrinsic muscles of the hands, and lacks palpably enlarged nerves. Extensive demyelination with "onion bulb" formation is not present in CMT2. MotorNCVs are normal or only slightly reduced in affected persons. A CMT2 locus was assigned by linkage studies to the short arm of chromosome 1 (1p35-36) and designated as CMT2A. One CMT2 pedigree was found to demonstrate linkage to markers from chromosome 3q13-q22 and has been designated CMT2B. Further genetic heterogeneity within CMT2 is likely as kindreds with the features of axonal neuropathy, weakness of the diaphragm, and vocal cord paralysis have been described and are designated as having CMT2C. Another form of CMT2, designated CMT2D, has been mapped to chromosome 7p14. More recently, in a large Russian pedigree a CMT2 gene was mapped to chromosome 8p21 (designated CMT2E) and a mutation was found in the neurofilament-light gene. Additionally, certain P_0 or connexin32 (Cx32, see below) mutations have been found to be the underlying genetic defect in a subset of patients with CMT1 or CMTX who were initially thought to have CMT2 because of only mild slowing of NCVs. DNA testing is not available for CMT2.

X-linked CMT Neuropathy The clinical features of X-linkedCMTdisease (CMTX) include demyelinating neuropathy, absence of male-to-male transmission, and an earlier age of onset and faster rate of progression in males.NCVsvary widely in CMTX from nearly normal to moderately slowed. CMTX accounts for ~10% of all patients thought to have a form of demyelinating CMT (i.e., CMT1). CMTX should be suspected when the commonly associated chromosome 17 duplication is not present and there is no history of father-to-son transmission of the neuropathy.

The gene forCMTX maps to chromosome Xq13-21 and results from point mutations in the connexin32 (*Cx32*) gene. Connexin32 encodes a major component of gap junctions and is expressed in peripheral nerves. Cx32 is structurally similar to PMP22, as both of these proteins contain four putative transmembrane domains in similar orientation. Over 200 different mutations in the *Cx32* gene have been described in patients with CMTX, and the distribution pattern of these mutations suggests that all parts of the connexin32 protein are functionally important. DNA testing is clinically available for Cx32 mutations causing CMTX.

Cx32 has a pattern of expression in peripheral nerve similar to that of other myelin protein genes; however, immunohistochemical studies show a different localization. Unlike PMP22 and P_0, which are present in compact myelin, Cx32 is located at uncompacted folds of Schwann cell cytoplasm around the nodes of Ranvier and at Schmidt-Lanterman incisures. This localization suggests a role for gap junctions composed of Cx32 in providing a pathway for the transfer of ions and nutrients around and across the myelin sheath. Mutations in the Cx32 protein have been suggested to alter its cellular localization and its trafficking and interfere with cell-to-cell communication.

CMT Variants Mutations in the putative zinc finger domain of the early growth response 2 gene (*EGR2*, or *Krox-20*) have been implicated as the underlying defect in CMT1 families that were found to be negative for the CMT1A duplication, as well as for mutations in either PMP22, P_0, or Cx32. Studies have shown that EGR2 acts as a direct transactivator of myelination genes in differentiating Schwann cells. EGR2 mutations have also been reported in a family withCHN.

Rare families with autosomal recessive motor and sensory neuropathy have been reported, particularly Tunisian families with parental consanguinity. Both demyelinating and axonal types of neuropathy have been described and given the designationCMT4. One form of autosomal recessive demyelinating neuropathy has been mapped to chromosome 8q13-q21 (CMT4A). Another form of CMT, characterized by focally folded myelin sheaths (CMT4B), has been mapped to chromosome 11q23 and recently shown to be caused by mutations in MTMR2, a gene encoding myotubularin-related protein-2, which is thought to be a transcriptional regulator. An additional pedigree with phenotypic features of CMT4B did not show linkage to chromosome 11 or to any other known CMT loci, implicating further genetic heterogeneity. Currently, DNA testing is not clinically available for any form of CMT4 or for mutations in EGR2.

Genetic Evaluation of CMT and HNPP An approach for evaluating an individual patient suspected of having an inherited peripheral neuropathy is presented inFig. 379-1. If a proband has evidence for CMT1, determination ofNCVs is a useful screening tool for parents and other at-risk family members. The *CMT1* gene is penetrant in early life, and correct disease status can probably be determined with nerve conduction screening by age 5. However, if a proband's nerve conduction is normal or only mildly prolonged, the diagnosis may be CMT2. In this case the screening examination will need to focus on determination of motor unit amplitudes and other electrical signs of denervation. Rare patients have been found to have point mutations in either P_0 or Cx32 resulting in very mild demyelination and misclassification as CMT2.

The overwhelming proportion ofCMT1 and CMT2 pedigrees have autosomal dominant inheritance. In pedigrees lacking male-to-male inheritance and/or those in which males are more severely affected than females and have an earlier onset, CMTX should be suspected. Determination of autosomal dominant versus X-linked CMT is important as the genetic counseling for these two modes of inheritance is different. For any form of autosomal dominant CMT, the likelihood of an affected parent (of either sex) having an affected child is 50% for each pregnancy, regardless of the sex of the child. For CMTX, all daughters of an affected father will inherit the gene, and none of the sons will be

affected. For a woman with CMTX, there is a 50% likelihood that her children will be affected regardless of their sex.

Sporadic cases in males can be especially difficult to evaluate, as the neuropathy could be nongenetic or the pattern of inheritance could be autosomal dominant, X-linked, or even autosomal recessive. Sporadic cases may also represent de novo duplications (CMT1A) or de novo deletions (HNPP). False paternity is another explanation for apparent sporadic CMT or HNPP.

Molecular genetic testing is currently available for the DNA duplication (or deletion) associated withCMT1A orHNPP and for point mutations in the *PMP22*, P_0or *Cx32* genes associated with other forms of CMT1 and CMTX.

CHEMOTHERAPY IN PATIENTS WITH CMT

Chemotherapeutic agents known to affect peripheral nerves should be used with great caution in patients with inherited neuropathies, and in the case of vincristine, total avoidance is strongly advised. A number of reports have documented the serious consequences of vincristine treatment administered in standard oncologic dosages in patients withCMT, including well-documented CMT1A and CMT2. The complications ranged from the precipitation of severe neuropathies in clinically asymptomatic at-risk individuals, through degrees of marked clinical worsening, and even death due to respiratory collapse.

OTHER INHERITED NEUROPATHIES

HEREDITARY SENSORY NEUROPATHIES

Hereditary sensory neuropathies (HSN) are a heterogeneous group of disorders affecting sensory neurons. The most common form of HSN, HSN type I, is an autosomal degenerative disorder of sensory and motor neurons. Phenotypically, distal sensory loss, distal muscle wasting and weakness, and variable neural deafness are observed. The disease involves progressive loss of dorsal root ganglion cells and axons in peripheral nerves. Age of onset is the second decade of life or later. The HSN-I locus maps to chromosome 9q22.1-q22.3. Because of the presence of muscular weakness in some patients with HSN, this disorder may be clinically confused withCMT.

FAMILIAL AMYLOID NEUROPATHY

Familial amyloid polyneuropathy (FAP) is an autosomal dominant disorder that classically presents as progressive sensory peripheral neuropathy, with early involvement of the autonomic nervous system and an associated cardiomyopathy. Postmortem studies have shown extensive amyloid deposition in multiple organs throughout the body. Transthyretin (TTR) is the most common constituent amyloid fibril protein deposited in FAP. Several different point mutations in the TTR gene have been described in TTR-related FAP, and DNA testing for these mutations is clinically available.**Amyloidosis is discussed in Chap. 319.*

REFSUM DISEASE

This autosomal recessive disorder is characterized by a progressive sensorimotor demyelinating polyneuropathy, associated with cerebellar ataxia and retinitis pigmentosa. Neural deafness, cardiomyopathy, cataracts, and icthyosis are additional features. Onset is in late childhood or early adulthood. Patients often complain of night blindness as the earliest symptom. TheCSFprotein is typically elevated. Diagnosis is made by demonstration of elevated levels of phytanic acid (a 20-carbon branched-chain fatty acid) in the serum and urine. The disorder appears to be due to a deficiency of a peroxysomal enzyme, phytanic acid oxidase, responsible for alpha oxidation of phytanic acid. Therapy, consisting of avoidance of dietary sources of phytanic acid, and plasmapheresis in some cases, is partially effective.

380. MYASTHENIA GRAVIS AND OTHER DISEASES OF THE NEUROMUSCULAR JUNCTION - *Daniel B. Drachman*

Myasthenia gravis (MG) is a neuromuscular disorder characterized by weakness and fatigability of skeletal muscles. The underlying defect is a decrease in the number of available acetylcholine receptors (AChRs) at neuromuscular junctions due to an antibody-mediated autoimmune attack. Treatment now available forMG is highly effective, although a specific cure has remained elusive.

PATHOPHYSIOLOGY

In the neuromuscular junction (Fig. 380-1), acetylcholine (ACh) is synthesized in the motor nerve terminal and stored in vesicles (quanta). When an action potential travels down a motor nerve and reaches the nerve terminal,ACh from 150 to 200 vesicles is released and combines withAChRsthat are densely packed at the peaks of postsynaptic folds. The structure of the AChR has been fully elucidated; it consists of five subunits (2a, b,d, and g ore) arranged around a central pore. When ACh combines with the binding sites on the AChR, the channels in the AChRs open, permitting the rapid entry of cations, chiefly sodium, which produces depolarization at the end-plate region of the muscle fiber. If the depolarization is sufficiently large, it initiates an action potential that is propagated along the muscle fiber, triggering muscle contraction. This process is rapidly terminated by hydrolysis of ACh by acetylcholinesterase (AChE) and by diffusion of ACh away from the receptor.

InMG, the fundamental defect is a decrease in the number of availableAChRs at the postsynaptic muscle membrane. In addition, the postsynaptic folds are flattened, or "simplified." These changes result in decreased efficiency of neuromuscular transmission. Therefore, althoughACh is released normally, it produces small end-plate potentials that may fail to trigger muscle action potentials. Failure of transmission at many neuromuscular junctions results in weakness of muscle contraction.

The amount ofAChreleased per impulse *normally* declines on repeated activity (termed *presynaptic rundown*). In the myasthenic patient, the decreased efficiency of neuromuscular transmission combined with the normal rundown results in the activation of fewer and fewer muscle fibers by successive nerve impulses and hence increasing weakness, or *myasthenic fatigue*. This mechanism also accounts for the decremental response to repetitive nerve stimulation seen on electrodiagnostic testing.

The neuromuscular abnormalities inMG are brought about by an autoimmune response mediated by specific anti-AChRantibodies. The anti-AChR antibodies reduce the number of available AChRs at neuromuscular junctions by three distinct mechanisms: (1) accelerated turnover of AChRs by a mechanism involving cross-linking and rapid endocytosis of the receptors; (2) blockade of the active site of the AChR, i.e., the site that normally bindsACh; and (3) damage to the postsynaptic muscle membrane by the antibody in collaboration with complement. The pathogenic antibodies are IgG and are T cell dependent. Thus, immunotherapeutic strategies directed against T cells are effective in this antibody-mediated disease.

How the autoimmune response is initiated and maintained inMG is not completely

understood. However, the thymus appears to play a role in this process. The thymus is abnormal in ~75% of patients with MG; in about 65% the thymus is "hyperplastic," with the presence of active germinal centers, while 10% of patients have thymic tumors (thymomas). Muscle-like cells within the thymus (myoid cells), which bearAChRs on their surface, may serve as a source of autoantigen and trigger the autoimmune reaction within the thymus gland.

CLINICAL FEATURES

MGis not rare, having a prevalence of at least 1 in 7500. It affects individuals in all age groups, but peaks of incidence occur in women in their twenties and thirties and in men in their fifties and sixties. Overall, women are affected more frequently than men, in a ratio of approximately 3:2. The cardinal features are *weakness* and *fatigability* of muscles. The weakness increases during repeated use (fatigue) and may improve following rest or sleep. The course of MG is often variable. Exacerbations and remissions may occur, particularly during the first few years after the onset of the disease. Remissions are rarely complete or permanent. Unrelated infections or systemic disorders often lead to increased myasthenic weakness and may precipitate "crisis" (see below).

The distribution of muscle weakness has a characteristic pattern. The cranial muscles, particularly the lids and extraocular muscles, are often involved early, and diplopia and ptosis are common initial complaints. Facial weakness produces a "snarling" expression when the patient attempts to smile. Weakness in chewing is most noticeable after prolonged effort, as in chewing meat. Speech may have a nasal timbre caused by weakness of the palate or a dysarthric "mushy" quality due to tongue weakness. Difficulty in swallowing may occur as a result of weakness of the palate, tongue, or pharynx, giving rise to nasal regurgitation or aspiration of liquids or food. In approximately 85% of patients, the weakness becomes generalized, affecting the limb muscles as well. The limb weakness inMG is often proximal and may be asymmetric. Despite the muscle weakness, deep tendon reflexes are preserved. If weakness of respiration becomes so severe as to require respiratory assistance, the patient is said to be in *crisis*.

DIAGNOSIS AND EVALUATION (Table 380-1)

The diagnosis is suspected on the basis of weakness and fatigability in the typical distribution described above, without loss of reflexes or impairment of sensation or other neurologic function. The suspected diagnosis should always be confirmed definitively before treatment is undertaken; this is essential because (1) other treatable conditions may closely resembleMG, and (2) the treatment of MG may involve surgery and the prolonged use of drugs with adverse side effects.

Anticholinesterase Test Drugs that inhibit the enzymeAChEallowACh to interact repeatedly with the limited number ofAChRs, producing improvement in the strength of myasthenic muscles. Edrophonium is used most commonly, because of the rapid onset (30 s) and short duration (about 5 min) of its effect. An objective end-point must be selected to evaluate the effect of edrophonium. The examiner should focus on one or more unequivocally weak muscle groups and evaluate their strength objectively. For

example, weakness of extraocular muscles, impairment of speech, or the length of time that the patient can maintain the arms in forward abduction may be useful measures. An initial dose of 2 mg of edrophonium is given intravenously. If definite improvement occurs, the test is considered positive and is terminated. If there is no change, the patient is given an additional 8 mg intravenously. The dose is administered in two parts because some patients react to edrophonium with unpleasant side effects such as nausea, diarrhea, salivation, fasciculations, and rarely syncope or bradycardia. Atropine (0.6 mg) should be drawn up in a syringe, ready for intravenous administration if these symptoms become troublesome.

False-positive tests occur in occasional patients with other neurologic disorders, such as amyotrophic lateral sclerosis, and in placebo-reactors. False-negative or equivocal tests also may occur. In some cases it is helpful to use a longer-acting drug such as neostigmine (15 mg given orally), since this permits more time for detailed evaluation of strength. In virtually all instances, it is desirable to carry out further testing to establish the diagnosis ofMGdefinitively.

Electrodiagnostic Testing *Repetitive nerve stimulation* often provides helpful diagnostic evidence of MG.Anti-AChEmedication is stopped 6 to 24 h before testing. It is best to test weak muscles or proximal muscle groups. Electric shocks are delivered at a rate of two or three per second to the appropriate nerves, and action potentials are recorded from the muscles. In normal individuals, the amplitude of the evoked muscle action potentials does not change at these rates of stimulation. However, in myasthenic patients there is a rapid reduction in the amplitude of the evoked responses of more than 10 to 15%. As a further test, a single dose of edrophonium may be given to prevent or diminish this decremental reaction.

Antiacetylcholine Receptor Antibody As noted above, anti-AChRantibodies are detectable in the serum of approximately 80% of all myasthenic patients, but in only about 50% of patients with weakness confined to the ocular muscles. The presence of anti-AChR antibodies is virtually diagnostic ofMG, but a negative test does not exclude the disease. The measured level of anti-AChR antibody does not correspond well with the severity of MG in different patients. However, in an individual patient, a treatment-induced fall in the antibody level often correlates with clinical improvement.

Inherited Myasthenic Syndromes The *congenital myasthenic syndromes* (CMS) comprise a heterogeneous group of disorders of the neuromuscular junction that are not autoimmune, but rather are due to genetic mutations in which virtually any component of the neuromuscular junction may be affected. Alterations in function of the presynaptic nerve terminal, the various subunits of theAChR orAChEhave been identified in the various forms of CMS. These disorders share many of the clinical features of autoimmuneMG, including weakness and fatigability of skeletal muscles, in some cases involving extraocular muscles (EOMs), lids, and proximal muscles, similar to the distribution in autoimmune MG. CMS should be suspected when symptoms of myasthenia have begun in infancy or childhood, and AChR antibody tests are consistently negative. Features of four of the most common forms of CMS are summarized in Table 380-2. Although clinical electrodiagnostic and pharmacologic tests may suggest the correct diagnosis, sophisticated electrophysiologic and molecular analysis are required for precise elucidation of the defect; this may lead to helpful

treatment as well as genetic counseling. In the forms that involve the AChR, a wide variety of mutations have been identified in each of the subunits, but the e subunit is affected in about 75% of these cases. In most of the recessively inherited forms of CMS, the mutations are heteroallelic; that is, *different* mutations affecting each of the two alleles are present.

Differential Diagnosis Other conditions that cause weakness of the cranial and/or somatic musculature include the nonautoimmuneCMSdiscussed above, drug-induced myasthenia, Lambert-Eaton myasthenic syndrome (LEMS), neurasthenia, hyperthyroidism, botulism, intracranial mass lesions, and progressive external ophthalmoplegia. Treatment with *penicillamine* (used for scleroderma or rheumatoid arthritis) may result in trueMG, but the weakness is usually mild, and recovery occurs within weeks or months after discontinuing its use. *Aminoglycoside antibiotics* in very large doses and *procainamide* can cause neuromuscular weakness in normal individuals or exacerbation of weakness in myasthenic patients.

LEMSis a presynaptic disorder of the neuromuscular junction that can cause weakness similar to that ofMG. The proximal muscles of the lower limbs are most commonly affected, but other muscles may be involved as well. Cranial nerve findings, including ptosis of the eyelids and diplopia, occur in up to 70% of patients and resemble features of MG. However, the two conditions are readily distinguished, since patients with LEMS have depressed or absent reflexes, show autonomic changes such as dry mouth and impotence, and show incremental responses on repetitive nerve stimulation. It is now known that LEMS is caused by autoantibodies directed against P/Q type calcium channels at the motor nerve terminals, which can be detected in approximately 85%of LEMS patients. These autoantibodies result in impaired release ofACh from nerve terminals. A majority of patients with this syndrome have an associated malignancy, most commonly small cell carcinoma of the lung, which is thought to trigger the autoimmune response. The diagnosis of LEMS may signal the presence of the tumor long before it would otherwise be detected, permitting early removal. Treatment of the neuromuscular disorder involves plasmapheresis and immunosuppression, as for MG.

Neurasthenia may present with weakness and fatigue, but muscle testing usually reveals the "jerky release" or "give-away weakness" characteristic of nonorganic disorders, and the complaint of fatigue in these patients means tiredness or apathy rather than decreasing muscle power on repeated effort. *Hyperthyroidism* is readily diagnosed or excluded by tests of thyroid function, which should be carried out routinely in patients with suspectedMG. Abnormalities of thyroid function (hyper- or hypothyroidism) may increase myasthenic weakness. *Botulism* can cause myasthenic-like weakness, but the pupils are often dilated, and repetitive nerve stimulation gives an *incremental* rather than decremental response. Diplopia that mimics the symptoms of MG may occasionally be due to an *intracranial mass lesion* that compresses nerves to theEOMs(e.g., sphenoid ridge meningioma), but magnetic resonance imaging (MRI) of the head and orbits usually reveals the lesion.

Progressive external ophthalmoplegia is a rare condition resulting in weakness of theEOMs, which may be accompanied by weakness of the proximal muscles of the limbs and other systemic features. Most patients with this condition have mitochondrial disorders that can be detected on muscle biopsy (Chaps. 67 and383).

Search for Associated Conditions (Table 380-3) Myasthenic patients have an increased incidence of several associated disorders. *Thymic abnormalities* occur in ~75% of patients, as noted above. Neoplastic change (thymoma) may produce enlargement of the thymus, which is detected by computed tomography (CT) orMRIscanning of the anterior mediastinum. A thymic shadow on CT scan may normally be present through young adulthood, but enlargement of the thymus in a patient>40 years is highly suspicious of thymoma. *Hyperthyroidism* occurs in 3 to 8% of patients and may aggravate the myasthenic weakness. Tests of thyroid function should be obtained. Because of the *association ofMGwith other autoimmune disorders*, blood tests for rheumatoid factor and antinuclear antibodies should be carried out in all patients. Chronic infection of any kind can exacerbate MG and should be sought carefully. Finally, measurements of *ventilatory function* are valuable because of the frequency and seriousness of respiratory impairment in myasthenic patients.

Because of the side effects of glucocorticoids and other immunosuppressive agents used in the treatment ofMG, a thorough medical investigation should be undertaken, searching specifically for evidence of chronic or latent infection (such as tuberculosis or hepatitis), hypertension, diabetes, renal impairment, and glaucoma.

TREATMENT

(Fig. 380-2) The prognosis has improved strikingly as a result of advances in treatment; virtually all myasthenic patients can be returned to full productive lives with proper therapy. The most useful treatments forMGinclude anticholinesterase medications, immunosuppressive agents, thymectomy, and plasmapheresis or intravenous immunoglobulin (IVIg).

Anticholinesterase Medications Anticholinesterase medication produces at least partial improvement in most myasthenic patients, although improvement is complete in only a few. There is no substantial difference in efficacy among the various anticholinesterase drugs; oral pyridostigmine is the one most widely used in the United States. As a rule, the beneficial action of oral pyridostigmine begins within 15 to 30 min and lasts for 3 to 4 h, but individual responses vary. Treatment is begun with a moderate dose, e.g., 60 mg three to five times daily. The frequency and amount of the dose should be tailored to the patient's individual requirements throughout the day. For example, patients with weakness in chewing and swallowing may benefit by taking the medication before meals so that peak strength coincides with mealtime. Long-acting pyridostigmine tablets may help to get the patient through the night but should never be used for daytime medication because of their variable absorption. The maximum useful dose of pyridostigmine rarely exceeds 120 mg every 3 h during daytime. Overdosage with anticholinesterase medication may cause increased weakness and other side effects. In some patients, muscarinic side effects of the anticholinesterase medication (diarrhea, abdominal cramps, salivation, nausea) may limit the dose tolerated. In these cases, propantheline bromide may be used to block the autonomic side effects without altering the beneficial effects on skeletal muscle. Loperamide is useful for the treatment of diarrhea.

Thymectomy Two separate issues should be distinguished: (1) surgical removal of

thymoma, and (2) thymectomy as a treatment forMG. Surgical removal of a thymoma is necessary because of the possibility of local tumor spread, although most thymomas are benign. In the absence of a tumor, the available evidence suggests that up to 85% of patients experience improvement after thymectomy; of these, ~35% achieve drug-free remission. However, the improvement is typically delayed for months to years. The advantage of thymectomy is that it offers the possibility of long-term benefit, in some cases diminishing or eliminating the need for continuing medical treatment. In view of these potential benefits and of the negligible risk in skilled hands, thymectomy has gained widespread acceptance in the treatment of MG. It is the consensus that thymectomy should be carried out in all patients with generalized MG who are between the ages of puberty and at least 55 years. Whether thymectomy should be recommended in children, in adults >55 years of age, and in patients with weakness limited to the ocular muscles is still a matter of debate. Thymectomy must be carried out in a hospital where it is performed regularly and where the staff is experienced in the pre- and postoperative management, anesthesia, and surgical techniques of total thymectomy.

Immunosuppression Immunosuppression using glucocorticoids, azathioprine, and other drugs is effective in nearly all patients withMG. The choice of drugs or other immunomodulatory treatments should be guided by the relative benefits and risks for the individual patient and the urgency of treatment. *It is helpful to develop a treatment plan based on short-term, intermediate-term, and long-term objectives. For example, if immediate improvement is essential either because of the severity of weakness or because of the patient's need to return to activity as soon as possible, plasmapheresis should be undertaken or intravenous immunoglobulin (IVIg) administered. For the intermediate term, glucocorticoids and cyclosporine generally produce clinical improvement within a period of 1 to 3 months. The beneficial effects of azathioprine and mycophenolate mofetil usually begin after many months (up to a year), but these drugs have advantages for the long-term treatment of patients with MG.* The side effects of each drug may preclude its use in some patients, as indicated below.

Assessment of Patient's Status In order to evaluate the effectiveness of treatment as well as drug-induced side effects, it is important to assess the patient's clinical status at baseline and on repeated interval examinations in a systematic manner. Because of the variability of symptoms ofMG, the interval history as well as findings on examination must be taken into account. The most useful clinical tests include forward arm abduction time (up to a full 5 min), forced vital capacity, range of eye movements, and time to development of ptosis on upward gaze. Manual muscle testing or, preferably, quantitative dynamometry of limb muscles, especially proximal muscles, is also important. An interval form can provide a succinct summary of the patient's status and a guide to treatment results; an abbreviated form is shown inFig. 380-3. A progressive reduction in the patient'sAChRantibody level also provides clinically valuable confirmation of the effectiveness of treatment; conversely, a rise in AChR antibody levels warns that tapering of immunosuppressive medication may lead to clinical exacerbation. Reliable quantitative measurement of AChR antibody levels provides important information about the results of treatment. It is best to compare antibody levels from prior frozen serum samples with current serum in simultaneously run assays.

Glucocorticoid Therapy Glucocorticoids, when used properly, produce improvement in myasthenic weakness in the great majority of patients. The initial dose of prednisone should be relatively low (15 to 25 mg/d) to avoid the early weakening that occurs in about one-third of patients treated initially with a high-dose regimen. The dose is increased stepwise, as tolerated by the patient (usually by 5 mg/d at 2- to 3-day intervals), until there is marked clinical improvement or a dose of 50 mg/d is reached. This dose is maintained for 1 to 3 months and then is gradually modified to an alternate-day regimen over the course of an additional 1 to 3 months; the goal is to reduce the dose to zero or to a minimal level on the "off day." Generally, patients begin to improve within a few weeks after reaching the maximum dose, and improvement continues to progress for months or years. The prednisone dosage may gradually be reduced, but usually months or years may be needed to determine the minimum effective dose, and close monitoring is required by patient and doctor. *Few patients are able to do without prednisone entirely*. Patients on long-term glucocorticoid therapy must be followed carefully to prevent or treat adverse side effects. The most common errors in the steroid treatment of myasthenic patients include (1) insufficient persistence -- improvement may be delayed and gradual; (2) too early, too rapid, or excessive tapering of steroid dosage; and (3) lack of attention to prevention and treatment of side effects.**The management of patients treated with glucocorticoids is discussed in Chap. 331.*

Other Immunosuppressive Drugs Azathioprine, cyclosporine, mycophenolate mofetil, or occasionally cyclophosphamide is effective in many patients, either alone or in combination with glucocorticoid therapy. Azathioprine has been the most widely used of these drugs because of its relative safety in most patients and long track record. Its therapeutic effect may add to that of glucocorticoids and/or allow the steroid dose to be reduced. However, up to 10% of patients are unable to tolerate azathioprine because of idiosyncratic reactions consisting of flulike symptoms of fever and malaise, bone marrow depression, or abnormalities of liver function. An initial dose of 50 mg/d should be used to test for adverse side effects. If this dose is tolerated, it is increased gradually until the white blood count falls to approximately 3000 to 4000/uL. In patients who are receiving glucocorticoids concurrently, leukocytosis precludes the use of this measure. A reduction of the lymphocyte count to<1000/uL and/or an increase of the mean corpuscular volume of red blood cells may be used as indications of adequacy of azathioprine dosage. The typical dosage range is 2 to 3 mg/kg total body weight (including fat in obese patients). The beneficial effect of azathioprine takes at least 3 to 6 months to begin and even longer to peak.

Cyclosporine is approximately as effective as azathioprine and is being used increasingly in the management ofMG. Its beneficial effect appears more rapidly than that of azathioprine. It may be used alone but is usually used as an adjunct to glucocorticoids to permit reduction of the steroid dose. The usual dose of cyclosporine is 4 to 5 mg/kg per day, given in two divided doses (to minimize side effects). Side effects of cyclosporine include hypertension and nephrotoxicity, which must be closely monitored. "Trough" blood levels of cyclosporine are measured 12 h after the evening dose. The therapeutic range, as measured by radioimmunoassay, is 150 to 200 ng/L.

Mycophenolate mofetil, which has been used for immunosuppression in transplant patients, is now proving useful in the treatment ofMG. A dose of 1 g bid is

recommended. Its mechanism of action involves inhibition of purine synthesis by the "de novo" pathway. Since lymphocytes lack the alternative "salvage" pathway that is present in all other cells, mycophenolate inhibits proliferation of lymphocytes but not proliferation of other cells. It does not kill or eliminate preexisting autoreactive lymphocytes, and therefore clinical improvement in autoimmune diseases such as MG may be delayed for many months to a year, until the preexisting autoreactive lymphocytes die spontaneously. The advantage of mycophenolate lies in its relative lack of adverse side effects, with only occasional production of diarrhea and rare development of leukopenia. This drug may become the choice for long-term treatment of myasthenic patients. Unfortunately, the present cost of mycophenolate may be prohibitively high.

Cyclophosphamide is reserved for occasional patients refractory to the other drugs, because of its relatively high risk of adverse side effects, including late development of malignancies.

Plasmapheresis and Intravenous Immunoglobulin Plasmapheresis has been used therapeutically inMG. Plasma, which contains the pathogenic antibodies, is mechanically separated from the blood cells, which are returned to the patient. A course of five exchanges (3 to 4 L per exchange) is generally administered over a 2-week period. Plasmapheresis produces a short-term reduction in anti-AChRantibodies, with clinical improvement in many patients. It is useful as a temporary expedient in seriously affected patients or to improve the patient's condition prior to surgery (e.g., thymectomy).

The indications for the use ofIVIg are the same as those for plasma exchange: to produce rapid improvement to help the patient through a difficult period of myasthenic weakness or prior to surgery. This treatment has the advantages of not requiring special equipment or large-bore venous access. The usual dose is 2 g/kg, which is typically administered over 5 days (400 mg/kg/per day). If tolerated, the course of IVIg can be shortened to administer the entire dose over a 3-day period. Improvement occurs in about 70% of patients, beginning during treatment, or within 4 to 5 days thereafter, and continuing for weeks to months. The mechanism of action of IVIg is not known; the treatment has no consistent effect on the measurable amount of circulating AChR antibody. Adverse reactions are uncommon, but include headache, fluid overload, and rarely renal shutdown.

The intermediate and long-term treatment of myasthenic patients requires other methods of therapy outlined earlier in this chapter.

Management of Myasthenic Crisis Myasthenic crisis is defined as an exacerbation of weakness sufficient to endanger life; it usually consists of respiratory failure caused by diaphragmatic and intercostal muscle weakness. Treatment should be carried out in an intensive care unit staffed with physicians experienced in the management of myasthenia gravis, respiratory insufficiency, infectious disease, and fluid and electrolyte therapy. The possibility that the deterioration could be due to excessive anticholinesterase medication ("cholinergic crisis") is best excluded by temporarily stopping anticholinesterase drugs. The most common cause of crisis is intercurrent infection. This should be treated *immediately*, because the mechanical and immunologic defenses of the patient can be assumed to be compromised. The myasthenic patient

with fever and early infection should be treated like other immunocompromised patients. Early and effective antibiotic therapy, respiratory assistance, and pulmonary physiotherapy are essentials of the treatment program. As discussed above, plasmapheresis orIVIg is frequently helpful in hastening recovery.

381. APPROACH TO THE PATIENT WITH MUSCLE DISEASE - *Jerry R. Mendell*

Skeletal muscle diseases, or myopathies, are defined as disorders with structural changes or functional impairment of muscle. These conditions can be differentiated from other diseases of the motor unit by characteristic clinical and laboratory findings.**Myasthenia gravis and related disorders are discussed in Chap. 380; inflammatory muscle diseases and inclusion body myositis in Chap. 382; muscular dystrophies and inherited, metabolic, and toxic myopathies in Chap. 383.*

CLINICAL FEATURES

Muscle Weakness Symptoms of muscle weakness can be either intermittent or persistent. Some patients complain of weakness that physicians more accurately classify as fatigue. Disorders causing intermittent weakness (Fig. 381-1) include myasthenia gravis, periodic paralyses (hypokalemic, hyperkalemic, and paramyotonia congenita), and metabolic energy deficiencies of glycolysis (especially myophosphorylase deficiency) and fatty acid utilization (carnitine palmitoyltransferase deficiency). The states of energy deficiency cause activity-related muscle breakdown accompanied by myoglobinuria, appearing as light-brown- to dark-brown-colored urine. Most muscle disorders cause persistent weakness (Fig. 381-2). In the majority of these, including most types of muscular dystrophy, polymyositis, and dermatomyositis, the proximal muscles are weaker than the distal, and the facial muscles are spared, a pattern referred to as *limb-girdle*. For other patterns of weakness the differential diagnosis is more restricted. Cranial innervated muscle weakness causing ptosis and extraocular muscle weakness without diplopia points to oculopharyngeal muscular dystrophy, mitochondrial myopathies, or myotubular myopathy. Facial weakness (difficulty with eye closure and impaired smile) and scapular winging (Fig. 381-3) are characteristic of facioscapulohumeral dystrophy. Facial and distal limb weakness associated with hand grip myotonia is virtually diagnostic of myotonic dystrophy. A pathognomonic pattern exclusive to inclusion body myositis includes loss of strength in both proximal and distal muscles, handgrip weakness, and wasting of quadriceps muscles. Less frequently, but important diagnostically, is the presence of a dropped head syndrome indicative of selective neck extensor muscle weakness. The most common neuromuscular diseases causing this pattern of weakness include myasthenia gravis, polymyositis, and amyotrophic lateral sclerosis. A final pattern, recognized because of preferential distal extremity weakness, is typical of a unique category of muscular dystrophy, the distal myopathies (Chap. 383).

It is important to examine functional capabilities to help disclose certain patterns of weakness (Table 381-1). The Gowers' sign (Fig. 381-4) is particularly useful. Observing the gait of an individual may disclose a lordotic posture caused by combined trunk and hip weakness, frequently exaggerated by toe walking (Fig. 381-5). A waddling gait is caused by the inability of weak hip muscles to prevent hip drop or hip dip. Hyperextension of the knee (genu recurvatum or backkneeing) is characteristic of quadriceps muscle weakness; and a steppage gait, due to footdrop, accompanies distal weakness.

Any disorder causing muscle weakness may be accompanied by fatigue, referring to an inability to maintain or sustain a force (pathologic fatigability). This condition must be

differentiated from asthenia, a type of fatigue caused by excess tiredness or lack of energy (Fig. 381-2). Associated symptoms may help differentiate asthenia and pathologic fatigability. Asthenia is often accompanied by a tendency to avoid physical activities, complaints of daytime sleepiness, necessity for frequent naps, and difficulty concentrating on activities, such as reading. There may be feelings of overwhelming stress and depression. Thus, asthenia is not a myopathy. In contrast, pathologic fatigability occurs in disorders of neuromuscular transmission and in disorders altering energy production, including defects in glycolysis, lipid metabolism, or mitochondrial energy production. Pathologic fatigability also occurs in chronic myopathies because of difficulty accomplishing a task with less muscle. Pathologic fatigability is accompanied by abnormal clinical or laboratory findings. Fatigue without those supportive features almost never indicates a primary muscle disease.

Muscle Pain, Cramps, and Stiffness Muscle pain can be associated with involuntary muscle activity producing cramps, contractures, and stiff or rigid muscles (Chap. 22). In distinction, true myalgia (muscle aching), which can be localized or generalized, has no involuntary activity but may be accompanied by weakness, tenderness to palpation, or swelling. Certain drugs cause true myalgia (Table 381-2).

There are two painful muscle conditions of particular importance, neither of which is associated with muscle weakness. Fibromyalgia is a common, yet poorly understood type of myofascial pain syndrome. Patients complain of severe muscle pain and tenderness and have specific painful trigger points, sleep disturbances, and easy fatigability (Chap. 325). Polymyalgia rheumatica occurs in patients older than 50 years and is characterized by stiffness (without involuntary activity) and pain in the shoulders, lower back, hips, and thighs (Chap. 317). The erythrocyte sedimentation rate is elevated, and temporal arteritis may be present. Polymyalgia rheumatica is important to recognize because treatment with glucocorticoids can relieve discomfort and prevent the associated ischemic arteritis, which threatens vision.

Muscle cramps are painful, involuntary, localized, muscle contractions with a visible or palpable hardening of the muscle. They are abrupt in onset and short in duration, and they may cause abnormal posturing of the joint. The electromyogram (EMG) shows firing of motor units, reflecting an origin from spontaneous neurogenic activity. Muscle cramps are not a feature of most primary muscle diseases, although they occur commonly in Duchenne and related forms of muscular dystrophy (Chap. 383). Muscle cramps more often accompany neurogenic disorders, especially motor neuron disease (Chap. 365), radiculopathies, and polyneuropathies (Chap. 377).

A muscle contracture is different from a muscle cramp. In both conditions, the muscle becomes hard, but a contracture is associated with energy failure in glycolytic disorders. The muscle is unable to relax after an active muscle contraction. TheEMGshows electrical silence. Confusion is created because contracture also refers to a muscle that cannot be passively stretched to its proper length (fixed contracture) because of fibrosis. In some muscle disorders, especially Emery-Dreifuss muscular dystrophy and Bethlem myopathy (Chap. 383), fixed contractures occur early and represent distinctive features of the disease.

Muscle stiffness can refer to different phenomena. Some patients with inflammation of

joints and periarticular surfaces feel stiff. This condition is different from the disorders of hyperexcitable motor nerves causing stiff or rigid muscles (Chap. 22). In *stiff-man syndrome* spontaneous discharges of the motor neuron of the spinal cord cause involuntary muscle contractions mainly involving the axial and proximal lower extremity muscles. Neuromyotonia (Isaac's syndrome) is another cause of motor nerve hyperexcitability.

Myotonia is a condition of prolonged muscle contraction followed by slow muscle relaxation. It always follows muscle activation, usually voluntary, but may be elicited by mechanical stimulation (percussion myotonia) of the muscle. Myotonia causes difficulty in releasing objects after a firm grasp. Usually it is worsened by cold temperatures and eases with continued activity. The sodium channelopathies (paramyotonia congenita and hyperkalaemic periodic paralysis) are accompanied by a unique phenomenon, paradoxical myotonia, in which repeated muscle contraction exacerbates the myotonia (Chap. 383). In hypokalemic periodic paralysis, myotonia of the eyelids may be present but limb muscles are usually spared.

Muscle Enlargement and Atrophy In most myopathies muscle tissue is replaced by fat and connective tissue, but the size of the muscle is usually not affected. However, in Duchenne and Becker muscular dystrophies enlarged calf muscles are typical. In the patients with these forms of dystrophy, the enlargement represents true muscle hypertrophy. The calf muscles remain very strong even late in the course of the disease. The term "pseudohypertrophy" should be avoided when referring to these patients. Muscle enlargement can also result from infiltration by sarcoid granulomas, amyloid deposits, bacterial and parasitic infections, and focal myositis. A tendon rupture, especially a biceps brachii tendon, is a common cause of focal muscle enlargement.

LABORATORY EVALUATION

A limited battery of tests can be used to evaluate a suspected myopathy. Nearly all patients require serum enzyme level measurements and electrodiagnostic studies as screening tools to differentiate muscle disorders from other motor unit diseases. The other tests described -- DNA studies, the forearm exercise test, and muscle biopsy -- are used to diagnose specific types of myopathies.

Serum Enzymes Creatine kinase (CK) is the preferred muscle enzyme to measure in the evaluation of myopathies. Damage to muscle causes the CK to leak from the muscle fiber to the serum. The MM isoenzyme predominates in skeletal muscle, while CK-MB is the marker for cardiac muscle. Serum CK can be elevated in normal individuals without provocation, presumably on a genetic basis or after strenuous activity, minor trauma (including theEMGneedle), a prolonged muscle cramp, or a generalized seizure. Aspartate aminotransferase (AST), alanine aminotransferase (ALT), and lactic dehydrogenase (LDH) are enzymes sharing an origin in both muscle and liver. Problems arise when the levels of these enzymes are found to be elevated in a routine screening battery, leading to the erroneous assumption that liver disease is present when in fact muscle could be the cause. An elevated gamma-glutamyl transferase (GGT) helps to establish a liver origin since this enzyme is not found in muscle. Aldolase is often thought to be a muscle-specific enzyme but is also present in liver.

Electrodiagnostic Studies EMG, repetitive nerve stimulation, and nerve conduction studies (Chap. 357) are essential methods for evaluation of the patient with suspected muscle disease. In combination they provide the information necessary to differentiate myopathies from neuropathies and neuromuscular junction diseases. Certain features of the EMG will point to an acquired, inflammatory muscle disorder (e.g., irritability on needle placement) versus a long-standing myopathic disorder that is more suggestive of a dystrophic process. The EMG can also be invaluable in helping to choose an appropriately affected muscle to sample for biopsy. The EMG can be used to fully characterize suspected involuntary activity seen during the examination, such as myokymia and myotonia.

DNA Analysis Advances in molecular diagnosis have evolved over the past decade and now serve as important tools for diagnosis. Certain muscle disorders can be definitively diagnosed by DNA analysis; these are fully discussed inChap. 383. Nevertheless, important limitations need to be mentioned in seeking a molecular diagnosis. For example, in some disorders, such as Duchenne and Becker dystrophies, two-thirds of patients have deletion- or duplication-mutations that are easy to detect, while the remainder have point mutations that are much more difficult to find. For patients without identifiable gene defects, the muscle biopsy remains the main diagnostic tool.

Forearm Exercise Test In myopathies with intermittent symptoms, and especially those associated with myoglobinuria, there may be a defect in glycolysis. Many variations of the forearm exercise test exist. For safety, the test should not be performed under ischemic conditions to avoid an unnecessary insult to the muscle causing rhabdomyolysis. The test is performed by placing a small indwelling catheter into an antecubital vein. A baseline blood sample is obtained for lactic acid and ammonia. The forearm muscles are exercised by asking the patient to vigorously squeeze a sphygmomanometer bulb for 1 min. Blood is then obtained at intervals of 1, 2, 4, 6, and 10 min for comparison with the baseline sample. Normal controls must be established for each laboratory. A three- to fourfold rise of lactic acid is typical. The simultaneous measurement of ammonia serves as a control, since it should also rise with exercise. In patients with myophosphorylase deficiency or other glycolytic defects (Chap. 383), the lactic acid rise will be absent or below normal, while the rise in ammonia will reach control values. If there is lack of effort, neither lactic acid nor ammonia will rise. Patients with selective failure to increase ammonia may have myoadenylate deaminase deficiency. This condition has been reported to be a cause of myoglobinuria, but deficiency of this enzyme in asymptomatic individuals makes interpretation controversial.

Muscle Biopsy Muscle biopsy analysis is an important step in establishing the final diagnosis of suspected myopathy. The microscopic evaluation uses a combination of techniques -- histochemistry, immunocytochemistry with a battery of antibodies, and electron microscopy. Not all techniques need to be used on every case. A specific diagnosis can be established in many disorders. A combination of stains to identify mononuclear cells (polymyositis), complement (dermatomyositis), and amyloid (inclusion body myositis) help to distinguish the inflammatory myopathies. Mitochondrial and metabolic (e.g., myophosphorylase and acid maltase deficiencies) myopathies demonstrate distinctive histochemical and electron microscopic profiles. A battery of

antibodies is available for the identification of missing components of the dystrophin-glycoprotein complex and related proteins to help diagnose specific types of muscular dystrophies. In addition, the congenital myopathies have distinctive histologic features essential for diagnosis.

382. POLYMYOSITIS, DERMATOMYOSITIS, AND INCLUSION BODY MYOSITIS - *Marinos C. Dalakas, Jr.*

The inflammatory myopathies represent the largest group of acquired and potentially treatable causes of skeletal weakness. On the basis of well defined clinical, demographic, histologic and immunopathological criteria, the inflammatory myopathies can be classified into three major groups: polymyositis (PM), dermatomyositis (DM), and inclusion body myositis (IBM).

GENERAL CLINICAL FEATURES

The incidence ofPM,DM, andIBM is approximately 1 in 100,000. PM is predominantly a disease of adults. DM affects both children and adults, and women more often than men. IBM is three times more frequent in men than in women, more common in Caucasians than African Americans, and is most likely to affect persons>50.

These disorders present as progressive and often symmetric muscle weakness. Patients usually report increasing difficulty with everyday tasks requiring the use of proximal muscles, such as getting up from a chair, climbing steps, stepping onto a curb, lifting objects, or combing hair. Fine-motor movements that depend on the strength of distal muscles, such as buttoning a shirt, sewing, knitting, or writing, are affected only late in the course ofPM andDM, but fairly early inIBM. Falling is common in IBM because of early involvement of the quadriceps muscle with buckling of the knees. Ocular muscles are spared, even in advanced, untreated cases; if these muscles are affected, the diagnosis of inflammatory myopathy should be in doubt. Facial muscles are unaffected in PM and DM, but mild facial muscle weakness occurs in up to 60% of patients with IBM. In all forms of inflammatory myopathy, pharyngeal and neck-flexor muscles are often involved, causing dysphagia or difficulty in holding up the head (*neck drop*). In advanced and rarely in acute cases, respiratory muscles may also be affected. Severe weakness, if untreated, is almost always associated with muscle wasting. Sensation remains normal. The tendon reflexes are preserved but may be absent in severely weakened or atrophied muscles, especially in IBM where atrophy of the quadriceps and the distal muscles is common. Myalgia and muscle tenderness may occur in a small number of patients, usually early in the diseaese and more often in DM than in PM. Weakness in PM and DM progresses subacutely over a period of weeks or months and rarely acutely; by contrast, IBM progresses very slowly, over years, and its course may simulate late-life muscular dystrophies (Chap. 383) or slowly progressive motor neuron disorders (Chap. 365).

SPECIFIC FEATURES (Table 382-1)

Polymyositis In most patients, the actual onset ofPM is not easily determined, and patients typically delay seeking medical advice for several months. This is in contrast toDM, in which the rash facilitates early recognition (see below). PM is a subacute inflammatory myopathy affecting adults, and rarely children, who *do not have* any of the following: rash, involvement of the extraocular and facial muscles, family history of a neuromuscular disease, history of exposure to myotoxic drugs or toxins, endocrinopathy, neurogenic disease, muscular dystrophy, biochemical muscle disorder (deficiency of a muscle enzyme), orIBM as excluded by muscle biopsy analysis (see

below). PM may occur either in isolation, in association with a systemic autoimmune or connective tissue disease, or with known viral or bacterial infection. D-Penicillamine and, on occasion, zidovudine (AZT) may also produce an inflammatory myopathy similar to PM.

Dermatomyositis (Figs. 382-CD1,382-CD2and382-CD3)DM is a distinctive entity identified by a characteristic rash accompanying, or more often preceding, muscle weakness. The rash may consist of a heliotrope rash (blue-purple discoloration) on the upper eyelids with edema, a flat red rash on the face and upper trunk, and erythema of the knuckles with a raised violaceous scaly eruption (*Gottron rash*) that later results in scaling of the skin (see Plates IIE-63 andIIE-65). The erythematous rash can also occur on other body surfaces, including the knees, elbows, malleoli, neck and anterior chest (often in a *V sign*), or back and shoulders (*shawl sign*), and may worsen after sun exposure. In some patients the rash is pruritic, especially on the scalp, chest, and back. Dilated capillary loops at the base of the fingernails are also characteristic. The cuticles may be irregular, thickened, and distorted, and the lateral and palmar areas of the fingers may become rough and cracked, with irregular, "dirty" horizontal lines, resembling *mechanic's hands*. The weakness can be mild, moderate, or severe enough to lead to quadraparesis. At times, the muscle strength appears normal, hence the term *dermatomyositis sine myositis*. When muscle biopsy is performed in such cases, however, significant perivascular and perimysial inflammation is seen. In children, DM resembles the adult disease, except for more frequent extramuscular manifestations, as discussed later. A common early abnormality in children is "misery," defined as an irritable child who appears uncomfortable, has a red flush on the face, is fatigued, does not wish to socialize, and has a varying degree of proximal muscle weakness. A tiptoe gait due to flexion contracture of the ankles is also common.

DMusually occurs alone but may overlap with scleroderma and mixed connective tissue disease. Fasciitis and thickening of the skin similar to that seen in chronic cases of DM have occurred in patients with the *eosinophilia-myalgia syndrome* associated with the ingestion of contaminated L-tryptophan.

Inclusion Body Myositis In patients ³50,IBM is the most common of the inflammatory myopathies. It is often misdiagnosed asPM and suspected only retrospectively when a patient with presumed PM does not respond to therapy. Weakness and atrophy of distal muscles, especially foot extensors and deep finger flexors, occur in almost all cases of IBM and may be a clue to early diagnosis. Some patients present with falls because their knees collapse due to early quadriceps weakness. Others present with weakness in the small muscles of the hands, especially finger flexors, and complain of inability to hold certain objects, such as golf clubs, or perform certain tasks, such as turning keys or tying knots. On occasion, the weakness and accompanying atrophy can be asymmetric and selectively involve the quadriceps, iliopsoas, triceps, biceps, and finger flexors, resembling a lower motor neuron disease. Dysphagia is common, occurring in up to 60% of IBM patients, and may lead to episodes of choking. Sensory examination is generally normal; some patients have mildly diminished vibratory sensation at the ankles that presumably is age-related. The distal weakness does not represent motor neuron or peripheral nerve involvement but results from the myopathic process affecting distal muscles. The diagnosis is always made by the characteristic findings on the muscle biopsy, as discussed below. Disease progression is slow but steady, and most

patients require an assistive device such as cane, walker, or wheelchair within several years of onset.

In at least 20% of cases,IBM is associated with systemic autoimmune or connective tissue diseases. Familial aggregation has also been noted in coaffected siblings with typical IBM; such cases have been designated as *familial inflammatory IBM*. This disorder is distinct from *hereditary inclusion body myopathy* (h-IBM), which describes a heterogeneous group of recessive and less frequently dominant, inherited syndromes. The h-IBMs are noninflammatory myopathies with clinical profiles distinct from sporadic IBM. A subset of h-IBM that spares the quadriceps muscle has emerged as a distinct entity. This disorder, originally described in Iranian Jews and now seen in many ethnic groups, is linked to chromosome 9p1.

ASSOCIATED CLINICAL FINDINGS

Extramuscular Manifestations In addition to the primary myopathy, a number of extramuscular manifestations may be present to a varying degree in patients withPM orDM:

1. *Systemic symptoms*, such as fever, malaise, weight loss, arthralgia, and Raynaud's phenomenon especially when inflammatory myopathy is associated with a connective tissue disorder.

2. *Joint contractures*, mostly in DM and especially in children.

3. *Dysphagia and gastrointestinal symptoms* due to involvement of the oropharyngeal striated muscles and upper esophagus. Dysphagia may be prominent in the active stages of DM and is frequent in IBM. Gastrointestinal ulcerations due to vasculitis and infection were common in children with DM before the use of immunosuppressive drugs.

4. *Cardiac disturbances*, including atrioventricular conduction defects, tachyarrythmias, dilated cardiomyopathy, and low ejection fraction. Congestive heart failure and myocarditis may also occur, either from the disease itself or from hypertension associated with long-term use of glucocorticoids.

5. *Pulmonary dysfunction*, due to primary weakness of the thoracic muscles, drug-induced pneumonitis (e.g., from methotrexate), or interstitial lung disease may cause dyspnea, nonproductive cough, and aspiration pneumonia. Interstitial lung disease may precede myopathy or occur early in the disease, and develops in up to 10% of patients with PM or DM.

6. *Subcutaneous calcifications*, sometimes extruding on the skin and causing ulcerations and infections, are seen in DM, primarily in children.

Malignancies Although all the inflammatory myopathies can have a chance association with malignant lesions, especially in older age groups, the incidence of malignant conditions appears to be specifically increased only in patients withDM but not PMor IBM. The most common tumors associated with DM are ovarian cancer, breast cancer, melanoma, and colon cancer. The extent of the search that should be conducted for an

occult malignant neoplasm in adults with DM depends on the clinical circumstances. Tumors in these patients are usually uncovered by abnormal findings in the medical history and physical examination and not through an extensive radiologic blind search. Thus the weight of evidence argues against performing expensive, invasive, and nondirected tumor searches. When a suspected malignancy is not apparent, a complete annual physical examination with pelvic, breast, and rectal examinations; urinalysis; complete blood count; blood chemistry tests; and a chest film should suffice.

Overlap The term *overlap syndrome* has been used loosely to describe the frequent association of inflammatory myopathies with connective tissue diseases. A well-characterized overlap syndrome occurs in patients withDM who also have manifestations of systemic sclerosis or mixed connective tissue disease, such as sclerotic thickening of the dermis, contractures, esophageal hypomotility, microangiopathy, and calcium deposits (Table 382-1). By contrast, signs of rheumatoid arthritis, systemic lupus erythematosus, or Sjogren's syndrome are very rare in patients with DM. Patients with the overlap syndrome of DM and systemic sclerosis may have a specific antinuclear autoantibody, the anti-PM/Scl, directed against a nucleolar-protein complex.

PATHOGENESIS

An autoimmune origin of these disorders is supported by their association with other systemic autoimmune, viral, or connective tissue diseases; the presence of various autoantibodies; their association with histocompatibility genes; the evidence of T cell-mediated myocytotoxicity or complement-mediated microangiopathy; and their response to immunotherapies. However, the specific muscle or capillary target antigens have not been identified, and the agents initiating self-sensitization are still unknown.

Autoantibodies and Immunogenetics Various autoantibodies against nuclear antigens (antinuclear antibodies) and cytoplasmic antigens are found in up to 20% of patients with inflammatory myopathies. The antibodies to cytoplasmic antigens, present in<10% of PM and DM patients, are directed against cytoplasmic ribonucleoproteins, which are involved in translation and protein synthesis. They include antibodies against various synthetases, translation factors, and proteins of the signal-recognition particles. The antibody directed against the histidyl-transfer RNA synthetase, called *anti-Jo-1*, accounts for 75% of all the anti-synthetases and is clinically useful because up to 80% of patients with anti-Jo-1 antibodies have interstitial lung disease. Some patients with the anti-Jo-1 antibody may also have Raynaud's phenomenon, nonerosive arthritis, and the HLA antigens DR3 and DRw52. In bothPM andIBM, there is an increased frequency (up to 75%) of haplotypes of DR3 (molecular designation DRB1*0301, DQB1*0201), suggesting that these alleles may be risk factors for the development of these disorders (Chap. 306).

Immunopathologic Mechanisms InDM, the endomysial infiltrates have a higher than normal percentage of B cells, a higher ratio of CD4+ cells (helper cells) to CD8+ cells (suppressor-cytotoxic T cells), proximity of CD4+ cells to B cells and macrophages, and a relative absence of lymphocytic invasion of nonnecrotic muscle fibers, all of which suggest a mechanism mediated primarily by humoral processes. The immune process is directed against microvascular antigens and is mediated by the complement C5b-9

membranolytic attack complex, resulting in necrosis of the endothelial cells, reduced numbers of endomysial capillaries, ischemia, muscle-fiber destruction often resembling microinfarcts, and inflammation. Larger intramuscular blood vessels may also be affected in the same pattern, leading to actual muscle infarction. Residual perifascicular atrophy reflects the endofascicular hypoperfusion that is prominent in the periphery of the fascicles. Complement activation is thought to trigger release of proinflammatory cytokines, induce expression of vascular cell adhesion molecule (VCAM)-1 and intracellular adhesion molecule (ICAM)-1 on endothelial cells, and facilitate migration of activated lymphoid cells to the perimysial and endomysial spaces.

InPM andIBMthere is evidence not of microangiopathy and muscle ischemia, as inDM, but of an antigen-directed cytotoxicity mediated by CD8+cytotoxic T cells. This conclusion is supported by the presence of CD8+ cells, which, along with macrophages, initially surround and eventually invade and destroy healthy, nonnecrotic muscle fibers that aberrantly express class I MHC molecules. MHC-I expression, absent from the sarcolemma of normal muscle fibers, is probably induced by cytokines secreted by activated T cells and macrophages. The cytotoxic autoinvasive CD8+ T cells contain perforin and granzyme granules directed towards the surface of the muscle fibers and capable of inducing cell death. The infiltrating endomysial T cells appear to be clonally restricted, suggesting an antigen-driven T cell response. The putative antigens are more likely to be endogenous sarcolemmal or cytoplasmic self-proteins synthesized within the muscle, rather than endogenous viral peptides, because viruses have not been identified within the muscle fibers.

T cell-derived cytokines (interleukins 2, 4, and 5 and interferong), the macrophage-derived cytokines (interleukins 1 and 6 and tumor necrosis factor a), and adhesion molecules on leukocytes (L-selectin and integrins LFA-1, VLA-4) and their respective ligands on endothelial cells (GlyCAM-1,ICAM-1,VCAM-1) in patients withPM,DM, andIBM; these may facilitate the adhesion and transmigration of activated T cells through the endothelial cell wall. T cell metalloproteinases (MMP-2 and MMP-9) are also upregulated and may facilitate adhesion of T cells to muscle, enhancing cytotoxicity.

The Role of Nonimmune Factors in IBM InIBM, the presence of vacuoles, the amyloid-positive deposits within some vacuolated muscle fibers, the abnormal muscle mitochondria with mitochondrial DNA deletions, and the relative resistance of the disease to immunosuppressive therapies suggest that, in addition to the autoimmune component, there is also a degenerative process. Similar to Alzheimer's disease, the amyloid deposits in IBM are immunoreactive against amyloid precurser protein (APP), chymotrypsin, apolipoprotein E, and phosphorylated tau, but it is unclear whether these deposits directly contribute to disease pathogenesis or are secondary phenomena. The same can be said for the mitochondrial abnormalities, which may also be secondary caused by the effects of aging and upregulated cytokines.

Association with Viral Infections and the Role of Retroviruses Several viruses, including coxsackieviruses, influenza, paramyxoviruses, mumps, cytomegalovirus, and Epstein-Barr virus have been indirectly associated with chronic and acute myositis. For the coxsackieviruses, an autoimmune myositis triggered by molecular mimicry has been proposed because of structural homology between histidyl-transfer RNA synthetase that

is the target of the Jo-1 antibody (see above) and genomic RNA of an animal picornavirus, the encephalomyocarditis virus. Very sensitive polymerase chain reaction (PCR) studies, however, have repeatedly failed to confirm the presence of such viruses in muscle biopsies from these patients.

The best evidence of a viral connection inPM andIBM is with the retroviruses. Monkeys infected with the simian immunodeficiency virus and humans infected with HIV and human T cell lymphotropic virus (HTLV) develop PM or, rarely, IBM. In humans infected with HIV or HTLV-1, an isolated inflammatory myopathy may occur as the initial manifestation of the retroviral infection or myositis may develop later in the disease course. Retroviral antigens have been detected only in occasional endomysial macrophages and not within the muscle fibers themselves, suggesting that persistent infection and viral replication within the muscle do not occur. Histologic findings in PM and IBM associated with HIV-1 and HTLV-1 infection are identical to retroviral-negative myositis, specifically CD8+ T cells and macrophages that invade or surround MHC-I antigen-expressing nonnecrotic muscle fibers. The development of PM or IBM in HIV-positive patients should be distinguished from a toxic myopathy related to long-term therapy with zidovudine, which is characterized by fatigue, myalgia, mild muscle weakness, and mild elevation of creatine kinase (CK). Zidovudine-induced myopathy, which generally improves when the drug is discontinued, is a mitochondrial disorder characterized histologically by the presence of numerous "ragged-red" fibers. Abnormal muscle mitochondria and depletion of the muscle mitochondrial DNA by zidovudine results from inhibition of g-DNA polymerase, an enzyme found solely in the mitochondrial matrix.

DIFFERENTIAL DIAGNOSIS

The clinical picture of skin rash and proximal or diffuse muscle weakness has few causes other thanDM. However, proximal muscle weakness without skin involvement can be due to many conditions other thanPM.

Subacute or Chronic Progressive Muscle Weakness This may be due to denervating conditions such as the spinal muscular atrophies or amyotrophic lateral sclerosis (Chap. 365). In addition to the muscle weakness, upper motor neuron signs in the latter aid in the diagnosis. The muscular dystrophies, such as those of Duchenne and Becker and the limb-girdle and facioscapulohumeral types, may be additional considerations (Chap. 383). However, the muscular dystrophies usually develop more slowly (over years rather than weeks or months) and rarely present after the age of 30. In rare patients it may be difficult, even with a muscle biopsy, to distinguish chronicPM from a rapidly advancing muscular dystrophy. This is particularly true of facioscapulohumeral muscular dystrophy, where interstitial inflammatory cell infiltration is commonly found early in the disease. Such doubtful cases should always be given an adequate trial of glucocorticoid therapy. Some metabolic myopathies, including glycogen storage disease due to myophosphorylase or acid maltase deficiency, lipid storage myopathies due to carnitine deficiency, and mitochondrial diseases produce muscle weakness, which is often associated with other characteristic clinical signs (Chap. 383); diagnosis rests upon histochemical and biochemical studies of the muscle biopsy. The endocrine myopathies such as those due to hypercorticosteroidism, hyper- and hypothyroidism, and hyper- and hypoparathyroidism require the appropriate laboratory investigations for diagnosis.

Muscle wasting in patients with an underlying neoplasm may be due to disuse, cachexia, or rarely to a paraneoplastic neuromyopathy (Chap. 101).

Diseases of the neuromuscular junction, including myasthenia gravis or the Lambert-Eaton myasthenic syndrome, cause fatiguing weakness that also affects the eye and cranial muscles (Chap. 380). Repetitive nerve stimulation and single-fiber electromyography (EMG) studies aid in diagnosis.

Acute Muscle Weakness This may be caused by an acute neuropathy such as Guillain-Barre syndrome (Chap. 378) or a neurotoxin. When combined with painful muscle cramps, rhabdomyolysis, and myoglobinuria, it may be due to metabolic disorders including some of the glycogen storage diseases, such as myophosphorylase deficiency (McArdle's disease), carnitine palmityltransferase deficiency, and myoadenylate deaminase deficiency (Chap. 383). Acute viral infections may cause a similar syndrome. Several animal parasites, such as protozoa (*toxoplasma*, *trypanosoma*), cestodes (cysticerci), and nematodes (trichinae), may produce a focal or diffuse inflammatory myopathy known as *parasitic polymyositis*. *Staphylococcus aureus*, *Yersinia*, *Streptococcus*, or other anaerobic bacteria may produce a suppurative myositis, known as *tropical polymyositis*, or *pyomyositis*. Pyomyositis, previously rare in the west, is now seen in occasional AIDS patients. Other bacteria, such as *Borrelia burgdorferi* (Lyme disease) and *Legionella pneumophila* (Legionnaire's disease) may infrequently cause myositis.

Chronic alcoholics may develop a painful myopathy with myoglobinuria after a bout of heavy drinking; present with a painless acute hypokalemic myopathy, which is completely reversible; or show an asymptomatic elevation of serumCK and myoglobin. Acute muscle weakness with myoglobinuria may occur with prolonged severe hypokalemia or with hypophosphatemia and hypomagnesemia, often seen in chronic alcoholics and in patients on nasogastric suction receiving parenteral hyperalimentation.

Macrophagic Myofasciitis This distinctive inflammatory muscle disorder, recently described in France, presents as diffuse myalgias, fatigue, and mild muscle weakness. Muscle biopsy reveals pronounced infiltration of the connective tissue around the muscle (epimysium, perimysium, and perifascicular endomysium) by sheets of periodic acid-Schiff-positive macrophages and occasional CD8+ T cells. TheCK or erythrocyte sedimentation rate is variably elevated. Most patients respond to glucocorticoid therapy, and the overall prognosis is favorable. Histologic involvement is focal and limited to sites of previous vaccinations, which may have been administered months or years earlier. This disorder, which to date has not been observed outside of France, has been linked to an aluminum-containing substrate used in vaccine preparation.

Drug-Induced Myopathies Penicillamine and procainamide may produce a true myositis resemblingPM, and aDM-like illness has been associated with contaminated preparations of L-tryptophan. As noted above, zidovudine causes a mitochondrial myopathy. Other drugs may elicit a toxic noninflammatory myopathy that is histologically different from DM, PM, or IBM. The most common drugs are the cholesterol-lowering agents such as clofibrate, lovastatin, simvastatin, or provastatin, especially when combined with cyclosporine or gemfibrozil. Rhabdomyolysis and myoglobinuria have been associated with amphotericin B, e-aminocaproic acid, fenfluramine, heroin, and

phencyclidine. The use of amiodarone, chloroquine, colchicine, carbimazole, emetine, etretinate, ipecac syrup, chronic laxative use resulting in hypocalcemia, licorice, glucocorticoids, and growth hormone has also been associated with myopathy. Some neuromuscular blocking agents such as pancuronium, in combination with glucocorticoids, may cause the acute critical illness myopathy. A careful drug history is essential for diagnosis of these drug-induced myopathies, which do not require immunosuppressive therapy.

Pain on Movement and Muscle Tenderness A number of conditions including *polymyalgia rheumatica* and arthritic disorders of adjacent joints may enter into the differential diagnosis of inflammatory myopathy, even though they do not cause myositis (Chap. 317). The muscle biopsy is either normal or discloses type II fiber atrophy. Patients with *fibrositis* and *fibromyalgia* complain of focal or diffuse muscle tenderness, fatigue, and aching, which is sometimes poorly differentiated from joint pain. In other patients there may be minor signs of a collagen vascular disorder, such as an increased erythrocyte sedimentation rate, antinuclear antibody, or rheumatoid factor. Occasionally there is slight but transient elevation of the serumCK. The muscle biopsy is usually normal and the prognosis favorable. Many such patients show some response to nonsteroidal anti-inflammatory agents, though most continue to have indolent complaints. *Chronic fatigue syndrome*, which may follow a viral infection, can present with debilitating fatigue, fever, sore throat, painful lymphadenopathy, myalgia, arthralgia, sleep disorder, and headache (Chap. 384). These patients do not have muscle weakness, and the muscle biopsy is usually normal.

DIAGNOSIS

The clinically suspected diagnosis ofPM,DM, orIBM is confirmed by examining the serum muscle enzymes,EMGfindings, and muscle biopsy (Table 382-2).

The most sensitive enzyme isCK, which in active disease can be elevated as much as 50-fold. Although the CK level usually parallels disease activity, it can be normal in some patients with activeDM and is frequently normal or only slightly above normal inIBM, even from disease onset. CK may also be normal in patients with untreated, even active, childhood DM and in some patients with DM associated with a connective tissue disease, reflecting the concentration of the pathologic process in the intramuscular vessels and the perimysium. Along with the CK, the serum glutamic-oxaloacetic and glutamate pyruvate transaminases, lactate dehydrogenase, and aldolase may be elevated.

NeedleEMGshows myopathic potentials characterized by short-duration, low-amplitude polyphasic units on voluntary activation and increased spontaneous activity with fibrillations, complex repetitive discharges, and positive sharp waves. Mixed potentials (polyphasic units of short and long duration) indicating a chronic process and muscle fiber regeneration are often present inIBM. These EMG findings are not diagnostic of an inflammatory myopathy but are useful to identify the presence of active or chronic myopathy and to exclude neurogenic disorders.

Magnetic resonance imaging is not routinely used for the diagnosis ofPM,DM, orIBM. However, it may guide the location of the muscle biopsy in certain clinical settings.

Muscle biopsy is the definitive test for establishing the diagnosis of inflammatory myopathy and for excluding other neuromuscular diseases. Inflammation is the histologic hallmark for these diseases; however, additional features are characteristic of each subtype.

InPM there are T cell infiltrates located primarily within the muscle fascicles (endomysially) and surrounding individual, healthy muscle fibers resulting in phagocytosis and necrosis. When the disease is chronic, connective tissue is increased and often reacts positively with alkaline phosphatase.

InDM the endomysial inflammation is predominantly perivascular or in the interfascicular septae and around, rather than within, the muscle fascicles. The intramuscular blood vessels show endothelial hyperplasia with tubuloreticular profiles, fibrin thrombi (especially in children), and obliteration of capillaries. The muscle fibers undergo necrosis, degeneration, and phagocytosis, often in groups involving a portion of a muscle fasiculus in a wedgelike shape or at the periphery of the fascicle, due to microinfarcts within the muscle. This results in perifascicular atrophy, characterized by 2 to 10 layers of atrophic fibers at the periphery of the fascicles. The presence of perifascicular atrophy is diagnostic of DM, *even in the absence of inflammation*.

InIBM, the following occur: (1) intense endomysial inflammation with T cells invading muscle fibers in a pattern identical to (but often more severe) from that seen in PM; (2) basophilic granular deposits distributed around the edge of slitlike vacuoles (rimmed vacuoles); (3) loss of fibers, replaced by fat and connective tissue, and angulated or round fibers, scattered or in small groups; (4) eosinophilic cytoplasmic inclusions; (5) abnormal mitochondria characterized by the presence of ragged-red fibers and cytochrome-oxidase (COX)-negative fibers and supported by the presence of mitochondrial DNA deletions in up to 75% of patients; (6) tiny congophilic amyloid deposits within or next to the vacuoles, best visualized by Texas-red fluorescent optics; and (7) characteristic filamentous inclusions seen by electron microscopy in the vicinity of the rimmed vacuoles. Such filaments can be seen in other vacuolar myopathies; thus they are not unique to IBM. Although demonstration of the filaments by electron microscopy was previously essential for the diagnosis of IBM, currently this is not absolutely necessary if all the other characteristic light-microscopic features, including amyloid deposits, are present.

In some patients with an acquired myopathy that fulfills the clinical criteria forPM orIBM, the muscle biopsy specimen may fail to confirm the suspected diagnosis; in such cases, a diagnosis of probable PM or probable IBM is assigned. An intramuscular inflammatory response around nonnecrotic muscle fibers is an invariable feature of both PM and IBM, and the absence of inflammation raises a critical question about the diagnosis. It is not unreasonable in such cases to obtain another muscle biopsy specimen from a different site. When the patient has the typical clinical phenotype of IBM but the muscle biopsy shows only features of chronic inflammatory myopathy without the typical vacuoles, the diagnosis of probable IBM is also appropriate.

Diagnostic criteria are summarized in Table 382-2. The diagnosis ofPM is *definite* if a patient has an acquired, subacute myopathy fulfilling the exclusion criteria noted above,

elevatedCKlevels, and a confirmatory muscle biopsy. The diagnosis ofDM is *definite* if the characteristic rash is present, even if there is no inflammation in the muscle biopsy specimen. The diagnosis ofIBM is *definite* when the characteristic histologic features are present in the muscle biopsy specimen from a patient with the appropriate clinical characteristics.

TREATMENT

The goal of therapy is to improve muscle strength, thereby improving function in activities of daily living. When strength improves the serumCK falls concurrently; however, the reverse is not always true. Unfortunately, there is a common tendency to "chase" or treat the CK level instead of the muscle weakness, a practice that has led to prolonged and unnecessary use of immunosuppressive drugs and erroneous assessment of their efficacy. It is prudent to discontinue these drugs if, after an adequate trial, there is no objective improvement in muscle strength whether or not CK levels are reduced. Agents used in the treatment ofPM andDMinclude:

1. *Glucocorticoids*. Oral prednisone is the initial treatment of choice; the effectiveness and side effects of this therapy determine the future need for stronger immunosuppressive drugs. High-dose prednisone, at least 1 mg/kg per day, is initiated as early in the disease as possible. After an initial period of 3 to 4 weeks, prednisone is tapered slowly over a period of 10 weeks to 1 mg/kg every other day. Then, if there is evidence of efficacy and no serious side effects, the dosage is further reduced by 5 or 10 mg every 3 to 4 weeks until the lowest possible dose that controls the disease is reached. The efficacy of prednisone is determined by an objective increase in muscle strength and activities of daily living, which almost always occurs by the third month of therapy. A feeling of increased energy or a reduction of theCK level without a concomitant increase in muscle strength is not a reliable sign of improvement. If prednisone provides no objective benefit after ~3 months of high-dose therapy, the disease is probably unresponsive to the drug and tapering should be accelerated while the next-in-line immunosuppressive drug is started. Although controlled trials have not been performed, almost all patients with true PMor DMrespond to glucocorticoids to *some degree and for some period of time*; in general, DM responds better than PM.

The long-term use of prednisone may cause increased weakness associated with a normal or unchangedCKlevel; this effect is referred to as *steroid myopathy*. In a patient who previously responded to high doses of prednisone, the development of increased weakness may be related to steroid myopathy or to disease activity that either will respond to a higher dose of glucocorticoids or has become glucocorticoid-resistant. In these circumstances, the decision to raise or lower the prednisone dosage may be influenced by reviewing the patient's history of muscle strength (especially with respect to mobility), serum CK levels, and changes in medications during the preceding 2 months. In uncertain cases, the prednisone dosage can be adjusted arbitrarily; judged by the changes in the patient's strength, the cause of the weakness is usually evident in 2 to 8 weeks.

2. *Immunosuppressive drugs*. Approximately 75% of patients ultimately require treatment with immunosuppressive drugs. Treatment is generally initiated when a patient fails to respond adequately to glucocorticoids after a 3-month trial, the patient

becomes glucocorticoid-resistant, glucocorticoid-related side effects appear, attempts to lower the prednisone dose repeatedly result in a new relapse, or rapidly progressive disease with evolving severe weakness and respiratory failure develops.

Drug selection is largely empirical, with choices based on personal experience, relative efficacy, and safety. The following agents are commonly used: (1) *Azathioprine* is well tolerated, has few side effects, and appears to be as effective for long-term therapy as other drugs. The dose is up to 3 mg/kg daily. (2) *Methotrexate* has a faster onset of action than azathioprine. It is given orally starting at 7.5 mg weekly for the first 3 weeks (2.5 mg every 12 h for 3 doses), with gradual dose escalation by 2.5 mg per week to a total of 25 mg weekly. An important side effect is methotrexate pneumonitis, which can be difficult to distinguish from the interstitial lung disease of the primary myopathy associated with Jo-1 antibodies (described above). (3) *Cyclophosphamide* (0.5 to 1 g/m2intravenously monthly for 6 months) has limited success and significant toxicity. (4) *Chlorambucil* has variable results. (5) *Cyclosporine* has inconsistent and mild benefit. (6) *Mycophenolate mofetil* has recently shown some effectiveness.

3. *Immunomodulating procedures*. In a double-blind study of patients with refractoryDM, intravenous immunoglobulin (IVIg) improved not only the strength and rash but also the underlying immunopathology. The benefit can be impressive but is short-lived (£8 weeks); repeated infusions every 6 to 8 weeks are required to maintain improvement. A dose of 2 g/kg divided over 2 to 5 days per course is recommended. A controlled double-blind study inPM is not yet completed, but uncontrolled observations suggest that IVIg is beneficial for some patients. Neither plasmapheresis or leukapheresis appears to be effective in PM and DM.

The following sequential empirical approach to the treatment ofPM andDM is suggested: *Step 1*: High-dose prednisone; *step 2*: azathioprine or methotrexate; *step 3*:IVIg; *step 4*: a trial, with guarded optimism, of one of the following agents, chosen according to the patient's age, degree of disability, tolerance, experience with the drug, and the patient's general health: cyclosporine, chlorambucil, cyclophosphamide, mycophenolate. Patients with interstitial lung disease may benefit from aggressive treatment with cyclophosphamide.

Common pitfalls leading to failure of steroid or immunosuppressive treatment are inadequate initial dose of prednisone or cytotoxic drugs, short duration of therapy or quick tapering, early development of preventable side effects necessitating early discontinuation of prednisone, and wrong diagnosis. A patient with presumedPM who has not responded to any form of immunotherapy most likely hasIBM or another disease. In these cases, a repeat muscle biopsy and a more vigorous search for the putative "other disease" are recommended. In addition to IBM, the most often misdiagnosed disorders are metabolic myopathy such as phosphorylase deficiency, a dystrophic process with endomysial inflammation resembling polymyositis, drug-induced myopathy, or an endocrinopathy.

Calcinosis, a manifestation ofDM, is difficult to treat; however, new calcium deposits may be prevented if the primary disease responds to the available therapies. Diphosphonates, aluminum hydroxide, probenecid, colchicine, low doses of warfarin, calcium blockers, and surgical excision have all been tried without success.

IBMis resistant to immunosuppressive therapies. Prednisone together with azathioprine or methotrexate have been disappointing, but most experts try these agents for a few months in newly diagnosed patients. Because occasional patients may feel subjectively weaker after these drugs are discontinued, some clinicians prefer to maintain some patients on low-dose, every-other-day prednisone or weekly methotrexate in an effort to halt disease progression, even though there is no objective evidence or controlled study to support this practice. In one double-blind study ofIVIg in IBM, minimal benefit in up to 30% of the patients was found; the strength gains, however, were not of sufficient magnitude to justify the routine use of this drug. A second controlled trial combining IVIg with prednisone was ineffective in 36 IBM patients. Despite these disappointing results, many experts believe that a 2- to 3-month trial with IVIg may be reasonable for selected patients with IBM who experience rapid progression of muscle weakness or choking episodes due to worsening dysphagia.

PROGNOSIS

Although accurate data from large series is not available, it is believed that the 5-year survival rate for treated patients withPM andDM is approximately 80%; death is usually due to pulmonary, cardiac, or other systemic complications. Patients severely affected at presentation or treated after long delays, those with severe dysphagia or respiratory difficulties, older patients, and those with associated cancer have a worse prognosis. DM responds more favorably to therapy than PM and thus has a better prognosis. Most patients improve with therapy, and many make a full functional recovery, which is often sustained with maintenance therapy. Up to 30% may be left with some residual muscle weakness. Relapses may occur at any time.

IBMhas the least favorable prognosis of the inflammatory myopathies. Most patients will require the use of an assistive device such as a cane, walker, or wheelchair within 5 to 10 years of onset. In general, the older the age of onset in IBM, the more rapidly progressive is the course.

383. MUSCULAR DYSTROPHIES AND OTHER MUSCLE DISEASES- *Robert H. Brown, Jr.*, *Jerry R. Mendell*

The muscle disorders discussed in this chapter include diseases that cause acute, subacute, and chronic muscle weakness. Some cause pain in addition to or instead of weakness.**Dermatomyositis and polymyositis are discussed in Chap. 382.*

HEREDITARY MYOPATHIES

Muscular dystrophy refers to a group of hereditary progressive diseases. Each type of muscular dystrophy has unique phenotypic and genetic features (Table 383-1).

DUCHENNE MUSCULAR DYSTROPHY

This X-linked recessive disorder, sometimes also called *pseudohypertrophic muscular dystrophy*, has an incidence of ~30 per 100,000 live-born males.

Clinical Features Duchenne dystrophy is present at birth, but the disorder usually becomes apparent between ages 3 and 5. The boys fall frequently and have difficulty keeping up with their friends when playing. Running, jumping, and hopping are invariably abnormal. By age 5, muscle weakness is obvious by muscle testing. On getting up from the floor, the patient uses his hands to climb up himself (Gowers' maneuver). Contractures of the heel cords and iliotibial bands become apparent by age 6, when toe walking is associated with a lordotic posture. Loss of muscle strength is progressive, with predilection for proximal limb muscles and the neck flexors; leg involvement is more severe than arm involvement. Between ages 8 and 10 walking may require the use of braces; joint contractures and limitations of hip flexion, knee, elbow, and wrist extension are made worse by prolonged sitting. By age 12, most patients are wheelchair dependent. Contractures become fixed, and a progressive scoliosis often develops that may be associated with pain. The chest deformity with scoliosis impairs pulmonary function, which is already diminished by muscle weakness. By age 16 to 18, patients are predisposed to serious, sometimes fatal pulmonary infections. Other causes of death include aspiration of food and acute gastric dilation.

A cardiac cause of death is uncommon despite the presence of a cardiomyopathy in almost all patients. Congestive heart failure seldom occurs except with severe stress such as pneumonia. Cardiac arrhythmias are rare. The typical electrocardiogram (ECG) shows an increase net RS in lead V_1; deep, narrow Q waves in the precordial leads; and tall right precordial R waves in V_1. Intellectual impairment in Duchenne dystrophy is common; the average intelligence quotient (IQ) is approximately one standard deviation below the mean. Impairment of intellectual function appears to be nonprogressive and affects verbal ability more than performance.

Laboratory Features Serum creatine kinase (CK) levels are invariably elevated to between 20 and 100 times normal. The levels are abnormal at birth but decline late in the disease because of inactivity and loss of muscle mass. Electromyography (EMG) demonstrates features typical of myopathy. The muscle biopsy shows muscle fibers of varying size as well as small groups of necrotic and regenerating fibers. Connective tissue and fat replace lost muscle fibers. A definitive diagnosis of Duchenne dystrophy

can be established on the basis of dystrophin deficiency in a biopsy of muscle tissue or mutation analysis on peripheral blood leukocytes as discussed below.

GENETIC CONSIDERATIONS

Duchenne dystrophy is caused by a mutation of the gene that encodes dystrophin, a 427-kDa protein localized to the inner surface of the sarcolemma of the muscle fiber. The dystrophin gene is more than 2000 kb in size and thus is one of the largest identified human genes. It is localized to the short arm of the X chromosome at Xp21. At present, mutations of the gene can be identified (in approximately two-thirds of Duchenne patients) with a battery of cDNA probes. Deletions are not uniformly distributed over the gene, but rather are most common near the beginning (5¢ end) and middle of the gene. Deletion size does not correlate with severity of disease. Less often, Duchenne dystrophy is caused by a gene duplication or point mutation. Identification of a specific mutation allows for an unequivocal diagnosis, makes possible accurate testing of potential carriers, and is useful for prenatal diagnosis.

A diagnosis of Duchenne dystrophy can also be made by western blot analysis of muscle biopsy specimens, revealing abnormalities on the quantity and molecular weight of dystrophin protein. In addition, immunocytochemical staining of muscle with dystrophin antibodies can be used to demonstrate absence or deficiency of dystrophin localizing to the sarcolemmal membrane. Carriers of the disease may demonstrate a mosaic pattern, but dystrophin analysis of muscle biopsy specimens for carrier detection is not reliable.

Pathogenesis Dystrophin is part of a large complex of sarcolemmal proteins and glycoproteins (Fig. 383-1). Dystrophin binds to F-actin at its amino terminus and to b-dystroglycan at the carboxyl terminus. b-Dystroglycan complexes toa-dystroglycan, which binds to laminin in the extracellular matrix (ECM). Laminin has a heterotrimeric molecular structure arranged in the shape of a cross with one heavy chain and two light chains,b1 and g1. The laminin heavy chain of skeletal muscle is designated laminin a2. Peripheral to laminin in the ECM are collagen proteins IV and VI. Likeb-dystroglycan, the transmembrane sarcoglycan proteins also bind to dystrophin; these five proteins (designateda- through e-sarcoglycan) complex tightly with each other. More recently, other membrane proteins implicated in muscular dystrophy have been found to be loosely affiliated with constituents of the dystrophin complex. These include caveolin-3 anda7 integrin (Fig. 383-1).

The dystrophin-glycoprotein complex appears to confer stability to the sarcolemma, although the function of each individual component of the complex is incompletely understood. Deficiency of one member of the complex may cause abnormalities in other components. For example, a primary deficiency of dystrophin (Duchenne dystrophy) may lead to secondary loss of the sarcoglycans and dystroglycan. The primary loss of a single sarcoglycan (see "Limb-Girdle Muscular Dystrophy," below) results in a secondary loss of other sarcoglycans in the membrane without uniformly affecting dystrophin. In either instance, disruption of the dystrophin-glycoprotein complexes weakens the sarcolemma, causing membrane tears and a cascade of events leading to muscle fiber necrosis. This sequence of events occurs repeatedly during the life of a patient with muscular dystrophy.

TREATMENT

Glucocorticoids, administered as prednisone in a dose of 0.75 mg/kg per day, significantly slow progression of Duchenne dystrophy for up to 3 years. Some patients cannot tolerate glucocorticoid therapy; weight gain in particular represents a significant deterrent for some boys.

BECKER MUSCULAR DYSTROPHY

This less severe form of X-linked recessive muscular dystrophy results from allelic defects of the same gene responsible for Duchenne dystrophy. Becker muscular dystrophy is approximately 10 times less frequent than Duchenne, with an incidence of about 3 per 100,000 live-born males.

Clinical Features The pattern of muscle wasting in Becker muscular dystrophy closely resembles that seen in Duchenne. Proximal muscles, especially of the lower extremities, are prominently involved. As the disease progresses, weakness becomes more generalized. Significant facial muscle weakness is not a feature. Hypertrophy of muscles, particularly in the calves, is an early and prominent finding.

Most patients with Becker dystrophy first experience difficulties between ages 5 and 15 years, although onset in the third or fourth decade or even later can occur. By definition, patients with Becker dystrophy walk beyond age 15, while patients with Duchenne dystrophy are typically in a wheelchair by the age of 12. Patients with Becker dystrophy have a reduced life expectancy, but most survive into the fourth or fifth decade.

Mental retardation may occur in Becker dystrophy, but it is not as common as in Duchenne. Cardiac involvement occurs in Becker dystrophy and may result in heart failure.

Laboratory Features SerumCKlevels, results ofEMG, and muscle biopsy findings closely resemble those in Duchenne dystrophy. The diagnosis of Becker muscular dystrophy requires western blot analysis of muscle biopsy samples demonstrating dystrophin of reduced amount or abnormal size. Mutation analysis of DNA from peripheral blood leukocytes recognizes deletions and duplications of the dystrophin gene in 65% of patients with Becker dystrophy, approximately the same percentage as in Duchenne dystrophy. In both Becker and Duchenne dystrophies, the size of the DNA deletion does not predict clinical severity; however, in ~95% of patients with Becker dystrophy, the DNA deletion does not alter the translational reading frame of messenger RNA. These "in-frame" mutations allow for production of some dystrophin, which accounts for the presence of altered rather than absent dystrophin on western blot analysis.

TREATMENT

The use of glucocorticoids has not been adequately studied in Becker dystrophy.

LIMB-GIRDLE MUSCULAR DYSTROPHY

The syndrome of limb-girdle muscular dystrophy (LGMD) represents more than one disorder.

Clinical Features Muscle weakness affects both males and females, with onset ranging from late in the first decade to the fourth decade. MostLGMDs are progressive and affect primarily the pelvic and shoulder girdle muscles. Respiratory insufficiency from weakness of the diaphragm may occur. The distribution of weakness and rate of progression vary from family to family. Similar to the dystrophinopathies, cardiac involvement may result in congestive heart failure or arrhythmias; occasional patients present with a cardiomyopathy. Intellectual function remains normal.

Laboratory Features An elevated serum CKlevel, myopathicEMGfindings, and muscle biopsy features indicative of myopathy are characteristic. Careful attention is required to exclude phenotypically similar disorders, such as spinal muscular atrophy (Chap. 365), inflammatory myopathies (Chap. 382), and metabolic myopathies (see below). The availability of western blot analysis for dystrophin allowsLGMD to be distinguished unequivocally from Becker and Duchenne muscular dystrophies.

GENETIC CONSIDERATIONS

LGMDmay be transmitted by autosomal dominant or autosomal recessive inheritance. In a new genetic classification, *LGMD1* refers to the dominantly inherited form and *LGMD2* to the recessively inherited form. Genetic linkage has identified three dominantly inherited disorders, LGMD1A-C. The recessively inherited forms of LGMD now number eight. In each case genetic linkage has been established; the specific protein deficiency is known for most forms (Table 383-2 andFig. 383-1). In LGMD2A the defect lies in a muscle-specific, calcium-activated neutral protease, calpain 3. LGMD2B arises from defects in dysferlin, a novel, membrane-associated muscle protein. Four sarcoglycans (a-d) are deficient in LGMD2C-F.

TREATMENT

At present, only supportive care can be offered. Long leg braces are useful for affected children but seldom helpful for adults. Wheelchairs may be essential or may be used to help preserve energy for work or recreational activities. Cardiac or respiratory muscle involvement may require individualized treatment. Studies of primary genetic therapy inLGMD are currently in progress.

EMERY-DREIFUSS MUSCULAR DYSTROPHY

This disorder is characterized by childhood onset of contractures at the elbows, weakness in the humeral and peroneal muscles, and cardiomyopathy. The contractures may precede the weakness. As the disease progresses, the weakness may spread to involve the proximal limb-girdle muscles. Perhaps the most critical clinical aspect of Emery-Dreifuss muscular dystrophy (EDMD) is the cardiomyopathy, which may appear as conduction defects of abrupt onset. Sudden death is not uncommon in EDMD, even in otherwise unaffected female carriers; early use of pacemakers may be lifesaving.

Most cases ofEDMD are X-linked, arising because of defects in a gene encoding emerin, a nuclear membrane protein. Another group is inherited as autosomal dominant traits. In these instances the molecular defects are in the gene located on chromosome 1, encoding the proteins lamin A and lamin C. These proteins are splice variants that localize to the nuclear envelope where, in some cells, they co-localize with emerin.

CONGENITAL MUSCULAR DYSTROPHY

This rare autosomal recessive disorder includes at least six subgroups with overlapping clinical features. Variable involvement of the brain and eyes can help differentiate these conditions; three have been mapped to specific chromosomes, with a specific defect identified in each (Table 383-3). All the forms of congenital muscular dystrophy present at birth or in the first few months of life with hypotonia and proximal limb weakness. Varying degrees of joint contractures at the elbows, hips, knees, and ankles are seen in most patients. Contractures present at birth are referred to as *arthrogryposis*. Weakness of facial muscles may occur, but other cranial nerve musculature is spared. Severity varies greatly, but about half of affected individuals never achieve the ability to stand independently. Death may ensue because of respiratory insufficiency early in life. Some patients learn to walk, although difficulty in motor activities (e.g., running) persists.

In patients with a deficiency of laminin a2 (formerly called merosin), diffuse white matter changes typical of hypomyelination are seen by magnetic resonance imaging. The clinical manifestations of the cerebral hypomyelination are mild, with learning disability as the most severe problem. In *Fukuyama congenital muscular dystrophy*, found mainly in Japan, patients are severely disabled and mentally retarded; most have seizures and die by age 20. Microcephaly and enlarged ventricles occur. Micropolygyria is common. The primary defect in this dystrophy is in the gene encoding fukutin, a secreted protein whose function remains ill-defined. In some patients, the fukutin gene is disrupted by insertion of a transposon, a novel pathogenetic mechanism. Recently, it has been reported that a form of congenital muscular dystrophy arises from the absence of a7 integrin, a muscle membrane protein.

MYOTONIC DYSTROPHY

This disorder, the most common adult muscular dystrophy, has an incidence of 13.5 per 100,000 live births and affects males and females equally.

Clinical Features The clinical expression of myotonic dystrophy varies widely and involves many systems other than muscle. Affected patients have a typical "hatchet-faced" appearance due to temporalis, masseter, and facial muscle atrophy and weakness. Neck muscles, including flexors and sternocleidomastoids, and distal limb muscles are involved early. Weakness of wrist extensors, finger extensors, and intrinsic hand muscles impairs function. Ankle dorsiflexor weakness may cause footdrop. Proximal muscles remain stronger throughout the course, although preferential atrophy and weakness of quadriceps muscles occur in many patients. Palatal, pharyngeal, and tongue involvement produce a dysarthric speech, nasal voice, and swallowing problems. Some patients have diaphragm and intercostal muscle weakness, resulting in respiratory insufficiency.

Myotonia, which usually appears by age 5, is demonstrable by percussion of the thenar eminence, the tongue, and wrist extensor muscles. Myotonia causes a slow relaxation of hand grip after a forced voluntary closure. Advanced muscle wasting makes myotonia more difficult to detect.

Congenital myotonic dystrophy is a more severe form of the disease and occurs in ~25% of infants of affected mothers. It is characterized by severe facial and bulbar weakness and transient neonatal respiratory insufficiency.

Cardiac disturbances occur in most patients with myotonic dystrophy. ECG abnormalities are common, including first-degree heart block and more extensive conduction system involvement. Complete heart block and sudden death can occur. Congestive heart failure occurs infrequently but may result from cor pulmonale secondary to respiratory failure. Mitral valve prolapse also occurs commonly.

Other features associated with myotonic dystrophy include intellectual impairment, hypersomnia, posterior subcapsular cataracts, frontal baldness, gonadal atrophy, insulin resistance, and decreased esophageal and colonic motility.

Laboratory Features The diagnosis of myotonic dystrophy can usually be made on the basis of clinical findings. Serum CK levels may be normal or mildly elevated. EMG evidence of myotonia is present in most cases. Muscle biopsy shows muscle atrophy, which selectively involves type 1 fibers in 50% of cases. Typically, increased numbers of central nuclei can be seen. Necrosis of muscle fibers and increased connective tissue, common in other muscular dystrophies, do not usually occur in myotonic dystrophy.

GENETIC CONSIDERATIONS

Myotonic dystrophy is an autosomal dominant disorder. New mutations do not appear to contribute to the pool of affected individuals. The disorder is transmitted by an intronic mutation consisting of an unstable expansion of a CTG trinucleotide repeat sequence at 19q13.3. An increase in the severity of the disease phenotype in successive generations (genetic anticipation) is accompanied by an increase in the number of trinucleotide repeats. A similar type of mutation has been identified in fragile X syndrome (Chap. 359). The unstable triplet repeat in myotonic dystrophy can be used for prenatal diagnosis. Congenital disease occurs almost exclusively in infants born to affected mothers; it is possible that sperm with greatly expanded triplet repeats do not function well.

How the CTG expansions impair function of muscle and other cells is not understood. They may alter expression of an adjacent protein kinase gene or of other neighboring genes. Alternatively, the expanded CTG might act as a sink that binds and inactivates important RNA binding proteins.

A subset of patients with multisystemic disease features similar to myotonic dystrophy do not have the diagnostic CTG expansion. Their weakness tends to be proximal rather than distal. This condition, termed proximal myotonic myopathy (PROMM), is genetically distinct from myotonic dystrophy.

TREATMENT

The myotonia in myotonic dystrophy rarely warrants treatment. Phenytoin is the preferred agent for the occasional patient who requires an antimyotonia drug; other agents, particularly quinine and procainamide, may worsen cardiac conduction. Cardiac pacemaker insertion should be considered for patients with unexplained syncope or advanced conduction system abnormalities with evidence of second-degree heart block, or trifascicular conduction disturbances with marked prolongation of the PR interval. Molded ankle-foot orthoses help prevent footdrop in patients with distal lower extremity weakness.

FACIOSCAPULOHUMERAL MUSCULAR DYSTROPHY

This form of muscular dystrophy has an incidence of approximately 1 in 20,000. It is distinct from a similar disorder known as scapuloperoneal dystrophy.

Clinical Features The condition typically has an onset in childhood and young adulthood. In most cases, facial weakness is the initial manifestation, appearing as an inability to smile, whistle, or fully close the eyes. Weakness of the shoulder girdles, rather than the facial muscles, usually brings the patient to medical attention. Loss of scapular stabilizer muscles makes arm elevation difficult. Scapular winging becomes apparent with attempts at abduction and forward movement of the arms. Biceps and triceps muscles may be severely affected, with relative sparing of the deltoid muscles. Weakness is invariably worse for wrist extension than for wrist flexion, and weakness of the anterior compartment muscles of the legs may lead to footdrop.

In most patients, the weakness remains restricted to facial, upper extremity, and distal lower extremity muscles. In 20% of patients, weakness progresses to involve the pelvic girdle muscles, and severe functional impairment and possible wheelchair dependency result.

Characteristically, patients with facioscapulohumeral (FSH) dystrophy do not have involvement of other organ systems, although labile hypertension is common, and there is an increased incidence of nerve deafness. Coats' disease, a disorder consisting of telangiectasia, exudation, and retinal detachment, also occurs.

Laboratory Features The serumCK level may be normal or mildly elevated.EMGusually indicates a myopathic pattern. The muscle biopsy shows nonspecific features of a myopathy. A prominent inflammatory infiltrate, which is often multifocal in distribution, is present in some biopsy samples. The cause or significance of this finding is unknown.

GENETIC CONSIDERATIONS

An autosomal dominant inheritance pattern with almost complete penetrance has been established, but each family member should be examined for the presence of the disease, since ~30% of those affected are unaware of involvement.FSHdystrophy is caused by deletions of telomeric heterochromatin at chromosome 4q35. There is a

significant correlation between disease severity and the size of the 4q35-associated deletion. Although a specific FSH gene and protein have not been identified, carrier detection and prenatal diagnosis are possible. Most sporadic cases represent new mutations. Genetic heterogeneity has been documented for FSH dystrophy; in occasional families, the disease is linked to chromosome 10.

TREATMENT

No specific treatment is available; ankle-foot orthoses are helpful for patients with footdrop. Scapular stabilization procedures improve scapular winging but may not improve function.

OCULOPHARYNGEAL DYSTROPHY

This form of muscular dystrophy represents one of several disorders characterized by *progressive external ophthalmoplegia*, which consists of slowly progressive ptosis and limitation of eye movements with sparing of pupillary reactions for light and accommodation. Patients usually do not complain of diplopia, in contrast to patients having conditions with a more acute onset of ocular muscle weakness (e.g., myasthenia gravis).

Clinical Features Oculopharyngeal muscular dystrophy has a late onset; it usually presents with ptosis and/or dysphagia in the fourth to sixth decade. The extraocular muscle impairment is less prominent in the early phase but may be severe later. The swallowing problem may become debilitating and result in pooling of secretions and repeated episodes of aspiration. Mild weakness of the neck and extremities also occurs.

Laboratory Features The serumCK level may be two to three times normal. MyopathicEMGfindings are typical. On biopsy, muscle fibers are found to contain vacuoles, which by electron microscopy are shown to contain membranous whorls, accumulation of glycogen, and other nonspecific debris related to lysosomes. A distinct feature of oculopharyngeal dystrophy is the presence of tubular filaments, 8.5 nm in diameter, in muscle cell nuclei.

GENETIC CONSIDERATIONS

Oculopharyngeal dystrophy has an autosomal dominant inheritance pattern with complete penetrance. The incidence is high in French-Canadians and in Spanish-American families of the southwestern United States. Large kindreds of Italian and of eastern European Jewish descent have been reported. The molecular defect in oculopharyngeal muscular dystrophy is a subtle expansion of a modest polyanine repeat tract in a poly-RNA binding protein (PABP2) in muscle; this disorder maps to chromosome 14q.

TREATMENT

Dysphagia can cause inanition, making oculopharyngeal muscular dystrophy a potentially life-threatening disease. Cricopharyngeal myotomy may improve swallowing, although it does not prevent aspiration. Eyelid crutches can improve vision in patients in

whom ptosis obstructs vision; candidates for ptosis surgery must be carefully selected -- those with severe facial weakness are not suitable.

DISTAL MYOPATHIES

Patients with predominantly distal weakness usually have a disease of peripheral nerve or anterior horn cells rather than of muscle. There is, however, a heterogeneous group of uncommon disorders of this type with histopathologic and electrophysiologic evidence of myopathy. These distal myopathies can be separated into two types with onset in late adulthood and two types with onset in early adulthood.

The most common late adult-onset form, described by Welander, is inherited as an autosomal dominant condition with onset in the fifth decade. Weakness begins in the hands, and distal anterior-compartment leg muscle involvement occurs later in the course. The serum CKlevel is either normal or mildly increased. Muscle biopsy shows vacuolated muscle fibers. This disorder genetically maps to chromosome 2p13.

Another late adult-onset form of distal myopathy, also inherited as an autosomal dominant trait, was first recognized in non-Scandinavian patients and also occurs in Finland. Weakness begins in the anterior compartment of the distal lower extremities. The serumCK level is normal or mildly elevated. Muscle fibers often have vacuoles. This disease, sometimes designated "Udd myopathy," maps to the locus for the skeletal muscle protein titin on chromosome 2q31-33.

Both of the distal myopathies with onset in early adulthood have autosomal recessive inheritance. In one type, the weakness usually begins in the anterior compartment of the distal lower extremities, although in some cases it begins in the hands. The serumCK level is moderately elevated (<10 times normal), and muscle biopsies reveal a myopathy with many fibers showing vacuoles. Many of these cases are genetically linked to the centromere on chromosome 9. The other form of early adult-onset distal myopathy (Miyoshi myopathy) is distinguished by weakness beginning in the posterior compartment, i.e., the gastrocnemius muscle. The serum CK level is markedly elevated (>10-fold), and biopsy shows a myopathy without vacuolated fibers. Like LGMB2B, Miyoshi myopathy is caused by defects in the gene encoding the protein dysferlin on chromosome 2p13.

CONGENITAL MYOPATHIES

These rare disorders are distinguished from muscular dystrophies by the presence of specific histochemical and structural abnormalities in muscle. Three major types are described: *central core disease*, *nemaline (rod) myopathy*, and *centronuclear (myotubular) myopathy*. Other rare types, such as multicore disease, fingerprint body myopathy, and sarcotubular myopathy, are not discussed here.

CENTRAL CORE DISEASE

Patients with central core disease may have decreased fetal movements and breech presentation. Hypotonia and delay in motor milestones, particularly in walking, are common. Later in childhood, patients develop problems with stair climbing, running, and

getting up from the floor. On examination, there is mild facial, neck-flexor, and proximal-extremity muscle weakness. Legs are more affected than arms. Skeletal abnormalities include congenital hip dislocation, scoliosis, and pes cavus; clubbed feet also occur. Most cases are nonprogressive, but exceptions are well documented.

The serumCK level is usually normal. NeedleEMGdemonstrates a myopathic pattern. Muscle biopsy shows fibers with single or multiple central or eccentric discrete zones (cores) devoid of oxidative enzymes. Cores occur preferentially in type 1 fibers and represent poorly aligned sarcomeres associated with Z disk streaming.

GENETIC CONSIDERATIONS

Autosomal dominant inheritance is characteristic; sporadic cases also occur. The disease is caused by point mutations of the ryanodine receptor gene on chromosome 19q, encoding the calcium-release channel of the sarcoplasmic reticulum of skeletal muscle; mutations of this gene also account for some cases of inherited malignant hyperthermia (Chap. 17).

Specific treatment is not required, but establishing a diagnosis of central core disease is extremely important, because these patients have a known predisposition to malignant hyperthermia during anesthesia.

NEMALINE MYOPATHY

The term *nemaline* refers to the distinctive presence in muscle fibers of rods or threadlike structures (Greek *nema*, "thread"). Nemaline myopathy is clinically heterogeneous. A severe neonatal form presents with hypotonia and feeding difficulties leading to early death. Most commonly, nemaline myopathy presents in infancy or childhood with delayed motor milestones. The course is nonprogressive or slowly progressive. The physical appearance may be striking because of the long, narrow facies, high-arched palate, and open-mouthed appearance due to a prognathous jaw. Other skeletal abnormalities include pectus excavatum, kyphoscoliosis, pes cavus, and clubfoot deformities. Facial and generalized muscle weakness are common. These two early childhood forms of nemaline myopathy are referred to as *congenital nemaline myopathy*, in contrast to an adult-onset disorder with progressive proximal weakness. Myocardial involvement is occasionally present in both the congenital and adult-onset forms of the disease.

The serumCK level is usually normal or slightly elevated. TheEMG in weak muscles demonstrates a myopathic pattern with occasional fibrillation potentials. Muscle biopsy demonstrates clusters of small rods (nemaline bodies), which occur preferentially, but not exclusively, in type 1 muscle fibers. The muscle often shows type 1 muscle fiber predominance. Rods originate from the Z disk material of the muscle fiber. In the severe neonatal variant, rods are commonly observed in the nucleus of muscle fibers.

GENETIC CONSIDERATIONS

Nemaline myopathy shows at least two patterns of inheritance: autosomal recessive and autosomal dominant with incomplete penetrance. Sporadic cases also occur.

Nemaline myopathy is associated with mutations of three genes: TPM3 (a-tropomyosin slow) in both dominant and recessive forms, NEB (encoding nebulin) in the slowly progressive autosomal dominant variant, and ACTA1 (a-actin) in the severe neonatal form.

CENTRONUCLEAR MYOPATHY

Three distinct variants of centronuclear myopathy occur. A *neonatal form*, also known as myotubular myopathy, presents with severe hypotonia and weakness at birth. The *late infancy-early childhood form* presents with delayed motor milestones. Later, difficulty with running and stair climbing becomes apparent. A marfanoid, slender body habitus, long narrow face, and high-arched palate are typical. Scoliosis and clubbed feet may be present. Most patients exhibit progressive weakness, some requiring wheelchairs. Progressive external ophthalmoplegia with ptosis and varying degrees of extraocular muscle impairment are characteristic of both the neonatal and the late-infantile forms. A third variant, the *late childhood-adult form*, has an onset in the second or third decade. Patients have full extraocular muscle movements and rarely exhibit ptosis. There is mild, nonprogressive limb weakness and no associated skeletal abnormalities.

Normal or slightly elevatedCKlevels occur in each of the forms.EMGstudies often give distinctive results, showing positive sharp waves and fibrillation potentials, complex and repetitive discharges, and rarely myotonic discharges. Muscle biopsy specimens in longitudinal section demonstrate rows of central nuclei, often surrounded by a halo. In transverse sections, central nuclei are found in 25 to 80% of muscle fibers.

GENETIC CONSIDERATIONS

A gene for the neonatal form of centronuclear myopathy has been localized to Xq28; this gene encodes myotubularin, a protein tyrosine phosphatase. Missense, frameshift and splice-site mutations predict loss of myotubularin function in affected individuals. Carrier identification and prenatal diagnosis are possible. The inheritance pattern for the late infancy-early childhood disorder is probably autosomal recessive, and for the late childhood-adult form is probably autosomal dominant.

DISORDERS OF MUSCLE ENERGY METABOLISM

There are two principal sources of energy for skeletal muscle -- fatty acids and glucose. Abnormalities in either glucose or lipid utilization can be associated with distinct clinical presentations that can range from an acute, painful syndrome with rhabdomyolysis and myoglobinuria to a chronic, progressive muscle weakness simulating muscular dystrophy.

GLYCOGEN STORAGE AND GYCOLYTIC DEFECTS

These disorders can be divided into those that can cause exercise intolerance, particularly intermittent muscle pain and myoglobinuria, and those in which fixed muscle weakness is the predominant clinical feature. The latter can mimicLGMD or inflammatory myopathies.

Disorders of Glycogen Storage Causing Fixed Muscle Weakness Three clinical forms of acid maltase deficiency (*type II glycogenosis*) can be distinguished, all of which have autosomal recessive inheritance. The gene for acid maltase is found on the long arm of chromosome 17. The *infantile form* is the most common, with onset of symptoms in the first 3 months of life. Infants develop severe muscle weakness, cardiomegaly, hepatomegaly, and respiratory insufficiency. Glycogen accumulation in motor neurons of the spinal cord and brainstem contributes to muscle weakness. Death usually occurs by 1 year of age. In the *childhood form*, the picture resembles muscular dystrophy. Delayed motor milestones result from proximal limb muscle weakness and involvement of respiratory muscles. The heart may be involved, but the liver and brain are unaffected. The *adult form* begins in the third or fourth decade. Respiratory failure and diaphragmatic weakness are often initial manifestations heralding progressive proximal muscle weakness. The heart and liver are not involved.

In all forms of acid maltase deficiency, the serumCK level is 2 to 10 times normal.EMGexamination demonstrates a myopathic pattern, but other features are especially distinctive, including myotonic discharges, trains of fibrillation and positive waves, and complex repetitive discharges. EMG discharges are very prominent in the lumbosacral paraspinal muscles. The muscle biopsy shows vacuoles containing glycogen and the lysosomal enzyme acid phosphatase. Electron microscopy reveals membrane-bound and free tissue glycogen. Definitive diagnosis is established by enzyme determination in muscle.

No satisfactory treatment exists for acid maltase deficiency. A high-protein diet has been advocated, but efficacy has not been documented. Intravenous enzyme replacement has not shown benefit.

In *debranching enzyme deficiency (type III glycogenosis)*, a slowly progressive form of muscle weakness can develop after puberty. Rarely, myoglobinuria may be seen. Patients are usually diagnosed in infancy, however, because of hypotonia and delayed motor milestones, hepatomegaly, growth retardation, and hypoglycemia. *Branching enzyme deficiency (type IV glycogenosis)* is a rare and fatal glycogen storage disease characterized by failure to thrive and hepatomegaly. Hypotonia and muscle wasting may be present, but the skeletal muscle manifestations are minor compared to liver failure.

Disorders of Glycolysis Causing Exercise Intolerance Five glycolytic defects are associated with recurrent myoglobinuria: *myophosphorylase deficiency (type V glycogenosis)*, *phosphofructokinase deficiency (type VII glycogenosis)*, *phosphoglycerate kinase deficiency (type IX glycogenosis)*, *phosphoglycerate mutase deficiency (type X glycogenosis)*, and *lactate dehydrogenase deficiency (glycogensosis type XI)*. Myophosphorylase deficiency, also known as McArdle's disease, is by far the most common of the glycolytic defects associated with exercise intolerance. All are inherited as autosomal recessive traits, except for phosphoglycerate kinase deficiency, which is X-linked recessive. These five glycolytic defects result in a common failure to support energy production at the initiation of exercise, although the exact site of energy failure remains controversial.

Clinical muscle manifestations in these five conditions usually begin in adolescence.

Symptoms are precipitated by brief bursts of high-intensity exercise, such as running or lifting heavy objects. A history of myalgia and muscle stiffness usually precedes the intensely painful muscle contractures, which may be followed by myoglobinuria. Acute renal failure accompanies significant pigmenturia. Exercise tolerance can be enhanced by a slow induction phase (warm-up) or brief periods of rest, allowing for the start of the "second-wind" phenomenon (switching to utilization of fatty acids).

Certain features help distinguish some enzyme defects. Varying degrees of hemolytic anemia accompany deficiencies of both phosphofructokinase (mild) and phosphoglycerate kinase (severe). In phosphoglycerate kinase deficiency, the usual clinical presentation is a seizure disorder associated with mental retardation; exercise intolerance is an infrequent manifestation.

In all of these conditions, the serumCKlevels fluctuate widely and may be elevated even during symptom-free periods. CK levels >100 times normal are expected, accompanying myoglobinuria. All patients with suspected glycolytic defects leading to exercise intolerance should undergo a forearm exercise test (Chap. 381). An impaired rise in venous lactate is highly indicative of a glycolytic defect. In lactate dehydrogenase deficiency, venous levels of lactate do not increase, but pyruvate rises to normal, after forearm exercise. In all glycolytic defects, a definitive diagnosis is made by muscle biopsy.

Training may enhance the second-wind phenomenon, but attempts to raise blood glucose or to modify these disorders through diet have not proved beneficial.

DISORDERS OF LIPID METABOLISM

Lipid is an important muscle energy source during rest and during prolonged, submaximal exercise. Fatty acids are derived from circulating very low-density lipoprotein (VLDL) in the blood or from triglycerides stored in muscle fibers. Oxidation of fatty acids occurs in the mitochondria. To enter the mitochondria, a fatty acid must first be converted to an "activated fatty acid," acyl-CoA. The acyl-CoA must be linked with carnitine by the enzyme carnitine palmitoyltransferase (CPT) I for transport into the mitochondria. CPT I is present on the inner side of the outer mitochondrial membrane. Carnitine is removed by CPT II, an enzyme attached to the inside of the inner mitochondrial membrane, allowing transport of acyl-CoA into the mitochondrial matrix forb-oxidation.

CARNITINE DEFICIENCY

Deficiency of this important substrate results in a myopathic and a systemic disorder.

Myopathic carnitine deficiency is associated with generalized muscle weakness, usually beginning in childhood. The clinical features overlap with those of muscular dystrophy and polymyositis. Patients develop progressive, painless proximal weakness. A severe cardiomyopathy may be present. SerumCKlevels may be mildly to markedly (>10-fold) elevated. The muscle biopsy shows striking lipid accumulation. The serum carnitine level is normal. The cause for decreased muscle carnitine is not understood. Most cases are sporadic, but the inheritance pattern is thought to be autosomal recessive.

Some patients respond to oral carnitine supplementation; this treatment should be tried in all cases. Other patients have responded to prednisone, riboflavin, or propranolol. A diet substituting medium-chain for long-chain triglycerides has been helpful for some patients.

Systemic carnitine deficiency usually presents in infancy and early childhood and is characterized by progressive weakness and episodes of hepatic encephalopathy with nausea, vomiting, confusion, coma, and early death. Carnitine levels are reduced in muscle, liver, kidney, and heart; but the low serum carnitine levels are especially useful in distinguishing this condition from the myopathic form. No single cause has been identified to explain the low serum carnitine levels. Decreased hepatic synthesis explains some cases, while increased urinary excretion occurs in others. SerumCKlevels may be slightly elevated. The muscle biopsy may show lipid storage. In some cases, the liver, heart, and kidney show increased lipid. Treatment with oral carnitine supplementation or glucocorticoids has helped some, but not all, patients.

Secondary carnitine deficiency accompanies a variety of disorders in which carnitine deficiency is caused by decreased synthesis (cirrhosis), insufficient intake (parenteral nutrition), or excessive loss (renal dialysis, Fanconi's syndrome, or organic acidemia). Carnitine deficiency may also be seen in the muscular dystrophies, where it is thought to be a nonspecific result of loss of muscle tissue. Oral carnitine supplementation has not been shown to clearly benefit patients with these secondary syndromes.

CARNITINE PALMITOYLTRANSFERASE DEFICIENCY

CPT II deficiency is the most common recognizable cause of recurrent myoglobinuria, more common than the glycolytic defects.

Clinical Features Onset is usually in the teenage years or early twenties. Muscle pain and myoglobinuria occur after prolonged exercise. Fasting predisposes to the development of symptoms. In contrast to disorders caused by defects in glycolysis, in which muscle cramps follow short, intense bursts of exercise, the muscle pain inCPT II deficiency does not occur until the limits of utilization have been exceeded and muscle breakdown has already begun. Episodes of rhabdomyolysis may produce severe weakness. In contrast to carnitine deficiency, strength is normal between attacks.

Laboratory Findings SerumCKlevels andEMGfindings are both usually normal between episodes. A normal rise of venous lactate during forearm exercise distinguishes this condition from glycolytic defects, especially myophosphorylase deficiency. Muscle biopsy does not show lipid accumulation and is usually normal between attacks. The diagnosis requires direct measurement of muscleCPT.

GENETIC CONSIDERATIONS

CPTII deficiency is much more common in men than women (5:1); nevertheless, all evidence indicates autosomal recessive inheritance. A mutation in the gene for CPT II causes the disease in some individuals.

TREATMENT

It has been suggested that frequent meals and a low-fat, high-carbohydrate diet can prolong exercise tolerance. Others suggest substituting medium-chain triglycerides in the diet. Neither approach has proven beneficial.

MYOADENYLATE DEAMINASE DEFICIENCY

The muscle enzyme myoadenylate deaminase converts adenosine 5¢-monophosphate (5¢-AMP) to inosine monophosphate (IMP) with liberation of ammonia. Myoadenylate deaminase may play a role in regulating adenosine triphosphate (ATP) levels in muscles. Most individuals with myoadenylate deaminase deficiency have no symptoms. Many questions have been raised about the clinical effects of myoadenylate deaminase deficiency, and, specifically, its relationship to exertional myalgia and fatigability; but there is no consensus. There have been a few reports of patients with this disorder who have exercise-exacerbated myalgia and myoglobinuria. The full clinical significance of myoadenylate deaminase deficiency has not been established.

MITOCHONDRIAL MYOPATHIES

In 1972, Olson and colleagues recognized that muscle fibers with significant numbers of abnormal mitochondria could be highlighted with the modified trichrome stain; the term "ragged red fibers" was coined. By electron microscopy, the mitochondria in ragged red fibers are enlarged and often bizarrely shaped and have crystalline inclusions. Since that seminal observation, the understanding of these disorders of muscle and other tissues has expanded (Chap. 67).

Mitochondria play a key role in energy production. Oxidation of the major nutrients derived from carbohydrate, fat, and protein leads to the generation of reducing equivalents. The latter are transported through the respiratory chain in the process known as oxidative phosphorylation. The energy generated by the oxidation-reduction reactions of the respiratory chain is stored in an electrochemical gradient coupled toATPsynthesis.

A novel feature of mitochondria is their genetic composition. Each mitochondrion possesses a DNA genome that is distinct from that of the nuclear DNA. Human mitochondrial DNA (mtDNA) consists of a double-stranded, circular molecule comprising 16,569 base pairs. It codes for 22 transfer RNAs, 2 ribosomal RNAs, and 13 polypeptides of the respiratory chain enzymes. The genetics of mitochondrial diseases differ from the genetics of chromosomal disorders. The DNA of mitochondria is directly inherited from the cytoplasm of the gametes, mainly from the oocyte. The sperm contributes very little of its mitochondria to the offspring at the time of fertilization. Thus, mitochondrial genes are derived almost exclusively from the mother, accounting for maternal inheritance of some mitochondrial disorders.

MTDNADISORDERS OF MUSCLE

Many different classifications of mitochondrial myopathies are possible. A convenient scheme allows for disorders to be grouped by the type of mtDNA mutation: deletions or point mutations.

Disorders Associated with mtDNA Deletions The *Kearns-Sayre syndrome* (KSS) is a sporadic, noninherited disorder with onset before age 20. The characteristic findings include a triad of clinical features: progressive external ophthalmoplegia, pigmentary degeneration of the retina, and heart block. Some patients have only extraocular manifestations. Patients with KSS may also have short stature, ataxia, dementia, sensorineural hearing loss, diabetes, and hypothyroidism. Cerebrospinal fluid (CSF) lactate and pyruvate levels are elevated. The course is progressively downhill, and most patients die in their third or fourth decade. In KSS, two populations of mtDNA, wild type and mutant, are present in the same cell; the mutations in the latter consist of single mtDNA deletions. Heteroplasmy can be recognized on Southern blot analysis. The highest percentage of deleted mtDNA can be detected in postmitotic tissues, especially skeletal muscle. Other tissues can harbor the mutation (e.g., peripheral blood leukocytes, brain, liver, and fibroblasts). The absence of mutant mtDNA reflects both mitotic segregation early in embryogenesis and selection against a mutant cell line in a rapidly dividing tissue. KSS is not inherited, since mutations leading to an affected individual take place in the fertilized ovum.

An *autosomal dominant disorder with progressive external ophthalmoplegia and proximal weakness* shares clinical features with KSS: hearing loss, ataxia, peripheral neuropathy, mental retardation, and hypoparathyroidism. Some of these patients also have weakness of respiratory muscles, exercise intolerance, cataracts, and early death. The patients have ragged red fibers on muscle biopsy and multiple mtDNA deletions, rather than single deletions as in KSS. The mutation accounting for the autosomal dominant inheritance occurs in a nuclear gene that encodes a protein involved in the control of mtDNA replication. A failure or disruption of binding of this nuclear-encoded protein during mtDNA replication results in multiple deletions.

Disorders Associated with mtDNA Point Mutations *Myoclonic epilepsy and ragged red fibers*, called the *MERRF syndrome*, consists of mitochondrial myopathy, myoclonus, generalized seizures, intellectual deterioration, ataxia, and hearing loss. Extraocular movements are normal in MERRF. Onset is often in childhood or early adult life. As with other mitochondrial disorders, individuals display varying manifestations of the disease. Serum and CSF lactate and pyruvate levels are increased. The course is progressively downhill, and most patients die with severe encephalopathy. MERRF syndrome is maternally inherited. Most often, point mutations in the lysine transfer RNA gene of mtDNA can be found. This abnormality can be detected in mtDNA isolated from peripheral blood leukocytes or skeletal muscle and is useful for clinical diagnosis and genetic counseling. These mutations alter the normal conformation of the transfer RNA, impairing translation probably at the ribosomal level.

Mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke-like episodes are referred to by the acronym *MELAS*. This disorder is a multisystem mitochondrial encephalomyopathy that begins in childhood after normal birth and early development. Patients have stunted growth and recurrent stroke-like episodes manifesting as hemiparesis, hemianopia, or cortical blindness. Episodic vomiting may occur, and some patients have hearing loss. Focal or generalized seizures and myoclonic epilepsy may be present. Full expression of the disease leads to dementia, a bedridden state, and death often before age 20. Lactic acidosis may be present. MELAS can be maternally

inherited, but sporadic cases are common. No large pedigrees have been reported. In 80 to 90% of patients, a point mutation of the leucine transfer RNA gene ofmtDNAhas been identified at nucleotide 3243. Some patients with this same mutation have only diabetes mellitus and hearing loss. Rarely, a mtDNA mutation of subunit 4 of complex I (ND4) of the respiratory chain causes MELAS. Mutation analysis provides a specific diagnostic test that can be performed on peripheral blood leukocytes or skeletal muscle.

A clinical syndrome with combined features of *skeletal and cardiac myopathies associated with lactic acidosis* that is distinct fromMELAShas been described with a point mutation at nucleotide 3260 of the leucine transfer RNA gene ofmtDNA.

ENDOCRINE AND METABOLIC MYOPATHIES

Many endocrine disorders cause weakness. Muscle fatigue is more common than true weakness. The cause of weakness in these disorders is not well defined. It is not even clear that weakness results from disease of muscle as opposed to another part of the motor unit since the serumCK level is often normal (except in hypothyroidism), and the muscle histology is characterized by atrophy rather than destruction of muscle fibers. Nearly all endocrine myopathies respond to treatment.

THYROID DISORDERS (See alsoChap. 330)

Abnormalities of thyroid function can cause a wide array of muscle disorders. These conditions relate to the important role of thyroid hormones in regulating the metabolism of carbohydrates and lipids as well as the rate of protein synthesis and enzyme production. Thyroid hormones also stimulate calorigenesis in muscle, increase muscle demand for vitamins, and enhance muscle sensitivity to circulating catecholamines.

Hypothyroidism Patients with hypothyroidism have frequent muscle complaints, and proximal muscle weakness occurs in about one-third of them. Muscle cramps, pain, and stiffness are common. Features of slow muscle contraction and relaxation occur in 25% of patients, and the relaxation phase of muscle stretch reflexes is characteristically prolonged. The serumCK level is often elevated (up to 10 times normal), even when there is minimal clinical evidence of muscle disease. In both children and adults, a distinct syndrome has been described. Severely hypothyroid children, especially boys, may have the Debre-Kocher-Semelaigne syndrome, characterized by weakness, slowness of movement, and striking muscle hypertrophy, causing an "infant Hercules appearance." In adult hypothyroidism, Hoffman's syndrome results in prominent muscle enlargement and weakness with muscle stiffness. The cause of muscle enlargement in these two syndromes has not been determined. The muscle biopsy shows no distinctive morphologic abnormalities.

Hyperthyroidism Patients who are thyrotoxic commonly have proximal muscle weakness and atrophy on examination, but they rarely complain of the deficit. Muscle stretch reflexes are preserved and often brisk. Bulbar, respiratory, and even esophageal muscles may occasionally be affected, causing dysphagia, dysphonia, and aspiration. When bulbar involvement occurs, it is usually accompanied by chronic proximal limb weakness, but occasionally it presents in the absence of generalized thyrotoxic myopathy. Other neuromuscular disorders occur in association with hyperthyroidism,

including periodic paralysis, myasthenia gravis, and a progressive ocular myopathy associated with proptosis (Graves' ophthalmopathy). Serum CKlevels are not elevated in thyrotoxic myopathy. The muscle histology usually shows only atrophy of muscle fibers.

PARATHYROID DISORDERS (See alsoChap. 341)

Hyperparathyroidism Muscle weakness is an integral part of primary and secondary hyperparathyroidism. Proximal muscle weakness, muscle wasting, and brisk muscle stretch reflexes are the main features of this endocrinopathy. SerumCKlevels are usually normal or slightly elevated. Serum calcium and phosphorus levels show no correlation with the clinical neuromuscular manifestations. Muscle biopsies show only varying degrees of atrophy without muscle fiber degeneration.

Hypoparathyroidism An overt myopathy due to hypocalcemia rarely occurs. Neuromuscular symptoms are usually related to localized or generalized tetany. SerumCKlevels may be increased secondary to muscle damage after tetany. Hyporeflexia or areflexia is usually present and contrasts with the hyperreflexia in hyperparathyroidism.

ADRENAL DISORDERS (See also Chap. 331)

Conditions associated with glucocorticoid excess cause a myopathy; in fact, steroid myopathy is the most commonly diagnosed endocrine muscle disease. Steroid excess, either endogenous or exogenous (see "Toxic Myopathies," below), produces various degrees of proximal limb weakness. Muscle wasting may be striking. A cushingoid appearance invariably precedes or accompanies clinical signs of myopathy. Histologic sections demonstrate muscle fiber atrophy rather than degeneration or necrosis of muscle fibers. Adrenal insufficiency commonly causes muscle fatigue. Objective weakness occurs less often and is typically mild.

In primary hyperaldosteronism, or Conn's syndrome, neuromuscular complications are due to potassium depletion. The clinical picture is one of persistent muscle weakness. Long-standing hyperaldosteronism may lead to proximal limb weakness and wasting. SerumCKlevels may be elevated, and a muscle biopsy may demonstrate degenerating fibers, some with vacuoles. These changes relate to hypokalemia and are not a direct effect of aldosterone on skeletal muscle.

PITUITARY DISORDERS (See alsoChap. 328)

Patients with acromegaly usually have mild proximal weakness without muscle atrophy. Muscles often appear enlarged, but they have decreased force generation. The duration of acromegaly, rather than the serum growth hormone levels, correlates with the degree of myopathy.

DIABETES MELLITUS (See also Chap. 333)

Neuromuscular complications of diabetes mellitus are most often related to neuropathy with cranial and peripheral nerve palsies or distal sensorimotor polyneuropathy.

"Diabetic amyotrophy" is now known to be a neuropathy affecting the proximal major nerve trunks and lumbosacral plexus. More appropriate terms for this disorder include *diabetic proximal neuropathy* and *lumbosacral radiculoplexopathy*.

The only notable myopathy of diabetes mellitus is ischemic infarction of thigh muscles. This condition occurs in patients with poorly controlled diabetes and presents with acute onset of pain, tenderness, and edema of one thigh with a palpable mass. The muscles most often affected include the vastus lateralis, thigh adductors, and biceps femoris. Computed tomography or magnetic resonance imaging can demonstrate focal abnormalities in the affected muscle. Imaging of the muscle renders muscle biopsy unnecessary.

VITAMIN DEFICIENCY

Vitamin D deficiency is the most important cause of myopathy occurring as an integral part of a vitamin deficiency. Vitamin D deficiency (Chaps. 75 and340) due to either decreased intake, decreased absorption, or impaired vitamin D metabolism (as occurs in renal disease) may lead to chronic muscle weakness. Pain reflects the underlying bone disease (osteomalacia). Vitamin E deficiency has been associated with a vacuolar myopathy. It has not been established that deficiency of other vitamins causes a myopathy.

MYOPATHIES OF SYSTEMIC ILLNESS

Systemic illnesses such as chronic respiratory, cardiac, or hepatic failure are frequently associated with severe muscle wasting and complaints of weakness. Strength testing often demonstrates mild weakness in such patients. Fatigue is a more significant problem.

Myopathy may be a manifestation of chronic renal failure, independent of the better known uremic polyneuropathy. Abnormalities of calcium and phosphorus homeostasis and bone metabolism in chronic renal failure result from a reduction in 1,25-dihydroxyvitamin D, leading to decreased intestinal absorption of calcium. Hypocalcemia, further accentuated by hyperphosphatemia due to decreased renal phosphate clearance, leads to secondary hyperparathyroidism. Renal osteodystrophy results from the compensatory hyperparathyroidism, which leads to osteomalacia from reduced calcium availability and to osteitis fibrosa from the parathyroid hormone excess. The clinical picture of the myopathy of chronic renal failure is identical to that of primary hyperparathyroidism and osteomalacia. There is proximal limb weakness with bone pain.

Gangrenous calcification represents a separate, rare, and sometimes fatal complication of chronic renal failure. In this condition, widespread arterial calcification occurs and results in ischemia. Extensive skin necrosis may occur along with painful myopathy and even myoglobinuria.

TOXIC MYOPATHIES

The classification of toxic myopathies is shown in Table 383-4. Drugs and chemicals

may produce focal or generalized damage to skeletal muscle.

The most common cause of focal damage is the injection of narcotic analgesics. Three agents in particular -- pentazocine, meperidine, and heroin -- may cause a severe fibrotic reaction in muscle. Common injection sites include deltoid, triceps, gluteus maximus, and quadriceps muscles. The muscles become indurated and may have local abscess formation. Cutaneous ulcerations and depressions may occur. Severe joint contractures may develop.

Other drugs may induce generalized muscle weakness, particularly affecting the proximal muscles. In most cases the exact mechanism of drug toxicity is poorly understood. D-Penicillamine induces a condition simulating the clinical and pathologic picture of polymyositis. A similar condition has been reported with cimetidine. Procainamide may cause myositis as part of a systemic lupus erythematosus-like reaction. Chloroquine administration may cause a vacuolar myopathy.

Zidovudine, used in the treatment of AIDS, produces proximal weakness and pain. On muscle biopsy, zidovudine myopathy demonstrates a distinctive pathologic alteration of skeletal muscle, affecting mitochondria and resembling ragged red fibers. Some patients may tolerate the reintroduction of zidovudine in lower doses.

The cholesterol-lowering agents, including fibric acid derivatives (clofibrate, gemfibrozil), 3-hydroxy-methyl-glutaryl-coenzyme A reductase inhibitors (lovastatin, simivastatin, pravastatin), and niacin have all been implicated in myopathies, occasionally causing myoglobinuria. Emetine hydrochloride (used for treatment of amebiasis), e-aminocaproic acid (an antifibrinolytic agent), and perhexiline (used for angina pectoris) have all been observed to cause muscle weakness and muscle fiber necrosis after several weeks of therapy.

Drug-induced myopathy accompanied by proximal weakness occurs with glucocorticoid therapy. Glucocorticoid drugs fluorinated in the 9a-position, such as triamcinolone, dexamethasone, and betamethasone, are most likely to cause weakness, but chronic administration of any glucocorticoid, including prednisone, causes weakness. Divided-dose, as opposed to single-morning-dose, regimens produce more severe weakness. A single-dose, alternate-day regimen is yet less toxic. The clinical diagnosis of steroid-induced muscle weakness can be difficult if the medication is being used to treat an underlying inflammatory myopathy. The presence of a normal serumCKlevel, minimal or no changes of myopathy onEMG, and type 2 muscle fiber atrophy on biopsy are helpful in suggesting steroid-induced weakness.

Excess alcohol intake causes acute muscle weakness with rhabdomyolysis and myoglobinuria by several different mechanisms, including prolonged obtundation, seizures, hypokalemia, and hypophosphatemia. The existence of a chronic myopathy causing slowly progressive weakness in this setting is controversial. Alcoholics often have chronic weakness resulting from neuropathy and poor nutrition.

A very serious drug-induced condition, *malignant hyperthermia*, occurs in susceptible individuals after exposure to certain general anesthetic and depolarizing muscle relaxants (Table 383-4). The local anesthetic amides, including lidocaine and

mepivacaine, have also been implicated as precipitating agents.

DISORDERS OF MUSCLE MEMBRANE EXCITABILITY

Elucidation of the molecular defects in the primary periodic paralyses provides insight into their pathogenesis and forms the basis for their classification (Table 383-5). These diseases are all characterized by muscle stiffness due to electrical irritability of the muscle membrane (myotonia), usually without significant permanent muscle weakness until late in the course. These clinical features (myotonia without dystrophy) distinguish these disorders from myotonic dystrophy in which there is significant distal weakness. In the nondystrophic myotonias, onset is usually in childhood or at adolescence; episodic weakness beginning after age 25 is almost never due to periodic paralysis. Attacks typically occur after rest or sleep and almost never in the midst of vigorous activity, although antecedent exercise often provokes weakness. Patients remain alert during the attacks. Early in the course of these disorders, interattack strength is normal. After many years of attacks, interictal weakness develops and may be progressive. These disorders are amenable to treatment, and progressive weakness can be prevented and even reversed. Diagnosis is based on the clinical history and confirmed by appropriate evaluation of serum electrolytes during attacks, by evaluation of the response of strength to provocative testing with glucose, insulin, potassium, and cold, or by DNA analysis of the appropriate gene.

CALCIUM CHANNEL DISORDERS OF MUSCLE

Hypokalemic Periodic Paralysis Hypokalemic periodic paralysis (hypoKPP) causes episodic weakness, which usually affects proximal limb muscles more than distal ones; rarely, ocular, bulbar, or respiratory muscles are affected. Respiratory muscle weakness may prove fatal. Meals high in carbohydrate or sodium can provoke attacks. Reflexes become hypoactive, and cardiac arrhythmias may occur during attacks owing to low serum potassium. Onset is at adolescence. Men are more often affected because of decreased penetrance in women. Some women have only infrequent attacks.

Diagnosis is established by demonstrating a low serum potassium level during a paralytic attack and by excluding secondary causes of hypokalemia. The molecular defect in the calcium channel can be defined in many patients. Muscle biopsy often shows the presence of single or multiple centrally placed vacuoles. Patients whose attacks are too infrequent for study of a spontaneous attack to be feasible require provocative testing with glucose and insulin administration. Provocative tests are potentially hazardous and require careful monitoring.

HypoKPPis caused by mutations in a voltage-sensitive, skeletal muscular calcium channel, although details of the pathogenesis are incompletely understood (Fig. 383-2).

The acute paralysis improves after the administration of potassium salts. Oral KCl (0.2 to 0.4 mmol/kg) should be given to patients with severe weakness and repeated at 15- to 30-min intervals depending on the response of theECG, serum potassium level, and muscle strength. Milder attacks usually resolve spontaneously. When patients are unable to swallow or are vomiting, intravenous therapy may be necessary. Small, repeated boluses of KCl (0.1 mmol/kg) may be administered over 5 to 10 min with

careful monitoring of the ECG and serum potassium level. If potassium is administered as a dilute solution (20 to 40 mmol/L) in 5% glucose or in physiologic saline solution, the serum potassium level may decline, and weakness may worsen. Mannitol is the preferred vehicle for administered intravenous potassium in such situations, since it facilitates rapid return of the serum potassium level to normal and does not cause the lowering of the serum potassium level that may be caused by glucose or saline solutions.

The goal of therapy is to eliminate attacks, which also prevents interattack weakness. Before effective means of attack prevention became available, chronic progressive interattack weakness frequently caused serious disability. Prophylactic administration of potassium salts, even in large doses, does not prevent attacks, but acetazolamide (125 to 1000 mg/d in divided doses) or dichlorphenamide (50 to 200 mg/d) abolishes attacks in most cases. The metabolic acidosis induced by acetazolamide may underlie the beneficial effect. Paradoxically, acetazolamide lowers the serum potassium level; to achieve an adequate response in some patients, it may be necessary to give supplementary potassium along with acetazolamide and to avoid high-carbohydrate meals. Chronic acetazolamide treatment may be associated with renal calculi, and patients should be monitored for this complication. In occasional patients, attacks may not respond to or may even be worsened by acetazolamide. In such patients, triamterene (25 to 100 mg/d) or spironolactone (25 to 100 mg/d) may prevent attacks.

SODIUM CHANNEL DISORDERS OF MUSCLE

Hyperkalemic Periodic Paralysis Hyperkalemic periodic paralysis (hyperKPP) causes episodic weakness of limb muscles; cranial and respiratory muscles are rarely involved. The term "hyperkalemic" is misleading, since patients are often normokalemic during attacks. It is the fact that attacks are precipitated by potassium administration that best defines the disorder. Paresthesias and muscle pain are present during many attacks.

Diagnosis is suggested by a modest elevation of the serum potassium level during attacks in nearly half of patients; at times, however, the serum potassium level is normal or even low. The so-called hyperkalemic and normokalemic forms of this disorder are not separate entities. Intravenous glucose-insulin loading does not precipitate weakness, but potassium-loading tests (0.05 to 0.15 g/kg) do induce weakness in such patients. Potassium-loading tests are potentially hazardous and are contraindicated in patients with renal disease and diabetes. Random serum potassium measurements may suggest the diagnosis, since potassium level elevations are frequent during attack-free intervals.EMGevidence of myotonia and the finding of vacuoles on muscle biopsy provide supporting data.

LikehypoKPP,hyperKPPmay also respond to chronic administration of acetazolamide or dichlorphenamide.

Paramyotonia Congenita Paramyotonia congenita (PC) causes attacks of paralysis either spontaneously or with cold provocation. PC with periodic paralysis is similar tohyperKPP, except that paradoxical myotonia (i.e., myotonia worsening with activity) and objective cold sensitivity are more prominent in PC.

InPC, attacks of weakness are seldom severe enough to require emergency treatment and are never fatal. Oral administration of glucose or other carbohydrate hastens recovery. Since interattack weakness may develop after repeated attacks, prophylactic treatment is usually indicated in PC. Thiazide diuretics (e.g., chlorothiazide, 250 to 1000 mg/d) are reported to be effective.

Potassium-Aggravated Myotonia Some patients with muscle sodium channel defects have severe muscle stiffness but no paralytic episodes. The stiffness is accentuated by elevations in serum potassium levels. Mutations in the skeletal muscle voltage-gated sodium channel SCN4A causehyperKPP,PC and potassium-aggravated myotonia (PAM) (Fig. 383-2). In vitro study of these mutations demonstrates increased conductance through the sodium channels, often because of subnormal, slowed inactivation of the channel after action potential firing.

CHLORIDE CHANNEL DISORDERS OF MUSCLE

Myotonia Congenita In some families, severe, cold-aggravated muscle stiffness with muscle hypertrophy is transmitted as an inherited trait (dominant or recessive). This problem is usually evident in childhood; symptoms may become less severe in the adult years. This problem is caused by mutations in a skeletal muscle chloride channel resulting in impaired membrane repolarization. Myotonia congenita due to chloride channel defects can be distinguished from sodium channel myotonia by the rather striking muscle hypertrophy and by DNA mutational screening.

DISORDERS OF UNKNOWN PATHOGENETIC MECHANISM

Thyrotoxic Periodic Paralysis This disorder is clinically indistinguishable fromhypoKPP. It is common in young Latin American and Asian men, among whom up to 10% of thyrotoxic patients may have this condition. The thyrotoxicosis may be overlooked for many months. Occasionally, the only indication of thyrotoxicosis is a depressed level of thyroid-stimulating hormone. Acute attacks respond to potassium administration. Treatment of the underlying thyrotoxicosis abolishes attacks. b-Adrenergic blocking agents are useful for reducing the frequency and severity of attacks while measures to control thyrotoxicosis are instituted. Acetazolamide is not helpful in preventing attacks. The pathogenesis of thyrotoxic periodic paralysis is uncertain, but there is evidence for a decrease in the activity of the calcium pump.

Andersen's Syndrome In this rare disorder patients manifest periodic paralysis (hyperkalemic or hypokalemic), cardiac dysrhythmias (even when normokalemic), and dysmorphic features (hypertelorism, low set ears, broad nose). Treatment of the episodic weakness is the same as for the other periodic paralyses, although cardiac status must be considered as well.

SECTION 4 -CHRONIC FATIGUE SYNDROME

384. CHRONIC FATIGUE SYNDROME - *Stephen E. Straus*

DEFINITION

Chronic fatigue syndrome (CFS) is the current name for a disorder characterized by debilitating fatigue and several associated physical, constitutional, and neuropsychological complaints (Table 384-1). This syndrome is not new; in the past, patients diagnosed with conditions such as the vapors, neurasthenia, effort syndrome, hyperventilation syndrome, chronic brucellosis, epidemic neuromyasthenia, myalgic encephalomyelitis, hypoglycemia, multiple chemical sensitivity syndrome, chronic candidiasis, chronic mononucleosis, chronic Epstein-Barr virus infection, and postviral fatigue syndrome may have had what is now called chronic fatigue syndrome. The U.S. Centers for Disease Control and Prevention (CDC) has developed diagnostic criteria for CFS based upon symptoms and the exclusion of other illnesses (Table 384-2).

EPIDEMIOLOGY

Patients with CFSare twice as likely to be women as men and are generally 25 to 45 years old, although cases in childhood and in later life have been described.

Cases are recognized in many developed countries. Most arise sporadically, but many clusters have also been reported. The most famous outbreaks ofCFSoccurred in Los Angeles County Hospital in 1934; in Akureyri, Iceland, in 1948; in the Royal Free Hospital, London, in 1955; in Punta Gorda, Florida, in 1956; and in Incline Village, Nevada, in 1985. While these clustered cases suggest a common environmental or infectious cause, none has been identified.

Estimates of the prevalence ofCFS have depended on the case definition used and the method of study. Chronic fatigue itself is a common symptom, occurring in as many as 20% of patients attending general medical clinics; CFS is far less common. Community-based studies find that 100 to 300 individuals per 100,000 population in the United States meet the currentCDC case definition.

PATHOGENESIS

The diverse names for the syndrome reflect the equally numerous and controversial hypotheses about its etiology. Several common themes underlie attempts to understand the disorder: It is often postinfectious, it is associated with immunologic disturbances, and it is commonly accompanied by neuropsychological complaints and depression.

Many studies in the 1980s and 1990s attempted to linkCFS to infection with a persistent virus such as a lymphotropic herpesvirus, retrovirus, or enterovirus. In many patients with chronic fatigue, titers of antibodies to herpesviruses, measles virus, rubella virus, and coxsackievirus B are elevated. Reports that viral antigens and nucleic acids could be specifically identified in patients with CFS have not been confirmed. One study from the United Kingdom failed to detect any association between acute infections and subsequent prolonged fatigue. Another study found that chronic fatigue did not develop

after typical upper respiratory infections but did in some individuals after infectious mononucleosis. Thus, while cumulative experience suggests that antecedent viral infections are associated with CFS, a direct viral pathogenesis is unproven.

Changes in immune parameters of uncertain functional significance have been reported inCFS. Modest and nonspecific elevations in titers of antinuclear antibodies, reductions in immunoglobulin subclasses, deficiencies in mitogen-driven lymphocyte proliferation, reductions in natural killer cell activity, disturbances in cytokine production, and shifts in lymphocyte subsets with increases in cells expressing activation markers have been described. None of the immune findings appears in all patients, nor do any correlate with the severity of CFS. None are specific; thus they remain nondiagnostic. In theory, symptoms of CFS could result from excessive production of a cytokine, such as interleukin 1, that induces asthenia and other flulike symptoms; however, conclusive data in support of this long-held hypothesis are lacking.

Disturbances in endocrine function, consistent with reduced production of corticotropin-releasing hormone in the hypothalamus, have been reported in controlled studies ofCFS. Mean serum cortisol concentrations were lower in patients than in controls; levels of adrenocorticotropic hormone were correspondingly high. Hypothetically, these neuroendocrine abnormalities could contribute to the impaired energy and depressed mood of patients.

Mild to moderate depression is present in half to two-thirds of patients. Much of this depression may be reactive, but its prevalence exceeds that seen in other chronic medical illnesses. Some propose that CFS is fundamentally a psychiatric disorder and that the various neuroendocrine and immune disturbances arise secondarily.

MANIFESTATIONS

Typically,CFSarises suddenly in a previously active individual. An otherwise unremarkable flulike illness or some other acute stress leaves unbearable exhaustion in its wake. Other symptoms, such as headache, sore throat, tender lymph nodes, muscle and joint aches, and frequent feverishness, lead to the belief that an infection persists, and medical attention is sought. Over several weeks, despite reassurances that nothing serious is wrong, the symptoms persist and other features of the syndrome become evident -- disturbed sleep, difficulty in concentration, and depression (Table 384-1).

Depending on the dominant symptoms and the beliefs of the patient, additional consultations may be sought from allergists, rheumatologists, infectious disease specialists, psychiatrists, ecologic therapists, homeopaths, or other professionals, frequently with unsatisfactory results. Once the pattern of illness is established, the symptoms may fluctuate somewhat. Many patients report that diverse complaints are linked -- that during periods of greatest fatigue they perceive the most pain and difficulty with concentration. Patients also commonly assert that excessive physical or emotional stress may exacerbate their symptoms.

Most patients remain capable of continuing to meet the obligations of family, work, or community despite their symptoms. The discretionary activities are abandoned first. Some feel unable to engage in any gainful employment. A minority of individuals require

help with the activities of daily living.

Ultimately, isolation, frustration, and pathetic resignation can mark the protracted course of illness. Patients may become angry at physicians for failing to acknowledge or resolve their plight. Fortunately,CFS does not appear to progress. On the contrary, many patients experience gradual improvement, and a minority recover fully.

DIAGNOSIS

Physical examination and routine laboratory tests are required to rule out other causes of the patient's symptoms. Prominent abnormalities argue strongly in favor of alternative diagnoses. No laboratory test, however, can diagnose this condition or measure its severity. In most cases, elaborate, expensive workups are not helpful. Magnetic resonance imaging of the brain may identify small T2 hyperintense signals in a minority of patients, but these findings do not aid diagnosis nor are they prognostic. The dilemma for patient and clinician alike is thatCFS has no pathognomonic features and remains a constellation of symptoms and a diagnosis of exclusion. Often the patient presents with features that also meet criteria for other subjective disorders such as fibromyalgia and irritable bowel syndrome.

TREATMENT

The primary responsibility of a physician confronted with a chronically fatigued patient is to address the cause by taking a thorough history, conducting a complete physical examination, judiciously using the laboratory, and, throughout this process, considering the differential diagnosis. After other illnesses have been excluded, there are several points to address in the long-term care of a patient with chronic fatigue.

The patient should be informed about the illness and what is known of its pathogenesis; its potential impact on the physical, psychological, and social dimensions of life; and its prognosis. Patients are relieved when their complaints are taken seriously. Periodic reassessment is appropriate to identify a possible underlying process that is late in declaring itself and to address intercurrent symptoms that should not be simply dismissed as yet another subjective complaint.

Many symptoms ofCFSrespond to treatment. Nonsteroidal anti-inflammatory drugs alleviate headache, diffuse pain, and feverishness. Allergic rhinitis and sinusitis are common; antihistamines or decongestants may be helpful. Although the patient may be averse to psychiatric diagnoses, depression is often a prominent symptom and, when present, should be treated. Expert psychiatric assessment is sometimes advisable. Nonsedating antidepressants improve mood and disordered sleep and thereby attenuate the fatigue somewhat. Even modest improvements in symptoms can make an important difference in the patient's degree of self-sufficiency and ability to appreciate life's pleasures.

Practical advice should be given regarding lifestyle. Sleep disturbances are common; consumption of heavy meals with alcohol and caffeine at night can make sleep even more elusive, compounding fatigue. Total rest leads to further deconditioning and the self-image of being an invalid, whereas overexertion may worsen exhaustion and lead

to total avoidance of exercise. A moderate, carefully graded regimen should be encouraged and has been proven to relieve symptoms and enhance exercise tolerance.

Controlled therapeutic trials have established that acyclovir, intramuscular liver extract-folic acid-cyanocobalamin injections, and intravenous immunoglobulin, among others, are of no value. Two studies showed that low doses of hydrocortisone provide modest benefit, but they may lead to adrenal suppression. Countless anecdotes circulate regarding other traditional and nontraditional therapies. It is important to guide patients away from those therapeutic modalities that are toxic, expensive, or unreasonable.

The physician should promote the patient's efforts toward improvement. Three clinical trials in England showed behavioral therapy to be helpful. This approach aims to dispel misguided beliefs and fears about the illness that can contribute to inactivity and despair. For CFS, as for many other conditions, a comprehensive approach to physical, psychological, and social aspects of well-being is in order.

SECTION 5 -PSYCHIATRIC DISORDERS

385. MENTAL DISORDERS - *Victor I. Reus*

The term "mental disorders," as defined in the 4th edition of the standard psychiatric *Diagnostic and Statistical Manual* (DSM-IV), encompasses a broad range of conditions characterized by patterns of abnormal behavioral and psychological signs and symptoms that result in dysfunction. The implication that mental disorders lack a physical cause is unfortunate and incorrect, and the term survives only for want of a better substitute. Mental disorders are highly prevalent in medical practice and may present either as a primary disorder or as a comorbid condition. The total direct and indirect costs of all mental disorders in the United States has been estimated to be $148 billion dollars, only slightly less than costs incurred by cardiovascular diseases.

The DSM-IV-PC (Primary Care) manual provides a useful synopsis of mental disorders most likely to be seen in primary care practice. The current system of classification is multiaxial and includes the presence or absence of a major mental disorder (axis I), any underlying personality disorder (axis II), general medical condition (axis III), psychosocial and environmental problems (axis IV), and overall rating of general psychosocial functioning (axis V).

Changes in health care delivery underscore the need for primary care physicians to assume responsibility for the initial diagnosis and treatment of the most common mental disorders. Prompt diagnosis is essential to ensure that patients have access to appropriate medical services and to maximize the clinical outcome. Validated patient-based questionnaires have been developed that systematically probe for signs and symptoms associated with the most prevalent psychiatric diagnoses and guide the clinician into a more targeted historic assessment. Prime MD and the Symptom-Driven Diagnostic System for Primary Care (SDDS-PC) are inventories that require only 10 min to complete and link patient responses to the formal diagnostic criteria of anxiety, mood, somatoform, and eating disorders and to alcohol abuse or dependence.

A physician who refers patients to a psychiatrist should know not only when doing so is appropriate but also how to do it, since societal misconceptions and the stigma of mental illness impede the process. Primary care physicians should base referrals to a psychiatrist on the presence of the signs and symptoms of a mental disorder and not simply on the absence of a physical explanation for a patient's complaint. The physician should discuss with the patient the reasons for requesting the referral or consultation and provide reassurance that he or she will continue to provide medical care and work collaboratively with the mental health professional. Consultation with a psychiatrist or transfer of care is appropriate when physicians encounter evidence of psychotic symptoms, mania, severe depression, or anxiety; symptoms of posttraumatic stress disorder (PTSD); suicidal or homicidal preoccupation; or a failure to respond to first-order treatment.**Eating disorders are discussed in Chap. 78.*

ANXIETY DISORDERS

Anxiety disorders, the most prevalent psychiatric illnesses in the general community, are present in 15 to 20% of medical clinic patients. Anxiety, defined as a subjective sense of

unease, dread, or foreboding, can indicate a primary psychiatric condition or can be a component of, or reaction to, a primary medical disease. The primary anxiety disorders are classified according to their duration and course and the existence and nature of precipitants.

When evaluating the anxious patient, the clinician must first determine whether the anxiety antedates or postdates a medical illness or is due to a medication side effect. Approximately one-third of patients presenting with anxiety have a medical etiology for their psychiatric symptoms, but an anxiety disorder can also present with somatic symptoms in the absence of a diagnosable medical condition.

PANIC DISORDER

Clinical Manifestations Panic disorder is defined by the presence of recurrent and unpredictable panic attacks, which are distinct episodes of intense fear and discomfort associated with a variety of physical symptoms, including palpitations, sweating, trembling, shortness of breath, chest pain, dizziness, and a fear of impending doom or death (Table 385-1). Paresthesias, gastrointestinal distress, and feelings of unreality are also common. Panic attacks have a sudden onset, developing within 10 min and usually resolving over the course of an hour, and they occur in an unexpected fashion. The frequency and severity of panic attacks varies, ranging from once a week to clusters of attacks separated by months of well-being. The first attack is usually outside the home. Onset is usually in late adolescence to early adulthood. In some individuals, anticipatory anxiety develops over time and results in a generalized fear and a progressive avoidance of places or situations in which a panic attack might recur. *Agoraphobia*, which occurs commonly in patients with panic disorder, is an acquired irrational fear of being in places where one might feel trapped or unable to escape (Table 385-2). Typically, it leads the patient into a progressive restriction in life-style and, in a literal sense, in geography. Frequently, patients are embarrassed that they are housebound and dependent on the company of others to go out into the world and do not volunteer this information; thus physicians will fail to recognize the syndrome if direct questioning is not pursued.

Differential Diagnosis A diagnosis of panic disorder is made after a medical etiology for the panic attacks has been ruled out. A variety of cardiovascular, respiratory, endocrine, and neurologic conditions can present with anxiety as the chief complaint. Patients with true panic disorder will often focus on one specific feature to the exclusion of others. For example, 20% of patients who present with syncope as a primary medical complaint have a primary diagnosis of a mood, anxiety, or substance-abuse disorder, the most common being panic disorder. The differential diagnosis of panic disorder is complicated by a high rate of comorbidity with other psychiatric conditions, especially alcohol and benzodiazepine abuse, which patients initially use in an attempt at self-medication. Some 75% of panic disorder patients will also satisfy criteria for major depression at some point in their illness.

When the history is nonspecific, physical examination and focused laboratory testing must be used to rule out medical anxiety states, such as those resulting from pheochromocytoma, thyrotoxicosis, or hypoglycemia. Electrocardiogram (ECG) and echocardiogram may detect some cardiovascular conditions associated with panic, such

as paroxysmal atrial tachycardia and mitral valve prolapse. In two studies, panic disorder was the primary diagnosis in 43% of patients with chest pain who had normal coronary angiograms and was present in 9% of all outpatients referred for cardiac evaluation. Panic disorder has also been diagnosed in many patients referred for pulmonary function testing or with symptoms of irritable bowel syndrome.

Etiology and Pathophysiology The etiology of panic disorder is unknown but appears to involve a genetic predisposition, altered autonomic responsivity, and social learning. Panic disorder shows familial aggregation, although concordance in monozygotic twins is only 30%. Acute panic attacks appear to be associated with increased noradrenergic discharge in the locus coeruleus. Intravenous infusion of sodium lactate evokes an attack in two-thirds of panic disorder patients, as do the α_2-adrenergic antagonist yohimbine and carbon dioxide inhalation. It is hypothesized that each of these stimuli activates a neural circuit involving noradrenergic neurons in the locus coeruleus and serotonergic neurons in the dorsal raphe. Agents that block serotonin reuptake are therapeutic in preventing attacks. It is theorized that panic-disorder patients have a heightened sensitivity to somatic symptoms, which triggers increasing arousal, setting off the "panic attack" mechanism. Accordingly, successful therapeutic intervention involves altering the patient's cognitive interpretation of anxiety-producing experiences as well as preventing the attack itself.

TREATMENT

Achievable goals of treatment are to decrease the frequency of panic attacks and to reduce their intensity. The cornerstone of drug therapy is antidepressant medications (Tables 385-3,385-4, and385-5). The tricyclic antidepressant (TCA) agents imipramine and clomipramine can benefit 75 to 90% of panic disorder patients. Low doses (e.g., 10 to 25 mg/d) are given initially to avoid any increased anxiety associated with heightened monoamine levels in the initial stages of treatment. Selective serotonin reuptake inhibitors (SSRIs) are equally effective and do not have the adverse effects of TCAs. SSRIs should be started at one-third to one-half of their usual antidepressant dose (e.g., 5 to 10 mg fluoxetine, 25 to 50 mg sertraline, 10 mg paroxetine). Monoamine oxidase inhibitors (MAOIs) are at least as effective as TCAs and may specifically benefit patients who have comorbid features of atypical depression (i.e., hypersomnia and weight gain). Insomnia, orthostatic hypotension, and the need to maintain a low-tyramine diet (avoidance of cheese and wine) have limited their use, however. Antidepressants typically take 2 to 6 weeks to become effective, and doses may need to be adjusted according to clinical response.

Because of anticipatory anxiety and the need for immediate relief of panic symptoms, benzodiazepines are useful early in the course of treatment and sporadically thereafter (Table 385-6). For example, alprazolam, starting at 0.5 mg qid and increasing to 4 mg/d in divided doses, is effective, but patients must be monitored closely, as some develop dependence and begin to escalate the dose of this medication. Clonazepam, at a final maintenance dose of 2 to 4 mg/d, is also helpful; its longer half-life permits twice-daily scheduling, and patients appear less likely to develop dependence on this agent.

Early psychotherapeutic intervention and psychoeducation aimed at symptom control enhances the effectiveness of drug treatment. Patients can be taught breathing

techniques, can be educated about physiologic changes that occur with panic, and can learn to expose themselves voluntarily to precipitating events. Homework assignments and monitored compliance are important components of successful treatment. Once patients have achieved a satisfactory response, drug treatment should be maintained for 1 to 2 years to prevent relapse.

GENERALIZED ANXIETY DISORDER

Clinical Manifestations Patients with generalized anxiety disorder (GAD) have persistent, excessive, and/or unrealistic worry associated with other signs and symptoms, which commonly include muscle tension, impaired concentration, autonomic arousal, feeling "on edge" or restless, and insomnia (Table 385-7). Onset is usually before age 20, and a history of childhood fears and social inhibition may be present. The incidence of GAD is increased in first-degree relatives of patients with the diagnosis; family studies also indicate that GAD and panic disorder segregate independently. Over 80% of patients with GAD also suffer from major depression, dysthymia, or social phobia. Comorbid substance abuse is common in these patients, particularly alcohol and/or sedative/hypnotic abuse. Patients with GAD readily admit to worrying excessively over minor matters, with life-disrupting effects; unlike in panic disorder, complaints of symptoms such as shortness of breath, palpitations, and tachycardia are relatively rare.

Etiology and Pathophysiology In experimental models of anxiety, anxiogenic agents share in common the property of altering the binding of benzodiazepines to theg-aminobutyric acid (GABA) A receptor/chloride ion channel complex. Benzodiazepines are thought to bind two separate $GABA_A$receptor sites: type I, which has a broad neuroanatomic distribution, and type II, which is concentrated in the hippocampus, striatum, and neocortex. The antianxiety effects of the various benzodiazepines and side effects such as sedation and memory impairment are influenced by their relative binding to type I and type II receptor sites. Serotonin [5-hydroxytriptamine (5HT)] also appears to have a role in anxiety. Buspirone, a partial $5HT_{1A}$receptor agonist, and certain $5HT_{2A}$and $5HT_{2C}$receptor antagonists (e.g., nefazodone) may also have beneficial effects.

TREATMENT

A combination of pharmacologic and psychotherapeutic interventions is most effective inGAD, but complete symptomatic relief is rare. A short course of a benzodiazepine is usually indicated, preferably lorazepam, oxazepam, or temazepam. (The first two of these agents are metabolized via conjugation rather than oxidation and thus do not accumulate if hepatic function is altered.) Administration should be initiated at the lowest dose possible and prescribed on an as-needed basis as symptoms warrant. Benzodiazepines differ in their milligram per kilogram potency, half-life, lipid solubility, metabolic pathways, and presence of active metabolites. Agents that are absorbed rapidly and are lipid soluble, such as diazepam, have a rapid onset of action and a higher abuse potential. Benzodiazepines should generally not be prescribed for>4 to 6 weeks because of the development of tolerance and the risk of abuse and dependence. It is important to warn patients that concomitant usage of alcohol or other sedating drugs may result in neurotoxicity and impair their ability to function. An optimistic

approach that encourages the patient to clarify environmental precipitants, anticipate his or her reactions, and plan effective response strategies are essential elements of therapy.

Adverse effects of benzodiazepines generally parallel their relative half-lives. Longer-acting agents, such as diazepam, chlordiazepoxide, flurazepam, and clonazepam, tend to accumulate active metabolites, with resultant sedation, impairment of cognition, and poor psychomotor performance. Shorter-acting compounds, such as alprazolam and oxazepam, can result in daytime anxiety, early morning insomnia, and with discontinuation, rebound anxiety and insomnia. Although patients develop tolerance to the sedative effects of benzodiazepines, they are less likely to habituate to the adverse psychomotor effects. Withdrawal from the longer half-life benzodiazepines can be accomplished through gradual, stepwise dose reduction (by ~10% every 1 to 2 weeks) over 6 to 12 weeks. It is usually more difficult to taper patients off shorter-acting benzodiazepines. Physicians may need to switch the patient to a benzodiazepine with a longer half-life or use an adjunctive medication, such as a beta blocker or carbamazepine, before attempting to discontinue the benzodiazepine. Withdrawal reactions vary in severity and duration; they can include depression, anxiety, delirium, lethargy, diaphoresis, tinnitus, autonomic arousal, unusual neuromuscular movements, and, rarely, seizures.

Buspirone, an azaspirone, is a nonbenzodiazepine anxiolytic agent. It is nonsedating, does not lead to tolerance or dependence, does not interact with benzodiazepine receptors or alcohol, and has no abuse or disinhibition potential. However, it requires several weeks to take effect and requires thrice-daily dosing. Patients who were previously responsive to a benzodiazepine are unlikely to rate buspirone as equally effective, but patients with head injury or dementia who have symptoms of anxiety and/or agitation may do well with this agent.

Administration of benzodiazepines to geriatric patients requires special care. Such patients have increased drug absorption; decreased hepatic metabolism, protein binding, and renal excretion; and an increased volume of distribution. These factors, together with the likely presence of comorbid medical illnesses and medication, dramatically increase the likelihood of toxicity. Iatrogenic psychomotor impairment can result in falls and fractures, confusional states, or motor vehicle accidents. If used, agents in this class should be started at the lowest possible dose, and results should be monitored closely. Benzodiazepines are contraindicated during pregnancy and breast-feeding.

PHOBIC DISORDERS

Clinical Manifestations The cardinal feature of phobic disorders is a marked and persistent fear of objects or situations, exposure to which results in an immediate anxiety reaction. The patient avoids the phobic stimulus, and this avoidance usually impairs occupational or social functioning. Panic attacks may be triggered by the phobic stimulus or may emerge spontaneously during the course of the illness. Unlike patients with other anxiety disorders, individuals with phobias experience anxiety only in specific situations. Common phobias include fear of closed spaces (claustrophobia), fear of blood, and fear of flying. Social phobia is distinguished by a specific fear of social or

performance situations in which the individual is exposed to unfamiliar individuals or to possible examination and evaluation by others. Examples include having to converse at a party, use public restrooms, and meet strangers. In each case, the affected individual is aware that the experienced fear is excessive and unreasonable given the circumstance. The specific content of a phobia may vary across gender, ethnic, and cultural boundaries.

Phobic disorders are common, with a 1-year prevalence rate of 9% and a lifetime rate of 10 to 11%. Onset is typically in childhood to early adulthood. Familial aggregation may occur. In one study of female twins, concordance rates for agoraphobia, social phobia, and animal phobia was found to be 23% for monozygotic twins and 15% for dizygotic twins. Full criteria for diagnosis are usually satisfied first in adulthood, but behavioral avoidance of unfamiliar people, situations, or objects dating from early childhood is common.

TREATMENT

Recent controlled trials have documented the efficacy of several pharmacologic agents in the treatment of phobic disorders. Beta blockers (e.g., propranolol, 20 to 40 mg orally 2 h before the event) are particularly effective in the treatment of "performance anxiety" (but not general social phobia) and appear to achieve their benefit by preventing the occurrence of peripheral manifestations of anxiety, such as perspiration, tachycardia, palpitations, and tremor.MAOIsalleviate social phobia independently of their antidepressant activity, andSSRIsappear to be effective also. Benzodiazepines can be helpful in reducing fearful avoidance, but the chronic nature of phobic disorders limits their usefulness.

Behaviorally focused psychotherapy is an important component of treatment, as relapse rates are high when medication is used as the sole treatment. Cognitive-behavioral strategies are the cornerstone of treatment; these are based upon the finding that distorted perceptions and interpretations of fear-producing stimuli play a major role in perpetuation of phobias. Individual and group therapy sessions teach the patient to identify specific negative thoughts associated with the anxiety-producing situation and help to reduce the patient's fear of loss of control. In desensitization therapy, hierarchies of feared situations are constructed and the patient is encouraged to pursue and master gradual exposure to the anxiety-producing stimuli.

Patients with social phobia, in particular, have a high rate of comorbid alcohol abuse, as well as of other psychiatric conditions (e.g., eating disorders), necessitating the need for parallel management of each disorder if anxiety reduction is to be achieved.

STRESS DISORDERS

Clinical Manifestations Patients may develop anxiety after exposure to extreme traumatic events such as the threat of personal death or injury or the death of a loved one. The reaction may occur shortly after the trauma (*acute stress disorder*) or be delayed and subject to recurrence (PTSD) (Table 385-8). In both syndromes, individuals experience associated symptoms of detachment and loss of emotional responsivity. The patient may feel depersonalized and unable to recall specific aspects of the trauma,

though typically it is reexperienced through intrusions in thought, dreams, or flashbacks, particularly when cues of the original event are present. Patients often actively avoid stimuli that precipitate recollections of the trauma and demonstrate a resulting increase in vigilance, arousal, and startle response. Patients with stress disorders are at risk for the development of other anxiety, mood, and substance-related disorders. Between 5 and 10% of Americans will at some time in their life satisfy criteria for PTSD, with women more likely to be affected than men.

Risk factors for the development ofPTSDinclude a past psychiatric history and personality characteristics of high neuroticism and extroversion. Studies of monozygotic and dizygotic twins showed a substantial influence of genetics on all symptoms associated with PTSD, with no evidence for an environment effect.

Etiology and Pathophysiology It is hypothesized that inPTSDthere is excessive release of norepinephrine from the locus coeruleus in response to stress. Increased noradrenergic activity at locus coeruleus projection sites in hippocampus and amygdala theoretically facilitates encoding of fear-based memories. Greater sympathetic responses to cues associated with the traumatic event occurs in PTSD.

TREATMENT

Acute stress reactions are usually self-limited, and treatment typically involves the short-term use of benzodiazepines and supportive/expressive psychotherapy. The chronic and recurrent nature ofPTSD, however, requires a more complex approach employing drug and behavioral treatments.TCAssuch as imipramine and amitriptyline, theMAOIphenelzine, and theSSRIs(fluoxetine, sertraline, citalopram, paroxetine) can all reduce anxiety, symptoms of intrusion, and avoidance behaviors. Trazodone, a sedating antidepressant, is frequently used at night to help with insomnia (50 to 150 mg qhs). Carbamazepine, valproic acid, or alprazolam have also independently produced improvement in uncontrolled trials. There is frequent comorbidity with substance abuse, especially alcohol.

Psychotherapeutic strategies are used in treatment ofPTSD to help the patient overcome avoidance behaviors and demoralization and master fear of recurrence of the trauma; therapies that encourage the patient to dismantle avoidance behaviors through stepwise focusing on the experience of the traumatic event are the most effective.

OBSESSIVE-COMPULSIVE DISORDER

Clinical Manifestations Obsessive-compulsive disorder (OCD) was previously considered a relatively rare condition, but recent epidemiologic data indicate a lifetime prevalence of 2 to 3% worldwide. OCD is characterized by obsessive thoughts and compulsive behaviors that impair everyday functioning. Fears of contamination and germs are common, as are handwashing, counting behaviors, and having to check and recheck such actions as whether a door is locked. The degree to which the disorder is disruptive for the individual varies, but in all cases obsessive-compulsive activities take up >1 h per day and are undertaken to relieve the anxiety triggered by the core fear. Patients often conceal their symptoms, usually because they are embarrassed by the content of their thoughts or the nature of their actions. Physicians must ask specific

questions regarding recurrent thoughts and behaviors, particularly if physical clues such as chafed and reddened hands or patchy hair loss (from repetitive hair pulling, or trichotillomania) are present. Tics are sometimes associated with OCD. OCD usually has a gradual onset, beginning in early adulthood, but childhood onset is not rare. The disorder usually has a waxing and waning course, but some cases may show a steady deterioration in psychosocial functioning.

Etiology and Pathophysiology A genetic contribution toOCD is suggested by a higher monozygotic than dizygotic concordance rate and the fact that familial studies show an aggregation with Tourette's disorder. OCD is more common in males and in first-born children.

The anatomy of obsessive-compulsive behavior is thought to involve a frontal-subcortical neural circuit involving the orbital frontal cortex, caudate nucleus, and globus pallidus. Neuroimaging studies have demonstrated a decrease in caudate nucleus volume, abnormalities in frontal lobe white matter, and increases in glucose metabolism in the orbital cortex of the frontal lobes and the head of the caudate nucleus. The caudate nucleus seems particularly involved in the acquisition and maintenance of habit and skill learning, and interventions that are successful in reducing obsessive-compulsive behaviors are paralleled by a comparable decrease in caudate glucose metabolic rate.

TREATMENT

Clomipramine, fluoxetine, and fluvoxamine are approved for the treatment ofOCD. Clomipramine is aTCA that is often tolerated poorly owing to significant anticholinergic and sedative side effects at the doses required to treat the illness (150 to 250 mg/d). Its efficacy in OCD is unrelated to its antidepressant activity. Fluoxetine (40 to 60 mg/d) and fluvoxamine (100 to 300 mg/d) are as effective as clomipramine and show a more benign side-effect profile. Fluvoxamine, a structurally uniqueSSRI, is metabolized through the hepatic P450 microsomal system (as is fluoxetine); it appears to inhibit the III A4 isoenzyme specifically and should not be given with other drugs that act on III A4, such as terfenadine and astemizole, because life-threatening cardiac arrhythmias may result. Only 50 to 60% of patients with OCD show an acceptable degree of improvement with pharmacotherapy alone. In treatment-resistant cases, augmentation with other serotonergic agents, such as buspirone, or with a neuroleptic or benzodiazepine may be beneficial. When a therapeutic response is achieved, long-duration maintenance therapy is usually indicated.

For many individuals, particularly those with time-consuming compulsions, behavior therapy will result in as much improvement as that afforded by medication. Effective techniques include the gradual increase in exposure to stressful situations, maintenance of a diary to clarify stressors, and homework assignments that substitute new activities for their compulsive behavior.

MOOD DISORDERS

Mood disorders are characterized by a disturbance in the regulation of mood, behavior, and affect. Mood disorders are subdivided into (1) depressive disorders, (2) bipolar

disorders, and (3) depression in association with medical illness or alcohol and substance abuse (Chaps. 387 through 389). Depressive disorders are differentiated from bipolar disorders by the absence of a manic or hypomanic episode. The relationship between pure depressive syndromes and bipolar disorders is not well understood; depression occurs at increased frequency in families of bipolar individuals, but the reverse is not true. Depression in general is associated with high disability and societal cost; in the Global Burden of Disease Study conducted by the World Health Organization, unipolar major depression ranked fourth in percentage of disability-adjusted life years and was projected to rank second in the year 2020.

DEPRESSION IN ASSOCIATION WITH MEDICAL ILLNESS

Depression occurring in the context of medical illness is difficult to evaluate. Depressive symptomatology may reflect the psychological stress of coping with the disease, may be caused by the disease process itself or by the medications used to treat it, or may simply coexist in time with the medical diagnosis.

Virtually every class of *medication* includes some agent that can induce depression. Antihypertensive drugs, anticholesterolemic agents, and antiarrhythmic agents are commonly used classes of medications that can trigger depressive symptoms. Among the antihypertensive agents, b-adrenergic blockers and, to a lesser extent, calcium channel blockers are the most likely to cause depressed mood. Iatrogenic depression should also be considered in patients receiving glucocorticoids, antimicrobials, systemic analgesics, antiparkinsonian medications, and anticonvulsants. To decide whether a causal relationship exists between pharmacologic therapy and a patient's change in mood, it is necessary to chart the chronology of symptoms and sometimes to undertake an empirical trial of an alternative medication.

Between 20 and 30% of cardiac patients manifest a depressive disorder; an even higher percentage experience depressive symptomatology when self-reporting scales are used. Depressive symptoms following myocardial infarction impair rehabilitation and are associated with higher rates of mortality and medical morbidity. Depressed patients often show decreased variability in heart rate (an index of reduced parasympathetic nervous system activity), and this has been proposed as one mechanism by which depression may predispose individuals to ventricular arrhythmia and increased morbidity. AlthoughTCAshave been used to treat depression in individuals with cardiac disease for a number of years, and although the quinidine-like effect of tricyclics may be useful in patients with preexisting arrhythmias, TCAs are contraindicated in patients with preexisting bundle branch block. They may also paradoxically precipitate arrhythmias. Tricyclic-induced tachycardia is an additional concern in patients with congestive heart failure. Experience with theSSRIs is more limited, but thus far they appear not to induceECGchanges or adverse cardiac events. SSRIs may interfere with hepatic metabolism of anticoagulants, however, causing increased anticoagulation.

Epidemiologic surveys of depression in patients with cancer show a wide variability in prevalence, as might be predicted by differences in tumor site, severity of illness, and type of medical or surgical intervention. There is an overall mean prevalence of 25%, but depression occurs in 40 to 50% of patients with cancers of the pancreas or oropharynx. Assessment of the validity of prevalence rates is complicated by the fact

that extreme cachexia may be misinterpreted as part of the symptom complex of depression. The higher prevalence of depression in patients with pancreatic cancer nevertheless persists when patients are compared to those with advanced gastric cancer. Initiation of antidepressant medication in cancer patients has been shown to improve quality of life as well as mood. Psychotherapeutic approaches, particularly group therapy, may have some effect on short-term depression, anxiety, and pain symptoms and on recurrence rates and long-term survival. In a study of female patients with metastatic breast cancer, patients in group therapy had longer survival than control patients.

Depression occurs frequently in patients with *neurologic disorders*, particularly cerebrovascular disorders, Parkinson's disease, multiple sclerosis, and traumatic brain injury. Left-hemisphere strokes, particularly those involving the dorsal lateral frontal cortex, are most likely to cause depression. Both tricyclic andSSRIantidepressants are effective in the treatment of depression secondary to stroke, as are stimulant compounds and, in some patients,MAOIs.

The reported prevalence of depression in patients with *diabetes mellitus* varies from 8 to 27%, with the severity of the mood state correlating with the physical symptoms of illness and the degree of hyperglycemia. Pharmacologic treatment of depression is complicated by antidepressant effects on the blood glucose level.MAOIscan induce hypoglycemia and weight gain.TCAs can lead to hyperglycemia and carbohydrate craving.SSRIs, like MAOIs, may cause a reduction in fasting plasma glucose, but they are easier to use and may also improve dietary and medication compliance.

Hypothyroidism is frequently associated with features of depression, most commonly depressed mood and memory impairment. Hyperthyroid states may also present in a similar fashion, usually in geriatric populations. Improvement in mood usually follows normalization of thyroid function, but adjunctive antidepressant medication is sometimes required. Patients with subclinical hypothyroidism can also experience symptoms of depression and cognitive difficulty that respond to thyroid replacement.

DEPRESSIVE DISORDERS

Clinical Manifestations *Major depression* is defined as depressed mood on a daily basis for a minimum duration of 2 weeks (Table 385-9). An episode may be characterized by sadness, indifference or apathy, or irritability and is usually associated with change in neurovegetative functions, including sleep patterns, appetite and weight, motor agitation or retardation, fatigue, impairment in concentration and decision making, feelings of shame or guilt, and thoughts of death or dying. Patients with depression have a profound loss of pleasure in all enjoyable activities, exhibit early morning awakening, feel that the dysphoric mood state is qualitatively different from sadness, and often notice a diurnal variation in mood (worse in morning hours). Paradoxically, these more severe features predict a good response to antidepressant treatment.

Approximately 15% of the population experiences a major depressive episode at some point in life, and 6 to 8% of all outpatients in primary care settings satisfy diagnostic criteria for the disorder. Depression is often undiagnosed, and, even more frequently, it is treated inadequately. If a physician suspects the presence of a major depressive

episode, the initial task is to determine whether it represents unipolar or bipolar depression or is one of the 10 to 15% of cases that are secondary to general medical illness or substance abuse. Physicians should also assess the risk of suicide by direct questioning, as patients are often reluctant to verbalize such thoughts without prompting. If specific plans are uncovered or if significant risk factors exist (e.g., a past history of suicide attempts, profound hopelessness, concurrent medical illness, substance abuse, or social isolation), the patient must be referred to a mental health specialist for immediate care. In evaluating suicidal risk the physician should specifically probe each of these areas in an empathic and hopeful manner, being sensitive to denial and possible minimization of distress. The presence of anxiety, panic, or agitation significantly increases near-term suicidal risk. Nearly 15% of patients whose depressive illness goes untreated will commit suicide; most will have sought help from a physician within 1 month of their death.

In some depressed patients, the mood disorder does not appear to be episodic and is not clearly associated with either psychosocial dysfunction or change from the individual's usual experience in life. *Dysthymic disorder* consists of a pattern of chronic (at least 2 years), ongoing, mild depressive symptoms that are less severe and less disabling than those found in major depression; the two conditions are sometimes difficult to separate, however, and can occur together ("double depression"). Many patients who exhibit a profile of pessimism, disinterest, and low self-esteem respond to antidepressant treatment. Dysthymic disorder exists in ~5% of primary care patients.

Studies of various cultures have shown that external manifestations of depression differ but the core symptoms remain the same. The incidence of depression increases with age; the disorder is approximately twice as prevalent in women as in men, regardless of age. These gender differences were previously believed to reflect sociocultural factors, but recent longitudinal twin studies indicate that the liability to major depression in adult women is largely genetic in origin, and that the effect of environmental factors is transitory and does not affect lifetime prevalence. The relationship between psychological stress, negative life events, and the onset of depressive episodes is complex. Negative life events can precipitate and contribute to depression, but recent data indicate that genetic factors influence the sensitivity of individuals to these stressful events. In most cases, both biologic and psychosocial factors are involved in the precipitation and unfolding of depressive episodes. The most potent stressors appear to involve death of a relative, assault, or severe marital or relationship problems.

Unipolar depressive disorders usually have their onset in early adulthood, and recurrences over the course of a lifetime are likely. The best predictor of future risk is the number of past episodes; 50 to 60% of patients who have a first episode have at least one or two more episodes. Some patients experience multiple episodes that become more severe and frequent over time. The duration of an untreated episode varies greatly, ranging from a few months to ³1 year. The pattern of recurrence and clinical progression in a developing episode is also variable. Within an individual, there is often long-term stability in phenotype (presenting symptoms, frequency and duration of episodes). In a minority of patients, the severity of the depressive episode may progress to psychotic symptomatology; in elderly patients, depressive symptoms may be associated with confusion and mistaken for dementia (i.e., "pseudodementia"). A seasonal pattern of depression, called *seasonal affective disorder*, may manifest with

onset and remission of episodes at predictable times of the year. This disorder is more common in women, whose symptoms are anergy, fatigue, weight gain, hypersomnia, and episodic carbohydrate craving. The prevalence increases with distance from the equator, and mood improvement may occur by altering light exposure.

Etiology and Pathophysiology The neurobiology of unipolar depression is poorly understood. Although evidence for genetic transmission is not as strong as in bipolar disorder, monozygotic twins have a higher concordance rate (46%) than dizygotic siblings (20%), with little evidence for any effect of a shared family environment. Parallels between the affective, motor, and cognitive dysfunctions seen in unipolar depression and those observed in diseases of the basal ganglia have suggested that neural networks involving prefrontal cortex and the basal ganglia may be involved. This hypothesis is supported by positron emission tomography (PET) studies of brain glucose metabolism that show a decrease in metabolic rate in the caudate nuclei and frontal lobes in depressed patients that returns to normal with recovery. Single-photon emission computed tomography (SPECT) studies show comparable changes in blood flow. Magnetic resonance imaging (MRI) findings in some patients include an increased frequency of subcortical white matter lesions. However, because these findings are more prevalent in patients with late onset of depressive illness, their significance remains unproven. A number of studies document increased ventricle-to-brain ratios in some patients with recurrent depression, but whether this finding is state-dependent or represents true cerebral atrophy is controversial.

Postmortem examination of brains of suicide victims suggest altered noradrenergic activity, including increased binding toa_1-,a_2-, and$b$-adrenergic receptors in the cerebral cortex and a decreased total number and density of noradrenergic neurons in the locus coeruleus. Involvement of the serotonin system is suggested by findings of reduced plasma tryptophan levels, a decreased cerebrospinal fluid level of 5-hydroxyindolacetic acid (the principal metabolite of serotonin in brain), and decreased platelet serotonergic transporter binding. An increase in brain serotonin receptors in suicide victims is also reported. Depletion of blood tryptophan, the amino acid precursor of serotonin, rapidly reverses the antidepressant benefit in depressed patients who have been successfully treated. However, a decrement in mood after tryptophan reduction is considerably less robust in untreated patients, indicating that, if presynaptic serotonergic dysfunction occurs in depression, it likely plays a contributing rather than a causal role.

Neuroendocrine abnormalities that reflect the neurovegetative signs and symptoms of depression include (1) increased cortisol and corticotropin-releasing hormone (CRH) secretion, (2) an increase in adrenal size, (3) a decreased inhibitory response of glucocorticoids to dexamethasone, and (4) a blunted response of thyroid-stimulating hormone (TSH) level to infusion of thyroid-releasing hormone (TRH). Antidepressant treatment leads to normalization of these pituitary-adrenal abnormalities.

Diurnal variations in symptom severity and alterations in circadian rhythmicity of a number of neurochemical and neurohumoral factors suggest that biologic differences may be secondary to a primary defect in regulation of biologic rhythms. Patients with major depression show consistent findings of a decrease in rapid eye movement (REM) sleep onset (REM latency), an increase in REM density, and, in some subjects, a decrease in stage IV delta slow-wave sleep.

Although antidepressant drugs result in a blockade of neurotransmitter uptake within hours, their therapeutic effects typically emerge over several weeks, implicating neuroadaptive changes in second messenger systems and transcription factors as possible mechanisms of action.

TREATMENT

Treatment planning requires coordination of short-term symptom remission with longer term maintenance strategies designed to prevent recurrence. The most effective intervention for achieving remission and preventing relapse is medication, but combined treatment, incorporating psychotherapy to help the patient cope with decreased self-esteem and demoralization, improves outcome (Fig. 385-1). About 40% of primary care patients with depression drop out of treatment and discontinue medication if symptomatic improvement is not noted within a month, unless additional support is provided. Outcome improves with (1) increased intensity and frequency of visits during the first 4 to 6 weeks of treatment, (2) supplemental educational materials, and (3) psychiatric consultation as indicated. Despite the widespread use ofSSRIs, there is no convincing evidence that this class of antidepressant is more efficacious thanTCAs. Between 60 and 70% of all depressed patients respond to any drug chosen, if it is given in a sufficient dose for 6 to 8 weeks. There is no ideal antidepressant; no current compound combines rapid onset of action, moderate half-life, a meaningful relationship between dose and blood level, a low side effect profile, minimal interaction with other drugs, and safety in overdose. A rational approach to selecting which antidepressant to use involves matching the patient's preference and medical history with the metabolic and side effect profile of the drug (Tables 385-4 and385-5). A previous response, or a family history of a positive response, to a specific antidepressant would suggest that that drug be tried first. Before initiating antidepressant therapy, the physician should evaluate the possible contribution of comorbid illnesses and consider their specific treatment. In individuals with suicidal ideation, particular attention should be paid to choosing a drug with a low toxicity if taken in overdose. The SSRIs and other newer antidepressant drugs are distinctly safer in this regard; nevertheless, the advantages of TCAs have not been completely superseded. The existence of generic equivalents make TCAs relatively cheap, and for several tricyclics, particularly nortriptyline, imipramine, and desipramine, well-defined relationships between dose, plasma level, and therapeutic response exist. The steady-state plasma level achieved for a given drug dose can vary more than tenfold between individuals. Plasma levels may help in understanding resistance to treatment and/or unexpected drug toxicity. The principal disadvantages of TCAs are antihistamine side effects (sedation) and anticholinergic side effects (constipation, dry mouth, urinary hesitancy, and blurred vision). Severe cardiac toxicity due to conduction block or arrhythmias can also occur but is uncommon at therapeutic levels. TCAs are probably contraindicated in patients with cardiovascular risk factors. Tricyclic agents are lethal in overdose, with desipramine carrying the greatest risk. Prescribing only a 10-day supply may be judicious. Most patients require a daily dose of 150 to 200 mg of imipramine or amitriptyline or its equivalent to achieve a therapeutic blood level of 150 to 300 ng/mL and a satisfactory remission; some patients show a partial effect at lower doses. Geriatric patients in particular may require a low starting dose and slow escalation. Ethnic differences in drug metabolism are significant; Hispanic, Asian, and African American patients generally require lower doses than

Caucasians to achieve a comparable blood level.

Second-generation antidepressants include amoxapine, maprotiline, trazodone, and bupropion. Amoxapine is a dibenzoxazepine derivative that blocks norepinephrine and serotonin reuptake and has a metabolite that shows a degree of dopamine blockade. Long-term use of this drug carries a risk of tardive dyskinesia. Maprotiline is a potent noradrenergic reuptake blocker that has little anticholinergic effect but may produce seizures. Bupropion is a novel antidepressant whose mechanism of action is thought to involve enhancement of noradrenergic function. It has no anticholinergic, sedating, or orthostatic side effects and has a low incidence of sexual side effects. It may, however, be associated with aversive stimulant-like side effects, may lower seizure threshold, and has an exceptionally short half-life, requiring multiple dosing. An extended-release preparation is available.

SSRIssuch as fluoxetine, sertraline, paroxetine, and citalopram cause a lower frequency of anticholinergic, sedating, and cardiovascular side effects but a possibly greater incidence of gastrointestinal complaints, sleep impairment, and sexual dysfunction than doTCAs. Akathisia, involving an inner sense of restlessness and anxiety, may also be more common, particularly during the first week of treatment. A serious concern, aside from drug interaction, is the risk of "serotonin syndrome," thought to result from hyperstimulation of brainstem $5HT_{1A}$receptors and characterized by myoclonus, agitation, abdominal cramping, hyperpyrexia, hypertension, and potentially death. Combinations of serotonergic agonists should be monitored closely for this reason. Considerations such as half-life, compliance, toxicity, and drug-drug interactions may guide the choice of a particular SSRI. Fluoxetine and its principal active metabolite, norfluoxetine, for example, have a combined half-life of almost 7 days, resulting in a delay of 5 weeks before steady-state levels are achieved and a similar delay for complete drug excretion once its use is discontinued. All the SSRIs may impair sexual function, resulting in diminished libido, impotence, or difficulty in achieving orgasm. Sexual dysfunction frequently results in noncompliance and should be asked about specifically in patients using SSRIs. Sexual dysfunction can sometimes be ameliorated by lowering the dose, by instituting drug holidays over the weekend (two or three times a month), or by treatment with amantadine (100 mg tid), bethanechol (25 mg tid), or buspirone (10 mg tid). Paroxetine appears to be more anticholinergic than either fluoxetine or sertraline, and sertraline carries a lower risk of producing an adverse drug interaction than the other two. Rare side effects of SSRIs include vasospastic angina and alterations of prothrombin time. Citalopram is the most specific of currently available SSRIs and appears to have no specific inhibitory effects on the P450 system.

Venlafaxine, like imipramine, blocks the reuptake of both norepinephrine and serotonin, but it produces relatively little in the way of traditional tricyclic side effects. Unlike theSSRIs, it has a relatively linear dose-response curve. Patients should be monitored for a possible increase in diastolic blood pressure, and multiple daily dosing is required because of the drug's short half-life. An extended-release form is available and has a somewhat lower incidence of gastrointestinal side effects. Nefazadone is a selective $5HT_2$receptor antagonist that also inhibits the presynaptic reuptake of serotonin and norepinephrine. Its side effects are similar to those of the SSRIs, and twice-daily dosing produces a steady state within 4 to 5 days. The drug is related structurally to trazodone, which is currently used more for its sedative than its antidepressant properties.

Nefazadone appears to produce a lower incidence of sexual side effects than do the SSRIs. Mirtazapine is a tetracyclic antidepressant that has a comparatively unique spectrum of activity. It increases noradrenergic and serotonergic neurotransmission through a blockade of central α_2-adrenergic auto- and heteroreceptors and postsynaptic $5HT_2$ and $5HT_3$ receptors. It is also strongly antihistaminic and, as such, may produce sedation at lower doses.

With the exception of citalopram, each of the SSRIs, as well as nefazadone, may inhibit one or more cytochrome P450 enzymes (Table 385-5). Depending on the specific isoenzyme involved, the metabolism of a number of concomitantly administered medications can be dramatically affected. Fluoxetine and paroxetine, for example, by inhibiting 2D6, can cause dramatic increases in the blood level of type 1C antiarrhythmics, while sertraline and nefazadone, by acting on 3A4, may alter blood levels of terfenadine, carbamazepine, and astemizole. Because many of these compounds have a narrow therapeutic window and can cause iatrogenic ventricular arrhythmias at toxic levels, the possibility of an adverse drug interaction should be considered.

Other treatment options include the MAOIs and electroconvulsive therapy. The MAOIs are highly effective, particularly in atypical depression, but the risk of hypertensive crisis following intake of tyramine-containing food or sympathomimetic drugs makes them inappropriate as first-line agents. Common side effects include orthostatic hypotension, weight gain, insomnia, and sexual dysfunction. MAOIs should not be used concomitantly with SSRIs, because of the risk of serotonin syndrome, or with TCAs, because of possible hyperadrenergic effects. Electroconvulsive therapy is at least as effective as medication, but its use is reserved for treatment-resistant cases and delusional depressions.

Regardless of the medication chosen, the treatment response should be evaluated after approximately 2 months of therapy. Three-quarters of patients show an adequate response by this time, but if remission is inadequate, the patient should be questioned about medication compliance, and an increase in dose should be considered if side effects are not troublesome. If there is no improvement, consultation with or referral to a mental health specialist is advised. Strategies for treatment then include selection of an alternative drug, combinations of antidepressants, and/or adjunctive treatment with other classes of drugs, including lithium, thyroid hormone, and dopamine agonists. Patients whose response to an SSRI disappears over time may benefit from the addition of buspirone (10 mg tid) or pindolol (2.5 mg tid) or small amounts of a tricyclic antidepressant such as desipramine (25 mg bid or tid). Once significant remission is achieved, drug treatment should be continued for at least 6 to 9 months to prevent relapse. In patients who have had two or more episodes of depression, indefinite maintenance treatment should be considered.

It is essential to counsel patients about depression and the medications they are receiving. An educational approach is best, describing what is known about the depressive syndrome and how the medications may help. Advice about stress reduction, side effects, and expected length of treatment and cautions that alcohol may exacerbate depressive symptoms and impede drug response are helpful. Patients should be given time to describe their experience and the impact it has had on them,

their family, and their outlook. Occasional empathic silence may be as helpful for the treatment alliance as verbal reassurance.

BIPOLAR DISORDER

Clinical Manifestations Bipolar disorder is common, affecting approximately 3 million persons in the United States, but often difficult to diagnose. It is characterized by unpredictable swings in mood from mania (or hypomania) to depression. Some patients suffer only from recurrent attacks of *mania*, which in its pure form is associated with increased psychomotor activity; excessive social extroversion; decreased need for sleep; impulsivity and impairment in judgment; and expansive, grandiose, and sometimes irritable mood (Table 385-10). In severe mania, patients may experience delusions and paranoid thinking indistinguishable from schizophrenia. Half of patients with bipolar disorder present with a mixture of psychomotor agitation and activation with dysphoria, anxiety, and irritability. It may be difficult to distinguish *mixed mania* from *agitated depression*. In some bipolar patients (*bipolar II disorder*), the full criteria for mania are lacking, and the requisite recurrent depressions are separated by periods of mild activation and increased energy (hypomania). In *cyclothymic disorder*, there are numerous hypomanic periods, usually of relatively short duration, alternating with clusters of depressive symptoms that fail, either in severity or duration, to meet the criteria of major depression. The mood fluctuations are chronic and should be present for at least 2 years before the diagnosis is made.

Manic episodes typically emerge over a period of days to weeks, but onset within hours is possible, usually in the early morning hours. An untreated episode of either depression or mania can be as short as several weeks or last as long as 8 to 12 months, and rare patients have an unremitting chronic course. The term *rapid cycling* is used for patients who have four or more episodes of either depression or mania in a given year. This pattern occurs in 15% of all patients, almost all of whom are women. In some cases, rapid cycling is linked to an underlying thyroid dysfunction and, in others, is iatrogenically triggered by prolonged antidepressant treatment.

Although bipolar illness is associated with frequent episodic recurrence, it was once thought to have a favorable prognosis and outcome. More recent data, however, show that approximately half of patients with the disorder have sustained difficulties in work performance and psychosocial functioning. The most frequent age of onset for bipolar disorder is between 20 and 30 years of age, but many individuals report premorbid symptoms in late childhood or early adolescence. The prevalence is similar for men and women; women are likely to have more depressive and men more manic episodes over a lifetime.

Differential Diagnosis The differential diagnosis of mania includes toxic effects of stimulant or sympathomimetic drugs as well as secondary mania induced by hyperthyroidism, AIDS, or neurologic disorders, such as Huntington's or Wilson's disease, or cerebrovascular accidents. Comorbidity with alcohol and substance abuse is common, either because of poor judgment and increased impulsivity or because of an attempt at self-medication.

Etiology and Pathophysiology Evidence for a genetic predisposition to bipolar

disorder is significant. The concordance rate for monozygotic twin pairs approaches 80%, and segregation analyses are consistent with autosomal dominant transmission. Several chromosomal locations for the gene have been proposed in the past decade on the basis of linkage analysis in affected families. None, however, has yet received convincing confirmation.

The pathophysiologic mechanisms underlying the profound and recurrent mood swings of bipolar disorder remain unknown. Cellular models of changes in membrane Na^+- and K^+-activated ATPase and proposals of disordered signal transduction mechanisms involving the phosphoinositol system and GTP-binding proteins have received the most attention. Alterations in glutamate regulation and in neuroprotective transcription factors are also being investigated as possible explanations for the therapeutic effects of lithium.

Neurophysiologic studies suggest that patients with bipolar disorder have altered circadian rhythmicity. Lithium may exert its therapeutic benefit through a resynchronization of intrinsic rhythms keyed to the light/dark cycle (Chap. 27). Neuroimaging techniques have also identified a higher rate of subcortical white matter abnormalities in patients than in age-matched controls.

TREATMENT

(Table 385-11) Lithium carbonate is the mainstay of treatment in bipolar disorder, although sodium valproate is equally effective in acute mania. Carbamazepine is also efficacious. The response rate to lithium carbonate is 70 to 80% in acute mania, with beneficial effects appearing in 1 to 2 weeks. Lithium also has a prophylactic effect in prevention of recurrent mania, and, to a lesser extent, in the prevention of recurrent depression. A simple cation, lithium is rapidly absorbed from the gastrointestinal tract and remains unbound to plasma or tissue proteins. Some 95% of a given dose is excreted unchanged through the kidneys within 24 h.

Serious side effects from lithium administration are rare, but minor complaints such as gastrointestinal discomfort, nausea, diarrhea, polyuria, weight gain, skin eruptions, alopecia, and edema are common. Over time, urine-concentrating ability may be decreased, but significant nephrotoxicity does not occur. In a small subset of patients in whom excessive polyuria occurs (>3000 mL/24 h), dose or schedule adjustments or the adjunctive use of diuretics should be considered. Lithium exerts an antithyroid effect by interfering with the synthesis and release of thyroid hormones. Approximately 5% of patients taking lithium for ^{3}18 months develop hypothyroidism, with women more likely to be affected than men. Iatrogenic hypothyroidism should be ruled out in any patient who experiences a recurrence of depressive symptomatology during lithium treatment. More serious side effects include tremor, interference with concentration and memory, ataxia, dysarthria, and incoordination.ECGchanges of T wave flattening and conduction delays may occur. There is suggestive, but not conclusive, evidence that lithium is teratogenic, inducing cardiac malformations in the first trimester.

In the treatment of acute mania, lithium is initiated at 300 mg bid or tid, and the dose is then increased by 300 mg every 2 to 3 days to achieve blood levels of 0.8 to 1.2 meq/L. Before initiating treatment the physician should obtain baseline measures of

electrolytes, creatinine, thyroid function, and a complete blood count (CBC). Because the therapeutic effect of lithium may not appear until 7 to 10 days of treatment, adjunctive usage of lorazepam (1 to 2 mg every 4 h) or clonazepam (0.5 to 1 mg every 4 h) may be beneficial to control agitation. Antipsychotics are indicated in patients with severe agitation who respond only partially to benzodiazepines. These agents should be discontinued in the transition to maintenance lithium therapy. Patients using lithium should be monitored closely, since the blood levels required to achieve a therapeutic benefit are close to those associated with neurotoxicity. Risk factors for neurotoxicity include concomitant medical illness, decrease in salt intake, or concurrent use of medications that may increase the serum level of lithium (neuroleptics, diuretics, and calcium channel blockers). Once stabilization is achieved, the lithium level can be monitored on a bimonthly basis, and thyroid and renal functions on a biannual basis, or more frequently if clinical change occurs.

Valproic acid is an alternative in patients who cannot tolerate lithium or respond poorly to it. Valproic acid may be better than lithium for patients who have a rapid-cycling course (i.e., more than four episodes a year) or who present with a mixed or dysphoric mania. Valproic acid is usually started at 500 to 750 mg/d in divided doses. The dose is increased every several days to achieve blood levels in the range of 50 to 100 ug/mL, which typically are achieved at a dose of 1000 to 2500 mg/d. The most serious adverse effects of valproic acid are hepatoxicity, which may be fatal, and hyponatremia. Such cases are fortunately rare, but periodic monitoring of liver enzymes, particularly during the first 90 days of treatment, is indicated.

Carbamazepine, although not formally approved by the U.S. Food and Drug Administration (FDA) for bipolar disorder, has clinical efficacy in the treatment of acute mania. Carbamazepine is initiated at 400 to 600 mg/d in divided doses, and the dose is increased to achieve a blood level of 4 to 12 mg/L. Carbamazepine may induce a benign leukopenia, but the risk of aplastic anemia is minimal. Nevertheless, it is wise to obtain aCBCperiodically.

Preliminary evidence also suggests that other anticonvulsant agents such as gabapentin, lamotrigine, and topiramate may possess some therapeutic benefit.

The recurrent nature of bipolar mood disorder necessitates maintenance treatment. Maintenance of blood lithium levels of at least 0.8 mg/L is important to achieve optimal prophylaxis. Compliance is frequently an issue and often requires enlistment and education of concerned family members to avoid relapse. Efforts to identify and limit psychosocial factors that may trigger episodes are important, as is an emphasis on life-style regularity. Antidepressant medications are sometimes required for the treatment of severe breakthrough depressions, but their use should generally be avoided during maintenance treatment because of the risk of precipitating mania or accelerating the cycle frequency. Loss of efficacy over time may be observed with any of the mood-stabilizing agents. In such situations, an alternative agent or combination therapy is usually helpful.

Consensus guidelines for the treatment of acute mania and bipolar depression are described inTable 385-12.

SOMATOFORM DISORDERS

CLINICAL MANIFESTATIONS

Patients with multiple somatic complaints that cannot be explained by a known medical condition or by the effects of alcohol or of recreational or prescription drugs are seen commonly in primary care practice; one survey indicates a prevalence of 5%. The somatoform disorders include a variety of conditions that differ in terms of the specific symptoms that are present and in whether or not the symptoms are intentionally produced. In *somatization disorder*, the patient presents with multiple physical complaints referable to different organ systems (Table 385-13). Onset is usually before age 30, and the disorder is persistent. Formal diagnostic criteria require the recording of at least four pain, two gastrointestinal, one sexual, and one pseudoneurologic symptom. Patients with somatization disorder often present with dramatic complaints, but the complaints are inconsistent. Symptoms of comorbid anxiety and mood disorder are common and may be the result of drug interactions due to regimens initiated independently by different physicians. Patients with somatization disorder may be impulsive and demanding and frequently qualify for a formal comorbid psychiatric diagnosis. In *conversion disorder*, the symptoms focus on deficits that involve voluntary motor or sensory function and on psychological factors that initiate or exacerbate the medical presentation. Like somatization disorder, the deficit is not intentionally produced or simulated, as is the case in factitious disorder (malingering). In *hypochondriasis*, the essential feature is a belief of serious medical illness that persists despite reassurance and appropriate medical evaluation. As with somatization disorder, patients with hypochondriasis have a history of poor relationships with physicians stemming from their sense that they have been evaluated and treated inappropriately or inadequately. Hypochondriasis can be disabling in intensity and is persistent, with waxing and waning symptomatology.

In *factitious illnesses*, the patient consciously and voluntarily produces physical symptoms of illness. The term *Munchausen's syndrome* is reserved for individuals with particularly dramatic, chronic, or severe factitious illness. In true factitious illness, the sick role itself is gratifying. A variety of signs, symptoms, and diseases have been either simulated or caused by factitious behavior, the most common including chronic diarrhea, fever of unknown origin, intestinal bleeding or hematuria, seizures, and hypoglycemia. Factitious disorder is usually not diagnosed until 5 to 10 years after its onset, and it can produce significant social and medical costs. In *malingering*, the fabrication derives from a desire for some external reward, such as a narcotic medication or disability reimbursement.

TREATMENT

Patients with somatization disorders are frequently subjected to multiple diagnostic testing and exploratory surgeries in an attempt to find their "real" illness. Such an approach is doomed to failure and does not address the core issue. Successful treatment is best achieved through behavior modification, in which access to the physician is tightly regulated and adjusted to provide a sustained and predictable level of support that is less clearly contingent on the patient's level of presenting distress. Visits can be brief and should not be associated with a need for a diagnostic or

treatment action. Although the literature is limited, some patients with somatization disorder may benefit from antidepressant treatment. Fluoxetine andMAOIshave both been found to be useful in reducing obsessive ruminations, dysphoria, and anxious preoccupation in patients with multiple somatic complaints.

The treatment of factitious disorder is complicated in that any attempt to confront the patient usually only creates a sense of humiliation and causes the patient to abandon treatment from that caregiver. A better strategy is to introduce psychological causation as one of a number of possible explanations and to include factitious illness as an option in the differential diagnoses that are discussed. Without directly linking psychotherapeutic intervention to the diagnosis, the patient can be offered a face-saving means by which the pathologic relationship with the health care system can be examined and alternative approaches to life stressors developed.

PERSONALITY DISORDERS

CLINICAL MANIFESTATIONS

Personality disorders are characteristic patterns of thinking, feeling, and interpersonal behavior that are relatively inflexible and cause significant functional impairment or subjective distress for the individual. The observed behaviors are not secondary to another mental disorder, nor are they precipitated by substance abuse or a general medical condition. This distinction is often difficult to make in clinical practice, as personality change may be the first sign of serious neurologic, endocrine, or other medical illness. Patients with frontal lobe tumors, for example, can present with changes in motivation and personality while the results of the neurologic examination remain within normal limits. Personality traits are stable over time and environmental situation and are recognizable in adolescence or early adult life. AlthoughDSM-IVportrays personality disorders as qualitatively distinct categories, there is an alternative perspective that personality characteristics vary as a continuum between normal functioning and formal mental disorder.

Personality disorders have been grouped into three clusters that share similar attributes. *Cluster A* includes paranoid, schizoid, and schizotypal personality disorders. It includes individuals who are odd and eccentric and who maintain an emotional distance from others. Individuals have a restricted emotional range and remain socially isolated. Patients with schizotypal personality disorder frequently have unusual perceptual experiences and express magical beliefs about the external world. The essential feature of paranoid personality disorder is a pervasive mistrust and suspiciousness of others to an extent that is unjustified by available evidence. *Cluster B* disorders include antisocial, borderline, histrionic, and narcissistic types and describe individuals whose behavior is impulsive, excessively emotional, and erratic. *Cluster C* incorporates avoidant, dependent, and obsessive-compulsive personality types; enduring traits are anxiety and fear. The boundaries between cluster types are to some extent artificial, and many patients who meet criteria for one personality disorder also meet criteria for aspects of another. The risk of a comorbid major mental disorder is increased in patients who qualify for a diagnosis of personality disorder.

TREATMENT

Historically, recommended treatment for personality disorders was long-term psychotherapy, in which the pathologic patterns of interaction with the world at large could be relived and examined through the corrective emotional experience of the controlled therapeutic relationship. More recently, the recognition that personality derives in part from biologically determined components of temperament has given rise to the empirical use of drugs to treat specific symptom clusters as well as any coexisting major mental disorder. Antidepressant medications and low-dose antipsychotic drugs have some efficacy in cluster A personality disorders, while anticonvulsant mood-stabilizing agents andMAOIsmay be considered for patients with cluster B diagnoses who show marked mood reactivity, behavioral dyscontrol, and/or rejection hypersensitivity. Anxious or fearful cluster C patients often have a response to medication that parallels that for patients with axis I anxiety disorders. In all cases, it is important for both the physician and the patient to have reasonable expectations as to the possible effect of the medication and any associated side effects. Beneficial responses may be subtle and observable only over time.

SCHIZOPHRENIA

CLINICAL MANIFESTATIONS

Schizophrenia is a heterogeneous syndrome characterized by perturbations of language, perception, thinking, social activity, affect, and volition. There are no pathognomonic features. The syndrome commonly begins in late adolescence, has an insidious onset, and, classically, a poor outcome, progressing from social withdrawal and perceptual distortions to a state of chronic delusions and hallucinations. Patients may present with positive symptoms (such as conceptual disorganization, delusions, or hallucinations) or negative symptoms (loss of function, anhedonia, decreased emotional expression, impaired concentration, and diminished social engagement) and must have at least two of these for a 1-month period and continuous signs for at least 6 months to meet formal diagnostic criteria. "Negative" symptoms predominate in one-third of the schizophrenic population and are associated with a poor long-term outcome and a poor response to drug treatment. However, marked variability in the course and individual character of symptoms is typical.

Schizophrenia can be classified according to the specific symptomatology present, although such distinctions do not correlate well with either course of illness or response to treatment, and many individuals have symptoms of more than one type. The four main symptom subtypes are catatonic, paranoid, disorganized, and residual. *Catatonic-type* describes patients whose clinical presentation is dominated by profound changes in motor activity, negativism, and echolalia or echopraxia. *Paranoid-type* describes patients who have a prominent preoccupation with a specific delusional system and who otherwise do not qualify as having *disorganized-type* disease, in which disorganized speech and behavior are accompanied by a superficial or silly affect. In *residual-type* disease, negative symptomatology exists in the absence of delusions, hallucinations, or motor disturbance. The diagnosis of *schizophreniform disorder* is reserved for patients who meet the symptom requirements but not the duration requirements for schizophrenia, and that of *schizoaffective disorder* is used for those whose symptoms of schizophrenia are independent of associated periods of mood

disturbance. Prognosis depends not on symptom severity but on the response to antipsychotic medication. Patients may present with acute rather than insidious onset of symptoms, and remission without recurrence does occur. About 10% of schizophrenic patients commit suicide. As currently defined, schizophrenia is present in 0.85% of individuals worldwide. Overall, lifetime prevalence is approximately 1 to 1.5%.

The societal costs of schizophrenia are substantial. An estimated 300,000 episodes of acute schizophrenia occur annually, resulting in direct and indirect costs that have been estimated at >$33 billion.

DIFFERENTIAL DIAGNOSIS

For a diagnosis of schizophrenia to be made, the symptom complex must cause significant dysfunction in social or occupational domains and last for at least 6 months. The diagnosis is principally one of exclusion, requiring the absence of significant associated mood symptoms, any relevant medical condition, and substance abuse. Drug reactions that cause hallucinations, paranoia, confusion, or bizarre behavior may be dose-related or idiosyncratic; b-adrenergic blockers, clonidine, cycloserine, quinacrine, and procaine derivatives are most commonly associated with these symptoms. Drug causes should be ruled out in any case of newly emergent psychosis. The general neurologic examination in patients with schizophrenia is usually normal, but motor rigidity, tremor, and dyskinesias are noted in one-quarter of untreated patients.

EPIDEMIOLOGY AND PATHOPHYSIOLOGY

Epidemiologic surveys identify three principal risk factors for schizophrenia: (1) genetic susceptibility, (2) early developmental insults, and (3) winter birth. Family, twin, and adoption studies show that genetic factors are involved in at least a subset of individuals who develop schizophrenia. Using conservative diagnostic definitions, schizophrenia is observed in approximately 6.6% of all first-degree relatives of an affected proband. If both parents are affected, the risk for offspring is 40%. The concordance rate for monozygotic twins is 50%, compared to 10% for dizygotic twins. Examination of families in which aggregation of schizophrenia occurs has revealed an increased incidence of other psychotic and nonpsychotic psychiatric disorders as well, including schizoaffective disorder and *schizotypal* and *schizoid personality disorders*, the latter terms designating individuals who show a lifetime pattern of social and interpersonal deficits characterized by an inability to form close interpersonal relationships, eccentric behavior, and mild perceptual distortions. Some relatives and individuals with schizophrenia have been found to have distinctive patterns in expressing emotion, most often involving increased criticism, hostility, and emotional overinvolvement.

There is evidence that environmental influences modulate genetic factors in the expression of schizophrenia, and, in sporadic cases, may serve as a sufficient cause. Gestational and birth complications, including Rh factor incompatibility, prenatal exposure to influenza during the second trimester, and prenatal nutritional deficiency have been implicated. Studies of monozygotic twins discordant for schizophrenia have reported neuroanatomic differences between affected and unaffected siblings, supporting a "two-strike" etiology involving both genetic susceptibility and an environmental insult. The latter might involve localized hypoxia during critical stages of

brain development.

Neuroimaging and postmortem studies have identified a number of structural and functional abnormalities, including (1) enlargement of the lateral and third ventricles with associated cortical atrophy and sulcal enlargement; (2) volumetric reductions in the amygdala, hippocampus, right prefrontal cortex, and thalamus; (3) altered asymmetry of the planum temporale; and (4) decreases in neuronal metabolism in the thalamus and prefrontal cortex. Some, but not all, prospective studies record progressive reduction in hemispheric volume over years. Neuropathologic studies have reported changes in the size, orientation, and density of cells in the hippocampus and, in the prefrontal cerebral cortex, decreases in neuronal number and the density of interneurons in layer II as well as an increased density of pyramidal cells in layer V. These observations suggest that schizophrenia results from a disturbance in a cortical striatal-thalamic circuit resulting in deficits in sensory filtering and attentional behavior. Although the formal diagnostic requirements for schizophrenia are not usually met until early adult life, children who eventually develop the disorder may exhibit subtle deficits in motor function, cognition, and emotional expression from an early age.

The hypothesized alterations in cortical neuronal circuitry are paralleled clinically by impairments in attention and cortical information processing, autonomic nervous system activation, and habituation. Schizophrenic individuals are highly distractible and demonstrate deficits in perceptual-motor speed, ability to shift attention, and filtering out of background stimuli. Event-related evoked potential studies of schizophrenia have defined a specific reduction in P300 amplitude to a novel stimulus, which implicates an impairment in cognitive processing. Impaired information processing is found in unaffected family members.

Despite evidence for a genetic causation, the results of molecular genetic linkage studies in schizophrenia are inconclusive. Reports of linkage of schizophrenia to loci on chromosomes 1, 5, 6, 8, 11, and 22 and other regions have not been formally replicated and have led to larger scale association studies currently underway.

The *dopamine hypothesis* of schizophrenia is based on the serendipitous discovery that agents that diminish dopaminergic activity have beneficial effects in reducing the acute symptoms and signs of psychosis, specifically agitation, anxiety, and hallucinations. Amelioration of delusions and social withdrawal is less dramatic. Thus far, however, evidence for increased dopaminergic activity is indirect. An increase in the activity of nigrostriatal and mesolimbic systems and a decrease in mesocortical tracts innervating the prefrontal cortex is hypothesized, although it is likely that other neurotransmitters, including serotonin, acetylcholine, glutamate, andGABAalso contribute to the pathophysiology of the illness. Involvement of excitatory amino acids is postulated, based on the finding that NMDA receptor antagonists and channel blockers, such as phencyclidine (PCP) and ketamine, produce characteristic signs of schizophrenia in normal individuals.

TREATMENT

Antipsychotic agents (Table 385-14) remain the cornerstone of acute and maintenance treatment of schizophrenia and are effective in the treatment of hallucinations,

delusions, and thought disorders, regardless of etiology. The exact mechanism of action remains incompletely understood, but dopaminergic receptor blockade in the limbic system and basal ganglia appears to be an essential element, since the clinical potencies of traditional antipsychotic drugs parallel their affinities for the D_2receptor, and even the newer "atypical" agents exert some degree of D_2receptor blockade. All neuroleptics induce expression of the immediate-early gene c-*fos* in the nucleus accumbens, a dopaminergic site connecting prefrontal and limbic cortices. The clinical efficacy of newer atypical neuroleptics, however, may involve D_1, D_3, and D_4receptor blockade,a_1- anda_2-noradrenergic activity, and/or altering the relationship between $5HT_2$ and D_2receptor activity.

Conventional neuroleptics differ in their potency and side-effect profile. Older agents, such as chlorpromazine and thioridazine, are more sedating and anticholinergic and more likely to cause orthostatic hypotension, while higher potency antipsychotics, such as haloperidol, perphenazine, and thiothixene, carry a higher risk of inducing extrapyramidal side effects. The model atypical antipsychotic agent is clozapine, a dibenzodiazepine that has a greater potency in blocking the $5HT_2$than the D_2receptor and a much higher affinity for the D_4 than the D_2receptor. Its principal disadvantage is risk of blood dyscrasia, requiring regular monitoring of theCBC. Unlike other antipsychotics, clozapine does not cause a rise in prolactin level. Approximately 30% of patients have a better antipsychotic response to these agents than to traditional neuroleptics, suggesting that they will increasingly displace the older-generation drugs. Clozapine appears to be the most effective member of this class; however, its side-effect profile makes it most appropriate for treatment-resistant cases. *Clozapine* increases the activity of the immediate-early gene c-*fos* in the prefrontal cortex, the neuroanatomic region having the highest concentration of D_4receptors and an area thought to mediate the specific executive functions that are prominently impaired in schizophrenia. *Risperidone*, a benzisoxazole derivative, is more potent at $5HT_2$than D_2receptor sites, like clozapine, but it also exerts significant$a_2$antagonism, a property that may contribute to its perceived ability to improve mood and increase motor activity. Risperidone is not as effective as clozapine in treatment-resistant cases but does not carry a risk of blood dyscrasia. *Olanzapine* is more similar neurochemically to clozapine but has a significant risk of inducing weight gain. *Quetiapine* is distinct in having a weak D_2effect but potenta_1 and histamine blockade.

Conventional antipsychotic agents are effective in ~70% of patients presenting with a first episode. Improvement may be observed within hours or days, but full remission usually requires 6 to 8 weeks. The choice of agent depends principally on the side-effect profile and cost of treatment or on a past personal or family history of a favorable response to the drug in question. Atypical agents appear to be more effective in treating negative symptoms and improving cognitive function. Equivalent treatment response can usually be achieved with relatively low doses of any drug selected, i.e., 4 to 6 mg/d of haloperidol, 10 to 15 mg of olanzapine, or 4 to 6 mg/d of risperidone. Doses in this range result in>80% D_2receptor blockade, and there is little evidence that higher doses increase either the rapidity or degree of response. Maintenance treatment requires careful attention to the possibility of relapse and monitoring for the development of a movement disorder. Intermittent drug treatment is less effective than regular dosing, but gradual dose reduction is likely to improve social functioning in many schizophrenic patients who have been maintained at high doses. If medications are completely

discontinued, however, the relapse rate is ~60% within 6 months. Long-acting injectable preparations (haloperidol decanoate and fluphenazine decanoate) are considered when noncompliance with oral therapy leads to relapses. In treatment-resistant patients, a transition to clozapine usually results in rapid improvement, but a prolonged delay in response in some cases necessitates a 6- to 9-month trial for maximal benefit to occur.

Antipsychotic medications can cause a broad range of side effects, including lethargy, weight gain, postural hypotension, constipation, and dry mouth. Extrapyramidal symptoms such as dystonia, akathisia, and akinesia are also frequent with traditional agents and may contribute to poor compliance if not specifically addressed. Anticholinergic and parkinsonian symptoms respond well to trihexyphenidyl, 2 mg bid, or benztropine mesylate, 1 to 2 mg bid. Akathisia may respond to beta blockers. In rare cases, more serious and occasionally life-threatening side effects may emerge, including ventricular arrhythmias, gastrointestinal obstruction, retinal pigmentation, obstructive jaundice, and neuroleptic malignant syndrome (characterized by hyperthermia, autonomic dysfunction, muscular rigidity, and elevated creatine phosphokinase levels). The most serious adverse effects of clozapine are agranulocytosis, which has an incidence of 1%, and induction of seizures, which has an incidence of 10%. Weekly white blood cell counts are required, particularly during the first 3 months of treatment.

A serious side effect of long-term use of the classic antipsychotic agents is *tardive dyskinesia*, characterized by repetitive, involuntary, and potentially irreversible movements of the tongue and lips (bucco-linguo-masticatory triad), and, in approximately half of cases, choreoathetoid movements of the limbs (Chap. 22). Tardive dyskinesia has an incidence of ~4% per year of exposure, and a maximal prevalence of ~20% in chronic patients treated with high-dose neuroleptics. The risk associated with the newer atypical agents is unknown but expected to be much less. The prevalence increases with age and with total dose and duration of drug administration, but unknown individual factors play the greatest part in determining risk. The cause of tardive dyskinesia is unknown, but evidence suggests that chronic neuroleptic treatment increases the formation of free radicals and perhaps damages mitochondrial energy metabolism. Vitamin E may reduce abnormal involuntary movements if given early in the syndrome.

Drug treatment of schizophrenia is by itself insufficient. Psychoeducational efforts directed towards families and relevant community resources have proven to be necessary to maintain stability and optimize prognosis. A treatment model involving a multidisciplinary case-management team that seeks out and closely follows the patient in the community has proven particularly effective, not only in maintaining pharmacologic adherence but also in facilitating occupational achievement and interactions with welfare, legal, and primary medical care systems.

ASSESSMENT AND EVALUATION OF VIOLENCE

Primary care physicians may encounter situations in which familial, domestic, or societal violence is discovered or suspected. Such an awareness can carry legal and moral obligations; many state laws mandate reporting of child, spousal, and elder abuse. Physicians are frequently the first point of contact for both victim and abuser. Between 1

and 2 million older Americans and 1.5 million U.S. children are thought to experience some form of physical maltreatment each year. Spousal abuse is thought to be even more prevalent. A recent survey of internal medicine practices found that 5.5% of all female patients had experienced domestic violence in the previous year, and that these individuals were more likely to suffer from depression, anxiety, somatization disorder, and substance abuse and to have attempted suicide. When domestic violence is suspected, direct but nonjudgmental questioning should be pursued with each party separately -- "Do you feel safe at home?" and "If there's a disagreement or a conflict between the two of you, how is it worked out?" In addition to obvious and suggestive physical injury, individuals who are abused frequently express low self-esteem, vague somatic symptomatology, social isolation, and a passive feeling of loss of control. Although it is essential to treat these elements in the victim, the first obligation is to ensure that the perpetrator has taken responsibility for preventing any further violence. Substance abuse and/or dependence and serious mental illness in the abuser may contribute to the risk of harm and require direct intervention. Depending on the situation, law enforcement agencies, community resources such as support groups and shelters, and individual and family counseling can be appropriate components of a treatment plan. A safety plan should be formulated with the victim, in addition to the provision of information about abuse, its likelihood of recurrence, and its tendency to increase in severity and frequency. Antianxiety and antidepressant medications may sometimes be useful in treating the acute symptoms, but only if independent evidence for an appropriate psychiatric diagnosis exists. Antidepressants are generally not indicated when the diagnosis is linked to the social situation, such as an adjustment disorder with depressed mood. The most important element in treatment is the development of a supportive doctor-patient relationship that avoids further blame of the victim.

In certain circumstances, a significant potential for societal violence may be discovered. Sympathetic, but direct, questioning about potential violent impulses, access to weapons, recreational drug use, and specific homicidal ideation is necessary and is sometimes therapeutic in its own right. The existence and possible contribution of such medical conditions as delirium and/or intoxication should be evaluated. Available disposition options for potentially violent patients include police custody, psychiatric hospitalization, and referral to home care, with involvement of family, friends, and caregivers. In deciding which treatment option is most appropriate, clinicians should endeavor to establish an empathic interaction with the patient, while avoiding interventions or stimuli that might precipitate or increase the risk of violent behavior. Formal verbal limit setting may be necessary if the patient reveals the existence of a weapon or becomes increasingly agitated or verbally abusive. Use of the least restrictive intervention is generally the best approach during the initial evaluation.

MENTAL HEALTH PROBLEMS IN THE HOMELESS

There is a high prevalence of mental disorders and substance abuse among homeless and impoverished people. The total number of homeless individuals in the United States is estimated at 2 to 3 million, one-third of whom qualify as having a serious mental disorder. Poor hygiene and nutrition, substance abuse, psychiatric illness, physical trauma, and exposure to the elements combine to make the provision of medical care a challenging enterprise. Only a minority of individuals receive formal mental health care; the main points of contact are outpatient medical clinics and emergency departments.

Primary care settings represent a critical site in which housing needs, treatment of substance dependence, and evaluation and treatment of psychiatric illness can most efficiently take place. Successful intervention is dependent on breaking down traditional administrative barriers to health care and recognizing the physical constraints and emotional costs imposed by homelessness. Simplifying health care instructions and follow-up, allowing frequent visits, and dispensing medications in limited amounts that require ongoing contact are possible techniques for establishing a successful therapeutic relationship. Child neglect, resulting in developmental delay and emotional difficulty in addition to other health problems, is unfortunately common and necessitates an effort to evaluate the well being of any offspring independently.

SECTION 6 -ALCOHOLISM AND DRUG DEPENDENCY

386. BIOLOGY OF ADDICTION - *Robert O. Messing*

Drug addiction is a chronic, relapsing disorder characterized by compulsion to take a drug and loss of self-control in limiting drug intake. The American Psychiatric Association (*DSM-IV*) uses the term *substance dependence* instead of drug addiction and requires at least three of the following symptoms to be present for diagnosis: (1) tolerance; (2) withdrawal; (3) persistent desire or unsuccessful attempts to reduce use; (4) use in larger amounts than intended; (5) reduction in important social, occupational, or recreational activities because of drug use; (6) considerable time spent obtaining the substance; and (7) continued use despite health, social, or economic problems resulting from substance use. *Substance abuse* is a milder disorder characterized by repetitive drug use that results in social or economic distress. Experimental studies in humans and in animal models (rodents and also simpler organisms such as flies and worms) have begun to elucidate the cellular and molecular mechanisms that mediate the loss of control in drug taking that is the hallmark of addiction. This chapter will review current understanding of the neurobiology of drug abuse relevant to the specific substances discussed in subsequent chapters, namely alcohol (Chap. 387), opioids (Chap. 388), cocaine and marijuana (Chap. 389), and nicotine (Chap. 390).

BEHAVIORAL RESPONSES TO DRUGS OF ABUSE

Drugs of abuse produce *euphoria*, which is an emotional state characterized by intensely pleasant feelings. A major reason why users are motivated to seek and take more of a drug is because they perceive the experience as *rewarding*. *Reinforcement* refers to the ability of a drug to produce a pleasurable response that motivates the user to take the drug repeatedly. The powerful reinforcing and rewarding properties of abusable drugs can be measured by the tremendous effort experimental animals will expend, e.g., by pressing a lever multiple times, to obtain an oral or intravenous dose of a drug.

Tolerance is a reduction in response to a drug after repeated use and is a normal, adaptive, physiologic response. *Pharmacokinetic tolerance* may arise through an increase in the rate of metabolism. For example, barbiturates induce hepatic microsomal enzymes resulting in more rapid metabolism. *Pharmacodynamic tolerance* results from drug-induced changes in cell signaling and gene expression. Behavioral *sensitization* is a process whereby repeated administration of a drug leads to a progressively stronger behavioral response. Sometimes called "reverse tolerance," it is often measured by examining drug-induced locomotor activation. It generally requires longer intervals between doses to develop than does tolerance. Both tolerance and sensitization can promote repeated drug use. Tolerance develops to the rewarding properties of most abusable drugs, requiring the user to employ higher doses to achieve a euphoric effect. Sensitization also promotes drug self-administration, since rodents will expend greater effort in lever-pressing for drugs to which they are sensitized.

Physical dependence is an adaptive state that develops through resetting of homeostatic mechanisms to permit normal function despite the continued presence of a drug. When drug intake is abruptly terminated in a physically dependent individual, a

withdrawal syndrome emerges. The symptoms of withdrawal tend to be opposite to those seen during acute drug exposure. Thus, abstinence from alcohol and other sedative-hypnotics causes nervous system hyperactivity, whereas withdrawal from cocaine and other stimulants is characterized by fatigue, sedation, and depression. Withdrawal symptoms are the principal evidence for physical dependence. Like tolerance, physical dependence is a normal physiologic response to repeated drug exposure and does not necessarily indicate drug abuse or addiction. However, withdrawal can cause intensely negative, unpleasant emotions such as dysphoria, anxiety, and irritability. In animal studies employing intracranial self-stimulation, withdrawal is also associated with reduced brain reward function. Thus, it appears that drug withdrawal can act as a negative reinforcer that contributes to repeated drug use.

Human patients prescribed opioids for treatment of pain may develop tolerance and physical dependence but rarely become addicted. Likewise, in experimental animals, establishing physical dependence is not sufficient to induce voluntary drug self-administration. Instead, it appears that animals and humans seek abusable drugs mainly for their positive reinforcing properties. In susceptible persons, repeated use of abusable drugs induces drug *craving*, a powerful motivational state in which the addict seeks the drug to the exclusion of other activities. Craving is a manifestation of *psychological dependence* on a drug and is most severe during acute abstinence. It is a long-lasting, conditioned response that may be evoked by environmental cues such as sights, smells, or situations associated with previous drug use, even after long periods of drug abstinence. Understanding the mechanisms that underlie susceptibility to drug craving is a critical task in addiction research.

GENETIC FACTORS IN ADDICTION

Genetic factors have been studied most extensively in alcoholism (Chap. 387). Patterns of inheritance in humans are most consistent with alcoholism being a polygenic disorder. Some genes confer a reduced risk for alcoholism. Approximately half of all individuals in Asian populations carry an allele of aldehyde dehydrogenase that encodes an isozyme with reduced enzymatic activity. After ingesting alcohol, they have increased blood levels of acetaldehyde and experience vasodilatation, tachycardia, hot sensations, and hypotension. They also report feeling intoxicated at very low doses of alcohol. Individuals expressing this isoenzyme rarely abuse alcohol. Other genetic factors predispose individuals to increased risk for alcoholism. A recent multicenter study of 105 families of alcoholics revealed evidence for susceptibility loci for alcohol dependence on chromosomes 1, 7, and possibly 2. An additional study of a Southwestern Native American population found evidence for genetic linkage to alcohol dependence on chromosomes 4 and 11. The identity of the genes associated with increased risk is not yet known.

NEUROANATOMY OF DRUG REWARD

Early studies of intracranial electrical self-stimulation in rodents identified key structures involved in drug reward and motivational aspects of drug dependence (Fig. 386-1). These include the midbrain ventral tegmental area (VTA), median forebrain bundle (MFB), nucleus accumbens, medial frontal cortex, amygdala, and lateral hypothalamus. Many of these structures are key components of a *mesocorticolimbic dopamine system*

that is now a principal focus of addiction research. Dopaminergic neurons in the VTA project axons via the MFB to the nucleus accumbens, amygdala, and frontal cortex. Reciprocal projections from g-aminobutyric acid (GABA)-containing neurons in the nucleus accumbens project back through the MFB onto VTA neurons. Other brain regions modulate this system through opioid peptide, GABA, serotonin, and glutamate inputs that interact with the VTA, nucleus accumbens, and other structures within the system.

Certain nuclei within the mesocorticolimbic dopamine system share similarities in architecture, receptor expression, and connectivity with other brain regions. These related structures reside in the basal forebrain and include the central medial amygdala, bed nucleus of the stria terminalis, and shell of the nucleus accumbens. They appear to constitute a functional entity that has been called the "extended amygdala." The extended amygdala receives inputs from the hippocampus, basolateral amygdala, midbrain, and lateral hypothalamus and sends efferents to the ventral pallidum, VTA, and lateral hypothalamus.

MOLECULAR TARGETS OF ABUSED DRUGS

Dopamine released from presynaptic terminals of VTA neurons in the nucleus accumbens is a major mediator of drug reward and reinforcement (Fig. 386-2*A*). Acute administration of all abusable drugs increases extracellular levels of dopamine in the shell of the nucleus accumbens. In addition, dopamine receptor antagonists injected into this region reduce drug self-administration in animals. Dopamine binds to a family of five G protein-coupled, seven-transmembrane receptors that can be grouped into two major classes, D_1-like (D_1 and D_5 receptors) and D_2-like (D_2, D_3, and D_4 receptors). D_1-like receptors activate adenylyl cyclase by coupling to the stimulatory G protein G_s, whereas D_2-like receptors inhibit adenylyl cyclase by coupling to inhibitory G_i proteins. Despite opposing actions on adenylyl cyclase, both classes of dopamine receptors appear to mediate drug reinforcement. Experimental animals will self-administer D_1-like and D_2-like receptor agonists, and antagonists of D_1, D_2, and D_3 receptors decrease the reinforcing properties of cocaine. These receptor-specific responses most likely result from dopamine actions on different subpopulations of cells in the nucleus accumbens.

Opioids, nicotine, psychostimulants, barbiturates, benzodiazepines, and cannabinoids elicit their acute behavioral effects by binding to specific seven-transmembrane neurotransmitter receptors (opioids and cannabinoids), neurotransmitter receptor-gated ion channels (nicotine, barbiturates, and benzodiazepines), or transporters (cocaine and amphetamines) on the plasma membrane of neuronal cells (Fig. 386-2). Ethanol interacts with several signaling proteins including serotonin 5HT-3 receptors, nicotinic receptors, voltage-gated calcium channels, and sodium-independent purine transporters, but $GABA_A$ receptors and the *N*-methyl-D-aspartate (NMDA) subtype of glutamate receptors appear to be most sensitive to intoxicating concentrations of ethanol. As discussed below, drug actions at these targets lead to elevation of extracellular dopamine levels in the nucleus accumbens. This appears to be extremely important for the reinforcing properties of psychostimulants. For several other drugs of abuse, dopamine-independent pathways also contribute.

Dopamine Transporter Much evidence indicates that the rewarding properties of

cocaine and amphetamine are due primarily to their ability to elevate extracellular dopamine levels in the nucleus accumbens. Specific populations of neurons within the nucleus accumbens are activated during cocaine self-administration in rodents. In addition, selective destruction of dopaminergic terminals within the nucleus accumbens or administration of dopamine receptor antagonists into that region eliminates cocaine self-administration. Cocaine and amphetamines act by altering transport of dopamine through plasma membrane dopamine transporters (DATs) in presynaptic nerve terminals (Fig. 386-2*A*). Reuptake of dopamine through DATs is the major mechanism for termination of dopaminergic neurotransmission. DAT is a 12-transmembrane glycoprotein and a member of the large sodium- and chloride-dependent transporter family, which also includes carriers forGABA, glycine, serotonin, norepinephrine, and other organic molecules. Cocaine binds to DATs and inhibits dopamine reuptake. Amphetamine causes intracellular release of dopamine from vesicles and reverse transport of dopamine through DATs. These actions serve to elevate levels of extracellular dopamine at dopaminergic synapses.

Recent studies of mice lacking theDAT gene have revealed redundancy in systems mediating cocaine reinforcement. Psychostimulants fail to alter extracellular dopamine levels or induce locomotor activity in these mice. However, DAT-null mice can still be trained to press a lever to receive intravenous cocaine, suggesting that other genes can also mediate the reinforcing properties of cocaine. In addition to inhibiting DAT function, cocaine blocks reuptake of serotonin and norepinephrine. In DAT-null mice, residual binding of a cocaine analogue can be displaced by serotonin reuptake inhibitors, and cocaine stimulates neurons in brain regions with a high density of serotonergic fibers. Therefore, inhibition of serotonin uptake through plasma membrane serotonin transporters may also contribute to psychostimulant reward.

$GABA_A$Receptors The major inhibitory neurotransmitter in the nervous system isGABA. Binding of GABA to $GABA_A$receptors activates a Cl^- current that is enhanced by benzodiazepines, barbiturates, and ethanol (Fig. 386-2*B*). Activation of this current maintains the neuronal plasma membrane close to its resting potential and thereby inhibits the generation of action potentials. $GABA_A$receptors appear to be pentameric membrane glycoproteins composed ofa, b,g, and possibly d peptide subunits. Fifteen subunits are known to be expressed in the mammalian central nervous system (six a, threeb, three g, oned, one e, oneq) and RNA splice variants have been identified. In rodents, the $GABA_A$receptor agonist muscimol substitutes for ethanol in tests of drug discrimination; when injected into the nucleus accumbens, muscimol terminates ethanol self-administration. These results suggest that the reinforcing properties of ethanol are mediated in part by ethanol's actions at $GABA_A$receptors in the nucleus accumbens.

NMDA Receptors In the nervous system, excitatory synaptic activity evoked by glutamate and aspartate is mediated by neurotransmitter receptor-gated ion channels (ionotropic receptors) that regulate cation conductances and by G protein-coupled receptors (metabotropic receptors) that stimulate phosphoinositide hydrolysis. Ionotropic glutamate receptors have been subclassified based on activation by selective agonists into three groups:NMDAreceptors, high-affinity kainate receptors, anda-amino-3-hydroxy-5-methyl-4-isoxazole propionic acid (AMPA) receptors. There is a rich glutamatergic projection from neurons in the frontal cortex to the nucleus accumbens where fibers terminate mainly on medium spiny GABA-ergic neurons.

NMDA receptors in the nucleus accumbens appear to play a role in the rewarding properties of several drugs. Thus, phencyclidine and other NMDA antagonists have rewarding actions when administered in the nucleus accumbens. The rewarding properties of ethanol may also be partly due to inhibition of NMDA-activated calcium currents. In addition, NMDA receptors modulate responses to psychostimulants since administration of the NMDA receptor antagonist MK-801 prior to cocaine or amphetamine prevents sensitization to these drugs.

Nicotinic Receptors Like other drugs of abuse, nicotine elicits dopamine release in the nucleus accumbens, and intravenous self-administration of nicotine is blocked by dopamine antagonists and by neurochemical lesions that destroy dopaminergic fibers in the nucleus accumbens. Nicotine increases dopamine release by activating nicotinic acetylcholine receptors (nAChRs) on cell bodies and nerve terminals of dopaminergicVTAneurons. Neuronal nAChRs are receptor-gated ion channels that allow entry of sodium into cells when acetylcholine is present. They appear to be pentameric complexes composed of different combinations of at least 10 different subunits. Targeted disruption of the$\beta_2$subunit gene eliminates most high-affinity nicotine binding in the brain and prevents nicotine-induced dopamine release in the nucleus accumbens. In addition, mice that lack the$\beta_2$subunit show attenuated nicotine self-administration, indicating thatβ_2-containing nAChRs mediate the reinforcing properties of nicotine.

Opioid Receptors Morphine and other opioids activate opioid receptors, which are a family of seven-transmembrane, G protein-coupled receptors (Figs. 386-2*C* and 386-3). Three classes, u,d, and k, have been identified. The rewarding action of opioids appears to be mediated by activation of u receptors since opioid reinforcement is blocked by selective u receptor antagonists and by targeted disruption of the u receptor gene. Binding of opioid agonists to u receptors activates the G proteins G_i and G_o. This results in inhibition of adenylyl cyclase, thereby decreasing levels of the intracellular second messenger cyclic AMP and reducing activity of cyclic AMP-dependent protein kinase A (PKA). In addition, these G proteins activate voltage-gated potassium channels and inhibit voltage-gated calcium channels. The net result is suppression of electrical excitability in neurons expressing u receptors.

GABA-containing interneurons in theVTAsuppress firing of dopaminergic VTA neurons that project to the nucleus accumbens. Opioids disinhibit these dopaminergic neurons by binding to u receptors expressed by the GABA-containing interneurons. This increases the firing rate of dopaminergic VTA neurons and promotes dopamine release in the nucleus accumbens. Rodents will self-administer opioids into both the VTA and the nucleus accumbens. Opioid self-administration into the nucleus accumbens occurs even after dopaminergic projections to that region are destroyed. Thus, dopamine-dependent mechanisms involving the VTA and dopamine-independent mechanisms in the nucleus accumbens both contribute to opioid reward.

Opioid receptors also regulate ethanol consumption. Ethanol acutely inhibits opioid binding tod-opioid receptors, and chronic ethanol exposure increases the density of u- and d-opioid receptors. Nonselective opioid antagonists reduce ethanol self-administration in animals. Several regions of the extended amygdala appear to mediate this response, although the central nucleus of the amygdala appears most important. In two independent clinical trials, the opioid receptor antagonist naltrexone, in

combination with counseling, reduced craving and relapse in abstinent alcoholics. Thus, opioid systems appear to modulate ethanol craving in addicted individuals.

Cannabinoid Receptors The active ingredient of cannabis, D_9-tetrahydrocannabinol (D-9-THC), and the endogenous cannabinoid anandamide bind two subtypes of G protein-coupled cannabinoid receptors. Studies with mutant mice lacking the CB_1 receptor gene have revealed that the CB_1 receptor is responsible for the reinforcing properties of cannabinoids. When administered intravenously, D-9-THC increases dopamine levels in the nucleus accumbens. This is blocked by cannabinoid receptor antagonists and by u-opioid receptor antagonists administered into the VTA. Conversely, morphine reinforcement and the severity of opioid withdrawal are reduced in mice that lack CB_1 receptors. These results suggest that opioids and cannabinoids share common signaling pathways in the brain and can interact to promote each other's reinforcing properties.

ADAPTATION TO CHRONIC DRUG USE

Repeated drug exposure elicits changes in neural function that lead to drug dependence and craving. Several mechanisms are being elucidated, including drug-induced alterations in receptor and ion channel function, intracellular signal transduction, gene expression, and synaptic connectivity.

Chronic exposure to drugs of abuse can change the function of receptors and ion channels by altering their density, subunit composition, or coupling to signal transduction cascades. For example, chronic exposure to ethanol increases the density of NMDA receptors and L-type voltage-gated calcium channels in the brain. These changes contribute to neuronal hyperactivity observed during alcohol withdrawal since NMDA and L-type channel antagonists reduce signs of withdrawal in alcohol-dependent rodents deprived of ethanol. In addition, chronic exposure to ethanol decreases $GABA_A$ receptor function and abolishes potentiation by ethanol. Downregulation of $GABA_A$ receptor function contributes to manifestations of alcohol withdrawal since benzodiazepines and barbiturates, which activate $GABA_A$ receptors, are very helpful in reducing alcohol withdrawal symptoms.

Chronic exposure to many drugs of abuse induces adaptive changes in neuronal signal transduction pathways. This has been most clearly demonstrated for opioids, which increase cyclic AMP signaling in the locus coeruleus after chronic administration (Fig. 386-3). The locus coeruleus is the principal adrenergic nucleus in the brain and regulates attention states and the autonomic nervous system. Hyperactivity of this nucleus has been implicated in opioid withdrawal. Chronic opioid exposure increases expression of adenylyl cyclase, PKA, and the cyclic AMP response element binding protein, CREB, which mediates cyclic AMP-dependent gene expression. These changes increase the intrinsic firing rate of neurons in the locus coeruleus, in part through activation of an inward sodium current. Thus, upregulation of cyclic AMP signaling opposes the acute inhibitory action of opioids on this pathway.

Chronic exposure to cocaine, opioids, or ethanol upregulates cyclic AMP-mediated signaling in other brain regions, including the VTA and the nucleus accumbens. Upregulation of cyclic AMP signaling in the nucleus accumbens contributes to

psychostimulant tolerance since pharmacologic inhibition ofPKA or overexpression ofCREB in the nucleus accumbens decreases the rewarding properties of cocaine. Upregulation of cyclic AMP signaling may also account for supersensitivity of neurons in the nucleus accumbens to D_1receptor agonists following chronic cocaine administration. Additional neuroadaptive changes in dopamine signaling can modify drug-seeking behavior in rodents. Rats can be readily trained to voluntarily self-administer intravenous cocaine for several hours. If during a course of self-administration, saline is substituted for cocaine, the rate of self-administration declines dramatically. However, exposure to a single intraperitoneal priming injection of cocaine or a D_2-like receptor agonist causes the animal to resume lever pressing. In contrast, treatment with a D_1-like receptor agonist blocks the ability of cocaine to reinstate drug-seeking behavior. It appears that D_1-like agonists inhibit relapse in drug seeking. Therefore, they may prove to be useful in treatment of cocaine addiction.

A current hypothesis views addiction as a form of learning mediated by maladaptive recruitment of memory systems involving limbic structures. Mechanisms that could contribute to such learned, long-term adaptation include drug-induced gene expression and synaptic reorganization. For example, the transcription factorCREB, which is activated by chronic drug use, has been implicated in models of learning. Repeated exposure to many drugs of abuse also causes prolonged activation of another transcription factor, *Fos*-related antigen, in the nucleus accumbens. Ethanol increases the number of dendritic spines on hippocampal pyramidal cells and somatosensory cortical neurons, whereas amphetamine increases dendritic length and the density of dendritic spines on neurons in the nucleus accumbens and prefrontal cortex. Such drug-induced changes in gene expression and neuronal connectivity could lead to long-term alterations in brain reward pathways that may underlie drug addiction in humans.

387. ALCOHOL AND ALCOHOLISM - *Marc A. Schuckit*

The yearly cost of alcohol-related problems in the United States is as much as $300 billion, including accidents, health problems, lost productivity, crime, and treatment. There are more than 22,000 deaths from alcohol-related auto accidents per year, as well as almost 2 million nonfatal injuries and damage to almost 5 million vehicles. In addition, alcohol is responsible for almost 5% of missed work time, with a 25% decrease in work performance among heavy drinkers. Men and women who fulfill criteria for alcohol use disorders decrease their life span by approximately 15 years, with abuse and dependence responsible for almost 25% of premature deaths in men and 15% in women, figures that represent a three- to sixfold odds ratio of early death even among people with higher levels of education and socioeconomic functioning.

PHARMACOLOGY AND NUTRITIONAL IMPACT OF ETHANOL

Ethanol is a weakly charged molecule that moves easily through cell membranes, rapidly equilibrating between blood and tissues. The effects of drinking depend in part on the amount of ethanol consumed per unit of body weight; the level of alcohol in the blood is expressed as milligrams or grams of ethanol per deciliter (e.g., 100 mg/dL or 0.10 g/dL). A level of 0.02 to 0.03 results from the ingestion of one to two typical drinks. In round figures, 340 mL (12 oz) of beer, 115 mL (4 oz) of nonfortified wine, and 43 mL (1.5 oz) (a shot) of 80-proof beverage each contain approximately 10 g of ethanol; 0.5 L (1 pint) of 86-proof beverage contains approximately 160 g, and 1 L of wine contains approximately 80 g of ethanol. Congeners found in alcoholic beverages may contribute to body damage with heavy drinking; these include low-molecular-weight alcohols (e.g., methanol and butanol), aldehydes, esters, histamine, phenols, tannins, iron, lead, and cobalt.

Ethanol is a central nervous system (CNS) depressant that decreases activity of neurons, although some behavioral stimulation is observed at low blood levels. This drug has cross-tolerance and shares a similar pattern of behavioral problems with other brain depressants, including the benzodiazepines and barbiturates. Alcohol is absorbed from mucous membranes of the mouth and esophagus (in small amounts), from the stomach and large bowel (in modest amounts), and from the proximal portion of the small intestine (the major site). The rate of absorption is *increased* by rapid gastric emptying; by the absence of proteins, fats, or carbohydrates (which interfere with absorption); by the absence of congeners; by dilution to a modest percentage of ethanol (maximum at about 20% by volume); and by carbonation (e.g., champagne).

Between 2% (at low blood alcohol concentrations) and about 10% (at high blood alcohol concentrations) of ethanol is excreted directly through the lungs, urine, or sweat, but the greater part is metabolized to acetaldehyde, primarily in the liver. At least two metabolic routes, each with different optimal concentrations of ethanol (K_m), result in the metabolism of approximately one drink per hour. The most important pathway occurs in the cell cytosol where alcohol dehydrogenase (ADH) produces acetaldehyde, which is then rapidly destroyed by aldehyde dehydrogenase (ALDH) in the cytosol and mitochondria. Each of these steps requires nicotinamide adenine dinucleotide (NAD) as a cofactor, and it is the increased ratio of the reduced cofactor (NADH) to NAD (NADH:NAD) that is responsible for many of the metabolic derangements observed

after drinking. A second pathway occurs in the microsomes of the smooth endoplasmic reticulum (the microsomal ethanol-oxidizing system, or MEOS), which is responsible for 10% or more of ethanol oxidation at high blood alcohol concentrations.

One gram of ethanol has approximately 29.7 kJ (7.1 kcal) of energy, and a drink contains between 293.0 and 418.6 kJ (70 and 100 kcal) from ethanol and other carbohydrates. However, these are "empty" of nutrients such as minerals, proteins, and vitamins. In addition, alcohol interferes with absorption of vitamins in the small intestine and decreases their storage in the liver. These actions affect folate (folacin or folic acid), pyridoxine (B_6), thiamine (B_1), nicotinic acid (niacin, B_3), and vitamin A. Heavy drinking can also produce low blood levels of potassium, magnesium, calcium, zinc, and phosphorus as a consequence of dietary deficiency and acid-base imbalances during excess alcohol ingestion or withdrawal.

An ethanol load in a fasting, healthy individual is likely to produce transient hypoglycemia within 6 to 36 h, secondary to the acute actions of ethanol on gluconeogenesis. This can result in glucose intolerance until the alcoholic has abstained for 2 to 4 weeks. Alcohol ketoacidosis, probably reflecting a decrease in fatty acid oxidation coupled with poor diet or recurrent vomiting, should not be misdiagnosed as diabetic ketosis. With the former, patients show an increase in serum ketones along with a mild increase in glucose but a large anion gap, a mild to moderate increase in serum lactate, and a b-hydroxybutyrate/lactate ratio of between 2:1 and 9:1 (with normal being 1:1).

BEHAVIORAL EFFECTS, TOLERANCE, AND DEPENDENCE

The effects of any drug depend on the dose, the rate of increase in plasma, the concomitant presence of other drugs, and the past experience with the agent. With alcohol, an additional factor is whether blood alcohol levels are rising or falling; the effects are more intense during the former period.

Even though "legal intoxication" requires a blood alcohol concentration of at least 80 to 100 mg/dL, behavioral, psychomotor, and cognitive changes are seen at levels as low as 20 to 30 mg/dL (i.e., after one to two drinks). Deep but disturbed sleep can be seen at twice the legal intoxication level, and death can occur with levels between 300 and 400 mg/dL. Beverage alcohol is probably responsible for more overdose deaths than any other drug.

The intoxicating effects of alcohol appear to be due to actions at specific neurotransmitter receptors and transporters. Alcohol enhances g-aminobutyric acid A ($GABA_A$) receptors, and inhibits *N*-methyl-D-asparate (NMDA) receptors (Chap. 386). In vitro studies suggest that additional effects involve inhibition of adenosine uptake and a translocation of the cyclic AMP-dependent protein kinase catalytic subunit from the cytoplasm to the nucleus. Neurons adapt quickly to these actions, and thus different effects may be present during chronic administration and withdrawal.

At least three types of compensation develop after repeated exposure to the drug, producing tolerance of higher ethanol levels. First, after 1 to 2 weeks of daily drinking, *metabolic or pharmacokinetic tolerance* develops, with a 30% increase in the rate of

hepatic ethanol metabolism. This alteration disappears almost as rapidly as it develops. Second, *cellular or pharmacodynamic tolerance* develops through neurochemical changes that may also contribute to physical dependence. Third, individuals can learn to adapt their behavior so that they can function better than expected under drug influence (*behavioral tolerance*).

The cellular changes caused by chronic ethanol exposure may not resolve for several weeks or longer following cessation of drinking. In the interim, the neurons require ethanol to function optimally, and the individual can be said to be physically dependent. This physical condition is distinct from psychological dependence, a concept indicating that the person is psychologically uncomfortable without the drug.

THE EFFECTS OF ETHANOL ON BODY SYSTEMS

While one to two drinks per day in an otherwise healthy and nonpregnant individual can have some beneficial effects, at higher doses alcohol is toxic to most body systems. Knowledge about the deleterious effects of alcohol helps the practicing physician to identify alcoholic patients. Signs and symptoms of ethanol abuse can be used to help motivate the patient to abstain. It is important to remember that the typical white- or blue-collar alcoholic functions at a fairly high level for years, and that not everyone develops each problem.

CENTRAL NERVOUS SYSTEM

Approximately 35% of drinkers may experience a *blackout*, an episode of temporary anterograde amnesia, in which the person forgets all or part of what occurred during a drinking evening. Another common problem, one seen after as few as one or two drinks, is that while alcohol can help someone to fall asleep, it also "fragments" the sleep pattern causing alterations between sleep stages and a deficiency in deep sleep. At the same time, alcohol diminishes rapid eye movement (REM) or dream sleep early in the evening, with resulting prominent and sometimes disturbing dreams later in the night. Finally, alcohol relaxes muscles in the pharynx, which can cause snoring and exacerbate sleep apnea, with symptoms of the latter in 75% of alcoholic men over age 60.

An additional problem related to the acute effects of alcohol on most drinkers is the impairment in judgment, balance, and motor coordination that contributes to the high incidence and severity of accidents. At least half of individuals who experience severe physical trauma in an accident have evidence of substance-related impairment, a finding that is consistent with the fact that 40% of drinkers in the United States have at some time driven while intoxicated with alcohol and that 15% of flight crews have evidence of repeated heavy drinking. Regarding the latter, at least one study noted that pilot performance is still impaired 14 h after a blood alcohol concentration of 100 mg/dL, despite subsequent abstinence.

The effect of alcohol on the nervous system is even more pronounced among alcohol-dependent individuals. Chronic intake of high doses of ethanol causes *peripheral neuropathy* in 5 to 15% of alcoholics, which is possibly related to thiamine deficiency. Patients complain of bilateral limb numbness, tingling, and paresthesias;

symptoms are more pronounced distally than proximally. The treatment is abstinence and thiamine supplementation.

Wernicke's syndrome (ophthalmoparesis, ataxia, and encephalopathy) and *Korsakoff's syndrome* (alcohol-induced persisting amnestic disorder), are seen in the United States at a rate of approximately 50 per million people per year. These disorders are the result of thiamine deficiency in vulnerable individuals, possibly owing to interaction with a genetic transketolase deficiency. Korsakoff's syndrome presents as profound and persistent anterograde amnesia (inability to learn new material) and a milder retrograde amnesia. Additional symptoms can include impairment in visuospatial, abstract, and conceptual reasoning but with a normal intelligence quotient (IQ). Some patients demonstrate an acute onset of Korsakoff's syndrome in association with the neurologic stigmata seen with Wernicke's syndrome (e.g., sixth nerve palsy and ataxia), whereas others have a more gradual onset. With oral thiamine replacement (50 to 100 mg/d), only one-quarter of Korsakoff's patients achieve full recovery, one-half experience partial improvement, and one-quarter show no improvement, even after many months of supplementation.**Wernicke's syndrome is discussed in detail in Chap. 376.*

About 1% of alcoholics develop *cerebellar degeneration*, a syndrome of progressive unsteady stance and gait often accompanied by mild nystagmus. Atrophy of the cerebellar vermis is seen on brain computed tomography and magnetic resonance imaging scans, but the cerebrospinal fluid is usually normal. Treatment consists of abstinence and multiple vitamin supplementation, although improvement is often minimal.

Alcoholics can show severe *cognitive* problems and impairment in recent and remote memory for weeks to months after an alcoholic binge. Increased size of the brain ventricles and cerebral sulci are seen in 50% or more of chronic alcoholics, but these changes are often reversible, returning toward normal after a year or more of abstinence. PermanentCNSimpairment (alcohol-induced persisting dementia) can develop and accounts for up to 20% of chronically demented patients. There is no single alcoholic dementia syndrome; rather, this label is used to describe patients who have apparently irreversible cognitive changes (possibly from diverse causes) in the midst of chronic alcoholism.

Finally, almost every psychiatric syndrome can be seen temporarily during heavy drinking or subsequent withdrawal. These include intense *sadness* lasting for days to weeks in the midst of heavy drinking in 40% of alcoholics, which is classified as an alcohol-induced mood disorder in the *Fourth Diagnostic and Statistical Manual* of the American Psychiatric Association (DSM-IV); severe *anxiety* in 10 to 30% of alcoholics, often beginning during alcohol withdrawal and which can persist for many months after cessation of drinking (alcohol-induced anxiety disorder); and auditory *hallucinations* and/or *paranoid delusions* in the absence of any obvious signs of withdrawal -- a state now called *alcohol-induced psychotic disorder* -- and reported at sometime in 1 to 10% of alcoholics. Treatment of all forms of alcohol-induced psychopathology includes abstinence and supportive care, with the likelihood of full recovery within several days to 6 weeks. A history of alcohol intake is an important consideration in *any* patient with one of these psychiatric symptoms.

THE GASTROINTESTINAL SYSTEM

Esophagus and Stomach Acute alcohol intake can result in inflammation of the esophagus (possibly secondary to reflux of gastric contents) and stomach (resulting from both an increase in acid production and damage to the gastric mucosal barrier). Esophagitis can cause epigastric distress, and gastritis, the most frequent cause of gastrointestinal bleeding in heavy drinkers, can present as anorexia and/or abdominal pain. Chronic heavy drinking, if associated with violent vomiting, can produce a longitudinal tear in the mucosa at the gastroesophageal junction -- a Mallory-Weiss lesion. Although many gastrointestinal problems are reversible, two complications of chronic alcoholism, esophageal varices secondary to cirrhosis-induced portal hypertension and atrophy of the gastric mucosa, may be irreversible.

Pancreas The incidence of acute pancreatitis in alcoholics (about 25 per 1000 per year) is almost threefold higher than in the general population, accounting for an estimated 10% or more of the cases of this disorder (Chap. 304).

Liver Ethanol absorbed from the small bowel is carried directly to the liver, where it becomes the preferred fuel; NADH accumulates and oxygen utilization escalates; gluconeogenesis is impaired (with a resulting fall in the amount of glucose produced from glycogen); lactate production increases; and there is a decreased oxidation of fatty acids in the citric acid cycle with an increase in fat accumulation within liver cells. In the healthy individual taking no medications, these changes are reversible, but with repeated exposure to ethanol, more severe changes in liver functioning are likely to occur. These include, in overlapping stages, fatty accumulation, alcohol-induced hepatitis, perivenular sclerosis, and cirrhosis, with the latter observed in an estimated 15 to 20% of alcoholics (Chap. 298).

CANCER

As discussed briefly below, the leading cause of death in alcoholics is cardiovascular disease, but cancer occupies a solid second place. Women drinking as few as 1.5 drinks per day increase their risk of breast cancer 1.4-fold. For both genders, four drinks per day increases the risk for oral and esophageal cancers by approximately threefold and rectal cancers by a factor of 1.5, whereas seven to eight or more drinks per day enhances the risks for many of these cancers by a factor of five. Overall, it has been estimated that alcoholics have a rate of carcinoma 10 times higher than the general population.

HEMATOPOIETIC SYSTEM

Ethanol exerts multiple reversible acute and chronic effects on all blood cells. The impact on red blood cells (RBC) is an increase in size (mean corpuscular volume, MCV), usually without anemia. This change appears to reflect the effect of alcohol on stem cells. If heavy drinking is accompanied by folic acid deficiency, there can also be hypersegmented neutrophils, reticulocytopenia, and hyperplastic bone marrow; if malnutrition is present, sideroblastic changes can also be observed. Chronic heavy drinking can also decrease production of most white blood cells (WBCs), decrease granulocyte mobility and adherence, and impair the delayed-hypersensitivity response

to new antigens (with a possible false-negative tuberculin skin test). Finally, many alcoholics present with mild thrombocytopenia. When due to repeated intoxication, the low platelet count usually resolves within a week of abstinence. Thrombocytopenia can also occur secondary to hepatic cirrhosis and congestive splenomegaly (increased destruction) or to folic acid deficiency (decreased production). Ethanol itself might not have a major effect on platelet function, but polyphenols and other constituents of some alcoholic beverages, particularly wine, may interfere with platelet aggregation.

CARDIOVASCULAR SYSTEM

Acutely, ethanol decreases myocardial contractility and causes peripheral vasodilation, with a resulting mild decrease in blood pressure and a compensatory increase in cardiac output. Exercise-induced increases in cardiac oxygen consumption are higher after alcohol intake. These acute effects have little clinical importance for the average healthy drinker but can produce problems in men and women with cardiac disease.

Chronic intake of even modest doses of alcohol can have both deleterious and beneficial effects. Regarding the latter, a maximum of one to two drinks per day over long periods may decrease the risk for cardiovascular death, perhaps through an increase in high-density lipoprotein (HDL) cholesterol or changes in clotting mechanisms. In one large national study, cardiovascular mortality was reduced by 30 to 40% among individuals reporting one or more drinks daily compared to nondrinkers, with overall mortality lowest among those consuming approximately one drink per day. Recent data have also corroborated the decreased risk for ischemic, but not hemorrhagic, stroke associated with regular light drinking.

The consumption of three or more drinks per day results in a dose-dependent increase in blood pressure, which returns to normal within weeks of abstinence. As a result, heavy drinking is an important contributor to mild to moderate hypertension. Chronic heavy drinking can cause cardiomyopathy, with symptoms ranging from unexplained arrhythmias in the presence of left ventricular impairment to heart failure with dilation of all four heart chambers and hypocontractility of heart muscle. Perhaps one-third of cases of cardiomyopathy are alcohol-induced. Mural thrombi can form in the left atrium or ventricle, while heart enlargement exceeding 25% can cause mitral regurgitation. Atrial or ventricular arrhythmias, especially paroxysmal tachycardia, can also occur after a drinking binge in individuals showing no other evidence of heart disease -- a syndrome known as the "holiday heart."

GENITOURINARY SYSTEM CHANGES, SEXUAL FUNCTIONING, AND FETAL DEVELOPMENT

Acutely, modest ethanol doses (e.g., blood alcohol concentrations of 100 mg/dL or even less) can both increase sexual drive and decrease erectile capacity in men. Even in the absence of liver impairment, a significant minority of chronic alcoholic men may show irreversible testicular atrophy with concomitant shrinkage of the seminiferous tubules, decreases in ejaculate volume, and a lower sperm count (Chap. 335).

The repeated ingestion of high doses of ethanol by women can result in amenorrhea, a decrease in ovarian size, absence of corpora lutea with associated infertility, and

spontaneous abortions. Heavy drinking during pregnancy results in the rapid placental transfer of both ethanol and acetaldehyde, which may have serious consequences for fetal development. The *fetal alcohol syndrome* can include any of the following: facial changes with epicanthal eye folds, poorly formed concha, and small teeth with faulty enamel; cardiac atrial or ventricular septal defects; an aberrant palmar crease and limitation in joint movement; and microcephaly with mental retardation. The specific amount of ethanol and/or specific time of vulnerability during pregnancy have not been defined, making it advisable for pregnant women to abstain completely.

OTHER EFFECTS OF ETHANOL

Between one-half and two-thirds of alcoholics have evidence of decreased skeletal muscle strength caused by acute *alcoholic myopathy*, a condition that improves but which might not disappear with abstinence. Effects of repeated heavy drinking on the *skeletal system* include alterations in calcium metabolism, lower bone density, and less growth in the epiphyses, with an increased risk for fractures and osteonecrosis of the femoral head. *Hormonal changes* include an increase in cortisol levels, which can remain elevated during heavy drinking; inhibition of vasopressin secretion at rising blood alcohol concentrations and the opposite effect at falling blood alcohol concentrations (with the final result that most alcoholics are likely to be slightly overhydrated); a modest and reversible decrease in serum thyroxine (T_4); and a more marked decrease in serum triiodothyronine (T_3).

ALCOHOLISM (ALCOHOL ABUSE OR DEPENDENCE)

Because many drinkers occasionally imbibe to excess, temporary alcohol-related pathology is common in nonalcoholics. The period of heaviest drinking is usually the late teens to the late twenties. This is also a time of high risk for temporary alcohol-related social, occupational, or driving difficulties. These phenomena are often isolated events or self-limited, but when repeated problems in multiple life areas develop, the person is likely to meet criteria for alcohol abuse or dependence.

DEFINITIONS AND EPIDEMIOLOGY

DSM-IVdefines alcohol dependence as repeated alcohol-related difficulties in at least three of seven areas of functioning that cluster together over any 12-month period. These problems include any combination of tolerance, withdrawal, taking larger amounts of alcohol over longer periods than intended, an inability to control use, spending a great deal of time associated with alcohol use, giving up important activities to drink, and continued use of alcohol despite physical or psychological consequences. In this diagnosis a special emphasis is placed on evidence of tolerance and/or withdrawal, a condition referred to as "dependence with a physiological component" and which is associated wtih a more severe clinical course. Dependence occurs in both men and women, in individuals from all socioeconomic strata, and in people of all racial backgrounds. The diagnosis predicts a course of recurrent problems with the use of alcohol and the consequent shortening of the life span by a decade or more. In the absence of alcohol dependence, an individual can be given a diagnosis of *alcohol abuse* if he or she demonstrates *repetitive* problems with alcohol in any one of four life areas: an inability to fulfill major obligations, use in hazardous situations such as driving,

legal problems, or use despite social or interpersonal difficulties.

The clinical diagnosis of alcohol abuse or dependence rests on the documentation of a pattern of *difficulties associated with alcohol use*; the definition is *not* based on the quantity and frequency of alcohol consumption. Thus, in screening for alcohol abuse or dependence, it is important to probe for life problems and then attempt to tie in use of alcohol or another substance. Information regarding marital or job problems, legal difficulties, histories of accidents, medical problems, evidence of tolerance, etc., is an important component of all evaluations and yields data that are of use even for nonalcoholic individuals.

The lifetime risk for alcohol dependence in most western countries is about 10 to 15% for men and 5% for women. When alcohol abuse is also considered, the rates are even higher. The typical alcoholic is a blue- or white-collar worker or homemaker and thus does not fit the common stereotype.

GENETICS OF ALCOHOLISM

Alcoholism is a multifactorial disorder in which both environmental and biologic factors contribute. The importance of genetic influences in alcoholism is supported by the higher risk for this disorder in the identical versus fraternal twin of an alcoholic and the fourfold increased risk for children of alcoholics even if adopted at birth and raised without knowledge of the problems of their biologic parents.

The evidence supporting genetic influences in alcoholism has stimulated a search for trait markers of a vulnerability toward the disorder. A 15-year follow-up of 453 men originally studied at age 20 has shown that subjects with alcoholic fathers demonstrated relatively lower levels of response to alcohol, including less intense subjective feelings of intoxication, less alcohol-related impairment in cognitive and psychomotor tests, and less intense alcohol-related changes in prolactin and cortisol secretion. This low level of response to alcohol at around age 20 was a powerful predictor of later alcoholism, explaining most of the relationship between a family history of this disorder and later alcohol problems. Additional genetically influenced characteristics that contribute to the risk of alcoholism appear to include some personality traits such as higher levels of impulsivity and sensation seeking, and several electrophysiologic measures such as the P300 wave of the event-related potential (Chap. 357), which might relate to cognitive styles or evidence ofCNSdisinhibition. All the genetic factors combined appear to explain up to 60% of the risk, with environmental influences contributing at least 40%.

NATURAL HISTORY

For the "average" alcoholic, the age of first drink and first minor problems (e.g., an argument with a friend while drunk or an alcoholic blackout) are similar to those in the general population. However, by the early to mid-twenties, most men and women moderate their drinking (perhaps learning from minor problems), whereas difficulties for alcoholics are likely to escalate, with the first major life problem from alcohol appearing in the mid-twenties to early forties. Once established, the course of alcoholism is likely to be one of exacerbations and remissions. As a rule, there is remarkably little difficulty in stopping alcohol use when problems develop, and this step is often followed by days

to months of carefully controlled drinking. Unfortunately, these periods are almost inevitably followed by escalations in alcohol intake and subsequent problems. The course is not hopeless, because between half and two-thirds of alcoholics maintain abstinence for extended periods after treatment. Even without formal treatment or self-help groups there is at least a 20% chance of long-term abstinence. However, should the alcoholic continue to drink, the life span is shortened by an average of 15 years, with the leading causes of death, in decreasing order, being heart disease, cancer, accidents, and suicide.

IDENTIFICATION OF THE ALCOHOLIC AND INTERVENTION

Physicians even in affluent areas should recognize that approximately 20% of patients have alcoholism. Therefore, it is important to pay attention to the alcohol-related symptoms and signs described above as well as laboratory tests that are likely to be abnormal in the context of regular consumption of 6 to 8 or more drinks per day. These include a high-normal or slightly elevatedMCV(e.g., ³91 fL),g-glutamyl transferase (GGT) (³30 units), serum uric acid [>416 umol/L (7 mg/dL)], carbohydrate-deficient transferrin (CDT) (³20 g/L), and triglycerides [³2.0 mmol/L (180 mg/dL)]. Mild and fluctuating hypertension (e.g., 140/95), repeated infections such as pneumonia, and otherwise unexplained cardiac arrhythmias should also raise the possibility that the patient is an alcoholic. Other disorders suggestive of alcoholism include cancer of the head and neck, esophagus, or stomach as well as cirrhosis, unexplained hepatitis, pancreatitis, bilateral parotid gland swelling, and peripheral neuropathy.

Once the likelihood of alcoholism is established, only a few moments are needed to gather the history of alcohol-related life problems. The patient and the spouse or another close family member should be asked about patterns of accidents, relationship difficulties, problems on the job, and driving-related difficulties, after which the role played by alcohol should be identified. All physicians should be able to take the time needed to gather such information. In addition, a simple 25-item form to be answered by the patient, the Michigan Alcohol Screening Test (MAST), is available to aid in identifying alcoholics. However, this is only a screening tool, and a careful face-to-face interview is still required for a meaningful diagnosis. The CAGE, which consists of asking about alcohol-related trouble *c*utting down on intake, being *a*nnoyed by criticisms, *g*uilt, or use of an "*e*ye-opener," can also be helpful as an initial screen.

After alcoholism is identified, the diagnosis must be shared with the patient. The presenting complaint can be used as an entree to the alcohol problem. For instance, the patient complaining of insomnia or hypertension could be told that these are clinically important symptoms and that physical findings and laboratory tests indicate that alcohol appears to have contributed to the complaints and is increasing the risk for further medical and psychological problems. The physician should share information about the course of alcoholism and explore possible avenues of attacking the problem. Some patients and family members will benefit from the opportunity to read additional material (see "Bibliography").

The process of intervention is rarely accomplished in one session. For the person who refuses to stop drinking at the first intervention, a logical step is to "keep the door open," establishing future meetings so that help is available as problems escalate. In the

meantime the family may benefit from counseling or referral to self-help groups such as Al-Anon (the Alcoholics Anonymous group for family members) and Alateen (for teenage children of alcoholics). The patient should be reminded that driving while intoxicated is dangerous and illegal.

THE ALCOHOL WITHDRAWAL SYNDROME

Once the brain has been repeatedly exposed to high doses of alcohol, any sudden decrease in intake can produce symptoms of withdrawal. As with allCNSdepressants, the symptoms are generally the opposite of those produced by intoxication. Features include tremor of the hands (shakes or jitters); agitation and anxiety; autonomic nervous system overactivity such as an increase in pulse, respiratory rate, and body temperature; insomnia, possibly accompanied by bad dreams; and gastrointestinal upset. These withdrawal symptoms generally begin within 5 to 10 h of decreasing ethanol intake, peak in intensity on day 2 or 3, and improve by day 4 or 5. Anxiety, insomnia, and mild levels of autonomic dysfunction may persist at decreasing levels for 6 months or more as a protracted abstinence syndrome, which may contribute to the tendency to return to drinking.

At some point in their lives, between 2 and 5% of alcoholics experience withdrawal seizures ("rum fits"), usually within 48 h of stopping drinking. These are usually generalized (unless there is an underlying focal lesion), and any electroencephalographic abnormalities are mild and generally return to normal within several days.

The term *delirium tremens* (DTs) refers to delirium (mental confusion with fluctuating levels of consciousness) along with a tremor, severe agitation, and autonomic overactivity (e.g., marked increases in pulse, blood pressure, and respirations). Fortunately, this serious and potentially life-threatening complication of alcohol withdrawal is rare. Only 5 to 10% of alcohol-dependent individuals ever experience DTs; the chance of DTs during any single withdrawal is less than 1% but is higher if there has been a withdrawal seizure. DTs are most likely to develop in patients with concomitant severe medical disorders or evidence of underlying brain damage, and thus can usually be avoided if the underlying medical problems can be identified and treated.

TREATMENT

Acute Intoxication The first priority is to be certain that the vital signs are relatively stable without evidence of respiratory depression, cardiac arrhythmia, or potentially dangerous changes in blood pressure. Life-threatening problems require appropriate emergency care and hospitalization. The clinician must recognize that a variety of causes may produce obtundation or coma in the alcoholic patient. The possibility of intoxication with other drugs should be considered, and a blood or urine sample is indicated to screen for opioids or otherCNSdepressants such as benzodiazepines or barbiturates. A coexisting seizure disorder, head injury, meningitis, brain abscess, or other potentially life-threatening neurologic disorder may be present. Other medical conditions that must be considered include hypoglycemia, hepatic failure, or diabetic ketoacidosis.

Patients who are medically stable should be placed in a quiet environment and asked to lie on their side if fatigued in order to minimize the risk of aspiration. When the behavior indicates an increased likelihood of violence, hospital procedures should be followed, including planning for the possibility of a show of force with an intervention team. In the context of aggressiveness, patients should be clearly reminded in a nonthreatening way that it is the goal of the staff to help them to feel better and to avoid problems. If the aggressive behavior continues, relatively low doses of a short-acting benzodiazepine such as lorazepam (e.g., 1 mg by mouth) may be used and can be repeated as needed, but care must be taken so that the addition of this secondCNSdepressant does not destabilize vital signs or worsen confusion. An alternative approach is to use an antipsychotic medication (e.g., 5 mg of haloperidol liquid), but this has the potential danger of lowering the seizure threshold. If aggression escalates, the patient might require a short-term admission to a locked ward, where medications can be used more safely and vital signs more closely monitored.

Withdrawal The first, and most important, step is to perform a *thorough* physical examination in all alcoholics who are considering stopping drinking. It is necessary to evaluate organ systems likely to be impaired, including a search for evidence of liver failure, gastrointestinal bleeding, cardiac arrhythmia, and glucose or electrolyte imbalance.

The second step in treating withdrawal for even the typical well-nourished alcoholic is to give patients adequate nutrition and rest. All patients should be given oral multiple B vitamins, including 50 to 100 mg of thiamine daily for a week or more. Most patients enter withdrawal with normal levels of body water or mild overhydration, and intravenous fluids should be avoided unless there is evidence of significant recent bleeding, vomiting, or diarrhea. Medications can usually be administered orally.

The third step in treatment is to recognize that most withdrawal symptoms are caused by the rapid removal of aCNSdepressant. Therefore, patients can be weaned by administering any drug of this class and gradually decreasing the levels over 3 to 5 days. While many CNS depressants are effective, the *benzodiazepines* have the highest margin of safety and are, therefore, the preferred class of drugs in the treatment of alcohol withdrawal. Benzodiazepines with short half-lives (Chap. 385) are especially useful for patients with serious liver impairment or evidence of preexisting encephalopathy or brain damage. On the other hand, short-half-life benzodiazepines, e.g., oxazepam or lorazepam, result in rapidly changing drug blood levels and must be given every 4 h to avoid abrupt fluctuations in blood levels that may increase the risk for seizures. Therefore, most clinicians use drugs with longer half-lives, such as diazepam or chlordiazepoxide. The goal is to administer enough drug on day 1 to alleviate most of the symptoms of withdrawal (e.g., the tremor and elevated pulse), and then to decrease the dose by 20% on successive days over a period of 3 to 5 days. The approach is flexible; the dose is increased if signs of withdrawal escalate, and the medication is withheld if the patient is sleeping or shows signs of increasing orthostatic hypotension. The average patient requires 25 to 50 mg of chlordiazepoxide or 10 mg of diazepam given orally every 4 to 6 h on the first day.

For the patient withDTs, treatment can be difficult and the condition is likely to run a course of 3 to 5 days regardless of the therapy employed. The focus of care is to

identify medical problems and correct them and to control behavior and prevent injuries. Many clinicians recommend the use of high doses of benzodiazepine (doses as high as 800 mg/day of chlordiazepoxide have been reported), a treatment that will decrease the agitation and raise the seizure threshold but probably does little to improve the confusion. Other clinicians recommend the use of antipsychotic medications, such as 20 mg or more per day of haloperidol, an approach less likely to exacerbate confusion but which may increase the risk of seizures. Antipsychotic drugs have no place in the treatment of mild withdrawal symptoms.

Generalized wtihdrawal seizures rarely require aggressive pharmacologic intervention beyond that given to the usual patient undergoing withdrawal, i.e., adequate doses of benzodiazepines. There is little evidence that anticonvulsants such as phenytoin are effective in drug-withdrawal seizures, and the risk of seizures has usually passed by the time effective drug levels are reached.*The rare patient with status epilepticus must be treated aggressively, as outlined in Chap. 361, initially with intravenous lorazepam.*

While alcohol withdrawal is often treated in a hospital, efforts at reducing costs have resulted in the development of outpatient detoxification for relatively mild abstinence syndromes. This is appropriate for patients in good physical condition who demonstrate mild signs of withdrawal despite low blood alcohol concentrations and for those without prior history ofDTs or withdrawal seizures. Such individuals still require a careful physical examination, evaluation of blood tests, and vitamin supplementation. Benzodiazepines can be given *in a 1- to 2-day supply* to be administered to the patient by a spouse or other family member four times a day. Patients are asked to *return daily* for evaluation of vital signs and to come to the emergency room if signs and symptoms of withdrawal escalate.

Rehabilitation of Alcoholics After completing alcoholic rehabilitation, 60% or more of middle-class alcoholics maintain abstinence for at least a year, and many for a lifetime. As is true for any long-term disorder for which treatment requires changes in life-style (e.g., diabetes or hypertension), therapeutic approaches include general supports that meet commonsense guidelines. Considering the lack of evidence for the superiority of any specific treatment type, it is best to keep interventions simple.

Maneuvers in rehabilitation fall into two general categories. First are attempts to help the alcoholic achieve and maintain a high level of motivation toward abstinence. These include education about alcoholism and instructing family and/or friends to stop protecting the person from the problems caused by alcohol. The second step is to help the patient to readjust to life without alcohol and to reestablish a functional lifestyle through counseling, vocational rehabilitation, and self-help groups such as Alcoholics Anonymous. The third component, called *relapse prevention*, helps the person to identify situations in which a return to drinking is likely, formulate ways of managing these risks, and develop coping strategies that increase the chances of a return to abstinence if a slip occurs.

There is no convincing evidence that inpatient rehabilitation is always more effective for the average alcoholic than is outpatient care. However, more intense interventions work better than those that are less intensive, and some alcoholics do not respond to outpatient care. The decision to hospitalize can be made if (1) the patient has medical

problems that are difficult to treat outside a hospital; (2) depression, confusion, or psychosis interferes with outpatient care; (3) the patient has such a severe life crisis that it is difficult to get his or her attention as an outpatient; (4) outpatient treatment has failed; or (5) the patient lives far from the treatment center. In any setting, the best predictors of continued abstinence include evidence of higher levels of life stability (e.g., supportive family and friends) and higher levels of functioning (e.g., job skills, higher levels of education, and absence of crimes unrelated to alcohol).

Whether the treatment begins in an inpatient or an outpatient setting, subsequent outpatient contact should be maintained for a minimum of 6 months and preferably a full year after abstinence is achieved. Counseling with an individual physician or through groups focuses on day-to-day living -- emphasizing areas of improved functioning in the absence of alcohol (i.e., why it is a good idea to continue to abstain) and helping the patient to manage free time without alcohol, develop a nondrinking peer group, and handle stresses on the job without alcohol.

The physician serves an important role in identifying the alcoholic, treating associated medical or psychiatric syndromes, overseeing detoxification, referring the patient to rehabilitation programs, and providing counseling. The physician is also responsible for selecting which (if any) medication might be appropriate during alcoholism rehabilitation. Patients often complain of continuing sleep problems or anxiety when acute withdrawal treatment is over, problems that may be a component of protracted withdrawal. Unfortunately, there is no place for hypnotics or antianxiety drugs in the treatment of most alcoholics after acute withdrawal has been completed. Regarding insomnia, patients should be reassured that the trouble in sleeping is normal after alcohol withdrawal and will improve over the subsequent weeks and months. They should then follow a rigid bedtime and awakening schedule and avoid any naps or the use of caffeine in the evenings. The sleep pattern will improve rapidly. Anxiety can be approached by helping the person to gain insight into the temporary nature of the symptoms and to develop strategies to achieve relaxation as well as using forms of cognitive therapy.

In addition, while the mainstay of alcoholic rehabilitation involves counseling, education, and cognitive techniques, several interesting medications are under active evaluation and might prove to be useful. The first is the opioid-antagonist drug naltrexone, which has been reported in several small-scale, short-term studies to decrease the probability of a return to drinking and to shorten periods of relapse. While this medication looks promising, longer-term large-scale trials in more diverse clinical settings will be required before the cost-effectiveness of naltrexone can be established. A second medication, acamprosate, has been tested in over 5000 patients in Europe, with results that appear similar to those reported for naltrexone. Currently, acamprosate is not available in the United States, although a long-term, trial of naltrexone, acamprosate, and their combination is in progress. A third medication, which has historically been used in the treatment of alcoholism, is the ALDH inhibitor disulfiram. Taken in doses of 250 mg/day, this drug produces an unpleasant (and potentially dangerous) reaction in the presence of alcohol, a phenomenon related to rapidly rising blood levels of the first metabolite of alcohol, acetaldehyde. However, few adequate double-blind controlled trials have demonstrated the superiority of disulfiram over placebo. Disulfiram has many side effects, and the reaction with alcohol can be dangerous, especially for patients with

heart disease, stroke, diabetes mellitus, and hypertension. Thus, most clinicians reserve this medication for patients who have a clear history of longer-term abstinence associated with prior use of disulfiram and for those who might take the drug under the supervision of another individual (such as a spouse), especially during discrete periods that they have identified as representing high-risk drinking situations for them (such as the Christmas holiday).

More data are required before any medication can be recommended for routine use in alcohol rehabilitation. However, additional support for alcoholics is available through Alcoholics Anonymous in almost every community. Alcoholics Anonymous is a self-help group of recovering alcoholics (men and women who have stopped drinking, perhaps many years ago) that offers an effective model of abstinence, provides a sober peer group, and makes crisis intervention available when the urge to drink escalates. No matter what type of rehabilitation program is planned, the alcoholic should be offered the option of joining Alcoholics Anonymous.

388. OPIOID DRUG ABUSE AND DEPENDENCE - *Marc A. Schuckit*, *David S. Segal*

The principal effects of the opioids (opiate-like drugs) are a damping of pain perception along with modest levels of sedation and euphoria. Drugs in this category include heroin, morphine, and codeine as well as many prescription analgesics and antitussive agents. Opioid drugs are widely used in medical practice, and, thus, dependence and abuse are not limited to the classic opiod-dependent person on the street.

Tolerance to any one opioid is likely to extend to the others (i.e., cross-tolerance is likely), and all opioids are associated with a similar pattern of drug-related problems. Each is capable of producing dependence as defined in the *Fourth Diagnostic and Statistical Manual* of the American Psychiatric Association (DSM-IV), including evidence of physical dependence, a diagnosis made in the context of a history of tolerance and/or withdrawal. The abstinence syndrome from any of the substances can be treated with administration of any of the others.

PHARMACOLOGY

The prototypic opiates, morphine and codeine (3-methoxymorphine), are taken directly from the milky juice of the poppy *Papaver somniferum*. The semisynthetic drugs produced from the morphine or thebane molecules include hydromorphone, diacetylmorphine (heroin), and oxycodone. The purely synthetic opioids, sharing many of the basic properties of opium and morphine, include meperidine, propoxyphene, diphenoxylate, fentanyl, buprenorphine, methadone, and pentazocine. Despite claims to the contrary, all these substances (including almost all prescription analgesics) are capable of producing euphoria as well as psychological and physical dependence when taken in high enough doses over prolonged periods.

The opioids produce their effects by binding to different types of opioid receptors throughout the body, including the central nervous system (CNS). Endogenous opioid peptides (i.e., enkephalins, endorphins, dynorphins, and others) have been identified that appear to be natural ligands for opioid receptors. These peptides have a distinct distribution in the CNS. The receptors with which opioid peptides interact are differentially engaged in production of the various opiate effects, such as analgesia, respiratory depression, constipation, and euphoria. Substances capable of antagonizing one or more of these actions include nalorphine, levallorphan, cyclazocine, butorphanol, buprenorphine, and pentazocine, each of which has mixed agonist and antagonist properties, as well as naloxone, nalmefene, and naltrexone, which are pure opiate antagonists. All antagonist drugs (including those with mixed agonist properties), can precipitate withdrawal symptoms if administered to a patient who is physically dependent on other opioids. The availability of relatively specific antagonists has helped identify different receptor subtypes, including u receptors, which influence some of the more classic opioid actions such as pain control, reinforcement, constipation, hormone levels, and respiration;k receptors, with possible similar functions along with sedation and effects on hormones; and dreceptors, thought to relate mostly to analgesia, mood, reinforcement, and breathing. The major features of tolerance, dependence, and withdrawal are thought to be mediated primarily by u receptors. All opioid receptors are coupled to inhibitory G proteins, which mediate their actions within cells (Chap. 386).

Opioid drugs are absorbed from the gastrointestinal system, the lungs, and/or the muscles. The most rapid and pronounced effects occur following intravenous administration, with only slightly less efficient absorption after smoking or inhaling the vapor ("chasing the dragon"), and the least intense actions are seen after absorption from the digestive tract. Most of the metabolism of opioids occurs in the liver, primarily through conjugation with glucuronic acid, and only small amounts are excreted directly in the urine or feces. The plasma half-lives of these drugs range from 2.5 to 3 h for morphine to more than 22 h for methadone and even longer for levomethadyl acetate (LAAM).

Street heroin is typically only 5 to 10% pure. The remainder consists of materials such as lactose and fruit sugars, quinine, powdered milk, phenacetin, caffeine, antipyrine, and strychnine, which are used to "cut" the drug and increase the profit margin. Any marked, unexpected increase in the purity of street drugs is likely to cause unintentional lethal overdoses in users expecting less effect from a "hit."

THE ACUTE AND CHRONIC EFFECTS OF OPIOID DRUGS

With the exception of overdose and physical dependence, most opioid effects are relatively benign and rapidly reversible. A major danger, however, comes through the use of contaminated needles by intravenous users, which increases the risk of hepatitis B and C, bacterial endocarditis, and infection with HIV (Chap. 309).

Effects on Body Systems Acute changes in the *gastrointestinal system* are the result of decreased motility with resulting constipation and anorexia. Chronic gastrointestinal problems in opioid-dependent individuals typically occur as a consequence of hepatitis in injection drug users.

Effects of opiods in the CNS include intoxication-induced nausea and vomiting (medulla), decreased pain perception (spinal cord, thalamus, and periaqueductal gray region), euphoria (limbic system), and sedation (reticular activating system). The adulterants added to street drugs may contribute to some of the more permanent nervous system damage, including peripheral neuropathy, amblyopia, myelopathy, and leukoencephalopathy. One study revealed abnormalities in cognitive function and brain computed tomography scans of opioid-dependent subjects; whether these abnormalities are due to the opioid itself, the adulterants, the consequences of dirty needles, or an unhealthy life-style is unknown. Acute opioid administration decreases levels of luteinizing hormone, with a subsequent reduction in testosterone, which might contribute to the decreased sex drive reported by most opioid-dependent people. Other hormonal changes include a decrease in the release of thyrotropin and increases in prolactin and possibly growth hormone (Chap. 328).

Acute changes in the *respiratory system* include respiratory depression, which results from a decreased response of the brainstem to carbon dioxide tension, a component of the drug overdose syndrome described below. At even low drug doses, this effect can be clinically significant in individuals with underlying pulmonary disease. *Cardiovascular* changes tend to be relatively mild, with no direct opiate effect on heart rhythm or myocardial contractility, but there is a potential problem from orthostatic hypotension, probably secondary to dilation of peripheral vessels. Bacterial infections of the lungs

and heart valves can occur from contaminated needles; the latter can result in emboli and thus an increased risk for stroke.

The Toxic Reaction or Overdose Syndrome High doses of opioids can result in a potentially lethal toxic reaction or overdose syndrome. While toxic reactions are seen with all opioids, the more potent drugs such as fentanyl (80 to 100 times more powerful than morphine) are especially dangerous. The typical syndrome, which occurs immediately with intravenous overdose, includes shallow respirations at a rate of two to four per minute, pupillary miosis (with mydriasis once brain anoxia develops), bradycardia, a decrease in body temperature, and a general absence of responsiveness to external stimulation. If this medical emergency is not treated rapidly, respiratory depression, cyanosis, cardiorespiratory arrest, and death can ensue. Postmortem examination reveals few specific changes except for diffuse cerebral edema. An "allergic-like" reaction to intravenous heroin, perhaps in part related to adulterants, can also occur and is characterized by decreased alertness, a frothy pulmonary edema, and an elevation in the blood eosinophil count.

The first step in managing overdose is to provide any needed respiratory or cardiovascular support including intubation for airway protection if needed. Definitive treatment for the typical opioid overdose is the administration of a narcotic antagonist such as naloxone in an initial dose of 0.4 mg to 2 mg intravenously, expecting a response in 1 to 2 min. This dose can be repeated every 2 to 3 min up to a dose of 10 mg. With the exception of overdoses with buprenorphene, if no response is seen after 10 mg, it is unlikely that an opioid overdose is responsible for the respiratory depression or coma. If an intravenous line is not available, the drug can be given intramuscularly. It is important to titrate the dose relative to the patient's symptoms. The goal is to ameliorate the respiratory depression but not provoke a severe withdrawal state. Because the effects of this drug diminish within 2 to 3 h, the individual must be monitored for at least 24 h after a heroin overdose and 72 h after an overdose of a longer-acting drug such as methadone. If there is little response to naloxone alone, the possibility of a concomitant overdose with a benzodiazepine should be considered and a challenge with intravenous flumazenil, 0.2 mg/min up to a maximum of 3 mg in an hour, might be used. Patients who are physically dependent on an opioid may experience a precipitous onset of an abstinence syndrome after administration of the opioid antagonist, but aggressive treatment of this syndrome is not appropriate until all vital signs are relatively stable.

As with any drug overdose, treatment of either the typical or the "allergic" type of opioid toxic reaction often requires continued supportive care until the drug effect subsides. Patients may require respiratory support (often with oxygen supplementation and positive-pressure breathing for the "allergic" type of overdose), intravenous fluids perhaps accompanied by pressor agents to support blood pressure, and gastric lavage to remove any remaining drug with care taken to use a cuffed endotracheal tube to prevent aspiration if the patient is not alert. It is important to evaluate and treat any possible anaphylactic reactions. Cardiac arrhythmias and/or convulsions, especially likely to be seen with codeine, propoxyphene, or meperidine, also need to be treated.

OPIOID ABUSE AND DEPENDENCE

Definition and Epidemiology Repeated opioid use to the point of developing multiple problems is a good indicator that future abuse and dependence are likely.DSM-IVcriteria for opioid dependence are the same as those for alcohol dependence (Chap. 387). An individual is dependent if within a 12-month period repeated difficulties occur in any three areas of functioning, including tolerance, withdrawal, use of greater amounts of opiates than intended, and use despite consequences. Patients who do not have dependence but demonstrate repeated difficulties with the law, impaired ability to meet obligations, use in hazardous situations, or continued use despite problems can be labeled as having abuse.

The use of opioids for intoxication is less prevalent than the use of alcohol, marijuana, and several other drugs. A 1997 national survey reported that almost 5% of men and women age 12 or above in the United States had used an opioid for intoxication, including almost 2% in the prior year and slightly less than 1% in the prior month. Focusing specifically on heroin, the lifetime prevalence was approximately 1%, with 0.3% having taken the drug in the prior year. Use patterns of these drugs were almost twice as high in another 1997 survey sampling 12th graders in high school. In all studies, prevalence rates were higher in males than females. None of the national surveys offered data regarding the prevalence of dependence.

Genetics While most data on the importance of genetic influences in substance use disorders apply to alcoholism, there are interesting findings regarding other drugs. One large study of over 3000 male twin pairs reported that there are genetic influences that relate uniquely to heroin dependence and also noted additional genetic factors related to an overall vulnerability toward substance-related problems. The genetic influences operate in the context of additional environmental factors that are likely to relate both to the family of upbringing and the general environment. Genetic factors might influence personality characteristics such as impulsivity and sensation-seeking or susceptibility to develop antisocial personality disorder. Genes relating to the actions of the drug on specific neurochemical systems such as dopamine are also potential candidates for an enhanced vulnerability toward developing opioid dependence.

Natural History Dependence on or abuse of opioids can be seen in at least three types of patients. First, a minority of people with nonfatal *chronic pain syndromes* (e.g., back, joint, and muscle disorders) misuse their prescribed drugs. If physical dependence is established, abstinence syndromes can then intensify the pain, promoting continued drug intake. Physicians can avoid contributing to physical dependence by helping the patient to accept the goal of minimization rather than disappearance of the pain and to recognize that discomfort may not be completely eliminated (Chap. 12). Analgesic medication should be only one component of treatment and limited to the oral administration of the least potent analgesic that is able to "take the edge off" the pain (e.g., ibuprofen or, if needed, propoxyphene). Behavior modification techniques, such as muscle relaxation and meditation, and carefully selected exercises should be used as appropriate to help increase function and decrease pain. Finally, nonmedicinal approaches, including electrical transcutaneous neurostimulation for muscle and joint disease, may be useful.

The second group at high risk are *physicians*, *nurses*, and *pharmacists*, primarily because of their easy access to substances of abuse. Physicians may begin to use

opioids to help them sleep or to reduce stress or physical aches and pains. This group appears to be at especially high risk for developing dependence on the highly potent drugs such as fentanyl. Because of the growing awareness of these problems, impaired-physician programs have been established in many hospitals and by most state medical societies. Such groups attempt to identify and aid substance-impaired physicians, giving them peer support and education to help them achieve abstinence before problems escalate to the point of licensure revocation. All doctors are advised never to prescribe opioids for themselves or for members of their family -- physicians deserve the same level of care and protection from future problems as their patients.

The third and most obvious group are those who buy street drugs to get high. While some of these men and women have prior histories of severe antisocial problems, most have a relatively high level of premorbid functioning. The typical person begins using opioids occasionally, often after experimenting with tobacco, then alcohol, then marijuana, and then brain depressants or stimulants. Occasional opiate use, or "chipping," might continue for some time, and some individuals never escalate their intake to the point of developing dependence.

Of course, opiate-dependent individuals are likely to continue to have experience with many other drugs. At least three of these often remain as problems during the course of opioid dependence. First, alcohol is typically used to moderate withdrawal problems, to enhance the opioid high, and as a substitute when the preferred drug is not readily available, including during methadone and other treatments. This pattern of problematic drinking, often meeting criteria for alcohol dependence, is present at some time in approximately half of opioid-dependent persons. The second drug, cocaine, appears to be taken for many of the same reasons as alcohol, and is often administered intravenously with the opioid in a mixture known as a "speedball." The third class of drugs misused in combination with opioids consists of the benzodiazepines, especially among people in methadone maintenance.

Once persistent opioid use is established, severe problems are likely to develop. At least 25% die within 10 to 20 years from suicide, homicide, accidents, or infectious diseases such as tuberculosis, hepatitis, or AIDS. The mortality rate has escalated in recent years in response to the AIDS epidemic among injection drug users, with an estimated 60% of these men and women carrying HIV (Chap. 309). At the same time, while the majority of opioid-dependent persons show frequent exacerbations and remissions, it is important to remember that approximately 35% achieve long-term, often permanent, abstinence. This remission is probably most often seen after the age of 40 but can occur at any point in the clinical course. While this favorable outcome can be observed in any opioid-dependent person, as is true with most drugs of abuse a better prognosis is associated with prior histories of marital and employment stability and fewer criminal activities unrelated to drugs.

TREATMENT

The key to diagnosis is to discard the erroneous stereotype that opioid-dependent men and women are always unemployed and homeless. Abuse or dependence is possible in any patient who demonstrates symptoms of what might be opioid withdrawal; anyone who has a chronic pain syndrome; physicians, nurses, and pharmacists or others with

easy access to opioids; and all patients who repeatedly seek out prescription analgesics. Therefore, it is important to take the time with *every* patient, especially those with complaints of pain, to gather a history that includes the patterns of opioid use and the list of doctors and clinics from which they have received prescriptions. If the chronic use of opioids is suspected, gathering further data from an additional informant such as a relative or close friend can be essential. Another indicator of an enhanced risk for opioid dependence is a history of pervasive antisocial problems beginning in the preteen years. Blood and urine screens can be used to identify opioids in patients in whom misuse is suspected, and clinicians should search for physical stigmata of misuse (e.g., needle marks).

After identifying opioid dependence, the next step is intervention. The need for active treatment of the abstinence syndrome can be presented, and the availability of help in establishing a drug-free life-style can be emphasized. The final decision, of course, rests with the patient. This approach to intervention is presented in relation to alcoholism in Chap. 387.

The Symptoms of Withdrawal Withdrawal symptoms, usually the opposite of the acute effects of the drug, include nausea and diarrhea, coughing, lacrimation, mydriasis, rhinorrhea, profuse sweating, twitching muscles, piloerection (or "goose bumps") as well as mild elevations in body temperature, respiratory rate, and blood pressure. In addition, diffuse body pain, insomnia, and yawning occur, along with intense drug craving. Drugs with a short half-life, such as morphine or heroin, cause symptoms typically within 8 to 16 h of the last dose (thus, many dependent individuals awake in mild withdrawal every morning); symptom intensity peaks within 36 to 72 h after discontinuation of the drug, and the acute syndrome disappears within 5 to 8 days. However, a protracted abstinence phase of mild symptoms (e.g., moodiness, slight changes in pupillary size, autonomic dysfunction, changes in sleep pattern) may persist for 6 or more months. These lingering symptoms, which can be relieved by administering an opioid, probably contribute to relapse.

Treatment of the Withdrawal Syndrome A thorough physical examination, including an assessment of neurologic function and a search for local and systemic infections, especially abscesses, is mandatory. Laboratory testing generally includes assessment of liver function and, in intravenous users, HIV status. Proper nutrition and rest must be initiated as soon as possible.

Optimal treatment of withdrawal requires administration of sufficient opioid medication on day 1 to decrease symptoms, followed by a more gradual withdrawal of the drug, usually over 5 to 10 days. Any opioid will work (all have some level of cross-tolerance), but for ease of administration, many physicians prefer to use a long-acting drug such as methadone. To estimate the first day's dose from the patient's history, 1 to 2 mg of methadone can be considered approximately equivalent to 3 mg of morphine, 1 mg of heroin, or 20 mg of meperidine. Most patients require between 10 and 25 mg of methadone orally twice on day 1, with higher doses given if prominent symptoms of withdrawal are not dampened. After several days of a stabilized drug dose, the opioid is then decreased by 10 to 20% of the original day's dose each day.

However, most states restrict the prescription of opioids to dependent persons, and, in

the absence of special permits, detoxification with opioids is often proscribed or limited. Thus, pharmacologic treatments often center on relief of symptoms of diarrhea with Imodium or a nonopioid drug, of "sniffles" with decongestants, and pain with nonopioid analgesics (e.g., ibuprofen). Comfort can be enhanced with thea$_2$-adrenergic agonist clonidine to decrease sympathetic nervous system overactivity. Given at doses of approximately 5 ug/kg (up to 0.3 mg given two to four times a day), clonidine decreases autonomic nervous system dysfunction and produces sedation. Blood pressure should be monitored closely. Some clinicians augment this regimen with low to moderate doses of benzodiazepines for 2 to 5 days to decrease agitation.

A special case of opioid withdrawal is seen in the newborn made passively dependent through the mother's drug abuse during pregnancy. Some level of withdrawal develops in 50 to 90% of children of heroin-dependent mothers. As few as 25% of infants of methadone-maintenance mothers show clinically relevant withdrawal symptoms, probably because of the longer half-life of this drug. The syndrome consists of irritability, crying, a tremor (in 80%), increased reflexes, increased respiratory rate, diarrhea, hyperactivity (in 60%), vomiting (40%), and sneezing/yawning/hiccuping (in 30%). The child usually has a low birth weight but may be otherwise unremarkable until the second day, when symptoms are likely to begin.

The treatment follows the same general steps used in the treatment of the physically dependent adult. The child must be carefully evaluated to rule out medical problems such as hypoglycemia, hypocalcemia, infections, and trauma; general support in a warm, quiet environment and regulation of electrolytes and glucose are also required. The infant with moderate to severe symptoms can be treated with any of the following: paregoric (0.2 mL orally every 3 to 4 h), methadone (0.1 to 0.5 mg/kg per day), phenobarbital (8 mg/kg per day), or diazepam (1 to 2 mg/kg every 8 h). Medication should be given in decreasing levels for 10 to 20 days. Dependent infants of mothers on methadone maintenance also benefit by breast feeding while the mother continues to take methadone.

Rehabilitation of Opioid-Dependent Persons Despite some differences in demographics, the same general rules for rehabilitation apply to opioid-dependent persons as to alcoholics. The basic strategy includes detoxification and family support, and the process can benefit from the use of reading materials or referral to self-help groups. It is also important to establish realistic patient goals and a program of counseling and education to increase motivation toward abstinence. A long-term commitment to rebuilding a life-style without the substance is essential for preventing recidivism.

Most rehabilitation approaches have common elements, regardless of the drug involved. Patients are educated about their responsibility for improving their lives, and *motivation for abstinence* is increased by providing information about the medical and psychological problems that can be expected if dependence continues. Patients and families are encouraged to *establish an opioid-free life-style* by learning to cope with chronic pain and develop realistic vocational planning (e.g., for pharmacists, physicians, and nurses). The dependent person is also encouraged to establish a drug-free peer group and to participate in self-help groups such as Narcotics Anonymous. Another important treatment component is *relapse prevention* aimed at identifying triggers for a

return to drugs and developing appropriate coping strategies.

Much of this advice and counseling can be given by the physician, but many clinicians refer patients to more formal drug programs, including methadone maintenance clinics, programs using narcotic antagonists, and therapeutic communities. Long-term follow-up of treated patients indicates that approximately one-third were completely drug free in the previous year; 60% were no longer using opioids, although some were misusing other substances. Individuals who stay in methadone maintenance or in therapeutic communities show significant improvement in antisocial behavior and employment status. In general, the best prognosis is for those individuals who are employed, who have higher levels of education, and who remain in treatment for at least 2 months. Dependence among health care providers, such as physicians, is treated similarly, but in addition a closely supervised "diversion" procedure is usually instituted and carried out for 1 to 2 years or more.

Methadone Maintenance Maintenance programs with methadone and the even longer-acting agentLAAMshould only be used in combination with education and counseling. It is important to note that drug maintenance is not aimed at "curing" opioid dependence; rather, it provides a substitute drug that is legally accessible, safer, can be taken orally, and has a long half-life so that it can be taken once a day. The goal is to help persons who have repeatedly failed in drug-free programs to improve functioning within the family and job, to decrease legal problems, and to improve health.

Methadone is a long-acting opioid that possesses almost all the physiologic properties of heroin. The recipient, who has been carefully screened to rule out prior psychiatric disorders, may be maintained on a relatively low dose (e.g., 30 to 40 mg/d); a better approach is to use a higher dose (80 to 120 mg/d), because it may be more effective in blocking heroin-induced euphoria and decreasing craving. There is some evidence that the higher methadone doses result in greater retention in treatment and consequently in lower levels of arrest and relapse to street drugs. Three-quarters or more of patients, especially those receiving the higher doses, are likely to remain heroin-free for 6 months or longer. Methadone is administered as an oral liquid given once a day at the program, with weekend doses taken by the patient at home. The longer-acting analogues, such asLAAM, can be given two or three times a week, with the dose of LAAM increased to as high as 80 mg three times a week if needed. After a period of maintenance (usually 6 months to 1 year or longer), the clinician can work closely with the patient to regulate the rate of drug decrease (by about 5% per week) if possible.

In the past, the British have used heroin maintenance with goals and guidelines similar to those of current methadone programs. There is no evidence that heroin maintenance has any advantages over methadone maintenance, but the heroin approach does add the risk that the drug will be easily sold on the streets. Treatment with mixed agonists-antagonists such as buprenorphine also appears beneficial, although results are not as good as with methadone.

Opioid Antagonists The opiate antagonists (e.g., naloxone) compete with heroin and other opioids for receptors, reducing the effects of the opioid agonists. Administered over long periods with the intention of blocking the "high" produced if the patient takes opioids, these drugs can be useful as part of an overall treatment approach that

includes counseling and support. The most widely used antagonist in rehabilitation is naltrexone; 50 mg per day antagonizes 15 mg of heroin for 24 h, and higher doses (125 to 150 mg) block the effects of 25 mg of intravenous heroin for up to 3 days. Naltrexone is free of agonist properties, produces no known withdrawal symptoms when stopped, and its side effects tend to be mild. To avoid precipitating a withdrawal syndrome, patients should be free of opioids for a minimum of 5 days before beginning treatment with this medication. In addition, they should first be challenged with 0.4 or 0.8 mg of the shorter-acting agent naloxone to be certain they are able to tolerate the long-acting antagonist. Following this procedure, a test dose of 10 mg of naltrexone can be given, with the expectation that any withdrawal symptoms will be seen in 0.5 to 2 h. Several variations of this approach can be used with detoxification from methadone maintenance, including a fairly rapid, medically supervised plan. Over a 10-day period, the daily dose should be increased to about 100 mg on Mondays and Wednesdays and 150 mg on Fridays. Unfortunately, despite the apparent advantages of this treatment approach, some patients are resistant to continuing care. In one study, only about 60% of the patients completed 6 days of naltrexone induction, and only 10% remained in the program at the end of 6 months. However, another study reported much higher rates of compliance, with almost a third achieving continuous abstinence for at least a year.

Drug-Free Programs Most existing halfway houses and recovery centers for opioid-dependent persons use some variant of the therapeutic community approach. This is an exception to the general preference for short-term residential (as opposed to outpatient) rehabilitation, since care can last a year or more while the person is taken out of the street culture and given a new life within the group. In this structure, members, including leaders who are themselves in the process of recovery, help participants gain insights into more successful strategies for coping with problems.

As is true for treatments of all substance-use disorders, it is likely that counseling, behavioral treatments, and relatively simple approaches to psychotherapy add significantly to a positive outcome. Most approaches focus on teaching participants to cope with stress, enhancing their understanding of personality attributes, teaching better cognitive styles, and, through the process of relapse prevention, addressing issues that might contribute to increased craving, easy access to drugs, or periods of decreased motivation. A combination of these therapies with the approaches described above appears to give the best results.

Finally, it is important to discuss prevention. Except for the terminally ill, physicians should carefully monitor opioid drug use in their patients, keeping doses as low as is practical and administering them over as short a period as the level of pain would warrant in the average person. Physicians must be vigilant regarding their own risk for opioid abuse and dependence, *never* prescribing these drugs for themselves. For the nonmedical intravenous drug-dependent person, all possible efforts must be made to prevent AIDS, hepatitis, bacterial endocarditis, and other consequences of contaminated needles both through methadone maintenance and by considering needle-exchange programs.

389. COCAINE AND OTHER COMMONLY ABUSED DRUGS - *Jack H. Mendelson*, *Nancy K. Mello*

The abuse of cocaine and other psychostimulant drugs appears to be increasing in many metropolitan and rural areas throughout the world, according to a year 2000 report by the National Institute on Drug Abuse (NIDA). The number of deaths associated with these drugs has also increased. In several urban areas of the United States, use of these drugs has increased more sharply among women than men. Although enhanced legal enforcement as well as educational prevention procedures have attenuated, in part, the increase in psychostimulant abuse among youths in the United States, there appears to be an enhanced worldwide risk for psychostimulant abuse and dependence.

The initiation and continuation of drug abuse are determined by a complex interaction of the pharmacologic properties and relative availability of each drug, the personality and expectations of the user, and the environmental context in which the drug is used. Polydrug abuse, the concurrent use of several drugs with different pharmacologic effects, is increasingly common among individuals from all socioeconomic strata. There has been an alarming increase in particularly dangerous forms of polydrug abuse, such as the combined use of heroin and cocaine intravenously. There is no simple explanation for this change in polydrug use patterns. Drug abusers may attempt to attenuate one drug effect with another, as when heroin or alcohol is used to modulate the cocaine high. Sometimes one drug is used to enhance the effects of another, as with benzodiazepines and methadone, or cocaine plus heroin in methadone-maintained patients.

Chronic cocaine and psychostimulant abuse may cause a number of adverse health consequences, ranging from pulmonary disease to reproductive dysfunction. Preexisting disorders such as hypertension and cardiac disease may be exacerbated by drug abuse, and the combined use of two or more drugs may accentuate medical complications associated with abuse of one of them. The adverse health consequences of drug abuse are further complicated by AIDS.

Drug abuse increases the risk of exposure to HIV. Cocaine and psychostimulant abuse contribute to the risk for HIV infection in part by the adverse immunomodulatory effects of these drugs. In addition, concurrent use of cocaine and opiates (the "speedball") is frequently associated with needle-sharing by intravenous drug users. These individuals continue to represent the largest single group of persons with HIV infection in several major metropolitan areas in the United States as well as in urban areas in Scotland, Italy, Spain, Thailand, and China.

COCAINE

Cocaine is a stimulant and local anesthetic with potent vasoconstrictor properties. The leaves of the coca plant (*Erythroxylon coca*) contain approximately 0.5 to l% cocaine. The drug produces physiologic and behavioral effects when administered orally, intranasally (snorting), intravenously, or via inhalation following pyrolysis (smoking). Cocaine increases synaptic concentrations of the monoamine neurotransmitters dopamine, norepinephrine, and serotonin by binding to transporter proteins in presynaptic neurons and blocking reuptake. The reinforcing effects of cocaine are

related to effects on dopaminergic neurons in the mesolimbic system (Chap. 386).

Prevalence of Cocaine Use Cocaine has become widely available throughout the United States, and cocaine abuse occurs in virtually all social and economic strata of society. The prevalence of cocaine abuse in the general population has been accompanied by an increase in cocaine abuse by heroin-dependent persons, including those in methadone maintenance programs. Intravenous cocaine is often used concurrently with intravenous heroin -- a combination that purportedly attenuates the postcocaine "crash" and substitutes a cocaine "high" for the heroin "high" blocked by methadone.

Acute and Chronic Cocaine Intoxication There has been an increase in both intravenous administration and inhalation of pyrolyzed cocaine via smoking. Following intranasal administration, changes in mood and sensation are perceived within 3 to 5 min, and peak effects occur at l0 to 20 min. The effects rarely last>1 h. Inhalation of pyrolyzed materials includes inhaling crack/cocaine or smoking coca paste, a product made by extracting cocaine preparations with flammable solvents, and cocaine free-base smoking. Free-base cocaine, including the free base prepared with sodium bicarbonate (crack), is becoming increasingly popular because of the relative high potency of the compound and its rapid onset of action (8 to 10 s following smoking).

Cocaine produces a brief, dose-related stimulation and enhancement of mood and an increase in cardiac rate and blood pressure. Body temperature usually increases, and high doses of cocaine may induce lethal pyrexia or hypertension. Because cocaine inhibits reuptake of catecholamines at adrenergic nerve endings, the drug potentiates sympathetic nervous system activity. Cocaine has a short plasma half-life of approximately 45 to 60 min. Cocaine is metabolized primarily by plasma esterases, and cocaine metabolites are excreted in urine. The very short duration of euphorigenic effects of cocaine observed in chronic abusers is probably due to both acute and chronic tolerance. Frequent self-administration of the drug (two to three times per hour) is often reported by chronic cocaine abusers. Alcohol is used to modulate both the cocaine high and the dysphoria associated with the abrupt disappearance of cocaine's effects. A metabolite of cocaine, cocaethylene, has been detected in blood and urine of persons who concurrently abuse alcohol and cocaine. Cocaethylene induces changes in cardiovascular function similar to those of cocaine alone, and the pathophysiologic consequences of alcohol abuse plus cocaine abuse may be additive when both are used together.

The prevalent assumption that cocaine inhalation or intravenous administration is relatively safe is contradicted by reports of death from respiratory depression, cardiac arrhythmias, and convulsions associated with cocaine use. In addition to generalized seizures, neurologic complications may include headache, ischemic or hemorrhagic stroke, or subarachnoid hemorrhage. Disorders of cerebral blood flow and perfusion in cocaine-dependent persons have been detected with magnetic resonance spectroscopy (MRS) studies. Severe pulmonary disease may develop in individuals who inhale crack cocaine; this effect is attributed both to the direct effects of cocaine and to residual contaminants in the smoked material. Hepatic necrosis has been reported to occur following crack cocaine use.

Although men and women who abuse cocaine may report that the drug enhances libidinal drive, chronic cocaine use causes significant loss of libido and adversely affects reproductive function. Impotence and gynecomastia have been observed in male cocaine abusers, and these abnormalities often persist for long periods following cessation of drug use. Women who abuse cocaine have reported major derangements in menstrual cycle function including galactorrhea, amenorrhea, and infertility. Chronic cocaine abuse may cause persistent hyperprolactinemia as a consequence of disordered dopaminergic inhibition of prolactin secretion by the pituitary. Cocaine abuse by pregnant women, particularly the smoking of crack, has been associated with both an increased risk of congenital malformations in the fetus and perinatal cardiovascular and cerebrovascular disease in the mother. However, cocaine abuse per se is probably not the sole cause of these perinatal disorders, since many problems associated with maternal cocaine abuse, including poor nutrition and health care status as well as polydrug abuse, also contribute to risk for perinatal disease.

Protracted cocaine abuse may cause paranoid ideation and visual and auditory hallucinations, a state that resembles alcoholic hallucinosis. Psychological dependence on cocaine, as manifested by inability to abstain from frequent compulsive use, has also been reported. Although the occurrence of withdrawal syndromes involving psychomotor agitation and autonomic hyperactivity remains controversial, severe depression ("crashing") following cocaine intoxication may accompany drug withdrawal.

TREATMENT

Treatment of cocaine overdose is a medical emergency that is often best managed in an intensive care unit. Cocaine toxicity produces a hyperadrenergic state characterized by hypertension, tachycardia, tonic-clonic seizures, dyspnea, and ventricular arrhythmias. Intravenous diazepam in doses up to 0.5 mg/kg administered over an 8-h period has been shown to be effective for control of seizures. Ventricular arrhythmias have been managed successfully by administration of 0.5 to 1.0 mg of propranolol intravenously. Since many instances of cocaine-related mortality have been associated with concurrent use of other illicit drugs (particularly heroin), the physician must be prepared to institute effective emergency treatment for multiple drug toxicities.

Treatment of chronic cocaine abuse requires combined efforts by primary care physicians, psychiatrists, and psychosocial care providers. Early abstinence from cocaine use is often complicated by symptoms of depression and guilt, insomnia, and anorexia, which may be as severe as those observed in major affective disorders. Individual and group psychotherapy, family therapy, and peer group assistance programs are often useful for inducing prolonged remission from drug use. A number of medications used for the treatment of various psychiatric disorders have been administered to reduce the duration and severity of cocaine abuse and dependence. However, no available medication is both safe and highly effective for either cocaine detoxification or maintenance of abstinence. Some psychotherapeutic interventions are occasionally effective; however, no specific form of psychotherapy or behavioral modification is uniquely beneficial.

MARIJUANA AND CANNABIS COMPOUNDS

Cannabis sativa contains>400 compounds in addition to the psychoactive substance, delta-9-tetrahydrocannabinol (THC). Marijuana cigarettes are prepared from the leaves and flowering tops of the plant, and a typical marijuana cigarette contains 0.5 to 1 g of plant material. Although the usual THC concentration varies between 10 and 40 mg, concentrations>100 mg per cigarette have been detected. Hashish is prepared from concentrated resin of *C. sativa* and contains a THC concentration of between 8 to 12% by weight. "Hash oil," a lipid-soluble plant extract, may contain a THC concentration of 25 to 60% and may be added to marijuana or hashish to enhance its THC concentration. Smoking is the most common mode of marijuana or hashish use. During pyrolysis,>150 compounds in addition to THC are released in the smoke. Although most of these compounds do not have psychoactive properties, they do have potential physiologic effects.

THCis quickly absorbed from the lungs into blood and is then rapidly sequestered in tissues. It is metabolized primarily in the liver, where it is converted to 11-hydroxy-THC, a psychoactive compound, and >20 other metabolites. Many THC metabolites are excreted through the feces at a rate of clearance that is relatively slow in comparison to that of most other psychoactive drugs.

Specific cannabinoid receptors (CB_1 and CB_2) have been identified in the central nervous system, including the spinal cord, and in the peripheral nervous system. High densities of these receptors have been found in the cerebral cortex, basal ganglia, and hippocampus. B lymphocytes also appear to have cannabinoid receptors. A naturally occurringTHC-like ligand has been identified in the nervous system, where it is widely distributed.

Prevalence of Marijuana Use Marijuana is the most commonly used illegal drug in the United States. Use is particularly prevalent among adolescents; studies suggest that ~40% of high school students in the United States have used marijuana. Marijuana is relatively inexpensive and is considered by many persons to be less hazardous than the use of other controlled drugs and substances. Very potent forms of marijuana (sinsemilla) are now available in many communities, and concurrent use of marijuana with crack/cocaine and phencyclidine is increasing. Marijuana abuse by individuals from all social strata has been increasing.

Acute and Chronic Marijuana Intoxication Acute intoxication from marijuana and cannabis compounds is related to both the dose ofTHC and the route of administration. THC is absorbed more rapidly from marijuana smoking than from orally ingested cannabis compounds. Acute marijuana intoxication usually consists of a subjective perception of relaxation and mild euphoria resembling mild to moderate alcohol intoxication. This condition is usually accompanied by some impairment in thinking, concentration, and perceptual and psychomotor function. Higher doses of cannabis may produce behavioral effects analogous to severe alcohol intoxication. Although the effects of acute marijuana intoxication are relatively benign in normal users, the drug can precipitate severe emotional disorders in individuals who have antecedent psychotic or neurotic problems. As with other psychoactive compounds, both set (user's expectations) and setting (environmental context) are important determinants of the type and severity of behavioral intoxication.

As is true of alcoholics, chronic marijuana abusers may lose interest in common socially desirable goals and steadily devote more time to drug acquisition and use. However, THC does not cause a specific and unique "amotivational syndrome." The range of symptoms sometimes attributed to marijuana use is difficult to distinguish from mild to moderate depression and the maturational dysfunctions often associated with protracted adolescence. Chronic marijuana use has also been reported to increase the risk of psychotic symptoms in individuals with a past history of schizophrenia.

Physical Effects of Marijuana Conjunctival injection and tachycardia are the most frequent immediate physical concomitants of smoking marijuana. Tolerance for marijuana-induced tachycardia develops rapidly among regular users; angina may be precipitated by marijuana smoking in persons with a history of coronary insufficiency. Exercise-induced angina may be increased after marijuana use to a greater extent than after tobacco cigarette smoking. Patients with cardiac disease should be strongly advised not to use cannabis compounds.

Significant decrements in pulmonary vital capacity have been found in regular daily marijuana smokers. Because marijuana smoking typically involves deep inhalation and prolonged retention of marijuana smoke, marijuana smokers may develop chronic bronchial irritation. Impairment of single-breath carbon monoxide diffusion capacity (DL_{CO}) is greater in persons who smoke both marijuana and tobacco than in tobacco smokers. Despite the well-documented association between tobacco smoking and lung cancer, at present there is no direct evidence that marijuana smoking induces lung cancer. However, heavy marijuana use among Americans may be too recent to permit detection of this problem.

Although marijuana has also been associated with adverse effects on a number of other systems, many of these studies await replication and confirmation. A reported correlation between marijuana use and decreased testosterone levels in males has not been confirmed. Decreased sperm count and sperm motility and morphologic abnormalities of spermatozoa following marijuana use have also been reported. Administration of high doses of marijuana to female rhesus monkeys suppresses pituitary gonadotropins and gonadal steroids. Prospective studies demonstrated a correlation between impaired fetal growth and development and heavy marijuana use during pregnancy. Marijuana has also been implicated in derangements of the immune system; in chromosomal abnormalities; and in inhibition of DNA, RNA, and protein synthesis; however, these findings have not been confirmed or related to any specific physiologic effect in humans.

Tolerance and Physical Dependence Habitual marijuana users rapidly develop tolerance to the psychoactive effects of marijuana and often smoke more frequently and try to secure more potent cannabis compounds. Tolerance for the physiologic effects of marijuana develops at different rates; e.g., tolerance develops rapidly for marijuana-induced tachycardia but more slowly for marijuana-induced conjunctival injection. Tolerance to both behavioral and physiologic effects of marijuana decreases rapidly upon cessation of marijuana use.

Withdrawal signs and symptoms have been reported in chronic cannabis users, with the severity of symptoms related to dosage and duration of use. These include tremor,

nystagmus, sweating, nausea, vomiting, diarrhea, irritability, anorexia, and sleep disturbances. Withdrawal signs and symptoms observed in chronic marijuana users are usually relatively mild in comparison to those observed in heavy opiate or alcohol users and rarely require medical or pharmacologic intervention. More severe and protracted abstinence syndromes may occur after sustained use of high potency cannabis compounds.

Therapeutic Use of Marijuana Marijuana, administered as cigarettes or as a synthetic oral cannabinoid (dronabinol), has been proposed to have a number of properties that may be clinically useful in some situations. These include antiemetic effects in chemotherapy recipients, appetite-promoting effects in AIDS, reduction of intraocular pressure in glaucoma, and reduction of spasticity in multiple sclerosis and other neurologic disorders. With the possible exception of AIDS-related cachexia, none of these attributes of marijuana compounds is clearly superior to other readily available therapies. Furthermore, any therapeutic benefit of marijuana must be balanced against the many unhealthy psychoactive effects associated with its use.

METHAMPHETAMINE

The abuse of methamphetamine, also referred to as "meth," "speed," "crank," "chalk," "ice," "glass," or "crystal," has been declining in many metropolitan areas and communities throughout the United States. This decrease is attributed in part to drug seizures and the closures of clandestine laboratories that produce methamphetamine illegally. Prevention programs focusing upon methamphetamine abuse have also increased.

Most persons who abuse amphetamine self-administer the drug orally, although there have been reports of methamphetamine administration by inhalation and intravenous injection. Individuals who abuse or become dependent upon methamphetamine state that use of this drug induces feelings of euphoria and decreases fatigue associated with aversive life situations. Adverse physiologic effects observed as a consequence of methamphetamine abuse include headache, difficulty concentrating, diminished appetite, abdominal pain, vomiting or diarrhea, disordered sleep, paranoid or aggressive behavior, and psychosis. Severe, life-threatening toxicity may present as hypertension, cardiac arrythmia or failure, subarachnoid hemorrhage, ischemic stroke, intracerebral hemorrhage, convulsions, or coma. Amphetamines increase the release of monoamine neurotransmitters (dopamine, norepinephrine, and serotonin) from presynaptic neurons. It is thought that the euphoric and reinforcing effects of this class of drugs are mediated through dopamine and the mesolimbic system, whereas the cardiovascular effects are related to norepinephrine. Magnetic resonance spectroscopy studies suggest that chronic abuse may injure the frontal areas and basal ganglia of the brain.

Therapy of acute methamphetamine overdose is largely symptomatic. Ammonium chloride may be useful to acidify the urine and enhance clearance of the drug. Hypertension may respond to sodium nitroprusside or a-adrenergic antagonists. Sedatives may reduce agitation and other signs of central nervous system overactivity. Treatment of chronic methamphetamine dependence may be accomplished in either an inpatient or outpatient setting using strategies similar to those described above for cocaine abuse.

MDMA (3,4-methylenedioxymethamphetamine), or *Ecstasy*, is a derivative of methamphetamine. Ecstasy is usually taken orally but may be injected or inhaled. In addition to amphetamine-like effects, MDMA can induce vivid hallucinations and other perceptual distortions. These toxicities are similar to those of lysergic acid diethylamide (LSD) and may be mediated through the release of serotonin.

LYSERGIC ACID DIETHYLAMIDE

The discovery of the psychedelic effects ofLSD in 1947 led to an epidemic of LSD abuse during the 1960s. Imposition of stringent constraints on the manufacture and distribution of LSD (classified as a Schedule I substance by the U.S. Food and Drug Administration), as well as public recognition that psychedelic experiences induced by LSD were a health hazard, have resulted in a reduction in LSD abuse. The drug still retains some popularity among adolescents and young adults, however, and there are indications that LSD use among young persons has been increasing in some communities in the United States.

LSDis a very potent drug; oral doses as low as 20 ug may induce profound psychological and physiologic effects. Tachycardia, hypertension, pupillary dilation, tremor, and hyperpyrexia occur within minutes following oral administration of 0.5 to 2 ug/kg. A variety of bizarre and often conflicting perceptual and mood changes, including visual illusions, synesthesias, and extreme lability of mood, usually occur within 30 min after LSD intake. The action of LSD may persist for 12 to 18 h, even though the half-life of the drug is only 3 h.

Tolerance develops rapidly forLSD-induced changes in psychological function when the drug is used one or more times per day for 4 or more days. Abrupt abstinence following continued use does not produce withdrawal signs or symptoms. There have been no clinical reports of death caused by the direct effects of LSD.

The most frequent medical emergency associated withLSD use is panic episode (the "bad trip"), which may persist up to 24 h. Management of this problem is best accomplished by supportive reassurance ("talking down") and, if necessary, administration of small doses of anxiolytic drugs. Adverse consequences of chronic LSD use include risk for schizophreniform psychosis and derangements in memory function, problem solving, and abstract thinking. Treatment of these disorders is best carried out in specialized psychiatric facilities.

PHENCYCLIDINE

Phencyclidine (PCP), a cyclohexylamine derivative, is widely used in veterinary medicine to briefly immobilize large animals and is sometimes described as a dissociative anesthetic. PCP binds to ionotropic *n*-methyl-*d*-aspartate (NMDA) receptors in the nervous system, blocking ion current through these channels. PCP is easily synthesized; its abusers are primarily young people and polydrug users. It is used orally, by smoking, or by intravenous injection. It is also used as an adulterant inTHC,LSD, amphetamine, or cocaine. The most common street preparation, *angel dust*, is a white granular powder that contains 50 to 100% of the drug. Low doses (5 mg) produce

agitation, excitement, impaired motor coordination, dysarthria, and analgesia. Users may have horizontal or vertical nystagmus, flushing, diaphoresis, and hyperacusis. Behavioral changes include distortions of body image, disorganization of thinking, and feelings of estrangement. Higher doses of PCP (5 to 10 mg) may produce hypersalivation, vomiting, myoclonus, fever, stupor, or coma. PCP doses of ³10 mg cause convulsions, opisthotonus, and decerebrate posturing, which may be followed by prolonged coma.

The diagnosis ofPCPoverdose is difficult because the patient's initial symptoms may suggest an acute schizophrenic reaction. Confirmation of PCP use is possible by determination of PCP levels in serum or urine; PCP assays are available at most toxicologic centers. PCP remains in urine for 1 to 5 days following high-dose intake.

PCPoverdose requires life-support measures, including treatment of coma, convulsions, and respiratory depression in an intensive care unit. There is no specific antidote or antagonist for PCP. PCP excretion from the body can be enhanced by gastric lavage and acidification of urine. Death from PCP overdose may occur as a consequence of some combination of pharyngeal hypersecretion, hyperthermia, respiratory depression, severe hypertension, seizures, hypertensive encephalopathy, and intracerebral hemorrhage.

Acute psychosis associated withPCP use should be considered a psychiatric emergency since patients may be at high risk for suicide or extreme violence toward others. Phenothiazines should not be used for treatment because these drugs potentiate PCP's anticholinergic effects. Haloperidol (5 mg intramuscularly) has been administered on an hourly basis to induce suppression of psychotic behavior. PCP, likeLSD and mescaline, produces vasospasm of cerebral arteries at relatively low doses. Chronic PCP use has been shown to induce insomnia, anorexia, severe social and behavioral changes, and, in some cases, chronic schizophrenia.

POLYDRUG ABUSE

Although drug abusers often report a preference for a particular drug, such as alcohol or opiates, the concurrent use of other drugs is common. Multiple drug use often involves substances that may have different pharmacologic effects from the preferred drug. Concurrent use of dissimilar compounds such as stimulants and opiates or stimulants and alcohol is not unusual. The diversity of reported drug use combinations suggests that achieving some perceptible change in state, rather than any particular direction of change (stimulation or sedation), may be the primary reinforcer in polydrug use and abuse. There is also evidence that intoxication with alcohol or opiates is associated with increased tobacco smoking. There is relatively little systematic information available about multiple drug abuse interactions. However, the combined use of cocaine, heroin, and alcohol increases the risk for toxic effects and adverse medical consequences over risks associated with use of a single drug. One determinant of polydrug use patterns is the relative availability and cost of the drugs. There are many examples of situationally determined drug-use patterns. For example, alcohol abuse, with its attendant medical complications, is one of the most serious problems encountered in former heroin addicts participating in methadone maintenance programs.

The physician must recognize that perpetuation of polydrug abuse and drug dependence is not necessarily a symptom of an underlying emotional disorder. Neither alleviation of anxiety nor reduction of depression accounts for initiation and perpetuation of polydrug abuse. Severe depression and anxiety are as frequently the consequences of polydrug abuse as they are the antecedents. There is also evidence that some of the most adverse consequences of drug use may be reinforcing and contributing to the continuation of polydrug abuse.

TREATMENT

Adequate treatment of polydrug abuse, as well as other forms of drug abuse, requires innovative programs of intervention. The first step in successful treatment is detoxification, a process that may be difficult because of the abuse of several drugs with different pharmacologic actions (e.g., alcohol, opiates, and cocaine). Since patients may not recall or may deny simultaneous multiple drug use, diagnostic evaluation should always include urinalysis for qualitative detection of psychoactive substances and their metabolites. Treatment of polydrug abuse often requires hospitalization or inpatient residential care during detoxification and the initial phase of drug abstinence. When possible, specialized facilities for the care and treatment of chemically dependent persons should be used. Outpatient detoxification of polydrug abuse patients is likely to be ineffective and may be dangerous.

As in the treatment of alcohol abuse, no single therapeutic modality has been shown to be uniquely effective in inducing remission. Polydrug abuse is a chronic disorder with an unpredictable pattern of remission and recrudescence. Even temporary remissions with attendant physical, social, and psychological improvements are preferable to the continuation or progressive acceleration of polydrug abuse and its related adverse medical and interpersonal consequences. In polydrug abuse, as in many chronic disorders, definitive "cures" rarely occur. The concerned physician should continue to assist polydrug abuse patients throughout the cyclic oscillations of this complex behavior disorder, recognizing that resumption of drug use may be the rule rather than the exception.

390. NICOTINE ADDICTION - *David M. Burns*

The use of tobacco leaf to create and satisfy nicotine addiction was introduced to Columbus by Native Americans and spread rapidly to Europe. The use of tobacco as cigarettes, however, is predominantly a twentieth century phenomenon, as is the epidemic of disease caused by this form of tobacco.

Nicotine is the principal constituent of tobacco responsible for its addictive character. Addicted smokers regulate their nicotine intake and blood levels by adjusting the frequency and intensity of their tobacco use both to obtain the desired psychoactive effects and avoid withdrawal.

Unburned cured tobacco contains nicotine, carcinogens, and other toxins capable of causing gum disease and oral cancer. When tobacco is burned, the resultant smoke contains, in addition to nicotine, carbon monoxide and >4000 other compounds that result from volatilization, pyrolysis, and pyrosynthesis of tobacco and various chemical additives used in making different tobacco products. The smoke is composed of a fine aerosol, with a particle size distribution predominantly in the range to deposit in the airways and alveolar surfaces of the lungs, and a vapor phase. The bulk of the toxicity and carcinogenicity of the smoke resides in the aerosolized particulate phase, which contains a large number of toxic constituents and >40 carcinogenic compounds. The aggregate of particulate matter, after subtracting nicotine and moisture, is referred to as tar. The vapor phase contains carbon monoxide, respiratory irritants, and ciliotoxins as well as many of the volatile compounds responsible for the distinctive smell of cigarette smoke.

The alkaline pH of smoke from blends of tobacco utilized for pipes and cigars allows sufficient absorption of nicotine across the oral mucosa to satisfy the smoker's need for this drug. Therefore, smokers of pipes and cigars tend not to inhale the smoke into the lung, confining the toxic and carcinogenic exposure (and the increased rates of disease) largely to the upper airway for most users of these products. The acidic pH of smoke generated by the tobacco used in cigarettes dramatically reduces absorption of nicotine in the mouth, necessitating inhalation of the smoke into the larger surface of the lungs in order to absorb quantities of nicotine sufficient to satisfy the smoker's addiction. The shift to using tobacco as cigarettes, with resultant increased deposition of smoke in the lung, has created the epidemic of heart disease, lung disease, and lung cancer that dominates the current disease manifestations of tobacco use.

DISEASE MANIFESTATIONS OF CIGARETTE SMOKING

Over 400,000 individuals die prematurely each year in the United States from cigarette use; this represents approximately one out of every five deaths in the United States. Approximately 40% of cigarette smokers will die prematurely due to cigarette smoking unless they are able to quit.

The major diseases caused by cigarette smoking are listed in Table 390-1, with the relative risks for each disease listed for male and female current smokers. The incidence of smoking-related diseases is proportionately greater in younger than in older smokers, particularly for coronary artery disease and stroke. At older ages, the

background rate of disease in nonsmokers increases, diminishing the fractional contribution of smoking and the relative risk; however, absolute excess rates of disease mortality found in smokers compared to nonsmokers increase with increasing age. The organ damage caused by smoking and the number of smokers who die from smoking are both greater among the elderly, as one would expect from a process of cumulative injury.

Cardiovascular Diseases Cigarette smokers are more likely than nonsmokers to develop large vessel atherosclerosis as well as small vessel disease. Approximately 90% of peripheral vascular disease in the nondiabetic population can be attributed to cigarette smoking, as can approximately 50% of aortic aneurysms. In contrast, 20 to 30% of coronary artery disease and approximately 10% of occlusive cerebrovascular disease are caused by cigarette smoking. There is a multiplicative interaction between cigarette smoking and other cardiac risk factors such that the increment in risk produced by smoking among individuals with hypertension or elevated serum lipids is substantially greater than the increment in risk produced by smoking for individuals without these risk factors.

In addition to its role in promoting atherosclerosis, cigarette smoking also increases the likelihood of myocardial infarction and sudden cardiac death by promoting platelet aggregation and vascular occlusion. Reversal of these effects may explain the rapid benefit of smoking cessation for a new coronary event demonstrable among those who have survived a first myocardial infarction. This effect may also explain the substantially higher rates of graft occlusion among continuing smokers following vascular bypass surgery for cardiac or peripheral vascular disease, as well as the high failure rate of angioplasty procedures among continuing smokers.

Cessation of cigarette smoking reduces the risk of a second coronary event within 6 to 12 months after quitting, and rates of first myocardial infarction or death from coronary heart disease also decline within the first few years following cessation. After 15 years of cessation, the risk of a new myocardial infarction or death from coronary heart disease in former smokers is similar to that in those who have never smoked.

Cancer Cancers of the lung, larynx, oral cavity, esophagus, pancreas, kidney, and urinary bladder are caused by cigarette smoking. In addition, there is evidence suggesting that cigarette smoking may play a role in increasing the risk of cervical and stomach cancer. There is conflicting evidence on the relationship of cigarette smoking and cancer of the breast, but overall there does not appear to be a causal link. There is a lower risk of uterine cancer among postmenopausal women who smoke.

The risks of cancer increase with the increasing number of cigarettes smoked per day and the duration of smoking, and there are synergistic interactions between cigarette smoking and alcohol use for cancer of the oral cavity, esophagus, and possibly lung. Several occupational exposures also synergistically increase lung cancer risk among cigarette smokers, most notably occupational asbestos and radon exposure.

Cessation of cigarette smoking reduces the risk of developing cancer relative to continuing smoking, but even 20 years after cessation there is a modest persistent increased risk of developing lung cancer.

Respiratory Disease Cigarette smoking is responsible for>90% of chronic obstructive pulmonary disease. Within 1 to 2 years of beginning to smoke regularly, many young smokers will develop inflammatory changes in their small airways, although lung function measures of these changes do not predict development of chronic airflow obstruction. After[3]20 years of smoking, pathophysiologic changes in the lungs develop and progress proportional to smoking intensity and duration. Chronic mucous hyperplasia of the larger airways results in a chronic productive cough in as many as 80% of smokers over age 60. Chronic inflammation and narrowing of the small airways and/or enzymatic digestion of alveolar walls resulting in pulmonary emphysema can result in reduced expiratory airflow sufficient to produce clinical symptoms of respiratory limitation in approximately 15% of smokers.

Changes in the small airways of young smokers will reverse after 1 to 2 years of cessation. There may also be a small increase in measures of expiratory airflow following cessation among individuals who have developed chronic airflow obstruction, but the major change following cessation is a slowing of the rate of decline in lung function with advancing age rather than a return of lung function toward normal.

Pregnancy Cigarette smoking is associated with several maternal complications of pregnancy: premature rupture of membranes, abruptio placentae, and placenta previa; there is also a small increase in the risk of spontaneous abortion among smokers. Infants of smoking mothers are more likely to experience preterm delivery, have a higher perinatal mortality, are small for their gestational age, are more likely to die of sudden infant death syndrome, and appear to have a developmental lag for at least the first several years of life.

Other Conditions Smoking delays healing of peptic ulcers; increases the risk of osteoporosis, senile cataracts, and macular degeneration; and results in premature menopause, wrinkling of the skin, gallstones and cholecystitis in women, and male impotence.

Environmental Tobacco Smoke Long-term exposure to environmental tobacco smoke increases the risk of lung cancer and coronary artery disease among nonsmokers. It also increases the incidence of respiratory infections, chronic otitis media, and asthma in children as well as causing exacerbation of asthma in children.

PHARMACOLOGIC INTERACTIONS

Cigarette smoking may interact with a variety of other drugs in ways that may have clinically significant implications (Table 390-2). Cigarette smoking induces the cytochrome P450 system, which may alter the metabolic clearance of drugs such as theophylline. This effect may result in more drug toxicity among nonsmokers on fixed drug dosage schedules and in inadequate serum levels in smokers as outpatients when the dosage is established in the hospital under nonsmoking conditions. Correspondingly, serum levels may rise when smokers are hospitalized and not allowed to smoke. Smokers may also have higher first-pass clearance for drugs such as lidocaine, and the stimulant effects of nicotine may reduce the effect of benzodiazepines or beta blockers.

OTHER FORMS OF TOBACCO USE

Other major forms of tobacco use are moist snuff deposited between the cheek and gum, chewing tobacco, pipes and cigars, and recently bidi (tobacco wrapped in tendu or temburni leaf and commonly used in India) and clove cigarettes. Oral tobacco use leads to gum disease and can result in oral cancer. All forms of burned tobacco generate toxic and carcinogenic smoke similar to that of cigarette smoke. The differences in disease consequences of use relate to frequency of use and depth of inhalation. The risk of upper airway cancers is similar among cigarette and cigar smokers, while those who have smoked only cigars have a much lower risk of lung cancer, heart disease, and chronic obstructive pulmonary disease. However, cigarette smokers who switch to pipes or cigars do tend to inhale the smoke, increasing their risk; and it is likely that comparable inhalation and frequency of exposure to tobacco smoke from any of these forms of tobacco use will lead to comparable disease outcomes.

Recent prevalence-of-use data have suggested a resurgence of cigar and bidi use among adolescents of both genders, raising concerns that these older forms of tobacco use are once again causing a public health concern.

LOWER TAR AND NICOTINE CIGARETTES

Since the bulk of the toxicity of cigarette smoke is contained in the tar, and since nicotine is the principal addictive agent in cigarettes, it has been suggested that cigarettes that deliver less tar and nicotine to the smoker might be safer. Studies of smokers of low-yield cigarettes suggest that there may be a 10 to 20% reduction in the risk of developing lung cancer among those who reduce the nominal tar yield of their cigarettes by³50%. However, this benefit is only evident if smokers do not compensate for the lower nicotine delivery with an increased intensity of smoking, and most studies show that smokers of low-yield cigarettes do compensate. Because of their addiction to nicotine, most smokers tend to preserve their intake of nicotine, and correspondingly their tar intake, when they shift to lower nicotine cigarettes.

Newer, very low yield cigarettes commonly use vents in the filters or other engineering designs to reduce the tar and nicotine when the cigarette is smoked by machine. However, the delivery of tar and nicotine is much higher when these cigarettes are smoked by actual smokers. Current evidence suggests that if there is any disease-reduction benefit for smokers of low-yield cigarettes, it is too small to be clinically meaningful, and individuals should be discouraged from thinking of low-yield cigarettes as a substitute for cessation.

CESSATION

The process of stopping smoking is often a cyclical one, with the smoker sometimes making multiple attempts to quit and failing before finally being successful. Approximately 70 to 80% of smokers would like to quit smoking, approximately one-third of current smokers attempt to quit each year, and ³90% of these unassisted quit attempts fail. Smokers have been categorized into those who are not thinking about quitting (precontemplation), those who are thinking about quitting (contemplation), and

those who are in the action phase of quitting. A useful conceptualization of the cessation process is one where smokers cycle through the stages of cessation; each time smokers go around the cycle, a few more smokers become successful in their cessation efforts. One goal of clinician-based smoking interventions then becomes moving smokers from one stage of the cessation cycle to another, and efforts can be focused on moving the smoker to the next stage rather than focusing exclusively on immediate cessation.

The move from thinking about quitting to making a quit attempt is often triggered by a variety of environmental stimuli independent of physician control. The cost of cigarettes can be a powerful trigger for cessation attempts. Media campaigns, particularly when coupled with cessation events, are also able to trigger cessation attempts in large numbers of smokers. Changes in workplace rules to restrict smoking in the workplace have been associated with quit attempts in substantial numbers of workers. However, physician advice to quit, particularly around an acute illness, is also a powerful trigger for cessation activity, with up to half of patients who are advised to quit making a cessation effort.

Telephone counseling and nicotine-replacement therapy are all useful enhancers of long-term cessation success. Clinic-based cessation programs have a substantial benefit for long-term cessation for those who can be recruited to participate, and physician recommendation can double the fraction of smokers who are willing to participate in these programs.

PREVENTION

Approximately 90% of individuals who will become cigarette smokers initiate the behavior during adolescence. Factors that promote adolescent initiation are parental or older generation cigarette smoking, tobacco advertising and promotional activities, the availability of cigarettes, and the social acceptability of smoking. The need for an enhanced self-image and to imitate adult behavior is greatest for those adolescents who have the least external validation of their self-worth, which may explain in part the enormous differences in adolescent smoking prevalence by socioeconomic and school performance strata.

Prevention of smoking initiation must begin early, preferably in the elementary school years. Physicians who deal with adolescents should be sensitive to the prevalence of this problem in their patient population. Effective physician-based interventions for adolescent smokers remain to be developed, but current clinical guidelines suggest that physicians should ask all adolescents whether they have experimented with tobacco or currently use tobacco, reinforce the facts that most adolescents and adults do not smoke, and explain that all forms of tobacco are both addictive and harmful.

GENETIC CONSIDERATIONS

Several genes have been associated with nicotine addiction. Some reduce the clearance of nicotine, and others have been associated with an increased likelihood of becoming dependent on tobacco and other drugs as well as a higher incidence of depression. Genetic alterations that involve the neurotransmitter dopamine, and

possibly the serotoninergic and cholinergic neuroregulatory pathways, are being explored for their contribution to development of addiction to tobacco and other substances. The precise role these genetic differences play in development and maintenance of nicotine addiction remains to be determined, but it is unlikely that genetic factors are the principal determinants of addiction. Rates of smoking initiation among males, and corresponding rates of nicotine addiction, have dropped by almost 50% since the mid-1950s, suggesting that factors other than genetics are the principal determinants of whether individuals will become addicted. It is more likely that genetic polymorphism represents a range of biologic susceptibility conditioning the intensity of cigarette use and the probability that experimentation with tobacco as an adolescent leads to addiction as an adult.

PHYSICIAN INTERVENTION

Physicians can make a clear difference in promoting successful cessation among their smoking patients, and the Agency for Health Care Policy and Research (AHCPR) has developed clinical guidelines for health care system-based smoking cessation (Table 390-3). All patients should be asked whether they smoke, their past experience with quitting, and whether they are currently interested in quitting. Those who are not interested in quitting should be encouraged and motivated to quit; provided a clear, strong, and personalized physician message that smoking is an important health concern; and offered assistance if they become interested in quitting in the future. There is a relationship between the amount of assistance a patient is willing to accept, and the success of the cessation attempt. A quit date should be negotiated, usually not the day of the visit but within the next few weeks, and a follow-up contact by office staff around the time of the quit date should be provided.

There are a variety of nicotine-replacement products, including over the counter nicotine patch and gum, as well as nicotine nasal and oral inhalers available by prescription. Clonidine and, more recently, antidepressants such as bupropion have also been shown to be effective; some evidence supports the combined use of nicotine-replacement therapy and antidepressants. Nicotine-replacement therapy is provided in different dosages for use with smokers of different numbers of cigarettes per day. Antidepressants are more effective in those with a history of depression symptoms. At this time there are few clear indications favoring the use of one agent over another as initial therapy. Current recommendations are to offer pharmacologic treatment to all who will accept it and to provide counseling and other support to the patient as a part of the cessation attempt. Cessation advice alone is likely to increase success by 50% compared with no intervention; a more comprehensive approach with advice, pharmacologic assistance, and counseling can increase cessation success by almost threefold.

In order for physicians to incorporate cessation assistance into their practice successfully, it is essential to change the infrastructure in which the physician practices. The following are simple changes: (1) including questions on smoking and interest in cessation on patient-intake questionnaires, (2) asking patients whether they smoke as part of the initial vital sign measurements made by office staff, (3) listing smoking as a problem in the medical record, and (4) automating follow-up contact with the patient on their quit date. These changes are essential to institutionalizing smoking intervention

within the practice setting; without this institutionalization, the best intentions of physicians to intervene with their patients who smoke are often lost in the time crush of a busy practice.

PART FIFTEEN -ENVIROMENTAL AND OCCUPATIONAL HAZARDS

SECTION 1 -SPECIFIC ENVIRONMENTAL AND OCCUPATIONAL HAZARDS

391. SPECIFIC ENVIRONMENTAL AND OCCUPATIONAL HAZARDS - *Howard Hu*, *Frank E. Speizer*

It cannot be overemphasized that an appropriate environmental/occupational history is an essential part of the medical workup of many chronic diseases. The general approach to the patient whose illness may have been caused or exacerbated by environmental or occupational hazards is detailed inChap. 5.

The term *hazards* in this context is generally synonymous with *toxins* and *toxic exposures* and encompasses chemical factors as well as other risks posed by the physical environment and by selected natural phenomena. These hazards may exist in the general environment or in the workplace. Strictly speaking, smoking, alcohol ingestion, nutritional factors, and infectious agents can also be considered chemical or environmental hazards.

Once a specific hazard has been identified as a factor in the pathogenesis of an illness or as an imminent threat, the clinical approach must include the development of a strategy for preventing further exposure and for treating the specific manifestations of the illness, using antidotes and supportive measures. In the following chapters, specific hazards are considered, including acute poisoning and drug overdose; heavy metal poisoning; disorders caused by venoms, bites, and stings; drowning and near-drowning; electrical injuries; and radiation injury. The health effects of ambient air pollution, occupational respiratory exposures, passive smoking, and assorted toxic air pollutants are discussed briefly inChap. 254. Space does not allow specific discussion in this text of many other important categories of hazards, such as organic solvents; chemicals used in the plastics, synthetic textiles, and rubber industries; and pesticides. The reader should consult other detailed texts or electronic information sources for clinical data on these topics. In this volume, however, brief attention is focused on several selected issues in light of recent developments in research that have enhanced our understanding of the way these hazards may interact with human behavior and consequently pose increased risks to both individuals and society.

HAZARDOUS WASTE AND GROUNDWATER CONTAMINATION

The term *hazardous waste* embodies toxic chemicals, radioactive materials, and biologic or infectious wastes. In many communities, hazardous waste has emerged as a major public health concern. In the United States, some 50,000 sites (defined by specific criteria) have been estimated to contain hazardous chemicals; 1000 or so of these have been included as "Superfund sites" on a National Priority List drawn up by the Environmental Protection Agency (EPA). New or unrecognized sites are likely to exist as well. These sites may require long-term remedial action. The spectrum of substances contained at the sites is wide and theoretically may include any of some 30,000 chemicals that are commonly used in commerce. However, the EPA keeps fewer than 200 chemicals on a special hazardous substance list in light of their toxicity, the frequency with which they are encountered, and other factors. One difficulty in

anticipating risks associated with hazardous waste sites is that the substances are usually present in mixtures whose composition is seldom fully known. In addition, with respect to toxicity, chemicals may interact with one another in an additive, protective, or synergistic fashion, and little knowledge exists on which to base predictions regarding the interactions of these complex mixtures.

Waste-site employees and the surrounding community can incur hazardous exposures through the inhalation of toxic vapors or dusts emanating directly from a waste site or an on-site incinerator; the ingestion of water contaminated by surface runoff or by material leaching through soil into surface water or groundwater; the ingestion of contaminated plants, fish, or other wildlife; or direct contact. This last risk is particularly likely for children, who may enter a poorly secured site. Perhaps the exposure of greatest concern to community residents has been the contamination of groundwater by volatile organic compounds or solvents (VOCs); together, the widespread detection of low levels of VOCs in groundwater and the several studies suggesting an association between heavy VOC contamination of drinking water and cancer probably account for the high priority given in public opinion polls to avoiding cancer risks. A 1983 study found that 11 of the 20 chemicals most commonly detected at National Priority List waste sites were VOCs (Table 391-1).

Current regulatory policy rests on the assumption that there is no threshold below which a carcinogen exerts no effect or risk. Thus, once a substance is identified as a probable carcinogen (see below), it is regulated to a concentration that is believed to be accompanied by an acceptable level of risk. Clearly, great uncertainty exists regarding methods used to classify drinking-water carcinogens and to extrapolate the risks related to exposure to these substances. Regardless,VOCcontamination in groundwater is likely to continue to be a high-priority issue in the public arena.

ENVIRONMENTAL CARCINOGENS

Based on studies and reviews of the literature by the International Agency for Research on Cancer, enough evidence exists to classify around 60 substances and processes as probably or definitely carcinogenic in humans (Table 391-2). Some processes are deemed carcinogenic on the basis of epidemiologic evidence, even though the specific causative agent cannot always be clearly identified. Tumor promoters are not distinguished from tumor initiators in this listing, and the chemical structures and modes of action are diverse. Around 150 additional agents and processes have been designated as possibly carcinogenic on the basis of studies of bacteria and animals as well as human epidemiologic studies. The extent to which inferences can be made from nonhuman studies is controversial but certainly depends on minimal standards in the execution of such studies. For example, the Interagency Regulatory Liaison Group recommends that for a carcinogen assay to be considered positive, the test must have been performed on at least 50 animals of each sex in two different species with at least three dose groups (control and two dose levels) over the lifetime of the animals.

BUILDING-RELATED ILLNESSES

Reports of discomfort and symptoms in relation to office environments began in the United States in the 1970s. Research has led to the recognition that some

building-related illnesses have a clear etiology; these illnesses include hypersensitivity diseases, infections, and exacerbations of asthma due to airborne irritants. However, the majority of such complaints, particularly those of mucous membrane irritation, fatigue, and headache, have no clear etiology. Terms such as *sick-building syndrome* (SBS; also called *tight-building syndrome*) and *nonspecific building-related illnesses* have been used to designate this constellation of symptoms, which have been found in most investigations to occur most often in sealed buildings with centrally controlled mechanical ventilation. Early characterizations of SBS as mass psychogenic illness have not been borne out in the majority of cases by subsequent epidemiologic investigations. Since indoor air-exchange rates were sharply reduced in the 1970s to conserve energy, current hypotheses focus on inadequate dilution of irritants arising from building materials (such as formaldehyde-containing particle board), office supplies (such as carbonless copy paper and photocopy developer solution), toxins from mold and bacterial endotoxin, and personal care products used by occupants as risk factors for SBS. Confirmation of these hypotheses and further characterization of SBS await additional research.

MULTIPLE-CHEMICAL SENSITIVITY

The multiple-chemical sensitivity (MCS) syndrome is a diagnosis that has increasingly been given to patients with a wide variety of symptoms that they attribute to exposure at very low levels to a number of commonly encountered chemicals. The syndrome usually begins after a well-defined environmental event, such as a reaction to a more clearly toxic dose of an organic solvent, pesticide, or respiratory irritant. Some cases of MCS begin asSBS. Affected persons commonly report symptoms such as fatigue, malaise, headache, dizziness, lack of concentration, memory loss, and "spaciness" -- symptoms that overlap somewhat with those of other diagnoses of uncertain etiology, such as chronic fatigue syndrome. The pathogenesis of MCS is obscure, and no proven methods exist for its diagnosis, evaluation, and treatment. Case series suggesting a high prevalence of affective disorders indicate that psychological factors may play a role in causing MCS and/or in determining its severity; however, evidence does not support MCS as a purely psychogenic illness. A few studies of MCS patients suggest that the biologic mechanism of MCS may involve neurogenic inflammation of the nasal mucosa (as indicated by abnormal rhinolaryngoscopic findings) linked to central nervous system dysfunction (as indicated by alterations seen on single photon emission computed tomography); however, well-controlled research remains sparse, and no firm conclusions can be drawn. Other than the ruling out of other treatable conditions and the avoidance of exacerbating exposures, no specific recommendations for the management of MCS patients can yet be made. A panel of European scientists convened by the World Health Organization recommended that the designation *MCS* be replaced by the term *idiopathic environmental illness* (IEI).

PERSISTENT ORGANIC POLLUTANTS

Persistent organic pollutants (POPs) are a class of chemical compounds that tend to travel thousands of miles if released into the atmosphere, to accumulate in the food chain, and to persist in the environment as well as in human tissues (principally fat cells). Although the list of POPs is long, 12 have been identified as particularly important: nine pesticides (aldrin, chlordane, DDT, dieldrin, endrin, heptachlor,

hexachlorobenzene, mirex, and toxaphene), dioxins and furans (byproducts of incineration), and polychlorinated biphenyls (PCBs, fluids used mainly as dielectrics in transformers). The persistence and lipid solubility of these compounds allow them to bioconcentrate several thousand-fold as they are passed up the food chain to humans. High levels of exposure to a number of POPs have been shown to contribute to birth defects, infertility, immunosuppression, impaired cognitive development, and some types of cancers. These effects have been linked to the potential of POPs to act as endocrine disruptors -- i.e., hormonal mimics. The further production and use of most POPs have been banned, but concern remains over the possible low-level effects of POPs that persist in the environment and in human tissues. Concern has been raised, for example, that population exposures to POPs are contributing to worldwide declines in sperm density and increased rates of congenital hypospadias and testicular and breast cancer; epidemiologic studies testing these theories have yielded mixed results, however, and more research is needed.

GLOBAL CLIMATIC CHANGES

An increasing body of evidence indicates that human activities are responsible for global climatic changes, which, in turn, may be directly or indirectly increasing human exposure to environmental hazards. The depletion of stratospheric ozone by chlorinated fluorocarbons, with a consequent increase in ultraviolet radiation exposure, has been firmly established. Increased risks of skin cancers and cataracts are accepted as results of this phenomenon. Less clear is whether the immunosuppressive effects of ultraviolet radiation detected in animals and in vitro have significant clinical impacts on human resistance to infection. Although uncertainties in climate modeling persist, an increasing if not overwhelming amount of evidence indicates that anthropogenic greenhouse gases are fostering global warming. A prominent concern is that global warming can abet the introduction and dissemination of serious infectious diseases, such as mosquito-borne infections (malaria, dengue, and viral encephalitis) and waterborne infectious and toxin-related illnesses (cholera, shellfish poisoning). The World Health Organization has identified global warming as one of the largest public health challenges facing the twenty-first century.

392. DROWNING AND NEAR-DROWNING - *Jerome H. Modell*

It is an unexpected tragedy when a previously healthy person dies or is exposed to severe cerebral hypoxia and suffers permanent brain damage. For many years, drowning was considered a "fight for survival": Arms flailing and screaming for help, a person who could not swim struggled to remain on the surface of the water to reach safety. This situation, however, is rarely reported by persons at the scene of aquatic emergencies. Furthermore, no single set of circumstances comprises drowning or near-drowning. It may be a secondary event following such precursors as head or spinal trauma; hypoxia-induced unconsciousness; or unconsciousness due to preexisting cardiovascular disease, sudden cardiac death, or myocardial infarction. The initiating event is usually unknown, so the drowned or near-drowned victim must be treated based on probable physiologic effects of the near-drowning itself. If survival with normal brain function is to occur, a thorough understanding of the pathophysiology of drowning and an organized approach to therapy are imperative.

PATHOPHYSIOLOGY OF DROWNING

Approximately 90% of near-drowning victims aspirate fluid into their lungs. In those who do not aspirate fluid, hypoxemia results simply from breath holding, laryngospasm, or apnea. In those who do aspirate, the volume and the composition of the fluid determine the physiologic basis of the hypoxemia. Freshwater aspiration alters the surface tension properties of pulmonary surfactant and makes alveoli unstable, which causes a decreased ventilation/perfusion ratio. Some alveoli collapse and become atelectatic, which produces a true or absolute intrapulmonary shunt, while others are poorly ventilated and produce a relative shunt; in either case, significant pulmonary venous admixture occurs. Fresh water in the alveoli is hypotonic and is rapidly absorbed and redistributed throughout the body. While some have proposed that water continues to enter the lungs after death, at autopsy the lungs of victims who died in the water frequently contain little water. Also, it has been shown experimentally that if a dead body is submerged in tagged or colored water, water is not found in the lungs at autopsy. These findings support the premise that active respiration determines the volume of water aspirated.

Hypertonic seawater pulls additional fluid from the plasma into the lungs, and thus the alveoli are fluid-filled but perfused, which causes substantial pulmonary venous admixture. With both types of water, pulmonary edema may occur secondary to events such as fluid shifts, a change in capillary permeability, or cerebral hypoxia, which causes neurogenic pulmonary edema. Regardless of the cause, pulmonary edema adds to the ventilation/perfusion abnormality.

Water that is grossly contaminated with bacteria or that contains particulate matter may complicate the picture. Particulate matter can obstruct the smaller bronchi and respiratory bronchioles. Grossly contaminated water increases the risk of severe pulmonary infection. Neither problem is sufficiently common, however, to justify recommending specific therapy routinely for all victims.

At least 85% of near-drowned victims are thought to aspirate 22 mL/kg of water or less, which does not result in a clinically significant alteration of blood volume or serum

electrolyte concentrations. After resuscitation, by the time blood is analyzed, serum electrolyte concentrations are usually normal or close to normal. Significant changes are documented in only approximately 15% of those who cannot be resuscitated and only rarely in those who are resuscitated. These findings suggest that either a small amount of water was aspirated, fluid was rapidly redistributed, or both. Therefore, electrolyte disturbance rarely needs treatment. When a large quantity of water is aspirated, seawater causes hypovolemia, which concentrates extracellular electrolytes, and fresh water causes acute hypervolemia. If enough water is aspirated that plasma becomes severely hypotonic and the patient is hypoxemic, red cell membranes can rupture, and plasma hemoglobin and serum potassium concentrations increase significantly. However, this development has been reported only rarely. With rapid redistribution of fluid and development of pulmonary edema, even freshwater victims frequently demonstrate hypovolemia by the time they reach the hospital.

Hypercarbia, which is associated with apnea and/or hypoventilation, is less often documented by blood gas analysis than is hypoxemia. While hypoxemia due to pulmonary venous admixture persists in all near-drowned victims who aspirate water, hypercarbia is usually corrected sooner with artificial mechanical ventilation and improved minute ventilation and, thus, is reported in only a small percentage of victims evaluated at the hospital. Besides hypoxemia, metabolic acidosis also persists in most patients. Abnormal cardiovascular function, usually ascribed to hypoxemia, is brief with effective, timely therapy. Abnormality in renal function is uncommon, but when it does occur, it too is secondary to hypoxemia, altered renal perfusion, or, in extremely rare circumstances, significant hemoglobinuria.

TREATMENT

The first step is retrieving the victim from the water, and, if necessary, performing artificial ventilation and circulation. The American Heart Association recommends that an abdominal thrust not be used routinely in victims of submersion. This recommendation was upheld by a special committee of the Institute of Medicine convened in 1994 specifically to evaluate the efficacy of an abdominal thrust in the treatment of near-drowned victims. In these patients, an abdominal thrust may lead to regurgitation of gastric contents and, thus, to aspiration of the vomitus. Further, an abdominal thrust may delay ventilatory or circulatory resuscitation. Therefore, an abdominal thrust should be used only when the airway is obstructed with a foreign body or when the victim fails to respond to mouth-to-mouth ventilation.

Because emergency services and intensive pulmonary and cardiovascular care have improved during the past 25 years, central nervous system depression now presents the major therapeutic challenge in near-drowning. The rate of survival with normal cerebral function varies considerably in retrospective studies. Some factors that adversely influence survival are prolonged submersion, delay in initiation of effective cardiopulmonary resuscitation, severe metabolic acidosis (pH< 7.1), asystole upon arrival at a medical facility, fixed dilated pupils, and a low Glasgow coma score (<5). None of these predictors is absolute, however, and, when maximally treated, normal survivors have been reported in all of the above categories. Absence of cortical evoked potentials does indicate irreversibility of the cerebral hypoxic lesion; this test, however, cannot be done in the field to guide rescuers. A comparison of outcomes between one

institution that added brain preservation techniques to intensive pulmonary and circulatory treatment and another institution that did not found no significant differences.

Hypothermia appears to be protective, but only if it occurs early, at the time of the accident, in which case it increases the victim's chance of cerebral salvage after relatively long periods of acute hypoxia and cardiac arrest. While hypothermia prolongs tolerance to hypoxia, it also can precipitate fatal cardiac arrhythmia; thus, its occurrence can be helpful on the one hand and harmful on the other. The diving reflex produces bradycardia, breath holding, and circulatory redistribution when the face is submerged in cold water. However, the effect of the diving reflex in explaining cerebral recovery after prolonged immersion has not been specifically documented.

Significant pulmonary venous admixture usually persists even after successful resuscitation; therefore, supplemental oxygen should be administered until arterial blood gas analysis confirms that oxygen is no longer needed. Intravenous access should be established as soon as possible. The trachea should be intubated if necessary for airway maintenance or to facilitate mechanical ventilatory support. Electrocardiographic monitoring will facilitate prompt treatment of cardiac arrhythmia.

Victims should be transported to a hospital for definitive testing of the adequacy of ventilation and blood gas exchange, cardiac activity, and effective circulating blood volume. Other variables, such as serum electrolyte concentrations, renal function, and cerebral status, should be analyzed as indicated.

The single most effective treatment for hypoxemia, regardless of cause, is mechanical ventilatory support including continuous positive airway pressure (CPAP). After freshwater aspiration, improvement in ventilation/perfusion matching is more consistent when CPAP is combined with mechanical inflation of the lung than with spontaneous respiration. The question of whether CPAP should be combined with spontaneous respiration or with mechanical ventilation should be decided by whether the specific patient can perform the necessary work of breathing, adequately eliminate carbon dioxide, and adequately match ventilation/perfusion ratios. Positive airway pressure should be withdrawn gradually as the lungs stabilize and ventilation/perfusion ratio returns toward normal.

The pH in near-drowned victims is commonly significantly acidotic, which, in turn, can depress cardiac function. The metabolic component of the acidosis, if it results in a pH< 7.20, should be corrected pharmacologically, although there is some disagreement on this point. With cardiovascular instability, cannulation of the pulmonary artery with a Swan-Ganz catheter or evaluation by transesophageal echocardiography is indicated. Many patients will be hypovolemic from loss of fluid into the lung as pulmonary edema or from decreased venous return secondary to increased intrathoracic pressure during mechanical ventilatory support.

Because recovery after long periods of submersion under frigid conditions has been reported, body temperature should be taken into account before a decision is made to terminate therapy. The body temperature of victims depends not only on the temperature of the water from which they are retrieved but also on how well they were insulated by clothing. The volume of water actually aspirated is also important, because

a large volume, if distributed before cardiac arrest occurs, can produce rapid central cooling. Thus, cold water can be protective when it produces total-body hypothermia, which decreases metabolic oxygen requirement. On the other hand, cold water may also contribute to the accident if hypothermia occurs before total submersion, and severe, or even fatal, cardiac arrhythmia results. Several methods of rewarming hypothermic victims have been advocated, but any technique that increases oxygen utilization, such as shivering, should be avoided.

Regardless of the conditions surrounding a drowning or near-drowning, treatment should adhere to the following sequence of priorities (Fig. 392-1):

1. Remove the victim from the water as soon as possible and stabilize the patient's head and neck if trauma is suspected.

2. Immediately follow the ABCs of cardiopulmonary resuscitation -- even in the water if this does not endanger the rescuer.

3. If the patient is unconscious, protect the airway as needed with endotracheal intubation.

4. Establish venous access as soon as possible.

5. Provide supplemental oxygen and ventilatory support until each is no longer needed. This can be judged from analysis of arterial blood for oxygen tension, carbon dioxide tension, and pH.

6. Monitor cardiac rhythm with an electrocardioscope as soon as possible.

7. Monitor body temperature and restore it to normal.

8. If the patient has persistent respiratory insufficiency, provide intensive pulmonary support withCPAP and mechanical ventilation therapy as necessary.

9. If the patient has cardiovascular instability, evaluate cardiac output and effective circulatory volume by invasive monitoring, and measure serum electrolyte concentrations. Intravenous fluid replacement should be provided as necessary.

10. Evaluate and treat renal function and cerebral status as indicated.

Glucocorticoid therapy, prophylactic antibiotic therapy, and monitoring of intracranial pressure are no longer recommended.

ACCIDENT PREVENTION

Because drowning begins as an accident that results in a medical problem, the definitive strategy is to prevent the accident. For those victims in whom the accident is secondary to a medical condition, as in persons susceptible to syncope or seizure, the only way to prevent the accident is to identify those who ought to avoid the water or to encourage them to use the buddy system. For young children, early swimming lessons, vigilant

caretakers, and stringent laws governing pool enclosures are needed. Those who teach parenting classes should routinely warn parents about the risk of toddlers' drowning in such household fixtures as toilets, buckets of water, and even washing machines. Preventing accidents during boating, athletics, and other water-related recreational activities requires public education. Rules associated with these activities to maximize safety and judicious, responsible behavior should be portrayed as life-saving measures. Similarly, drinking alcohol, a "ubiquitous catalyst" to drowning, should be portrayed as life-threatening whenever water is nearby.

393. ELECTRICAL INJURIES - *Raphael C. Lee*

EPIDEMIOLOGY

Electrical injury occurs when the body experiences levels of current that alter electrophysiologic function or cause tissue damage. Most commonly, such injuries result from contact with commercial electrical power sources in the home and workplace. Microwave, radiofrequency, light irradiation, and other injuries are less common. Ionizing electromagnetic fields (radiation) involve atomic absorption and free radical production, leading to biochemical alterations.

Electrical shock is one of the leading causes of work related injury, comprising 7% of all workplace fatalities. The exact incidence is unknown because many victims don't report minor injuries. The economic impact of industrial electrical injury in the United States is estimated to be in excess of $1 billion annually. Approximately one-third of high-power electrical injuries occur in the construction industry, one-third occur in the utility and petrochemical industries, and one-third are non-work related. More than 90% of the injuries occur in males, most commonly between the ages of 20 and 34. The extremities are nearly always involved, and limb amputation may be required.

Most injuries are due to low-voltage (<1000 V) electrical shock. Low-voltage power-frequency electrical shocks usually occur in and around the home. The household electric power in the United States is 120 V, AC 60-cycle current. In Europe it is 220 V. Low-voltage shocks carry a significant risk of electrocution due to cardiac arrest because they may cause muscle spasm that results in prolonged contact. Roughly 3 to 4% of all United States hospital burn unit admissions are for electrical injury, mostly a result of high-voltage (>1000 V) shocks. Extensive tissue damage, rather than electrocution, is characteristic of high-voltage shocks.

PATHOPHYSIOLOGY

The term *direct current* (DC) is used to indicate a field frequency of zero (i.e., constant voltage gradient), and *alternating current* (AC) indicates that the field is changing direction (i.e., alternating polarity) with time. DC electrical power passes through the body on direct electrical contact. AC current can be carried by direct contact, capacitive coupling, and magnetic induction.

Tissue damage can result from exposure to harmful levels of current at any frequency in the electromagnetic spectrum that ranges fromDC toz-hertz (ionizing irradiation). The tissue effects of electricity depend as much on the frequency as on the magnitude of current.Table 393-1 presents a classification of electrical injury according to frequency range. Commercial electrical power operates in the narrow frequency range of DC to 150 Hz in the low frequency regime. An electrical shock in this frequency range is most common.

When the voltage is<1000 V, direct mechanical contact is usually required for electrical contact. For high voltages (>1000 V), arcing usually initiates the electrical contact. On direct electrical contact, the electron flow in the metal conductor or arc is converted at the skin surface into electrolyte ions that carry the current through the body. This

electrochemical process generates heat and toxic chemical by-products that contribute to contact area injury. In high-voltage contacts, exposure to the expanding arc, an excellent conductor, brings the victim into the electrical circuit. The arc can reach very high temperatures, leading to skin burns or clothing ignition. At higher frequencies (>10 MHz) electrical power can couple electrical energy across an air gap into the body without charge transport across the skin surface (capacitive coupling).

Low-frequency electricity causes tissue injury primarily by permeabilizing cell membranes, electroconformational denaturation of cell membrane proteins, and thermal denaturation of tissue proteins. Factors that determine the anatomic pattern, the extent of tissue injury, and the relative contribution of heat versus direct electrical damage include the amount of current, anatomic location, and the contact duration. The type of clothing, the use of protective gear, and the power capability of the electrical source also contribute to the wide range of clinical manifestations in victims of electrical shock. In addition, a very high-energy electrical arc can produce a strong thermoacoustic blast force leading to barotrauma. Associated falls and skin burns are frequent, exacerbating the injury. Cataracts characteristically occur after rapid and brief exposure of the eyes to hot gases and arc-mediated electrical current. The latency period for development of cataracts averages approximately 6 months.

Peripheral nerve and skeletal muscle tissues are most vulnerable to membrane damage by applied electrical currents. The "no-let-go" phenomenon results from the passage of more than 14 to 16 mA longitudinally through the forearm that induces tetanic contractions of muscles controlling handgrip. The resulting involuntary muscle spasm may lead to joint dislocations and spine fractures. When current of>50 mA is passed hand-to-hand or hand-to-foot, there is enough induced depolarization of myocardial membranes to cause cardiac arrhythmias, particularly if the induced depolarization occurs during early myocardial repolarization. Disruption of extremity skeletal muscle and nerve cell membranes by the process of electroporation results when more than 0.5 to 1 A is passed through the extremity. Electroporation damage accumulates on the time scale of milliseconds, leading to lethal cellular injury. With more prolonged contacts in the range of seconds, thermal damage in the subcutaneous tissues becomes substantial. Because the vulnerability to supraphysiologic temperature exposure is similar regardless of tissue type, all tissues in the current path are burned when pathologic levels of heating occur. Extensive disruption of cell membranes leads to release of myoglobin and hemoglobin, which enter the circulation. Acute renal failure can result from intrarenal crystalization of these molecules. Acute renal failure superimposed on extensive tissue injury has a very high mortality rate.

DIAGNOSIS

For the more common low-frequency electrical injuries, at least two skin contact wounds are present. Differences in wound size and topography are largely determined by the surface contact area, the shape of the objects that conducted the current through the victim, and the duration of contact.

Cardiac arrhythmias and most respiratory disturbances must be rapidly detected by examination of the pulse, chest, and electrocardiogram. The next priority is to determine the location and extent of tissue damage. Injured skeletal muscle and nerves are often

found beneath undamaged skin. Lateral spine x-rays or computed tomography (CT) are needed to rule out unstable spine fracture patterns. X-ray images of the extremities involved are also important to rule out skeletal fractures or joint dislocations. Blood chemistries should be immediately evaluated and monitored. Metabolic acidosis and elevated serum potassium levels may exist as consequences of extensive skeletal muscle injury. Serum CPK levels will rise over several hours if there is significant rhabdomyolysis.

Tissue edema begins to form because of increased vascular permeability and the release of intracellular contents into the extravascular space. Muscle compartment syndrome and compression neuropathies are common manifestations. If available, magnetic resonance imaging (MRI) scans can rapidly localize tissue edema. Where severe heating has coagulated the blood vessels, tissue injury may exist in the absence of edema. Muscle compartment fluid pressures should be measured where edema is present. If MRI is not available, then the muscle compartments in the current path between contact points should be monitored for elevated interstitial fluid pressure. Elevated compartment pressures may evolve during resuscitation. Muscle compartment fluid pressures >30 cmH_20 are indications for fasciotomy. It may be necessary to check the pressures every 8 h for 24 h. Radionucleotide scanning with ^{99m}Tc-pyrophosphate can also be useful to detect tissue damage. These scans, however, take 4 to 6 h to complete and are mostly useful in the less severe injuries. If there is a history of loss of consciousness, CT of the head is indicated.

TREATMENT

The first priority is to disconnect the patient from the electrical power source. When high-capacity circuits are involved, disconnection must not be attempted before the circuit is deenergized. Cervical spine fracture should be assumed until proven otherwise. Critical initial considerations are evaluation and support of vital organ function and, secondarily, assessment of the extent of injury. After very-high voltage trauma, prolonged cardiopulmonary resuscitation (CPR) may be necessary before the stunned myocardium regains the ability to sustain a coordinated rhythm.

Patients with significant wounds and tissue injury as well as those with vital organ injury require hospital admission. It is unlikely for cardiac arrhythmias to develop if cardiac injury is not detectable on initial presentation. Peripheral nerve injury invariably occurs even in minor shocks and usually resolves over several days. If symptoms persist, however, they may be controlled with cyclooxygenase inhibitors alone or with antioxidants. Small wounds can be managed by cleaning and applying topical antibiotics. Major neuropsychological and stress disorders often follow a terrifying "no-let-go" experience. Management often involves psychiatric consultation.

For more substantial trauma, a Foley catheter and large bore peripheral intravenous lines delivering normal saline at a rate sufficient to generate a 30 to 50 mL/h urine output are essential. If the urine is visibly pigmented with myoglobin or hemoglobin, the output should be doubled and alkalinized to a pH >6 by adding bicarbonate to the intravenous solutions until the urine has cleared. In the most severe injuries, hyperpermeability of peripheral capillaries may result in rapid interstitial (third space) fluid accumulation. In such cases, it may be necessary to increase blood oxygen levels

and add dextran to resuscitation fluids.

Cardiac arrhythmias must be immediately controlled by antiarrhythmic drugs simultaneously with the correction of serum pH and electrolyte abnormalities. Brain injury-related seizures must be controlled with antiepileptic agents. Patients who have lost central nervous system (CNS) control of respiration or airways should be intubated and mechanically ventilated. A paralyzed ventilated patient may need monitoring by electroencephalogram (EEG) to assess seizure control. Appropriate management of corneal burns or abrasions, tympanic membrane rupture, and closed head injury should be instituted.

Large skin burn wounds are often present because of arc-mediated contacts and clothing ignition. Care should be taken to prevent rapid loss of body heat through open wounds. Tetanus prophylaxis should be administered.

Perfusion of devascularized tissue must be quickly restored. Diminished pulses or decreased tissue oxygen by transcutaneous pulse oximetry are indications for escharotomy releases. Fasciotomy is often required. The classic clinical signs of pain in acute compartment syndrome cannot be relied on because of associated nerve injury. In addition to decompression of extremity muscle compartments, decompression of nerve within edematous fibrous and osseous conduits (e.g., carpal tunnel, Guyon's canal, and tarsal tunnel) should be carried out to help prevent compression neuropathy. Care to avoid tissue drying or desiccation is important. Debridement of nonviable subcutaneous tissue should be performed as soon as a general anesthetic can be safely administered.

Anaerobic bacterial infection of devascularized skeletal muscle is a common complication. Intravenous penicillin G and/or hyperbaric oxygen as prophylactic antibiotics are sometimes utilized but have unproven value. Radiographs taken to rule out fractures may reveal air bubbles in the subcutaneous tissues. This gas results from tissue boiling when prolonged Joule heating has occurred.

Rehabilitation into society and gainful employment are the ultimate objectives. For severely injured victims these goals require functional muscle and nerve reconstruction as well as correction of scar contractures. Psychological and neurocognitive problems are expected and require treatment by experts. Persistent peripheral neurologic problems are also common and often require detailed evaluation and therapeutic intervention.

LIGHTNING INJURIES

Lightning injury is a powerful manifestation of arc-mediated electrical contact. Arcing occurs when the voltage gradient in air exceeds 2 million V/m. The arc consists of a hot ionized gas of subatomic particles that is highly conductive. Peak lightning currents reach into the range of 30,000 to 50,000 A for a duration of 5 to 10 us. Lightning arc temperatures reach up to 30,000°K, which generates thermoacoustic blast waves, commonly called thunder. Peak blast pressures reach 4 or 5 atm in the immediate vicinity of a lightning strike, and up to 1 or 2 atm 1 m away. Substantial barotrauma can result.

Like radiofrequency current, lightning current flows along the surfaces of conducting objects. Initially, the flow of an enormous current through the lightning strike generates a very large surrounding magnetic field pulse. This magnetic field pulse can induce current flow in the body, enough to disrupt cardiac andCNSfunction. When lightning current enters the ground, it spreads out radially, which sets a large current traveling along the surfaces of the ground. A substantial voltage drop can occur between the feet of a nearby individual. The voltage drops between widely separated feet can reach 1500 to 2000 V and can induce a 2 to 3 A current flow in the legs for a 10-us period.

Victims of direct lightning strikes experience a multimodal injury. Superficial burns on the skin represent the current path along the skin surface. The intense brief shock pulse seems to arrest all electrophysiologic processes. The victim appears lifeless. ProlongedCPR may be necessary. Muscle and nerve necrosis is rare in survivors. Deeper injury results when the victim is in contact with a large conducting object such as a truck or fence that has been struck by lightning, which then discharges over several milliseconds through the victim.

Delay in resuscitation is the most common cause of death. Bystanders are usually afraid to touch the victim while precious minutes pass. However, unless the victim is on an insulating platform, there is no residual electric charge on the body afer several milliseconds. When needed,CPRshould be given without hesitation. Victims should be cared for in an intensive care unit until life-threateningCNS and cardiac injuries are ruled out. Late neurologic and ophthalmologic sequelae often develop.

394. RADIATION INJURY - *Stephen M. Hahn*, *Eli Glatstein*

All human beings are constantly exposed to ionizing radiation. Environmental sources include the cosmic radiation from space and radiation from the ground and from inhaled and ingested materials. Airline travel and mining both increase exposure to the background radiation. For example, air travel at 30,000 ft exposes individuals to a dose equivalent of 0.5 mrem/h. Radiation originating in the body comes mainly from radioactive potassium, which emits beta and gamma rays. Lungs are exposed to irradiation from inhaled air, which contains small amounts of radioactive radon. The cosmic exposure contributes approximately 28 mrem per year. The ground and internal sources contribute approximately 26 and 27 mrem per year, respectively. The most prominent man-made sources of radiation include x-ray equipment, nuclear weapons, and radioactive medications.

TERMINOLOGY AND DEFINITIONS

The first major unit of radiation exposure was the roentgen (R), defined as an amount of x-rays or gamma rays that produces a specific amount of ionization in a unit of air under standard temperature and pressure (Table 394-1); this quantity can be measured directly in an ionization chamber. The rad, or *r*adiation *a*bsorbed *d*ose, is defined as 100 ergs/g of tissue. Thus, the rad represents a net deposition of energy in a three-dimensional volume, because x-rays attenuate as they traverse tissue. The rad has been replaced by the Systeme Internationale (SI) unit of the gray (Gy), which represents 100 rad. Roentgens and rads can be converted by means of various tables; the relation between them depends on photon energy.

The above definitions reflect physical variables. The unit that reflects the biologic response and that can be used to compare the effects of various types of radiation is the unit of *dose equivalence*, the rem (*r*oentgen *e*quivalent in *m*an). The rem has been replaced by theSI unit, the sievert (Sv), which equals 100 rem. These units reflect the exposure or absorption dose multiplied by a biologic factor that represents the biologic effectiveness of the specific type of radiation (see below).

TYPES OF IONIZING RADIATION

The absorption of energy from radiation in tissue often leads to excitation or ionization. Excitation involves elevation of an electron in an atom or molecule to a higher energy state without actual ejection of the electron. Ionization involves actual ejection of one or more electrons from the atom. Ionizing radiation is subclassified as electromagnetic (photon) or particulate radiation (Table 394-2). X-rays and gamma rays are examples of electromagnetic photon radiation. They differ only in their source: X-rays are produced mechanically, by making electrons strike a target, which causes the electrons to give up their kinetic energy as x-rays, while gamma rays are produced by nuclear disintegration of radioactive isotopes.

X-rays can be thought of as packets of energy, or photons. X-rays have no mass or charge, travel in straight lines, and attenuate continuously as they traverse tissue. Gamma rays have similar properties. Each photon contains an amount of energy equal to *hn*, where *h* is Planck's constant. The critical difference between nonionizing and

ionizing radiation is the energy of individual photons, not the energy of the total dose.

Types of *particulate radiation* include electrons, protons, alpha particles, neutrons, negative pi-mesons, and heavy charged ions; these have discrete mass and charge (except for neutrons, which lack charge; Table 394-2). *Electrons*, or *beta particles*, are small and negatively charged and can be accelerated to close to the speed of light. They decelerate fairly rapidly in tissue and penetrate it to only a limited depth. Thus, electron beams are often used to treat superficial problems. *Protons* are positively charged and have a mass about 2000 times that of an electron. Protons stop abruptly, depending on their energy; in the process of sudden deceleration, most of their energy is given up, which tends to cause ionization just before the proton stops. This region of enhanced ionization, sometimes called the Bragg peak, means that proton beams exert their effects in a relatively compact region. *Alpha particles* are helium nuclei, consisting of two protons and two neutrons. The mass and charge are great enough that these particles do not penetrate far through matter unless they have tremendous energy; even a piece of paper is enough to protect against most alpha particles. Because these particles are charged, they can be accelerated in electrical fields.

Neutrons are similar in mass to protons (having an atomic mass of 1), but they are not charged and therefore cannot be accelerated in an electrical field. Neutron beams are produced by colliding charged particles into a suitable target or are emitted as a fission product of heavy radioactive atoms. *Heavy charged ions* are nuclei of heavier elements that have a positive charge owing to the stripping away of some or all of the orbiting electrons.

Equal doses of different types of radiation do not necessarily produce equal biologic effects; thus 1 Gy of neutrons produces a greater biologic effect than 1 Gy of x-rays. The biologic effects produced by a given dose of radiation can be quantified by the relative biologic effectiveness (RBE) value, which relates them to the effects produced by 250-kV photon radiation as a standard. In general, the greater the RBE value for a given type of radiation, the greater the biologic effect. The RBE value will be greater for more densely ionizing radiation, such as neutrons. The RBE value depends on the linear energy transfer (see below), the dose, the dose rate, and the nature of the biologic system.

The linear energy transfer (LET) is the amount of ionization occurring per unit length of the radiation track. It is usually expressed as kilovolts per micron and increases with the square of the charge of the incident particle. High-LET radiation is biologically different from low-LET (i.e., conventional) radiation: Hypoxic and oxygenated cells respond similarly to high-LET irradiation, whereas it takes about three times as much low-LET radiation to produce a given killing effect in hypoxic cells as in oxygenated cells. It is thought that low-LET radiation must produce multiple hits on DNA to destroy a cell, whereas high-LET radiation need produce only a single hit on DNA to kill a cell. Representative values of LET andRBE are given in Table 394-3.

Radiation, especially x-rays, is absorbed and causes ionization in three major ways: the *photoelectric effect*, the *Compton effect*, and *pair production*. At low energies (30 to 100 keV), as in diagnostic radiology, the photoelectric effect is important. In this process, the incident photon interacts with an electron in one of the outer shells of an atom (typically

K, L, or M). If the energy of the photon is greater than the binding energy of the electron, then the electron is expelled from the orbit with a kinetic energy that is equal to the energy of the incident photon minus the binding energy of the electron. The photoelectric effect varies as a function of the cube of the atomic number of the material exposed (Z_3); this fact explains why bone is visualized much better than soft tissue on radiographs.

At higher energies, as used in therapeutic radiology, the Compton effect dominates. In this process, the incident photon interacts with an electron in an orbital shell. Part of the incident photon energy appears as kinetic energy of electrons, and the residual energy continues as a less energetic deflected photon.

At energy levels above 1.02 MeV, the photons may be absorbed through pair production. In this process, both a positron and an electron are produced in the absorbing material. A positron has the same mass as an electron but has a positive instead of a negative charge. The positron travels a very short distance in the absorbing medium before it interacts with another electron. When that happens, the entire mass of both particles is converted to energy, with the emission of two photons in exactly opposite directions.

BIOLOGIC EFFECTS OF RADIATION

Radiation must produce double-strand breaks in DNA to kill a cell, owing partly to the high capacity of mammalian cells for repairing single-strand damage. Radiation can also produce effects indirectly by interacting with water (which makes up approximately 80% of a cell's volume) to generate free radicals, which can damage the cell. Free radicals are highly reactive chemical entities that lack a stable number of outer-shell electrons. A free radical is not stable and has a life span of a fraction of a second. It is estimated that most x-ray-induced cell damage is due to the formation of hydroxyl radicals, as follows:

The result of radiation damage is cell death. The biologic effects on epithelial cell reproduction are typically expressed only when the damaged cells attempt to divide. Another biologic effect is the induction of cancerous growth by mutation many years after radiation exposure. Patients who receive radiation have a significant risk of neoplasm two to three decades after their exposure; this risk is significantly higher than that of the population as a whole.

RADIATION-INDUCED CHROMOSOME ABERRATIONS

Chromosome breaks can occur when cells are irradiated. The broken ends of chromosomes can combine with broken ends of different chromosomes. These abnormal combinations are most readily seen during mitosis. Chromosome abnormalities typically occur in cells irradiated in the G1 phase of the cell cycle, before the doubling of genetic material. If cells are irradiated in the G2 phase, chromatid aberrations may result. The frequency of chromosomal aberrations in peripheral circulating lymphocytes correlates with the dose received. The dose can be estimated by comparing the chromosomal changes to in vitro cultures exposed to controlled doses

of irradiation. The minimum dose that can be detected by peripheral lymphocyte analysis is about 0.1 to 0.2 Sv (10 to 20 rem). Lymphocyte analysis may provide evidence of recent total-body exposure.

CELL SURVIVAL CURVE

The dose-response curve for all mammalian cells appears to have a linear-quadratic relationship. In simple terms, the mathematical model that explains the relationship between the dose and the fraction of surviving cells has both linear and exponential components. The linear component results from double-stranded chromosomal breaks produced by single hits. The exponential component represents breaks produced by multiple hits. Figure 394-1 shows the shape of a typical survival curve for mammalian cells exposed to radiation. The fraction of cells surviving is plotted on a semilogarithmic scale. For x-rays or gamma rays, the dose-response curve has a shoulder that is followed by a straight line curve as the dose is increased. The shoulder represents the cell's ability to repair sublethal injury. For alpha particles or lower energy neutrons, the dose-response curve is a straight line from the origin. Thus, the survival rate is an exponential function of the dose.

In all mammalian cell lines studied, increases in the radiation dose decrease the survival rate of cells. However, a number of factors may contribute to a relative resistance to radiation in human tumors in vivo, including hypoxia and expression of particular oncogenes, such as *ras*. The biologic basis for radiation resistance has not been fully defined.

Four important processes that occur after radiation exposure can be summarized as the "four R's" of radiobiology. The first is *repair*. Repair is temperature dependent and is thought to represent the enzymatic mechanisms for healing intracellular injury. The second R is *reoxygenation*, a process whereby oxygen (and other nutrients) are actually better distributed to viable cells following radiation injury and cell killing. The third R is *repopulation*, the ability of the cell population to continue to divide and to replace dying and dead cells. The fourth R is *redistribution*, which reflects the variability of a cell's radiosensitivity over the cell cycle. Radiosensitivity can vary through the cell cycle by as much as a factor of 3. The G1 phase has the most variable length of all the phases of the cell cycle. For most cell lines, cells that have a short G1 period are most sensitive at the G2/mitosis interface, less sensitive in G1, and most resistant toward the end of the synthesis (S) period.

Radiation therapy is effective in cancer treatment when it exerts greater cytotoxic effects on tumor cells than on normal tissues. A major determinant of the therapeutic index is exploiting differences in the four R's between tumor cells and normal tissues by delivering the radiation in dose fractions.

CLINICAL FINDINGS ON FRACTIONATION

The clinical radiation response may be related to the interactions of various growth factors and cytokines. For example, radiation can induce growth factors and cytokines such as tumor necrosis factor (TNF), interleukin (IL) 1. TNF can induce proliferation of fibroblasts and enhance the inflammatory response. TNF and IL-1 have been shown to

radioprotect hematopoietic cells in vitro by increasing the D_0 of the cell survival curve. TNF also enhances killing of a human tumor cell line by irradiation. TNF may produce radioprotection or radiosensitization depending on the cell type. Efforts to modulate radiation effects with TNF remain experimental. Other factors implicated in the radiation response are basic fibroblast growth factor and platelet-derived growth factorb, which may be associated with late effects of radiation on vessels.

The degree and the duration of functional recovery of normal tissues are related to the number of stem cells surviving after irradiation. If the stem cells are destroyed in the irradiated volume and replacement from adjacent tissues is inadequate, radiation injury will persist. True late effects develop independent of early reactions; they occur despite recovery from acute radiation injury.

Table 394-4 shows the frequency of radiation tolerance seen with fractionated radiotherapy at 5 years of follow-up. These numbers are rough estimates at best. The clinical manifestations of irradiation will depend on the volume of the organ irradiated, the total dose, the dose per fraction, and the length of time taken to deliver the dose. Dose per fraction is the most important factor determining normal tissue effects. In addition, the cellular consequences of treatment can be progressive over time. Thus, length of follow-up is also crucial in judging clinical sequelae.

Central Nervous System Traditionally, the central nervous system (CNS) has been described as relatively resistant to radiation-induced changes. When the human brain is treated with standard fractionation (1.8 to 2.0 Gy/d), acute reactions are seldom observed.

SubacuteCNSreactions to radiation treatment are more common. The clinical manifestations may include *Lhermitte's sign*, which is a self-limited paresthesia occurring with flexion of the neck. It is believed to be due to transient demyelination of the spinal cord following significant radiation exposure. It can be seen 1 to 3 months after completion of radiation treatment to the spinal cord. The frequency of Lhermitte's sign varies according to the type of radiation therapy and can be as high as 15% after mantle-field radiation. Mild encephalopathy and focal neurologic changes can occur after irradiation limited to the cranium. If radiation treatments to the brain are given at the same time that chemotherapeutic agents are administered, the effects can be more severe, presumably reflecting altered permeability to the drugs. The effect of cranial irradiation is believed to be secondary to radiation effects on the replicating oligodendrocytes and possibly on the microvasculature. Both clinical and radiologic changes may simulate tumor progression and can often pose diagnostic and treatment dilemmas.

Postirradiation pathology and associated clinical symptoms typically begin 6 to 36 months after radiation therapy and are related to the total dose and volume treated. Fraction size appears to be the most important variable affecting the rate of postirradiation brain necrosis. Neurocognitive changes can also be seen in children after cranial irradiation. The important pretreatment factors that predict the degree of lateCNSeffects include the age at which cranial irradiation was given and neurocognitive functional level at the time of treatment.

A unique late effect of cranial irradiation combined with chemotherapy, known as *leukoencephalopathy*, has been described in some patients. Leukoencephalopathy is a necrotizing reaction usually noted 4 to 12 months after combined treatment with methotrexate and cranial irradiation. Dementia and dysarthria may progress to seizures, ataxia, or death.

Transverse myelitis after radiation treatment is a spinal cord reaction similar to cerebral necrosis. This syndrome consists of progressive and irreversible leg weakness and loss of bladder function and sensation referrable to a single spinal cord level. Flaccid paralysis eventually occurs. Symptoms can occur as early as 6 months after radiation treatment, but the usual time to onset is 12 to 24 months. Lhermitte's sign does not correlate with transverse myelitis.

Skin Skin reaction can be seen within 2 weeks of fractionated radiotherapy, a delay that correlates with the time required for cells to move from the basal to the keratinized layer of skin. The severity of the reaction depends on the skin dose per fraction and the total dose delivered to an area of skin. Erythema is observed, soon followed by dry desquamation. The skin at this time can be erythematous, warm, and sometimes edematous. The vessels in the upper dermis are dilated, and inflammatory infiltration with granulocytes, macrophages, eosinophils, plasma cells, and lymphocytes is noted.

When a severe skin reaction occurs, it is usually located where the beam strikes the skin tangentially. *Moist desquamation* consists of eruption of the epidermal layer. Healing is through reepithelialization from cells of less affected basal layers. When skin reactions are severe, treatment interruptions are needed to permit healing.

Dry desquamation is treated conservatively. Symptoms of dryness can be alleviated by advising the patient to wear only cotton fabric next to the affected skin and to refrain from the use of irritants of any kind. If treatment becomes necessary, hydrophilic agents that do not contain heavy metals are recommended. Petroleum jellies should not be used, as they may trap bacteria and increase the chance of infection. Moist desquamation is best managed by leaving the affected area dry and open to air.

A chronic reaction to radiation can be seen starting 6 to 12 months after irradiation. The epidermis is usually atrophic and may be more easily injured than normal skin. Interstitial fibrosis may also be increased. Hyperpigmentation of irradiated skin outlining the treatment field can be seen within a couple of months after completion of irradiation. This will fade gradually. The skin becomes thin, and hair loss may be permanent. Radiation therapy can induce second malignancies, which tend to be more aggressive than cancers arising in patients without significant radiation exposure.

Heart and Blood Vessels When cardiac disease appears after radiation treatment, it is often difficult to tell to what extent the radiation treatment was causative. The pathogenesis of atherosclerotic heart disease is multifactorial. Exposure of a large heart volume to high-dose radiation therapy accelerates the development of coronary artery disease. Acute "pericarditis" may result from cardiac irradiation. The symptoms may include chest pain and fever, with or without pericardial effusion. This syndrome is usually self-limited and typically manifests itself a few months after treatment. Asymptomatic pericardial effusion may be the most common manifestation of

radiation-induced heart disease. It is usually detected by chest x-ray and confirmed by an echocardiogram.

Most patients with symptomatic radiation-induced constrictive pericarditis will have received more than 40 Gy to a large portion of the heart. The risk increases significantly with cardiac doses greater than 50 Gy.

Chronic cardiac changes may have their onset from 6 months to several years after irradiation. The clinical symptoms may indicate chronic constrictive disease due to pericardial, myocardial, and endocardial fibrosis -- a pancarditis. The clinical signs may include dyspnea, chest pain, venous distention, pleural effusion, and paradoxical pulse.

Lung The clinical symptoms of radiation pneumonitis can be separated into early and late phases. During the early phase, clinical manifestations may include dyspnea, cough, and fever. Shortness of breath is relatively infrequent. It is more common to observe only the radiologic changes on a chest x-ray, without clinical symptoms. The clinical signs and symptoms of radiation pneumonitis may appear in 3 to 6 weeks if a large region of lung is irradiated to a dose above 25 Gy. An infiltrate outlining the treatment field may become evident on the chest x-ray. Radiation changes should not occur outside the treated field. Computed tomography can often help in distinguishing radiation pneumonitis from other causes of the infiltrate. The incidence of radiation pneumonitis can be reduced with careful treatment planning designed to lower the total dose given to the treated lung volume. Permanent scarring that results in respiratory compromise may develop if the dose and the volume of lung irradiated are excessive. Dyspnea and cough may be severe and debilitating.

Patients with symptoms of radiation pneumonitis may respond rapidly to glucocorticoids, but the medication has little effect on fibrotic changes. Glucocorticoids must be tapered very slowly to avoid rebound exacerbation of symptoms, which can prove lethal for some patients. Prophylactic administration of glucocorticoids is of no proven merit. Supportive care includes bronchodilators and oxygen at the lowest possible FI_{O2}.

Digestive Tract Pathologic changes of the epithelial layer occur early during radiation treatments. The underlying submucosa may become edematous, with dilation of capillaries. Recovery from radiation damage can be expected within a few weeks after completion of radiation therapy, provided that sufficient numbers of stem cells are left. The radioresponsiveness of the aerodigestive tract, like that of other structures, is not uniform but varies according to the location.

Patients often have symptoms from radiation exposure that are similar to other forms of acute gastritis. The clinical signs include epigastric pain, loss of appetite, nausea, and vomiting. Decreased gastric acidity is observed after 15 to 20 Gy of fractionated radiation therapy. The tolerance of the stomach to radiation is also aggravated by addition of systemic chemotherapy, such as 5-fluorouracil.

The germinal centers of the bowel mucosa are in the crypts of Lieberkuhn. Newly formed cells move upward along the walls of the crypts as transitional cells, undergoing maturation. The epithelial lining of the small bowel is the most rapidly renewed system in the human body and is completely renewed in 3 to 6 days. Within 12 to 24 h after the

first dose of radiation therapy, pathologic evidence of dead cells are seen in the mucosal lining. Complete denudation of the mucosal surface rarely occurs during a regular course of radiation treatment because of the high capacity of the mucosa for regeneration. However, a focal area of erosion may be seen. The histologic appearance may be nearly normal within 2 to 3 weeks after radiation therapy.

Clinical manifestations of acute radiation enteropathy are nausea and vomiting, diarrhea, and cramping pain. Relevant factors contributing to the pathogenesis of diarrhea include malabsorption and alterations in the intestinal bacterial flora. The severity of symptoms, as in other anatomic areas, is proportional to the irradiated volume and the total dose.

Symptoms of chronic radiation enteropathy include diarrhea, abdominal cramping, nausea, malabsorption, vomiting, and obstruction. Progressive fibrosis, perforation, fistula formation, and stenosis of the irradiated portion of the bowel can occur during the chronic phase of radiation enteropathy. Most clinical manifestations of chronic changes occur between 6 months and 5 years after radiation therapy.

Conservative noninvasive treatment can frequently control gastrointestinal symptoms. A low-residue or elemental diet may be beneficial. When nonsurgical treatment fails to relieve severe symptoms, surgical intervention is often indicated.

Bladder Radiation injury to the bladder generally becomes symptomatic 3 to 6 weeks after the start of treatment, and symptoms usually subside 3 to 4 weeks after completion of radiation therapy. Patients often complain of increased frequency and dysuria. Cystoscopy often shows diffuse mucosal changes similar to those of acute cystitis. Sometimes desquamation and ulceration can be seen. Without infection, urinary symptoms are managed symptomatically. Concurrent chemotherapy with cytotoxic agents such as cyclophosphamide increases the severity of the acute bladder reaction.

The late effects of high radiation doses to the bladder may include interstitial fibrosis, telangiectasia, and ulceration. The blood vessels may be dilated and prone to rupture, resulting in painless hematuria. These changes are often difficult to distinguish from tumor recurrence and progression. A contracted bladder may result from doses in excess of 60 Gy.

Testes and Ovaries In general, type B spermatogonia are exquisitely sensitive to the effects of radiation. The type A spermatogonia are thought to be more resistant because their longer cell cycle time allows considerable variation in radiosensitivity among different phases of the cell cycle. Sertoli cells and Leydig cells are less radiosensitive than the spermatogonia. Elevated levels of follicle-stimulating hormone (FSH) and luteinizing hormone (LH) have been observed after as little as 75 cGy. Doses as low as 10 cGy to the testicles may result in injury to the type B spermatogonia. The single dose required for permanent sterilization on normal human males is believed to be between 6 and 10 Gy. In normal human males, sperm count recovery requires 9 to 18 months after a fractionated dose of 8 to 100 cGy.

The radiation dose necessary to induce ovarian failure is age-dependent. A single dose of 3 to 4 Gy can induce amenorrhea in almost all women over 40 years of age. In young

women, oogenesis is much less sensitive to radiation than is spermatogenesis in men.

ACUTE TOTAL-BODY IRRADIATION

The data regarding the acute effects of total-body irradiation on humans come primarily from Japanese survivors of the atomic bomb, Marshallese exposed to radioactive fall-out in 1954, and persons exposed to radiation from the Chernobyl nuclear accident. Early symptoms of acute total-body irradiation, known as the *prodromal radiation syndrome*, last for a limited time. Clinical manifestations depend on the total-body dose. At doses >100 Gy, death usually occurs 24 to 48 h later from neurologic and cardiovascular failure. This is known as the *cerebrovascular syndrome*. Because cerebrovascular damage causes death very quickly, the failures of other systems do not have time to develop.

At doses between 5 and 12 Gy, death may occur in a matter of days as a result of the *gastrointestinal syndrome*. The symptoms during this period may include nausea, vomiting, and prolonged diarrhea for several days leading to dehydration, sepsis, and death. A total-body dose >10 Gy is uniformly fatal unless supportive therapy (fluid, electrolytes, blood products, and antibiotics) is given. The process of intestinal denudation depends on the dose and may take between 3 and 120 days. Death from intestinal denudation usually occurs before the full effects of radiation on the blood-forming elements are seen.

At total-body doses between 2 and 8 Gy, death may occur 2 to 4 weeks after exposure from bone marrow failure, the *hematopoietic syndrome*. The full effect of radiation is not apparent until the mature hematopoietic cells are depleted. Clinical symptoms during this period may include chills, fatigue, and petechial hemorrhage. Peripheral blood lymphopenia develops during the first 12 to 48 h after any significant exposure. Beyond 5 to 6 Gy, the rate and magnitude of the drop are not well correlated to radiation exposure. Some stem cells may survive acute exposure to^{3}10 Gy. Death is from infection or bleeding and usually occurs before anemia can develop (red blood cell half-life is 100 to 120 days).

The $LD_{50/60}$(the dose at which 50% of the population is dead by 60 days) is around 3.25 Gy if support is not given. There is considerable variability in the total-body dose tolerated. The very young and the old are more radiosensitive than middle-aged and young adult individuals. Females in general appear to be more tolerant of radiation than males. Persons exposed to<2 Gy will require little or no therapy but should probably be observed closely with daily blood counts for a few days.

The role of bone marrow transplantation for patients exposed to acute total-body irradiation is debated. At doses<8 Gy, the patient is likely to survive with supportive care. Most people exposed to doses higher than 10 Gy will die from the gastrointestinal syndrome. Therefore, 8 to 10 Gy may be the dose range in which bone marrow transplantation could have a role, although the Chernobyl experience did not confirm this prediction. Estimating the dose received by a given patient after radiation exposure is difficult. However, exposure estimation must be done quickly because bone marrow transplantation is most effective if it is performed within the first 3 to 5 days after exposure.

RADIATION AND CANCER INDUCTION

Some nonlethal changes in DNA sequences caused by irradiation may cause malignant transformations. Thus, it is not surprising that second neoplasms can be caused by exposure to ionizing radiation. However, paradoxically, this risk is actually less with doses above a certain level. Whether there is a "safe" dose that will not have any adverse biologic effect is unclear. Estimates of the risk of developing cancer after low-level exposure to ionizing radiation are often derived by extrapolation from the risks for higher doses and acute exposures. Predicted risks of cancer are, therefore, prone to modification depending on the assumptions made about the data available for analysis.

Throughout the history of human exposure to ionizing radiation, increased rates of cancer have been noted after exposure to radiation. The populations studied include survivors of the atomic bomb during World War II; radium watch-dial painters who shaped their brush tips with their tongues; and patients who underwent multiple fluoroscopic examinations for tuberculosis, received spinal irradiation for ankylosing spondylitis, and received breast irradiation for postpartum mastitis; and others. Exposure to ionizing radiation at an earlier age appears to increase the chance of developing radiation-induced carcinomas. However, the radiation-induced cancers have an age of onset similar to that of the native cancers, and the available data argue against radiation as the only cause of the increased incidence of cancers seen after exposure to radiation.Table 394-5 shows examples of cancer observed in specific situations.

Because a safe dose of radiation is unknown at present, it is prudent to avoid routine exposures to ionizing irradiation.

ACKNOWLEDGEMENT

The authors wish to acknowledge Dr. L. Chinsoo Cho for his contribution to this chapter in the 14th edition.

395. HEAVY METAL POISONING - *Howard Hu*

Metals constitute a major category of toxins that pose a significant threat to health through occupational as well as environmental exposures. One indication of their importance relative to other potential hazards is their ranking by the U.S. Agency for Toxic Substances and Disease Registry, which lists all hazards present in toxic waste sites according to their prevalence and the severity of their toxicity. The first, second, third, and sixth hazards on the list are heavy metals: lead, mercury, arsenic, and cadmium, respectively. This chapter offers specific information on the sources and metabolism of each of these metals as well as on the toxic effects produced by each and the appropriate treatment for poisoning by each.

The intrinsic atomic stability of metals allows their relatively easy tracing and measurement in biologic material, although the clinical significance of the levels measured is not always clear. Metals are inhaled primarily as dusts and fumes (the latter defined as tiny particles generated by combustion). Metal poisoning can also result from exposure to vapors (e.g., mercury vapor in the manufacture of fluorescent lamps). When metals are ingested in contaminated food or drink or through hand-to-mouth activity (implicated especially often in children), their gastrointestinal absorption varies greatly with the specific chemical form of the metal and the nutritional status of the host. Once a metal is absorbed, blood is the main medium for its transport, with the precise kinetics dependent on diffusibility, binding forms, rates of biotransformation, availability of intracellular ligands, and other factors. Some organs (such as bone, liver, and kidney) sequester metals in relatively high concentrations for years. Most metals are excreted through renal clearance and gastrointestinal excretion; some proportion is also excreted through salivation, perspiration, exhalation, lactation, skin exfoliation, and loss of hair and nails.

Some metals, such as copper and selenium, are essential to normal metabolic function as trace elements (Chap. 75) but are toxic at high levels of exposure. Others, such as lead and mercury, are xenobiotic and theoretically are capable of exerting toxic effects at any level of exposure. Indeed, much research is currently focused on the contribution of low-level xenobiotic metal exposure to chronic diseases and to subtle changes in health that may have significant public health consequences.

The most important component of treatment for metal toxicity is the termination of exposure. Another component is the use of *chelating agents*, which are used to bind metals into stable cyclic compounds with relatively low toxicity and to enhance their excretion. The principal chelating agents are dimercaprol (British Anti-Lewisite, BAL), edetate (EDTA), succimer (DMSA, dimercaptosuccinic acid), and penicillamine; their specific use depends on the metal involved and the clinical picture. Activated charcoal does not bind metals and thus is of limited usefulness in cases of acute metal ingestion.

Besides the four metals discussed in detail in this chapter, several others deserve mention. *Aluminum* contributes to the encephalopathy occurring in patients with severe renal disease who are undergoing dialysis (Chap. 341). High levels of aluminum are found in the neurofibrillary tangles in the cerebral cortex and hippocampus of patients with Alzheimer's disease as well as in the drinking water and soil of areas with an unusually high incidence of Alzheimer's disease. The experimental and epidemiologic

evidence for the aluminum-Alzheimer's disease link is so far relatively weak, however, and it cannot be concluded that aluminum is a causal agent or a contributing factor in neurodegenerative disease. Hexavalent *chromium* is corrosive and sensitizing. Workers in the chromate and chrome pigment production industries have consistently had an excess risk of lung cancer. The introduction of *cobalt* chloride as a fortifier in beer led to outbreaks of fatal cardiomyopathy among heavy consumers. Occupational exposure (e.g., of some miners, dry-battery manufacturers, and arc welders) to *manganese* can cause a Parkinsonian syndrome within 1 to 2 years, including gait disorders; postural instability; a masked, expressionless face; tremor; and psychiatric symptoms. With the introduction of methylcyclopentadienyl manganese tricarbonyl (MMT) as a gasoline additive, concern has arisen over the toxic potential of environmental manganese exposure. *Nickel* exposure induces an allergic response, and inhalation of nickel compounds with low aqueous solubility (such as nickel subsulfide and nickel oxide) in occupational settings is associated with an increased risk of cancer of the lung. Overexposure to *selenium* may cause local irritation of the respiratory system and eyes, gastrointestinal irritation, liver inflammation, loss of hair, depigmentation, and peripheral nerve damage. Workers exposed to certain organic forms of *tin* (particularly trimethyl and triethyl derivatives) have developed psychomotor disturbances, including tremor, convulsions, hallucinations, and psychotic behavior.

Finally, *thallium*, which is a component of some insecticides, metal alloys, and fireworks, is absorbed through the skin as well as through ingestion and inhalation. Severe poisoning follows a single ingested dose of >1 g or>8 mg/kg. Nausea and vomiting, abdominal pain, and hematemesis precede confusion, psychosis, organic brain syndrome, and coma. Thallium is radiopaque. Induced emesis or gastric lavage is indicated within 4 to 6 h of acute ingestion; Prussian blue prevents absorption and is given orally at 250 mg/kg in divided doses. Unlike other types of metal poisoning, thallium poisoning may be less severe when activated charcoal is used to interrupt its enterohepatic circulation. Other measures include forced diuresis, treatment with potassium chloride (which promotes renal excretion of thallium), and peritoneal dialysis.

LEAD

SOURCE

Lead has been mined and used in industry and in household products for centuries. The dangers of lead toxicity, the clinical manifestations of which are termed *plumbism*, have been known since ancient times. The twentieth century saw both the greatest-ever exposure of the general population to lead and an extraordinary amount of new research on lead toxicity.

Populations are exposed to lead chiefly via paints, cans, plumbing fixtures, and leaded gasoline. The intensity of these exposures, while decreased by regulatory actions, remains high in some segments of the population because of the deterioration of lead paint used in the past and the entrainment of lead from paint and vehicle exhaust into soil and house dust. Many other environmental sources of exposure exist, such as leafy vegetables grown in lead-contaminated soil, improperly glazed ceramics, lead crystal, and certain herbal folk remedies. Many industries, such as battery manufacturing, demolition, painting and paint removal, and ceramics, continue to pose a significant risk

of lead exposure to workers and surrounding communities.

New research on lead toxicity has been stimulated by advances in toxicology and epidemiology as well as by a shift of emphasis in toxicology away from binary outcomes (life/death; 50% lethal dose) to grades of function, such as neuropsychological performance, indices of behavior, blood pressure, and kidney function.

Tests for levels of lead in blood have facilitated both research on lead and surveillance of individuals at risk. Blood lead is now measured with stringent quality controls in commercial laboratories throughout the United States. Measurement of the blood lead levels of children 6 months to 5 years of age is mandated by some states, and the U.S. Occupational Safety and Health Administration (OSHA) requires the testing of workers who may be exposed to lead in the course of their jobs.

METABOLISM

Elemental lead and inorganic lead compounds are absorbed through ingestion or inhalation. Organic lead (e.g., tetraethyl lead, the lead additive to gasoline) is absorbed to a significant degree through the skin as well. Pulmonary absorption is efficient, particularly if particle diameters are<1 um (as in fumes from burning lead paint). Children absorb up to 50% of the amount of lead ingested, whereas adults absorb only ~10 to 20%. Gastrointestinal absorption of lead is enhanced by fasting and by dietary deficiencies in calcium, iron, and zinc; such absorption is minimal, however, for lead in the form of lead sulfide, a common constituent of mining waste. Lead is absorbed into blood plasma, where it equilibrates rapidly with extracellular fluid, crosses membranes (such as the blood-brain barrier and the placenta), and accumulates in soft and hard tissues. In the blood, ~95 to 99% of lead is sequestered in red cells, where it is bound to hemoglobin and other components. As a consequence, lead is usually measured in whole blood rather than in serum. The largest proportion of absorbed lead is incorporated into the skeleton, which contains>90% of the body's total lead burden. Lead is excreted mainly in the urine (in a process that depends on glomerular filtration and tubular secretion) and in the feces. Lead also appears in hair, nails, sweat, saliva, and breast milk. The half-life of lead in blood is ~25 days; in soft tissue, ~40 days; and in the nonlabile portion of bone,>25 years. Thus, blood lead levels may decline significantly while the body's total burden of lead remains heavy.

The toxicity of lead is probably related to its affinity for cell membranes and mitochondria, as a result of which it interferes with mitochondrial oxidative phosphorylation and sodium, potassium, and calcium ATPases. Lead impairs the activity of calcium-dependent intracellular messengers and of brain protein kinase C. In addition, lead stimulates the formation of inclusion bodies that may translocate the metal into cell nuclei and alter gene expression.

CLINICAL TOXICOLOGY

Symptomatic lead poisoning in childhood generally develops at blood lead levels>3.9 umol/L (80 ug/dL) and is characterized by abdominal pain and irritability followed by lethargy, anorexia, pallor (resulting from anemia), ataxia, and slurred speech. Convulsions, coma, and death due to generalized cerebral edema and renal failure

occur in the most severe cases. Subclinical lead poisoning [blood lead level>1.4 umol/L (> 30 ug/dL)] can cause mental retardation and selective deficits in language, cognitive function, balance, behavior, and school performance despite the lack of discernible symptoms. Epidemiologic studies and meta-analyses of studies regarding lead's effect on the intellectual function of children indicate that cognition is probably impaired in a dose-related fashion at blood lead levels well below 1.4 umol/L (30 ug/dL) and that no threshold for this effect is likely to exist above the lowest measurable blood lead level of 0.05 umol/L (1 ug/dL). The impact is greatest when the exposure is of long duration and has been most apparent when it takes place around the age of 2 years; however, the impact of fetal lead exposure remains to be clarified, particularly in view of the observation that maternal bone lead stores can be mobilized to a significant degree during pregnancy, with consequent exposure of the fetus.

In adults, symptomatic lead poisoning, which usually develops when blood lead levels exceed 3.9 umol/L (80 ug/dL) for a period of weeks, is characterized by abdominal pain, headache, irritability, joint pain, fatigue, anemia, peripheral motor neuropathy, and deficits in short-term memory and the ability to concentrate. Encephalopathy is rare. A "lead line" sometimes appears at the gingiva-tooth border after prolonged high-level exposure. Some individuals develop these symptoms and signs at lower blood lead levels [1.9 to 3.9 umol/L (40 to 80 ug/dL)] and/or with briefer periods of exposure. Chronic subclinical lead exposure is associated with interstitial nephritis, tubular damage (with tubular inclusion bodies), hyperuricemia (with an increased risk of gout), and a decline in glomerular filtration rate and chronic renal failure. Epidemiologic evidence also suggests that blood lead levels in the range of 0.34 to 1.7 umol/L (7 to 35 ug/dL) are associated with increases in blood pressure, decreases in creatinine clearance, and decrements in cognitive performance that are too small to be detected as a lead effect in individual cases but nevertheless may contribute significantly to the causation of chronic disease.

An additional issue for both children and adults is whether lead that has accumulated in bone and lain dormant for years can pose a threat later in life, particularly at times of increased bone resorption such as pregnancy, lactation, and senile osteoporosis. Elevation of the bone lead level appears to be a risk factor for anemia, hypertension, cardiac conduction delays, and impairment of cognitive function. Hyperthyroidism has been reported to cause lead toxicity in adults by mobilizing stores of bone lead acquired during childhood.

Genetic polymorphisms, such as variants of the gene that codes for aminolevulinic acid dehydratase (a critical enzyme in the production of heme) or the C282Y hemochromatosis gene, may confer differences in susceptibility to lead retention and toxicity; ~15% of Caucasians have a variant form of one of these genes. This issue is the focus of continued research.

LABORATORY FINDINGS

In 1991, the Centers for Disease Control and Prevention designated 0.48 umol/L (10 ug/dL) as the blood lead level of concern in children. A specific set of interventions is recommended when the level exceeds this value. OSHA requires the regular measurement of blood lead in lead-exposed workers and the maintenance of blood lead

levels<1.9 umol/L (40 ug/dL). Concentrations of heme precursors (such as d-aminolevulinic acid) in plasma and urine are sometimes increased at blood lead levels as low as 0.73 umol/L (15 ug/dL). Levels of protoporphyrin (free erythrocyte or zinc) rise -- although not consistently -- once blood lead levels have exceeded 1.2 umol/L (25 ug/dL) for several months. Lead-associated anemia is usually normocytic and normochromic and may be accompanied by basophilic stippling. Lead-induced peripheral demyelination is reflected by prolonged nerve conduction time and subsequent paralysis, usually of the extensor muscles of the hands and feet (wristdrop and footdrop). An increased density at the metaphyseal plate of growing long bones (lead lines) can develop in children and resemble those seen in rickets. Children with high-level lead exposure sometimes develop Fanconi's syndrome, pyuria, and azotemia. Adults chronically exposed to lead can develop elevated serum creatinine levels, decreased creatinine clearance rates, and chronic changes and intranuclear inclusion bodies (detected at renal biopsy). Deficits may be apparent in neuropsychometric tests of both children and adults; these abnormalities by themselves are not pathognomonic. Bone lead levels measured in vivo by K-x-ray fluorescence, a technique adapted for this purpose, are more sensitive than blood lead levels as a predictor of hypertension, cognitive impairments, and reproductive toxicity in epidemiologic studies; however, measurement of bone lead levels has not yet been shown to be of clinical value and is not widely available.

TREATMENT

It is absolutely essential to prevent further exposure of affected individuals to lead. Cases of lead poisoning should be reported to OSHA (if the exposure is occupational) and to local boards of health so that home evaluations can be performed. Pharmacologic treatment for lead toxicity entails the use of chelating agents, principally edetate calcium disodium (CaEDTA), dimercaprol, penicillamine, and succimer, which is given orally and has relatively few side effects. Chelation is recommended for the treatment of all children whose blood lead levels are >2.7 umol/L (55 ug/dL), with the addition of dimercaprol if lead encephalopathy is found. Chelation is also recommended for children if blood lead levels are between 1.2 and 2.7 umol/L (25 and 55 ug/dL) and the total amount of lead excreted in urine during the 8 h after a single dose of edetate calcium disodium exceeds 9.7 umol/L (200 ug/dL). Chelation is recommended for adults if blood lead levels exceed 3.9 umol/L (80 ug/dL) or if these levels exceed 2.9 umol/L (60 ug/dL) and symptoms have developed. The ability of chelation to improve subclinical outcomes (such as performance on psychometric testing) at lower levels of blood lead in both children and adults is the subject of current research.

MERCURY

SOURCE

Metallic mercury (Hg^0) is used in thermometers, dental amalgams, and some batteries. Mercurous mercury (Hg^+) and mercuric mercury (Hg^{2+}) can be combined with other chemicals, such as carbon, chlorine, or oxygen, to form inorganic or organic mercury compounds. All three forms of mercury are toxic to various degrees. Organic mercury compounds are slowly broken down into inorganic compounds; conversely, inorganic mercury can be converted by microorganisms in soil and water into the organic

compound methyl mercury. Fish, particularly tuna and swordfish, can concentrate methyl mercury at high levels; such contamination of fish by industrial runoff and their subsequent ingestion was responsible for the Minamata Bay epidemic of mercury poisoning in Japan in 1955. Occupational exposure to inorganic mercury compounds continues in some chemical, metal-processing, electrical-equipment, automotive, and building industries and in medical and dental services. Environmental exposure probably takes place most commonly through ingestion of contaminated fish and through inhalation of the vapor generated by ordinary dental amalgam, which typically contains ~50% metallic mercury. There is also concern about exposure to drinking water contaminated by toxic waste sites included on the National Priority List, almost half of which contain mercury, and about the inhalation of fumes from incinerators burning mercury-contaminated waste products. Such incineration can also lead to environmental mercury contamination, methylation of the contaminating mercury by environmental bacteria, concentration of the resultant organic mercury compounds up the food chain, and consequent human exposure (particularly to contaminated fish). Ironically, the medical/hospital industry has been identified as a major incinerator of mercury-contaminated waste.

METABOLISM

Elemental mercury is not well absorbed by the gastrointestinal tract and is excreted almost entirely in the feces after being ingested; however, when left standing, mercury is volatilized at room temperature into a vapor that is well absorbed by the lungs. Once absorbed, mercury in this form is lipid soluble, crosses the blood-brain barrier and the placenta, and can be oxidized by catalase and hydrogen peroxide into mercuric chloride, which is retained by the kidney and brain for years. Elemental mercury in blood has a half-life of ~60 days and is excreted mainly in the urine and feces.

The gastrointestinal and dermal absorption of inorganic mercury is significant. Large overdoses disrupt gastrointestinal barriers, further enhancing absorption. Once absorbed, inorganic mercury breaks down into metallic and mercuric mercury. Relatively little of this mercury crosses the blood-brain barrier; most is excreted in the urine or feces, with a half-life of 40 days, or is retained by the kidneys as mercuric mercury.

Organic mercury, particularly methyl mercury, can evaporate and undergo pulmonary absorption. Forms that are ingested (e.g., in contaminated fish) are well absorbed. Only small amounts are absorbed through the skin. Absorbed organic mercury is lipid soluble, readily crosses the blood-brain barrier and the placenta, appears in breast milk, and concentrates in the kidneys and central nervous system. Methyl mercury is acetylated in the liver, excreted in bile, reabsorbed, and then excreted in urine. Methyl mercury can also be conjugated with cysteine or glutathione. Only 1% of organic mercury is excreted unchanged into urine. The half-life of organic mercury compounds is in the range of 70 days. Exposure to mercury in any form stimulates the kidney to produce metallothionein, a metal-binding protein that affords partial protection against mercury toxicity.

CLINICAL TOXICOLOGY

Inhalation of metallic mercury vapor is the form of mercury exposure that has been best

studied in terms of toxicity. High levels of exposure are most likely in an occupational setting in which mercury vapors are generated by heat-induced volatilization of metallic mercury. Cough, dyspnea, and tightness or burning pain in the chest are common symptoms that may be accompanied by diffuse infiltrates or a pneumonitis-like appearance on chest x-ray. Respiratory distress, pulmonary edema, lobar pneumonia, fibrosis, and desquamation of the bronchiolar epithelium can occur in relatively severe cases and have sometimes led to death. Acute inhalation of mercury vapor can also cause neurologic toxicity manifested by tremors (beginning in the hands), emotional lability, headaches, and polyneuropathy. Chronic exposure to metallic mercury produces a characteristic intention tremor and mercurial *erethism*, a constellation of findings including excitability, memory loss, insomnia, timidity, and sometimes delirium that was described in workers with occupational exposure in the felt-hat industry -- hence the expression "mad as a hatter." Dentists with occupational exposure to mercury score below normal on neurobehavioral tests of motor speed, visual scanning, verbal and visual memory, and visuomotor coordination. Low-level exposure from dental amalgams may also be associated with adverse immunologic reactions in individuals with certain major human leukocyte antigen genotypes; further research is needed in this area.

Acute high-dose ingestion of inorganic mercury causes severe gastrointestinal corrosion with nausea, vomiting, hematemesis, and abdominal pain; acute renal failure, cardiovascular collapse, and shock may ensue. The lethal dose of inorganic mercury is estimated to be in the range of 10 to 42 mg/kg. Lower levels of exposure cause milder forms of gastrointestinal inflammation, gingivitis and loosening of the teeth, increased blood pressure and tachycardia, and the nephrotic syndrome. Symptoms similar to erethism may develop. Skin exposure to mercuric salts can cause exfoliative dermatitis.

Ingestion of organic mercury compounds is followed by diarrhea, tenesmus, and blisters of the upper gastrointestinal tract. The fatal dose of organic mercury is estimated at 10 to 60 mg/kg. People who ingested flour contaminated with *N*-(ethylmercuri)-*p*-toluenesulfonanilide developed bradycardia, QT prolongation, ST-segment depression, and T-wave inversions. The neurotoxicity resulting from organic mercury exposure is characterized by paresthesia; impaired peripheral vision, hearing, taste, and smell; slurred speech; unsteadiness of gait and limbs; muscle weakness; irritability; memory loss; and depression. In general, such symptoms begin at doses>1.7 mg/kg. Autopsy findings suggest that lesions in the basal ganglia and gray matter of the cortex and cerebellum are chiefly responsible for these symptoms. Organic mercury exposure, primarily through the ingestion of grain treated with mercuric fungicides or of contaminated fish, is also associated with an increased risk of fetal toxicity. After the 1955 mercury poisoning outbreak in Minamata, Japan, exposed mothers gave birth to infants with mental retardation; retention of primitive reflexes; cerebellar symptoms; dysarthria; hyperkinesia; hypersalivation; atrophy of the cerebral cortex, corpus callosum, and cerebellum; and abnormal neuronal cytoarchitecture. This last change may reflect derangement of neuronal migration during fetal development.

Worthy of special note is dimethylmercury, a "supertoxic" compound encountered exclusively in laboratory settings. The physical properties of dimethylmercury permit transdermal absorption (against which latex gloves do not afford protection) as well as volatilization with inhalation. Exposure to ~400 mg (an amount equivalent to a few drops) is lethal, with cerebellar degeneration as a prominent feature.

Exposure of children to mercury in any of its forms can cause a particular syndrome known as *acrodynia*, or pink disease. This condition is characterized by flushing, itching, swelling, tachycardia, elevated blood pressure, excessive salivation or perspiration, irritability, weakness, morbilliform rashes, and desquamation of the palms and soles.

LABORATORY FINDINGS

Levels of mercury in blood and urine should not exceed 180 nmol/L (3.6 ug/dL) and 0.7 umol/L (15 ug/L), respectively. Symptoms may develop when blood and urine mercury levels exceed 1 umol/L (20 ug/dL) and 3 umol/L (60 ug/L), respectively. If a baseline 24-h urinary mercury value is low, repetition of the measurement after a single 2-g oral dose of succimer may be useful in documenting elevated renal mercury burdens in retired mercury-exposed workers; an increase of>20 ug in a 24-h urine sample suggests previous exposure. Levels in hair may be used as a dosimeter for chronic organic mercury exposure; neurobehavioral dysfunction in children may occur if the maternal mercury concentration in hair exceeds 30 nmol/g (6 ug/g).

TREATMENT

Acute ingestion of mercuric salts can be treated by induced emesis or gastric lavage. Polythiol resins can be administered orally to bind mercury in the gastrointestinal tract. The most effective chelating agents are dimercaprol, succimer, and penicillamine, which have active mono- or dithiol groups. Acute inorganic mercury poisoning can be treated with dimercaprol at a dose not exceeding 24 mg/kg per day and given intramuscularly in divided doses. Therapy is usually given in 5-day courses separated by several days of rest. The *N*-acetyl form of penicillamine is also useful at a dose of 30 mg/kg per day in divided doses. Peritoneal dialysis, hemodialysis, and extracorporeal regional complexing hemodialysis with succimer have all been used with some success in the treatment of patients with renal failure.

Chronic inorganic mercury poisoning is best treated with *N*-acetyl penicillamine.

ARSENIC

SOURCE

Significant exposure to arsenic occurs through both anthropogenic and natural sources. Arsenic is released into the air by volcanoes and is a natural contaminant of some deep-water wells. Occupational exposure to arsenic is common in the smelting industry (in which arsenic is a byproduct of ores containing lead, gold, zinc, cobalt, and nickel) and is increasing in the microelectronics industry (in which gallium arsenide is responsible). Low-level arsenic exposure continues to take place in the general population (as do some cases of high-dose poisoning) through the commercial use of inorganic arsenic compounds in common products such as wood preservatives, pesticides, herbicides, fungicides, and paints; through the consumption of foods and the smoking of tobacco treated with arsenic-containing pesticides; and through the burning of fossil fuels in which arsenic is a contaminant. Arsenic was also a major ingredient of Fowler's solution and continues to be found in some folk remedies.

METABOLISM

The toxicity of an arsenic-containing compound depends on its valence state (zero-valent, trivalent, or pentavalent), its form (inorganic or organic), and the physical aspects governing its absorption and elimination. In general, inorganic arsenic is more toxic than organic arsenic, and trivalent arsenite is more toxic than pentavalent and zero-valent arsenic. The normal intake of arsenic by adults occurs primarily through ingestion and averages ~50 ug/d (range, 8 to 104 ug/d). Most (~64%) of this amount is accounted for by organic arsenic from fish, seafood, and algae; the specific arsenic compounds obtained from these sources are arsenobentaine and arsenocholine, which are relatively nontoxic and are rapidly excreted in unchanged form in the urine. After absorption, inorganic arsenic accumulates in the liver, spleen, kidneys, lungs, and gastrointestinal tract. It is then rapidly cleared from these sites but leaves a residue in keratin-rich tissues such as skin, hair, and nails. Arsenite (+5) undergoes biomethylation in the liver to the less toxic metabolites methylarsenic acid and dimethylarsenic acid; biomethylation can quickly become saturated, however, and the result is the deposition of increasing doses of inorganic arsenic in soft tissues. Arsenic, particularly in its trivalent form, inhibits critical sulfhydryl-containing enzymes. In the pentavalent form, the competitive substitution of arsenic for phosphate can lead to rapid hydrolysis of the high-energy bonds in compounds such as ATP.

CLINICAL TOXICOLOGY

Acute arsenic poisoning from ingestion results in increased permeability of small blood vessels and inflammation and necrosis of the intestinal mucosa; these changes manifest as hemorrhagic gastroenteritis, fluid loss, and hypotension. Delayed cardiomyopathy accompanied by electrocardiographic abnormalities may develop. Symptoms include nausea, vomiting, diarrhea, abdominal pain, delirium, coma, and seizures. A garlicky odor may be detectable on the breath. Acute tubular necrosis and hemolysis may develop. The reported lethal dose of arsenic ranges from 120 to 200 mg in adults and is 2 mg/kg in children. Arsine gas causes severe hemolysis within 3 to 4 h of exposure and can lead to acute tubular necrosis and renal failure.

In chronic arsenic poisoning, the onset of symptoms comes at 2 to 8 weeks. Typical findings are skin and nail changes, such as hyperkeratosis, hyperpigmentation, exfoliative dermatitis, and Mees' lines (transverse white striae of the fingernails); sensory and motor polyneuritis manifesting as numbness and tingling in a "stocking-glove" distribution, distal weakness, and quadriplegia; and inflammation of the respiratory mucosa. Epidemiologic evidence has linked chronic consumption of water containing arsenic at concentrations in the range of 10 to 1820 ppb with diabetes, vasospasm, and peripheral vascular insufficiency culminating in "blackfoot disease," a gangrenous condition affecting the extremities. Chronic arsenic exposure has also been associated with a greatly elevated risk of skin cancer and possibly of cancers of the lung, liver (angiosarcoma), bladder, kidney, and colon.

LABORATORY FINDINGS

When acute arsenic poisoning is suspected, an x-ray of the abdomen may reveal

ingested arsenic, which is radiopaque. The serum arsenic level may exceed 0.9 umol/L (7 ug/dL); however, arsenic is rapidly cleared from the blood. Electrocardiographic findings may include QRS complex broadening, QT prolongation, ST-segment depression, T-wave flattening, and multifocal ventricular tachycardia. Urinary arsenic should be measured in 24-h specimens collected after 48 h of abstinence from seafood ingestion; normally, levels of total urinary arsenic excretion are<0.67 umol/d (50 ug/d). Arsenic may be detected in the hair and nails for months after exposure. Abnormal liver function, anemia, leukocytosis or leukopenia, proteinuria, and hematuria may be detected. Electromyography may reveal features similar to those of Guillain-Barre syndrome.

TREATMENT

Vomiting should be induced with ipecac in the alert patient with acute arsenic ingestion. Gastric lavage may be useful; activated charcoal with a cathartic (such as sorbitol) may be tried, although its efficacy is not clear. Aggressive therapy with intravenous fluid and electrolyte replacement in an intensive-care setting may be life-saving. Dimercaprol is the chelating agent of choice and is administered intramuscularly at an initial dose of 3 to 5 mg/kg on the following schedule: every 4 h for 2 days, every 6 h on the third day, and every 12 h thereafter for 10 days. (An oral chelating agent may be substituted.) Succimer is sometimes an effective alternative, particularly if adverse reactions to dimercaprol develop (such as nausea, vomiting, headache, increased blood pressure, and convulsions). In cases of renal failure, doses should be adjusted carefully, and hemodialysis may be needed to remove the chelating agent-arsenic complex. Arsine gas poisoning should be treated supportively with the goals of maintaining renal function and circulating red-cell mass. Other than the avoidance of additional exposure, specific treatment is not of proven benefit in chronic arsenic toxicity. Recovery, particularly from the resulting peripheral neuropathy, may take months and may never be complete.

CADMIUM

SOURCE

Environmental exposure to cadmium can result from the ingestion of basic foodstuffs, especially grains, cereals, and leafy vegetables, which readily absorb cadmium occurring naturally or in soil contaminated by sewage sludge, fertilizers, and polluted groundwater. Serious cadmium poisoning can follow the contamination of food and water by mining effluents, as took place in the 1946 outbreak of *itai-itai* ("ouch-ouch") disease (so named because cadmium-induced bone toxicity caused painful bone fractures) in the Jintzu River basin in Japan. Airborne cadmium can be released during smelting or during the incineration of municipal waste containing plastics and nickel-cadmium batteries. Cigarette smoke contains cadmium. Occupational exposure takes place in the metal-plating, pigment, battery, and plastics industries.

METABOLISM

The normal daily intake of cadmium through ingestion or inhalation is from 20 to 40 ug, although only 5 to 10% of this amount is absorbed. Most absorbed cadmium is concentrated in the liver and kidneys. In erythrocytes and soft tissues, cadmium is

bound to metallothionein, a low-molecular-weight protein that mitigates the toxicity of the unbound ion. This complex is filtered at the glomerulus but is then reabsorbed by the proximal tubules. The lack of an effective elimination pathway is responsible for cadmium's biologic half-life of 10 to 30 years. The toxicity of cadmium may involve its binding to key cellular sulfhydryl groups, its competition with other metals (zinc and selenium) for inclusion in metalloenzymes, and its competition with calcium for binding sites on regulatory proteins such as calmodulin.

CLINICAL TOXICOLOGY

Acute high-dose cadmium inhalation can cause severe respiratory irritation with pleuritic chest pain, dyspnea, cyanosis, fever, tachycardia, nausea, and life-threatening noncardiogenic pulmonary edema. The onset of symptoms may be delayed from 4 to 24 h. Acute exposure through ingestion can cause severe nausea, vomiting, salivation, abdominal cramps, and diarrhea. Single lethal oral doses have reportedly ranged from 350 to 8900 mg. Chronic effects of cadmium exposure are dose-dependent and include anosmia, yellowing of the teeth, emphysema, minor changes in liver function, microcytic hypochromic anemia unresponsive to iron therapy, renal tubular dysfunction characterized by proteinuria and increased urinary excretion ofb_2-microglobulin, and (with prolonged poisoning) osteomalacia leading to bone lesions and pseudofractures. In follow-up studies of occupationally exposed workers,b_2-microglobulinuria was found to be irreversible. Associations with hypertension, prostate cancer, and lung cancer have been suggested by some studies but await confirmation. In one study of men and women living in an area moderately contaminated with cadmium, higher body cadmium burdens were found to be a significant risk factor for lower bone density, a higher incidence of fractures, and a faster decline in height. These changes may be related to cadmium's calciuric effect on the kidney.

LABORATORY FINDINGS

The daily level of excretion of cadmium by persons without known cadmium exposures is usually<10 nmol/L (1 ug/L or 1 ug/g of creatinine). This level increases somewhat with age and smoking. Toxicity, including renal dysfunction, is considered unlikely until the urinary cadmium level exceeds 100 nmol/L (10 ug/g of creatinine). Serum cadmium levels reflect recent rather than chronic exposure and generally are <30 nmol/L (0.3 ug/dL) in unexposed persons. A blood level >500 nmol/L (5 ug/dL) is considered toxic. An increased urinary concentration ofb_2-microglobulin is the most sensitive indicator of an elevated cadmium dose and of nephropathy but may also be detected in other renal diseases, such as chronic pyelonephritis.

TREATMENT

There is no effective treatment for cadmium poisoning. Chelation therapy is not useful, and dimercaprol is contraindicated as this agent may exacerbate nephrotoxicity. Avoidance of further exposure and supportive therapy (including vitamin D if osteomalacia exists) are the mainstays of management.

SECTION 2 -ILLNESSES DUE TO POISONS, DRUG OVERDOSAGE, AND ENVENOMATION

396. POISONING AND DRUG OVERDOSAGE - *Christopher H. Linden*, *Michael J. Burns*

Poisoning refers to the development of dose-related adverse effects following exposure to chemicals, drugs, or other xenobiotics. To paraphrase Paracelsus, the dose makes the poison. In excessive amounts, substances that are usually innocuous, such as oxygen and water, can cause poisoning. Conversely, in small doses, substances commonly regarded as poisons, such as arsenic and cyanide, can be consumed without ill effect. There is, however, substantial individual variability in the response to, and disposition of, a given dose (Chaps. 70 and71). Some of this variability is genetic, and some is acquired on the basis of enzyme induction, inhibition, or because of tolerance. Poisoning may be local (e.g., skin, eyes, or lungs) or systemic depending on the chemical and physical properties of the xenobiotic, its mechanism of action, and the route of exposure. The severity and reversibility of poisoning also depend on the functional reserve of the individual or target organ, which is influenced by age and preexisting disease. All of these factors must be considered when attempting to predict the effects of a particular exposure.

EPIDEMIOLOGY

In the United States, exposure to xenobiotics results in over 5 million requests for medical advice or treatment each year. Most exposures are acute, accidental, involve a single agent, occur in the home, result in minor or no toxicity, and involve children under 6 years of age. Common routes of exposure are ingestion (74%), dermal (8.2%), inhalation (6.7%), ocular (6%), bites and stings (3.9%), and parenteral injections (0.3%). Exposures most frequently involve cleaning agents, analgesics, cosmetics, plants, cough and cold preparations, and bites and envenomations (Chaps. 397 and398). Pharmaceuticals are involved in 41% of exposures and 75% of serious or fatal poisonings.

Accidental exposures can result from the improper use of chemicals at work or play; product mislabeling; label misreading; mistaken identification of unlabeled chemicals; uninformed self-medication; and dosing errors by nurses, parents, pharmacists, physicians, and the elderly. Excluding the recreational use of ethanol, attempted suicide is the most common reason for intentional exposure. Unintended poisonings may result from the intentional use of drugs for psychotropic effects (abuse) or excessive self-dosing (misuse).

About 5% of exposures require hospitalization. They account for 5 to 10% of all ambulance transports, emergency room visits, and intensive care unit admissions. Up to 30% of psychiatric admissions are prompted by attempted suicide via overdosage.

Overall, the mortality rate is low: 0.03% of all exposures. It is much higher (1 to 2%) in hospitalized patients with nonaccidental (suicidal) overdose, who account for the majority of serious poisonings. Carbon monoxide poisoning is the leading cause of death; patients with such poisoning are typically dead when discovered and are

included in medical examiner but not hospital or poison center statistics. Drug-related fatalities are most commonly due to analgesics, antidepressants, sedative-hypnotics, neuroleptics, stimulants and street drugs, cardiovascular drugs, anticonvulsants, antihistamines, and asthma therapies. Nonpharmaceutical agents most often implicated in fatal poisoning include alcohols and glycols, gases and fumes, chemicals, cleaning substances, pesticides, and automotive products.

DIAGNOSIS

Although poisoning can mimic other illnesses, the correct diagnosis can usually be established by the history, physical examination, routine and toxicologic laboratory evaluations, and characteristic clinical course. The *history* should include the time, route, duration, and circumstances (location, surrounding events, and intent) of exposure; the name and amount of each drug, chemical, or ingredient involved; the time of onset, nature, and severity of symptoms; the time and type of first aid measures provided; and the medical and psychiatric history.

In many cases the victim is confused, comatose, unaware of an exposure, or unable or unwilling to admit to one. Suspicious circumstances include unexplained illness in a previously healthy person; a history of psychiatric problems (particularly depression); recent changes in health, economic status, or social relationships; and onset of illness while working with chemicals or after ingesting food, drink (especially ethanol), or medications. Patients who become ill soon after arriving from a foreign country or being arrested for criminal activity should be suspected of "body packing" or "body stuffing" (ingesting or concealing illicit drugs in a body cavity). Relevant history may be available from family, friends, paramedics, police, pharmacists, physicians, and employers, who should be questioned regarding the patient's habits, hobbies, behavior changes, available medications, and antecedent events. A search of clothes, belongings, and place of discovery may reveal a suicide note or a container of drugs or chemicals. The imprint code on pills and the label on chemical products may be used to identify the ingredients and potential toxicity of a suspected poison by consulting a reference text, a computerized database, the manufacturer, or a regional poison information center.

In the absence of a history of exposure, the *clinical course* may suggest a diagnosis of poisoning. Poisoning typically evolves and resolves more rapidly than other disorders. Signs and symptoms characteristically develop within an hour of acute exposure, peak within several hours, and resolve over hours to days. However, the absence of signs and symptoms soon after an overdose does not rule out a poisoning.

The *physical examination* should focus initially on the vital signs, cardiopulmonary system, and neurologic status. On the basis of the pulse, blood pressure, respiratory rate, temperature, and mental status, the physiologic state can be characterized as excited, depressed, discordant, or normal. A differential diagnosis can then be formulated (Table 396-1). Examination of the eyes (for nystagmus, pupil size and reactivity), abdomen (for bowel activity and bladder size), and skin (for burns, bullae, color, warmth, moisture, pressure sores, and puncture marks) may narrow the diagnosis to a particular disorder. Grading the severity of poisoning (Table 396-2) is useful for assessing the clinical course and response to treatment.

The patient should also be examined for evidence of trauma and underlying illnesses. Except with carbon monoxide, theophylline, and drugs that cause hypoglycemia or hypoxia, seizures and neurologic manifestations of poisoning are nonfocal. Hence, focal findings should prompt evaluation for a structural central nervous system (CNS) lesion. When the history is unclear, all orifices should be examined for the presence of chemical burns and drug packets. The odor of breath or vomitus and the color of nails, skin, or urine may provide diagnostic clues.

Laboratory assessment may be helpful in the differential diagnosis of poisoning (Fig. 396-1). An increased anion-gap metabolic acidosis is characteristic of advanced methanol, ethylene glycol, and salicylate intoxication but can occur with other agents (Table 396-1) and in any poisoning that results in hepatic, renal, or respiratory failure, seizures, or shock. The serum lactate concentration is low (less than the anion gap) in the former and high (nearly equal to the anion gap) in the latter. An abnormally low anion gap can be due to elevated blood levels of bromide, calcium, iodine, lithium, magnesium, or nitrate. An increased osmolal gap -- the difference between the serum osmolality (measured by freezing point depression) and that calculated from the serum sodium, glucose, and blood urea nitrogen (BUN) of>10 mmol/L -- suggests the presence of a low-molecular-weight solute such as an alcohol, glycol, or ketone or an unmeasured electrolyte or sugar. The osmolal gap can also provide an estimate of the amount of anion present (Table 396-3). Ketosis suggests acetone, isopropyl alcohol, or salicylate poisoning. Hypoglycemia may be due to poisoning withb-adrenergic blockers, ethanol, insulin, oral hypoglycemic agents, quinine, and salicylates, whereas hyperglycemia can occur in poisoning with acetone, b-adrenergic agonist, calcium channel blockers, iron, theophylline, or Vacor. Hypokalemia can be caused by barium, a b-adrenergic agonist, a diuretic, theophylline, or toluene; hyperkalemia suggests poisoning with ana-adrenergic agonist, ab-adrenergic blocker, cardiac glycosides, or fluoride.

Radiologic studies may also be useful for diagnostic purposes. Pulmonary edema (adult respiratory distress syndrome, or ARDS) can be caused by poisoning with carbon monoxide, cyanide, an opioid, paraquat, phencyclidine, a sedative-hypnotic, or salicylate; by inhalation of irritant gases, fumes, or vapors (ammonia, metal oxides, mercury); or by prolonged anoxia, hyperthermia, or shock. Aspiration pneumonia is common in patients with coma, seizures, and petroleum distillate ingestion. Radiopaque densities may be visible on abdominal x-rays following the ingestion of calcium salts, chloral hydrate, chlorinated hydrocarbons, heavy metals, illicit drug packets, iodinated compounds, potassium salts, psychotherapeutic agents, lithium, phenothiazines, enteric-coated tablets, or salicylates.

Theelectrocardiogram (ECG) can be useful to assist with the differential diagnosis and to guide treatment. Bradycardia and atrioventricular (AV) block may occur in patients poisoned bya-adrenergic agonists, antiarrhythmic agents, beta blockers, calcium channel blockers, cholinergic agents (carbamate and organophosphate insecticides), cardiac glycosides, lithium, magnesium, or tricyclic antidepressants. QRS- and QT-interval prolongation may be caused by hyperkalemia and by membrane-active drugs (Table 396-1). Ventricular tachyarrhythmias may be seen in poisoning with cardiac glycosides, fluorides, membrane-active drugs, sympathomimetics, or agents that cause hyperkalemia or potentiate the effects of endogenous catecholamines (e.g.,

chloral hydrate, aliphatic and halogenated hydrocarbons).

Analysis of urine and blood (and occasionally of gastric contents and chemical samples) may be useful to confirm or rule out suspected poisoning. Interpretation of laboratory data requires knowledge of the tests used for screening and confirmation (thin-layer, gas-liquid, or high-performance liquid chromatography; colorimetric and fluorometric assays; enzyme-multiplied and radioimmunoassays; gas chromatography; mass spectrometry), their sensitivity (limit of detection) and specificity, the preferred biologic specimen for analysis, and the optimal time of specimen sampling. Personal communication with the laboratory is essential. A negative result on a screen may mean the substance is not detectable by the test used or that its concentration is too low for detection at the time of sampling. In the latter case, repeating the test at a later time may yield a positive result.

Although some rapid screening tests for a limited number of drugs of abuse are available, comprehensive screening tests require 2 to 6 h for completion, and immediate management must be based on the history, physical examination, and routine ancillary tests. In addition, when the patient is asymptomatic, or when the clinical picture is consistent with the reported history, qualitative screening is neither clinically useful nor cost-effective. It is of greatest value in patients with severe or unexplained toxicity who have coma, seizures, cardiovascular instability, metabolic or respiratory acidosis, and nonsinus cardiac rhythms. Quantitative analysis is useful for poisoning with acetaminophen, acetone, alcohol (including ethylene glycol), antiarrhythmics, anticonvulsants, barbiturates, digoxin, heavy metals, lithium, paraquat, salicylate, and theophylline, as well as for carboxyhemoglobin and methemoglobin. Results can often be available within an hour.

The *response to antidotes* may be useful for diagnostic purposes. Resolution of altered mental status and abnormal vital signs within minutes of intravenous administration of dextrose, naloxone, or flumazenil is virtually diagnostic of hypoglycemia, narcotic poisoning, and benzodiazepine intoxication, respectively. The prompt reversal of acute dystonic (extrapyramidal) reactions following an intravenous dose of benztropine or diphenhydramine confirms a drug etiology. Although the reversal of both central and peripheral manifestations of anticholinergic poisoning by physostigmine is diagnostic, this antidote may cause arousal in patients withCNSdepression of any etiology.

TREATMENT

General Principles Treatment goals include support of vital signs, prevention of further poison absorption, enhancement of poison elimination, administration of specific antidotes, and prevention of reexposure (Table 396-4). Specific treatment depends on the identity of the poison, the route and amount of exposure, the time of presentation relative to the time of exposure, and the severity of poisoning. Knowledge of the offending agents' pharmacokinetics and pharmacodynamics is essential.

During the *pretoxic phase*, prior to the onset of poisoning, decontamination is the highest priority, and treatment is based solely on the history. The maximum potential toxicity based on the greatest possible exposure should be assumed. Since decontamination is more effective when accomplished soon after exposure, the initial

history and physical examination should be focused and brief. It is also advisable to establish intravenous access and initiate cardiac monitoring, particularly in patients with potentially serious ingestions or unclear histories.

When an accurate history is not obtainable, and a poison causing delayed toxicity or irreversible damage is suspected, blood and urine should be sent for toxicologic screening and, if indicated, for quantitative analysis. During absorption and distribution, blood levels may be greater than those in tissue and may not correlate with toxicity. However, high blood levels of agents whose metabolites are more toxic than the parent compound (acetaminophen, ethylene glycol, or methanol) may indicate the need for additional interventions (antidotes, dialysis).

Most patients who remain or become asymptomatic 4 to 6 h after ingestion will not develop subsequent toxicity and can be discharged safely. Longer observation may be necessary for patients who have ingested agents that slow gastric emptying and intestinal motility as this will delay dissolution, absorption, and distribution characteristics. Extended observation may also be indicated for agents that are converted in the body to toxic metabolites (Table 396-1).

During the *toxic phase*, the time between the onset of poisoning and the peak effects, management is based primarily on clinical and laboratory findings. *Effects after an overdose begin sooner, peak later, and last longer than they do after a therapeutic dose*. Resuscitation and stabilization are the first priority. All symptomatic patients should have an intravenous line, oxygen saturation determination, cardiac monitoring, and continuous observation. Baseline laboratory, ECG, and x-ray evaluation may also be appropriate. Intravenous glucose (unless documented to be normal), naloxone, and thiamine should be considered in patients with altered mental status, particularly those with soma or seizures. Decontamiation may also be appropriate.

Measures that enhance poison elimination may shorten the duration of toxicity and lessen its severity. However, the risks must be weighed against the benefits. Diagnostic certainty (usually via laboratory confirmation) is generally a prerequisite. Intestinal dialysis with repetitive doses of activated charcoal is usually safe and can enhance the elimination of many poisons. Diuresis and chelation therapy enhance the elimination of a relatively small number of poisons, and their use is associated with potential complications. Extracorporal methods are effective in removing many poisons, but their expense and risk make their use reasonable only in patients who would otherwise have an unfavorable outcome.

During the *resolution phase* of poisoning, supportive care and monitoring should continue until clinical, laboratory, andECGabnormalities have resolved. Since chemicals are eliminated from the blood before tissues, blood levels are usually lower than tissue levels during this phase and may not correlate with toxicity. This is particularly true when extracorporeal elimination procedures are used. Redistribution from tissues may cause a rebound increase in the blood level after termination of these procedures. When a metabolite is responsible for toxic effects, continued treatment of an asymptomatic patient might be necessary because of a potentially toxic blood level (acetaminophen, ethylene glycol, and methanol).

Supportive Care The goal of supportive therapy is to maintain physiologic homeostasis until detoxification is accomplished and to prevent and treat secondary complications such as aspiration, bedsores, cerebral and pulmonary edema, pneumonia, rhabdomyolysis, renal failure, sepsis, thromboembolic disease, and generalized organ dysfunction due to prolonged hypoxia or shock.

Admission to an intensive care unit is indicated for the following: patients with severe poisoning (coma, respiratory depression, hypotension, cardiac conduction abnormalities, cardiac arrhythmias, hypothermia or hyperthermia, seizures); those needing close monitoring, antidotes, or enhanced elimination therapy; those showing progressive clinical deterioration; and those with significant underlying medical problems. Patients with mild to moderate toxicity can be managed on a general medical service, intermediate care unit, or emergency department observation area, depending on the anticipated duration and level of monitoring needed (intermittent clinical observation versus continuous clinical, cardiac, and respiratory monitoring). Patients who have attempted suicide require continuous observation and measures to prevent self-injury until they are thought unlikely to make further attempts.

Respiratory care Endotracheal intubation for protection against the aspiration of gastrointestinal contents is of paramount importance in patients withCNSdepression or seizures as this complication can increase morbidity and mortality. Mechanical ventilation may be necessary for patients with respiratory depression or hypoxia and to facilitate therapeutic sedation or paralysis in order to prevent hyperthermia, acidosis, and rhabdomyolysis associated with neuromuscular hyperactivity. Since clinical assessment of respiratory function is often inaccurate, the need for oxygenation and ventilation is best determined by oximetry or arterial blood gas analysis. The gag reflex is not a reliable indicator of the need for intubation. A patient may maintain airway patency while being stimulated but not if left unattended. Those who cannot respond to voice or who are unable to sit and drink fluids without assistance are best managed by prophylactic intubation.

Drug-induced pulmonary edema is usually noncardiac rather than cardiac in origin. ProfoundCNSdepression and cardiac conduction abnormalities suggest the latter etiology. Measurement of pulmonary artery pressure may be necessary to establish etiology and direct appropriate therapy. Extracorporeal measures (membrane oxygenation, venoarterial perfusion, cardiopulmonary bypass), partial liquid (perfluorocarbon) ventilation, and hyperbaric oxygen therapy may be appropriate for severe but reversible respiratory failure.

Cardiovascular therapy Maintenance of normal tissue perfusion is critical to allow for complete recovery once the offending agent has been eliminated. If hypotension is unresponsive to volume expansion, treatment with norepinephrine, epinephrine, or high-dose dopamine may be necessary (Chap. 38). Intraaortic balloon pump counterpulsation and venoarterial or cardiopulmonary perfusion techniques should be considered for severe but reversible cardiac failure. Bardyarrhythmias associated with hypotension generally should be treated as described inChap. 229. Glucagon and calcium may be effective in both beta blocker and calcium channel blocker poisoning. Antibody therapy may be indicated for cardiac glycoside poisoning.

Supraventricular tachycardia associated with hypertension andCNSexcitation is almost always due to agents that cause generalized physiologic excitation (Table 396-1). Most cases are mild or moderate in severity and require only observation or nonspecific sedation with a benzodiazepine. For cases that are severe or associated with hemodynamic instability, chest pain, orECGevidence of ischemia, specific therapy is indicated. For patients with sympathetic hyperactivity, treatment with a combined alpha and beta blocker (labetalol), a calcium channel blocker (verapamil or diltiazem), or a combination of a beta blocker and a vasodilator (esmolol and nitroprusside) is preferred. For those with anticholinergic poisoning, physostigmine is the treatment of choice. Supraventricular tachycardia without hypertension is generally secondary to vasodilation or hypovolemia and responds to fluid administration.

Lidocaine and phenytoin are generally safe for ventricular tachyarrhythmias, but beta blockers can be hazardous unless the arrhythmia is clearly due to sympathetic hyperactivity. For ventricular tachyarrhythmias due to tricyclic antidepressants and probably other membrane-active agents (Table 396-1), class IA, IC, and III antiarrhythmic agents are contraindicated (because of similar electrophysiologic effects), but sodium bicarbonate may be helpful. Magnesium sulfate and overdrive pacing (by isoproterenol or a pacemaker) may be useful in patients with torsade de pointes and prolonged QT intervals. Magnesium and antidigoxin antibodies should be considered in patients with severe cardiac glycoside poisoning. Invasive (esophageal or intracardiac)ECGrecording may be necessary to determine the origin (ventricular or supraventricular) of wide-complex tachycardias (Chap. 230). If the patient is hemodynamically stable, however, it may be prudent to observe rather than to treat with another potentially proarrhythmic agent. Arrhythmias may be resistant to drug therapy until underlying acid-base, electrolyte, oxygenation, and temperature derangements are corrected.

Central nervous system therapies Neuromuscular hyperactivity and seizures can lead to hyperthermia, lactic acidosis, and rhabdomyolysis, with their attendant complications, and should be treated aggressively. Seizures caused by excessive stimulation of catecholamine receptors (sympathomimetic or hallucinogen poisoning and drug withdrawal), or decreased activity ofg-aminobutyric acid (GABA) (isoniazid poisoning) or glycine (strychnine poisoning) receptors are best treated with enhancers of GABA effects such as benzodiazepines or barbiturates. Since benzodiazepines and barbiturates act by slightly different mechanisms (the former increases the frequency and the latter increases the duration of chloride channel opening in response to GABA), therapy with both may be effective when neither is effective alone. Seizures caused by isoniazid, which inhibits the synthesis of GABA, may require high doses of pyridoxine (which facilitates the synthesis of GABA). Seizures resulting from membrane destabilization (beta blocker or cyclic antidepressant poisoning) may require a membrane-active anticonvulsant such as phenytoin as well as GABA enhancers. For poisons with central dopaminergic effects (phencyclidine), an agent with opposing activity, such as haloperidol, may be useful. In anticholinergic and cyanide poisoning, specific antidotal therapy may be necessary. The treatment of seizures secondary to ischemia, edema, or metabolic abnormalities should include correction of the underlying cause. Neuromuscular paralysis is indicated in refractory cases. Electroencephalographic (EEG) monitoring and continuing treatment of seizures are necessary to prevent permanent neurologic damage.

Other measures Temperature extremes, metabolic abnormalities, hepatic and renal dysfunction, and secondary complications should be treated by standard therapies.

Prevention of Poison Absorption

Gastrointestinal Decontamination Whether or not to perform gastrointestinal decontamination, and which procedure to use, depends on the time since ingestion; the existing and predicted toxicity of the ingestant; the availability, efficacy, and contraindications of the procedure; and the nature, severity, and risk of complications. In animal and human volunteer studies, the efficacy of activated charcoal, gastric lavage, and syrup of ipecac decreases with time, and there are insufficient data to support or exclude a beneficial effect when they are used more than 1 h after ingestion. Due to the lack of clinical studies using control groups without treatment, the efficacy of these procedures for improving the outcome of overdose patients has not been established.

The average time from ingestion to presentation for treatment is over 1 h for children and over 3 h for adults. Most patients will recover from poisoning uneventfully with good supportive care alone, but complications of gastrointestinal decontamination, particularly aspiration, can prolong this process. Hence, gastrointestinal contamination should be performed selectively, not routinely, in the management of overdose patients. It is clearly unnecessary when predicted toxicity is minimal or the time of expected maximal toxicity has passed without significant effect.

Activated charcoal has comparable or greater efficacy, fewer contraindications and complications, is less aversive and invasive than ipecac or gastric lavage, and is the preferred method of gastrointestinal decontamination in most situations.

Activated charcoal is prepared as a suspension in water, either alone or with a cathartic. It is given orally via a nippled bottle (for infants), or via a cup, straw, or small-bore nasogastric tube. The recommended dose is 1 g/kg body weight, using 8 mL of diluent per gram of charcoal if a premixed formulation is not available. Palatability may be increased by adding a sweetener (sorbitol) or a flavoring agent (cherry, chocolate, or cola syrup) to the suspension. Charcoal adsorbs ingested poisons within the gut lumen, allowing the charcoal-toxin complex to be evacuated with stool. The complex can also be removed from the stomach by induced emesis or lavage. In vitro, charcoal adsorbs^{3}90% of most substances when given in an amount equal to 10 times the weight of the substance. Charged (ionized) chemicals such as mineral acids, alkalis, and highly dissociated salts of cyanide, fluoride, iron, lithium, and other inorganic compounds are not well adsorbed by charcoal. In animal and human volunteer studies, charcoal decreases the absorption of ingestants by an average of 73% when given within 5 min of ingestant administration, 51% when given at 30 min, and 36% at 60 min. Charcoal is at least equally as effective as ipecac syrup or gastric lavage. Experimentally, lavage followed by charcoal is more effective than charcoal alone, and charcoal before and after lavage is more effective than charcoal alone or charcoal after lavage. In the treatment of poisoned patients, however, charcoal alone generally results in a better clinical outcome than either treatment with ipecac followed by charcoal or lavage followed by charcoal. Side effects of charcoal include nausea, vomiting, and diarrhea or constipation. Charcoal may also prevent the absorption of orally administered

therapeutic agents. Complications include mechanical obstruction of the airway, aspiration, vomiting, and bowel obstruction and infection caused by inspissated charcoal. Charcoal is not recommended for patients who have ingested corrosives because it obscures endoscopy.

Gastric lavage is performed by sequentially administering and aspirating about 5 mL fluid per kilogram of body weight through a no. 28 French orogastric tube in children and a no. 40 French tube in adults. Except for infants, tap water is acceptable. The patient should be placed in Trendelenburg and left lateral decubitus positions to prevent aspiration (even if an endotracheal tube is in place). Lavage decreases ingestant absorption by an average of 52% if performed within 5 min of ingestion administration, 26% if performed at 30 min, and 16% if performed at 60 min. Its efficacy is similar to that of ipecac. Significant amounts of ingested drug are recovered in one-tenth of patients. Aspiration is a common complication (occurring in up to 10% of patients), especially when lavage is perfomed improperly. Serious complications (tracheal lavage, esophageal and gastric perforation) occur in approximately 1% of patients. For this reason, the physician should personally insert the lavage tube and confirm its placement, and the patient must be cooperative or adequately restrained (with pharmacologic sedation if necessary) during the procedure. Gastric lavage is contraindicated in corrosive or petroleum distillate ingestions because of the respective risks of gastroesophageal perforation and aspiration-induced hydrocarbon pneumonitis.

Syrup of ipecac can be used for the home management of patients with accidental ingestions, reliable histories, and mild predicted toxicity. It may delay the administration and decrease the effectiveness of activated charcoal, oral antidotes, and whole-bowel irrigation and is very rarely appropriate for patients treated at a health care facility. It is administered orally in a dose of 30 mL for adults, 15 mL for children, and 10 mL for small infants. Clear liquids should also be given. Ipecac irritates the stomach and stimulates the central chemoreceptor trigger zone. Vomiting usually occurs about 20 min after administration. The dose may be repeated if vomiting does not occur. In animal and human volunteer studies, ipecac decreases ingestant absorption by an average of 60% if given within 5 min of ingestant administration, 32% if given at 30 min, and 30% if given at 60 min. Side effects include lethargy in children (12%) and protracted vomiting (8 to 17%). Chronic ipecac use (by patients with anorexia nervosa or bulimia) may cause electrolyte and fluid abnormalities, cardiac toxicity, and myopathy. Except for aspiration, serious complications are rare. Gastric or esophageal tears and perforations and stroke have been reported. Ipecac is contraindicated in patients with recent gastrointestinal surgery,CNSdepression, or seizures, and in those who have ingested corrosives or rapidly acting CNS poisons (camphor, cyanide, tricyclic antidepressants, propoxyphene, strychnine).

Whole-bowel irrigation is performed by administering a bowel-cleansing solution containing electrolytes and polyethylene glycol (Golytely, Colyte) orally or by gastric tube at a rate of up 0.5 L/h in children and 2.0 L/h in adults until rectal effluent is clear. The patient must be in a sitting position. Although data are limited, whole-bowel irrigation may be at least equally as effective as other decontamination procedures. It may be appropriate for those who have ingested foreign bodies, packets of illicit drugs, slow-release or enteric-coated medications, and agents that are poorly adsorbed by charcoal (e.g., heavy metals). It is contraindicated in patients with bowel obstruction,

ileus, hemodynamic instability, and compromised unprotected airways.

Cathartic salts (disodium phosphate, magnesium citrate and sulfate, sodium sulfate) or *saccharides* (mannitol, sorbitol) promote the rectal evacuation of gastrointestinal contents. The most effective cathartic is sorbitol in a dose of 1 to 2 g/kg of body weight. Alone, cathartics do not prevent ingestant absorption and should not be used as a method of gut decontamination. Their primary use is to prevent constipation following charcoal administration. Abdominal cramps, nausea, and occasional vomiting are side effects. Complications of repeated dosing include hypermagnesemia and excessive diarrhea. Cathartics are contraindicated in patients who have ingested corrosives and in those with preexisting diarrhea. Magnesium-containing cathartics should not be used in patients with renal failure.

Dilution (i.e., drinking 5 mL/kg of body weight of water or another clear liquid) should be accomplished as soon as possible after the ingestion of corrosives (acids, alkali). However, it may increase the dissolution rate (and hence absorption) of capsules, tablets, and other solid ingestants and should *not* be used in these circumstances.

Endoscopic or surgical removal of poisons may be useful in rare situations, such as ingestion of a potentially toxic foreign body that fails to transit the gastrointestinal tract, a potentially lethal amount of a heavy metal (arsenic, iron, mercury, thallium), or agents that have coalesced into gastric concretions or bezoars (barbiturates, gluthethimide, heavy metals, lithium, meprobamate, sustained-release preparations). Patients who become toxic from cocaine due to its leakage from multiple ingested drug packets require immediate surgical intervention.

Decontamination of Other Sites Immediate, copious flushing with water, saline, or another available clear, drinkable liquid is the initial treatment for topical exposures (exceptions include alkali metals, calcium oxide, phosphorus). Saline is preferred for eye irrigation. A triple wash (water, soap, water) may be best for dermal decontamination. Inhalational exposures should be treated initially with fresh air or oxygen. The removal of liquids from body cavities such as the vagina or rectum is best accomplished by irrigation. Solids (drug packets, pills) should be removed manually, preferably with visual guidance.

Enhancement of Poison Elimination Although the elimination of most poisons can be accelerated by therapeutic interventions, the pharmacokinetic efficacy (removal of drug at a rate greater than that accomplished by intrinsic elimination) and clinical benefit (in terms of a shortened duration of toxicity or improved outcome) of such interventions are often more theoretical than proven. Hence, the decision to use such measures should be based on the actual or predicted toxicity and the potential efficacy, cost, and risks of therapy.

Multiple-Dose Activated Charcoal Repetitive oral dosing with charcoal can enhance the elimination of previously absorbed substances by binding them within the gut as they are excreted in the bile, secreted by gastrointestinal cells, or passively diffuse into the gut lumen (reverse absorption or enterocapillary exsorption). Doses of 0.5 to 1 g/kg body weight every 2 to 4 h, adjusted downward to avoid regurgitation in patients with decreased gastrointestinal motility, are generally recommended. Experimentally, this

treatment enhances the elimination of nearly all substances tested. Pharmacokinetic efficacy approaches that of hemodialysis for some agents (e.g., phenobarbital, theophylline). Multiple-dose therapy is not effective in accelerating elimination of chlorpropamide, tobramycin, or agents that adsorb poorly to charcoal. Complications include intestinal obstruction, pseudoobstruction, and nonocclusive intestinal infarction in patients with decreased gut motility.

Forced Diuresis and Alteration of Urinary pH Diuresis and ion trapping via alteration of urine pH may prevent the renal reabsorption of poisons that undergo excretion by glomerular filtration and active tubular secretion. Since membranes are more permeable to nonionized molecules than to their ionized counterparts, acidic (low-pK_a) poisons are ionized and trapped in an alkaline urine, and basic poisons are ionized and trapped in an acid urine. Saline diuresis can enhance the renal excretion of alcohols, bromide, calcium, fluoride, lithium, meprobamate, potassium, and isoniazid. Alkaline diuresis (a urine pH^{3}7.5 and a urine output of 3 to 6 mL/kg body weight per hour) enhances the elimination of chlorphenoxyacetic acid herbicides, chlorpropamide, diflunisal, fluoride, methotrexate, phenobarbital, sulfonamides, and salicylates. Contraindications include congestive heart failure, renal failure, and cerebral edema. Acid-base, fluid, and electrolyte parameters should be monitored carefully. Acid diuresis enhances the renal elimination of amphetamines, chloroquine, cocaine, local anesthetics, phencyclidine, quinidine, quinine, strychnine, sympathomimetics, tricyclic antidepressants, and tocainide. Its use, however, has been largely abandoned because of potential complications and lack of clinical efficacy.

Extracorporeal Removal Peritoneal dialysis, hemodialysis, charcoal or resin hemoperfusion, hemofiltration, plasmapheresis, and exchange transfusion are capable of removing any toxin from the bloodstream. Agents most amenable to enhanced elimination by dialysis have low molecular mass (<500 Da), high water solubility, low protein binding, small volumes of distribution (<1 L/kg body weight), prolonged elimination (long half-life), and high dialysis clearance relative to total-body clearance. Molecular weight, water solubility, or protein binding do not limit the efficacy of the other forms of extracorporeal removal.

Dialysis should be considered in cases of severe poisoning due to barbiturates, bromide, chloral hydrate, ethanol, ethylene glycol, isopropyl alcohol, lithium, methanol, procainamide, theophylline, salicylates, and possibly heavy metals. Although hemoperfusion may be more effective in removing some of these poisons, it does not correct associated acid-base and electrolyte abnormalities. Hemoperfusion should be considered in cases of severe poisoning due to carbamazepine, chloramphenicol, disopyramide, and hypnotic-sedatives (barbiturates, ethchlorvynol, glutethimide, meprobamate, methaqualone), paraquat, phenytoin, procainamide, theophylline, and valproate. Both techniques require central venous access and systemic anticoagulation and often result in transient hypotension. Hemoperfusion may also cause hemolysis, hypocalcemia, and thrombocytopenia. Peritoneal dialysis and exchange transfusion are less effective but may be used when other procedures are either not available, contraindicated, or technically difficult (e.g., in infants). Exchange transfusion removes poisons affecting red blood cells (as in methemoglobinemia or arsine-induced hemolysis). The roles of hemofiltration and plasmapheresis are not yet defined.

Candidates for these treatments include patients with severe toxicity who deteriorate despite aggressive supportive therapy; those with potentially prolonged, irreversible, or fatal toxicity; those with dangerous blood levels of toxins; those who lack the capacity for self-detoxification because of liver or renal failure; and those with a serious underlying illness or complication that will adversely affect recovery.

Other Techniques The elimination of heavy metals can be enhanced by chelation, and the removal of carbon monoxide can be increased by hyperbaric oxygenation as discussed in sections on specific poisons.

Administration of Antidotes Antidotes counteract the effects of poisons by neutralizing them (e.g., antibody-antigen reactions, chelation, chemical binding) or by antagonizing their physiologic effects (e.g., activation of opposing nervous system activity, provision of competitive metabolic or receptor substrate). Poisons or conditions with specific antidotes include acetaminophen, anticholinergic agents, anticoagulants, benzodiazepines, beta blockers, calcium channel blockers, carbon monoxide, cardiac glycosides, cholinergic agents, cyanide, drug-induced dystonic reactions, ethylene glycol, fluoride, heavy metals, hydrogen sulfide, hypoglycemic agents, isoniazid, methemoglobinemia, narcotics, sympatomimetics, Vacor, and a variety of evenomations. Antidotes can significantly reduce morbidity and mortality, but most are potentially toxic. Since their safe use requires correct identification of a specific poisoning or syndrome, details of antidotal therapy are discussed with the conditions for which they are indicated.

Prevention of Reexposure Poisoning is a preventable illness. Unfortunately, some adults and children are poison-prone, and recurrences are common. Adults with accidental exposures should be instructed regarding the safe use of medications and chemicals (according to labeling instructions). Confused patients may need assistance with the administration of medications. Errors in dosing by health care providers may require educational efforts. Patients should be advised to avoid circumstances that result in chemical exposure or poisoning. Appropriate agencies and health departments should be notified in cases of environmental or workplace exposure. The best approach with young children and patients with intentional overdose is to limit access to poisons. In households where children live or visit, alcoholic beverages, medications, household products (automotive, cleaning, fuel, pet-care, toiletry products), nonedible plants, and vitamins should be kept out of reach or in locked or child-proof cabinets. Depressed or psychotic patients should receive psychiatric assessment, disposition, and follow-up. They should be given prescriptions for a limited supply of drugs and with a limited number of refills and be monitored for compliance and response to therapy.

SPECIFIC POISONS

The following discussion focuses on poisonings that are common, produce life-threatening toxicity, or require unique therapeutic interventions. Poisonings not covered here are described in the referenced texts.**Alcohol, cocaine, hallucinogens, and opioids are discussed in Chaps. 386 to 389, and heavy metal poisoning is discussed in Chap. 395.*

ACETAMINOPHEN

Acetaminophen is absorbed rapidly and has a volume of distribution of 1 L/kg body weight. Plasma concentrations range from 160 to 660 umol/L (5 to 20 ug/mL) following therapeutic doses. Most acetaminophen is metabolized by hepatic conjugation with sulfate and glucuronide to form nontoxic metabolites, with minor amounts being excreted unchanged or oxidized by hepatic cytochrome P450 enzymes (primarily CYPIIE1) to form a highly reactive, electrophilic, and potentially toxic intermediary metabolite *n*-acetyl-*p*-benzoquinoneimine (NAPQI). After therapeutic doses, NAPQI is rapidly detoxified by conjugation with glutathione and excreted as cysteine and mercapturic acid conjugates. Following an acute ingestion of [3]140 mg/kg body weight, sulfate and glucuronide pathways become saturated, resulting in an increased fraction and amount of acetaminophen metabolized to NAPQI and eventual glutathione depletion. When this occurs, free NAPQI binds covalently to hepatocytes and causes their lysis (centrilobular necrosis). Less often, hepatotoxicity develops following the chronic ingestion of therapeutic or slightly greater amounts in conditions associated with decreased glutathione reserves (e.g., alcoholism, childhood, acute starvation, chronic malnutrition) and possibly in conditions with enhanced P450 enzyme activity (e.g., anticonvulsant and antitubercolosis drug use). The plasma half-life is usually 2 to 4 h but may be prolonged if hepatotoxicity develops.

Clinical Toxicity Early manifestations of poisoning are nonspecific and not predictive of subsequent hepatotoxicity. Within 2 to 4 h of acute overdose, nausea, vomiting, diaphoresis, and pallor may develop.CNSdepression is typically absent unless massive doses are ingested. Within 24 to 48 h, hepatotoxicity is evidenced by right upper quadrant tenderness and mild hepatomegaly. Renal function may also be impaired. Laboratory evidence of hepatic toxicity includes prolongation of the prothrombin time and elevation of serum bilirubin and transaminase activity (aspartate transaminase, alanine transaminase). Severe poisoning may cause hepatic failure. Greater than twofold prolongation of prothrombin time, a serum bilirubin level>68 umol/L (4 mg/dL), pH<7.30, serum creatinine>3.3, and a high-grade encephalopathy indicate a poor prognosis. In patients who recover, liver function returns to normal within 1 week, and liver histology returns to normal within 3 months. Chronic poisoning is usually similar, but alcoholics may present with a syndrome of severe combined hepatic and renal insufficiency with dehydration, jaundice, coagulopathy, hypoglycemia, and acute tubular necrosis.

Diagnostic Evaluation A serum acetaminophen level should be obtained between 4 and 24 h after ingestion. A level above the lower line on the Rumack-Matthew nomogram (Fig. 396-2) indicates possible hepatotoxicity and the need for antidote therapy.

TREATMENT

Activated charcoal is recommended for patients who present within 4 h of ingestion. (Charcoal does not interfere significantly with acetylcysteine therapy.) Antidotal therapy consists of oral *N*-acetylcysteine (NAC), diluted 3:1 with a nonalcoholic, nondairy beverage. It is given at a loading dose of 140 mg/kg body weight, followed by a maintenance dose of 70 mg/kg body weight every 4 h for 17 additional doses. Treatment is most effective if started within 8 to 10 h of an overdose and should be

administered before the serum level is known. If the level is subsequently shown to be nontoxic, therapy may be discontinued. Side effects of NAC include nausea, vomiting, and epigastric discomfort. The dose should be repeated if vomiting occurs within an hour of dosing. Antiemetics (metoclopramide, droperidol, odansetron) may be necessary. Liver and renal function should be monitored during therapy. Patients with severe hepatotoxicity should be considered for liver transplantation.

ACIDS AND ALKALI

Common alkaline products include ammonia, bleach (sodium hypochlorite), drain cleaners (sodium hydroxide), surface cleaners (phosphates), laundry and dishwasher detergents (phosphates, carbonates), disk batteries, denture cleaners (borates, phosphates, carbonates), and Clinitest tablets (sodium hydroxides). Acids are used in toilet bowl cleaners (hydrofluoric, phosphoric, and sulfuric acids), soldering fluxes (hydrochloric acid), antirust compounds (hydrofluoric and oxalic acids), automobile battery fluid (sulfuric acid), and stone cleaners (hydrofluoric and nitric acids). Other corrosives include hydrogen peroxide, hydrazine, and phenol.

Alkalis produce liquefactive necrosis with rapidly penetrating tissue injury and a higher risk of perforation of the esophagus and stomach than do acids. Acids produce coagulative necrosis. Both may burn the mouth, esophagus, stomach, and proximal small bowel. Liquids tend to produce superficial, often circumferential burns over a larger surface area, while solids and tablets cause localized but deeper burns. The severity of the burn relates to the contact time, the amount ingested, and the pH (especially if<2 or >12) of the ingested product.

Clinical Toxicity Burns of the mouth result in excess salivation, pain, dysphonia, and dysphagia and are manifested by erythema, edema, ulceration, and necrosis. Deep burns may destroy mucosal nerve endings and produce anesthesia. Lack of oral findings does not rule out esophageal or gastric injury. Esophageal symptoms and signs include drooling, painful swallowing, retrosternal pain, and neck tenderness. Vomiting of blood and mucus may occur. Esophageal perforation is suggested by increased severity of chest pain, often with respiratory distress. Epigastric pain, vomiting, and tenderness may occur with burns to the stomach. Aspiration of acids and alkalis may cause fulminant tracheitis and bronchial pneumonia. In severe cases, hypotension, shock, metabolic acidosis, liver and renal dysfunction, hemolysis, and disseminated intravascular coagulation may be seen. Deep burns, particularly if extensive or circumferential, may be followed by fibrosis with stricture formation and obstruction of the esophagus (alkalis) or of the gastric outlet (acids).

Diagnosis Endoscopy, best performed 12 to 24 h after ingestion, is used to document the site of injury and its severity and should be performed in symptomatic patients. Chest and abdominal x-rays and routine laboratory testing should be obtained to evaluate for aspiration, perforation, and organ dysfunction. Residual effects of the ingestion can be assessed by barium swallow.

TREATMENT

Treatment includes immediate dilution with milk or water. Administration of a weak acid

(carbonated beverage or citrus juice) or base (antacid) is also acceptable. Glucocorticoids and esophageal stents have traditionally been used for alkali burns to prevent esophageal stricture formation, but their efficacy is not proven. Animal studies suggest that glucocorticoids may be effective if begun immediately on presentation. If used, a dose of 1 to 2 mg of methylprednisolone per kilogram every 4 to 6 h for at least 2 weeks is suggested. Concomitant prophylactic broad-spectrum antibiotic use is also recommended. Glucocorticoids are not useful for acid burns. Antacids should be used for burns of the stomach. Esophageal stricture or gastric outlet obstruction may require subsequent dilatation and bouginage or surgical reconstruction.

ANTIARRHYTHMIC DRUGS

Class IA (disopyramide, moricizine, procainamide, and quinidine), IB (lidocaine, mexiletine, phenytoin, and tocainide), and IC (encainide, flecainide, propafenone) antiarrhythmics block myocardial cell membrane fast sodium channels and slow cardiac conduction, whereas class III agents (amiodarone, bretylium, ibutilide, and sotalol) block potassium currents and prolong refractoriness. These agents are rapidly absorbed (except for disopyramide and sustained-release formulations), have volumes of distribution ranging from 1 to 10 L/kg, have half-lives of 3 to 16 h, and are eliminated mainly by hepatic metabolism.

Clinical Toxicity The acute ingestion of more than twice the usual daily dose is potentially toxic. Effects generally begin within 1 h and peak within several hours. Toxicity may also develop during chronic therapeutic use. Manifestations include nausea, vomiting, and diarrhea, followed by lethargy, confusion, ataxia, bradycardia, hypotension, and cardiovascular collapse. Anticholinergic effects (blurred vision, dry mucosae) may be seen in disopyramide poisoning. Quinidine and class IB agents may cause agitation, dysphoria, and seizures.ECGfindings include bradycardia withAVblock, ventricular tachycardia, ventricular fibrillation (including the polymorphous form, torsade de pointes), and QT-interval prolongation. More specifically, class IA agents prolong the PR, QRS, and JT intervals, class IC agents prolong the QRS interval, and class III agents prolong the JT interval. Class IB agents have little or no effects on conduction intervals. Depressed myocardial contractility and arrhythmias may lead to decreased cardiac output and pulmonary edema. Hypoglycemia and mild hypokalemia may be seen with disopyramide and quinidine intoxication, respectively.

Diagnosis Comprehensive toxicology screening will detect most of these agents. Measurement of serum levels are used for monitoring therapy and for confirmation of overdose.

TREATMENT

Activated charcoal is the procedure of choice for gastrointestinal decontamination. Hypotension, bradyarrhythmias, and seizures are treated with standard measures. Patients with persistent hypotension may benefit from pulmonary arterial pressure measurement. Cardiac pacing, intraaortic balloon pump counterpulsation, and cardiopulmonary bypass may be necessary. Ventricular tachyarrhythmias that cause hemodynamic instability should be treated with lidocaine. Bretylium is probably also safe. Sodium bicarbonate (0.5 to 1 mmol/kg by intravenous bolus) may be effective for

tachyarrhythmias due to class IA or IC agents. Mild hypokalemia may be protective, and potassium levels as low as 3.0 mmol/L may be best treated by watchful waiting. Magnesium sulfate (4 g or 40 mL of a 10% solution given intravenously as an initial dose) and overdrive pacing (with isoproterenol or electricity) are used for torsade de pointes. Hemodialysis and hemoperfusion may enhance the elimination of disopyramide, the active procainamide metabolite *N*-acetylprocainamide, and possibly other agents.

ANTICHOLINERGIC AGENTS

Agents that can competitively block the binding of acetylcholine toCNS and parasympathetic postganglionic muscarinic neuroreceptors include antihistamines (H_1blockers), belladonna alkaloids and related agents (atropine, glycopyrrolate, homatropine, hyoscine, ipratropium, scopolamine), drugs for Parkinson's disease (benztropine, biperiden, trihexyphenidyl), topical mydriatics (cyclopentolate, tropicamide), neuroleptics (clozapine, olanzepine, phenothiazines), skeletal muscle relaxants (cyclobenzaprine, orphenadrine), smooth-muscle relaxants (clidinium, dicyclomine, isometheptene, oxybutynin), tricyclic antidepressants, and some plants (e.g., *Datura stramonium*, or jimson weed) and mushrooms. Their absorption can be delayed following an overdose. Most are weak bases, exhibit variable binding to plasma proteins (18 to 98%), and have moderate volumes of distribution (2 to 6 L/kg). They are eliminated primarily by hepatic metabolism and have half-lives ranging from 2 to 24 h or more.

Clinical Toxicity Manifestations usually begin within an hour of acute overdosage and 1 to 3 days after beginning treatment in cases of chronic poisoning. Toxic doses are only slightly greater than therapeutic ones.CNSmanifestations include agitation, ataxia, confusion, delirium, hallucinations, and movement disorders (choreoathetoid and picking movements). Lethargy, respiratory depression, and coma may occur. Peripheral nervous system findings include decreased or absent bowel sounds, dilated pupils, dry skin and mucosal surfaces, urinary retention, and increases in pulse rate, blood pressure, respiratory rate, and temperature. Neuromuscular hyperactivity may lead to rhabdomyolysis and hyperthermia. First-generation H_1blockers (diphenhydramine and probably others) can sometimes cause tricyclic antidepressant-like cardiotoxicity and seizures. Because of class III antiarrhythmic activity, original nonsedating or second-generation antihistamines (astemizole, terfenadine) caused QT-interval prolongation with subsequent ventricular tachyarrhythmias, especially torsade de pointes, and were withdrawn from U.S. markets.

Diagnosis The diagnosis is supported by detecting these agents in the urine. It can be confirmed by demonstrating resolution of anticholinergic toxicity in response to physostigmine.

TREATMENT

Activated charcoal adsorbs these agents effectively and is the preferred method of gastrointestinal decontamination. Agitation may respond to benzodiazepines, and comatose patients may require intubation and mechanical ventilation. Cardiovascular toxicity and arrhythmias should be treated as described for antiarrhythmics and tricyclic

antidepressants. Physostigmine, an acetylcholinesterase inhibitor, reverses anticholinergic toxicity. It is indicated primarily for uncontrolled agitation and delirium. The dose is 1 to 2 mg given intravenously over 2 to 5 min; the dose can be repeated if there is an incomplete response or recurrent toxicity. If signs of cholinergic poisoning occur (see "Organophosphate and Carbamate Insecticides," below), they can be reversed by atropine in half the amount of physostigmine given. Physostigmine should not be given for seizures or for coma; its arousal effects are nonspecific and cannot be used for diagnostic purposes. Physostigmine is contraindicated in the presence of cardiac conduction defects or ventricular arrhythmias because it can cause asystole in such patients.

ANTICONVULSANTS

Carbamazepine, lamotrigine, phenytoin and other hydantoins, topiramate, and valproate act primarily to limit the spread of a seizure from its focus by inhibiting the passive influx of sodium through voltage-dependent sodium channels in neuronal membranes, an activity analogous to that of class I antiarrhythmics (see above). This action, and the resultant inhibition of the release of excitatory neurotransmitters (e.g., aspartate, glutamate), limits posttetanic potentiation of synaptic transmission. Like the barbiturates and benzodiazepines (see below), felbamate, gabapentin, and the investigational agents tiagabine and vigabatrin enhance synaptic transmission of the inhibitory neurotransmitterGABA. The succimides ethosuximide and methsuximide elevate the seizure threshold by reducing calcium conduction through T-type calcium channels. Valproate also inhibits GABA metabolism and calcium conductance. Valproate and its metabolites interfere with enzymes involved in fatty acid synthesis and oxidation, gluconeogenesis, and the urea cycle. Carbamazepine is structurally similar to the tricyclic antidepressants and can cause similar toxicity (see "Cyclic Antidepressant," below) in overdose.

Anticonvulsants are well absorbed after oral administration. Phenytoin is also available for intravenous use, both as phenytoin and the prodrug phosphenytoin. A prodrug formulation of valproate, divalproex, a molecule of which dissociates into two molecules of valproate, is also marketed. Gastrointestinal absorption is prolonged with regular and sustained-release formulations of carbamazepine, extended-release phenytoin, and enteric-coated divalproex, particularly following overdose. The volume of distribution is small for valproate (0.1 to 0.4 L/kg); moderate for phenytoin (0.5 to 0.8 L/kg); large for carbamazepine, felbamate, gabapentin, and lamotrigine (³1 L/kg); and unknown for other agents. All are eliminated primarily by hepatic metabolism. Carbamazepine has an active (10,11-epoxide) metabolite. Half-lives, therapeutic doses, serum concentrations, adverse effects, and drug interactions are listed inTable 360-9. The half-life of phenytoin, valproate, and possibly carbamazepine and other agents is prolonged following overdose.

Clinical Toxicity Anticonvulsants primarily causeCNSdepression (Table 396-2). Cerebellar and vestibular function are affected first, with cerebral depression occurring later. Effects are the same and occur at similar blood levels, regardless of whether overdose is acute or chronic. Ataxia, blurred vision, diplopia, dizziness, nystagmus, slurred speech, tremors, and nausea and vomiting are common initial manifestations. Paradoxical excitation can occur, and membrane-active agents can sometimes cause

de novo seizures and exacerbation of epilepsy. Coma with respiratory depression usually occurs at serum carbamazepine concentrations >20 ug/mL, serum phenytoin levels >60 ug/mL, and serum valproate levels >180 ug/mL. Anticholinergic effects (see above) may be present in carbamazepine poisoning, and tricyclic antidepressant-like cardiotoxicity (see below) can occur at drug levels>30 ug/mL.

Hypotension and arrhythmias (e.g., bradycardia, conduction disturbances, ventricular tachyarrhythmias) can occur during the rapid infusion of phenytoin. Although these effects have been attributed to its propylene glycol diluent, they have also been reported with rapid infusions of phosphenytoin, which does not contain this solvent. Cardiovascular toxicity after oral phenytoin overdose, however, is essentially nonexistent. Extravasation of phenytoin can result in local tissue necrosis due to the high pH of this formulation. Intravenous phenytoin may also cause the "purple glove syndrome" (limb edema, discoloration, and pain). This can occur hours after infusion and without signs of extravasation. A compartment syndrome with limb ischemia and muscle necrosis is a potential complication. Multiple metabolic abnormalities, including anion-gap metabolic acidosis, hyperosmolality, hypocalcemia, hypoglycemia, hypophosphatemia, hypernatremia, and hyperammonemia (with or without other evidence of hepatotoxicity), can occur in valproate poisoning. Three or more days may be required for resolution of toxicity in severe carbamazepine, phenytoin, and valproate poisoning.

Diagnosis The diagnosis of carbamazepine, phenytoin, and valproate poisoning can be confirmed by measuring serum drug concentrations. Serial drug levels should be obtained until a peak is observed following acute overdose. Quantitative serum levels of other agents are not generally available. Most anticonvulsants can be detected by comprehensive urine screening tests.

TREATMENT

Activated charcoal is the method of choice for gastrointestinal decontamination. Multiple-dose charcoal therapy can enhance the elimination of carbamazepine, phenytoin, valproate, and perhaps other agents. Airway protection and support of respiration with endotracheal intubation and mechanical ventilation, if necessary, are the mainstays of treatment. Seizures should be treated with benzodiazepines or barbiturates. Physostigmine (see "Anticholinergic Agents," above) should be considered for anticholinergic poisoning due to carbamazepine. The treatment of carbamazepine-induced hypotension, cardiac conduction disturbances, and ventricular tachyarrhythmias should include sodium bicarbonate (see "Antiarrhythmic Drugs," above). Phenytoin and phosphenytoin cardiotoxicity usually resolves promptly upon discontinuation of the infusion. Crystalloids and lidocaine can be given if necessary. Tissue injury secondary to phenytoin extravasation should be treated by standard wound care measures. Treatment of the purple glove syndrome includes elevation of the affected extremity. A vascular surgeon should evaluate this condition, if signs of ischemia are present. Occasionally,CNSdepression due to valproate will respond to naloxone (2 mg intravenously). Metabolic derangements should be corrected. Hemodialysis and hemoperfusion can enhance the elimination of valproate and its metabolites. Hemodialysis can also correct associated metabolic disturbances. Hemoperfusion only modestly increases carbamazepine elimination. These procedures

should be reserved for patients with persistently high drug levels (e.g., carbamazepine³40 ug/mL and valproate³1000 ug/mL) who do not respond to supportive care.

BARBITURATES

Barbiturates bind to theGABAreceptor complex and prolong the opening of the chloride channels in response to GABA, thereby inhibiting excitable cells of theCNS and other tissues. They can be classified as long-acting (6 to 12 h; mephobarbital, barbital, phenobarbital, primidone), intermediate-acting (3 to 6 h; amobarbital, aprobarbital, butabarbital, butalbital), short-acting (1 to 3 h; hexobarbital, pentobarbital, and secobarbital), and ultrashort-acting (<30 min; methohexital, thiamylal, and thiopental).

Barbiturates are weak acids with p$K_a$values ranging from 7.2 to 8.5, volumes of distribution of 0.8 to 1.5 L/kg of body weight, and 45 to 70% protein binding in the plasma. With therapeutic doses, plasma concentrations generally peak in 1 to 4 h (earlier for short-acting agents than for long-acting ones). Most barbiturates are metabolized by the liver. Some are converted to active metabolites: mephobarbital to barbital, and primidone to phenobarbital and phenylethylmalonamide (PEMA). In contrast to short-acting agents, long-acting ones also undergo significant renal excretion: 95% for barbital, 25 to 33% for phenobarbital, 15 to 42% for primidone, and 95% for PEMA. Half-lives range from 1 h for ultrashort-acting agents to 6 d for long-acting ones.

Clinical Toxicity Barbiturates causeCNSdepression (Table 396-2). Hypothermia, hypotension, pulmonary edema, and cardiac arrest may occur in severe cases. Pressure sores, bullous skin lesions, and rhabdomyolysis can develop with prolonged coma. Maximal toxicity usually occurs within 4 to 6 h but may be delayed to 10 h or more after overdosage with long-acting barbiturates.

Diagnosis Serum drug levels can confirm the diagnosis. Significant toxicity is usually apparent when serum concentrations of long-acting barbiturates exceed 170 umol/L (4 mg/dL) and those of short-acting barbiturates exceed 88 umol/L (2 mg/dL). Because of tolerance, the degree ofCNSdepression relative to dose and drug level is dependent on prior exposure to the drug.

TREATMENT

Activated charcoal effectively adsorbs barbiturates and is the method of choice for gastrointestinal decontamination. Hemodynamic and respiratory support and correction of temperature and electrolyte derangements may be necessary. Renal elimination of phenobarbital (and probably other long-acting agents) is enhanced by alkalinization of urine to a pH of 8 (by giving intravenous sodium bicarbonate) and by saline diuresis. Elimination can also be enhanced by repeated doses of activated charcoal. Since short-acting barbiturates are predominantly metabolized by the liver, diuresis is ineffective. Hemodialysis and hemoperfusion are effective in removing both long- and short-acting barbiturates, but their use should be reserved for patients with refractory hypotension.

BENZODIAZEPINES

Benzodiazepines potentiate the inhibitory effect ofGABA onCNSneurons by binding to the GABA receptor complex and increasing the frequency of opening of chloride channels in response to GABA stimulation. They can be classified as long-acting (chlordiazepoxide, clonazepam, clorazepate, diazepam, flurazepam, prazepam, quazepam), short-acting (alprazolam, flunitrazepam, lorazepam, and oxazepam), and ultrashort-acting (estazolam, midazolam, temazepam, and triazolam). Benzodiazepines are readily absorbed, exhibit 85 to 99% protein binding in the plasma, are lipid soluble, and have an apparent volume of distribution of 0.3 to 2 L/kg body weight. They are weak acids with p$K_a$values ranging from 1.3 to 6.2 and are eliminated mainly by hepatic metabolism. Some have active metabolites. Half-lives range from 2 h for short-acting agents to 8 days for long-acting ones.

Clinical Toxicity CNSdepressant effects (Table 396-2) begin within 30 min of acute overdose. Coma and respiratory depression are rare but can occur with ultrashort-acting agents and when benzodiazepines are combined with other CNS depressants. Paradoxical excitation may occur early in the course of poisoning.

Diagnosis The diagnosis is supported by identification of benzodiazepine metabolites in urine. Since immunoassays do not detect all benzodiazepines, a negative result does not exclude the diagnosis. A response to flumazenil confirms the diagnosis.

TREATMENT

Activated charcoal adsorbs benzodiazepines and is the method of choice for gastrointestinal decontamination. Respiratory support should be provided as necessary. Flumazenil, a competitive benzodiazepine receptor antagonist, can reverseCNS and respiratory depression and obviate the need for endotracheal intubation. Doses of 0.1 mg should be given intravenously at 1-min intervals until the desired effect is achieved or a cumulative dose of 3 mg has been given. Since flumazenil has a relatively short duration of action, patients must be monitored carefully for relapse. Should relapse occur, treatment can be repeated (at intervals of 20 min with a maximum dose of 3 mg/h). Flumazenil can cause seizures in patients who have coingested stimulants and tricyclic antidepressants or who are physically dependent on benzodiazepines as a result of chronic use. It should not be used in patients with ECG evidence of tricyclic antidepressant cardiotoxicity.

b-ADRENERGIC BLOCKING AGENTS

b-Adrenergic blocking agents act by competitively inhibiting b-adrenergic neurohumoral receptors. This activity defines them as class II antiarrhythmics. At therapeutic doses, some beta blockers act at bothb_1 and$b_2$receptors and are "nonselective" (carvedilol, labetalol, nadolol, pindolol, propranolol, timolol); some act predominantly on$b_1$receptors and are "cardioselective" (acebutolol, atenolol, betaxolol, bisoprolol, esmolol, metoprolol). Certain beta blockers have partial agonist or sympathomimetic activity (acebutolol, carteolol, pindolol, and possibly penbutolol), some have an$a_1$blocking activity and the additional property of vasodilation (carvedilol, labetalol), and some have quinidine-like antiarrhythmic effects (acebutolol, metoprolol, pindolol, propranolol,

sotalol, and possibly betaxolol). Antiarrhythmic effects are due to a reduction of sodium and calcium influx during membrane depolarization (phase 0) as a consequence of decreased production of cyclic AMP by adenylate cyclase. Decreased cardiac contractility results from inhibition of calcium influx into cells and the release of calcium from sarcoplasmic reticulum.

Beta blockers are readily absorbed and exhibit variable protein binding (5 to 93%), water solubility, and volumes of distribution (0.23 to 10.0 L/kg body weight). Most beta blockers are eliminated predominantly by hepatic metabolism. Atenolol, nadolol, and sotalol are eliminated primarily by renal excretion, and esmolol is metabolized by erythrocyte esterases.

Clinical Toxicity Effects usually begin within 1/2 h following an overdose and peak within 2 h. Onset may be delayed with the ingestion of sustained-release preparations. Findings include nausea and vomiting followed by bradycardia, hypotension, andCNSdepression. However, agents with sympathomimetic activity can cause hypertension and tachycardia. CNS effects can include seizures and tend to be more pronounced with highly lipophilic agents (penbutolol, propranolol). The skin is often pale and cool. Bronchospasm and pulmonary edema are uncommon unless there is a history of asthma, chronic obstructive pulmonary disease, or congestive heart failure. Metabolic abnormalities include hyperkalemia and hypoglycemia (as a direct result of b-adrenergic receptor blockade) and metabolic acidosis (due to seizures, shock, or respiratory depression).ECGmanifestations include all degrees ofAVblock, bundle branch block, prolonged QRS duration, and asystole. Sotalol may cause QT-interval prolongation with ventricular tachycardia, ventricular fibrillation, and torsade de pointes occurring up to 20 h after overdose. Patients with mild poisoning usually recover within 6 to 12 h, whereas those with severe poisoning and ingestions of sustained-release preparations may be symptomatic for 24 to 48 h.

Diagnosis The diagnosis is primarily based on the clinical presentation. Urine toxicology screening may identify the presence of beta blockers, but blood levels are neither generally available nor helpful in guiding therapy.

TREATMENT

Activated charcoal adsorbs these agents effectively and is the preferred method of gastrointestinal decontamination. Gastric emptying procedures may produce vagal stimulation and exacerbate bradyarrhythmias. Bradycardia associated with hypotension will sometimes respond to atropine, isoproterenol, and vasopressors (amrinone, dopamine, dobutamine, epinephrine, and norepinephrine have been used with variable success, alone or in combination). With severe poisoning, these agents may be ineffective, and glucagon, calcium, cardiac pacing (external or internal), and intraaortic balloon pump support may be necessary. Glucagon, which stimulates adenylate cyclase by a nonadrenergic mechanism, is given at an initial dose of 5 to 10 mg. Patients who respond favorably can be treated with an infusion of 1 to 5 mg/h. Calcium and high-dose insulin can be given with glucose and potassium to reverse negative inotropic effects, as described for calcium channel blocker poisoning. Bronchospasm may be treated with an inhaled beta agonist, subcutaneous epinephrine, and intravenous aminophylline. Lidocaine, magnesium (as for antiarrhythmic poisoning), or overdrive pacing may be

used for sotalol-induced ventricular tachyarrhythmias. Extracorporeal elimination procedures are probably not of benefit, except possibly for atenolol, metoprolol, nadolol, and sotalol.

CALCIUM CHANNEL BLOCKERS

Bepridil, diltiazem, verapamil, and the dihydropyridine derivatives amlodipine, felodipine, isradipine, nicardipine, nifedipine, nimodipine, and nisoldipine decrease the influx of calcium across slow (L-type) calcium channels in the membranes of myocardial and vascular smooth-muscle cells during phases 2 (plateau) and 4 (spontaneous depolarization) of the action potential. These actions define them as class IV antiarrhythmics. Bepridil also has class I antiarrhythmic activity. Electrophysiologic effects include decreased cardiac contractility, heart rate [sinoatrial (SA) node rate], andAV nodal conduction. At therapeutic doses, all calcium channel blockers cause vasodilation. Diltiazem and verapamil also have significant negative inotropic and chronotropic activity.

Calcium channel blockers are well absorbed and exhibit high (80 to 99%) plasma protein binding. Most have distribution volumes ranging from 1 to 8 L/kg body weight. They are eliminated mainly by hepatic metabolism, and the half-lives typically range from 1 to 24 h.

Clinical Toxicity Toxic effects begin within 2 h of ingestion of immediate-release preparations but may be delayed up to 18 h following overdoses of sustained-release preparations. Manifestations include nausea, vomiting, bradycardia, hypotension, andCNSdepression (Table 396-2). Hypotension caused by diltiazem and verapamil is usually due to myocardial depression (decreased cardiac output), whereas that caused by the dihydropyridine derivatives is usually due to low peripheral vascular resistance. Reflexive tachycardia is sometimes seen in dihydropyridine poisoning. Seizures can occur and are the result of direct membrane effects as well as cerebral hypoperfusion. Hypotension may precipitate mesenteric or myocardial ischemia or infarction, and depression of cardiac function may lead to pulmonary edema.ECGfindings include all degrees ofAVblock, prolonged QRS and QT intervals (mainly with verapamil), evidence of ischemia or infarction, and asystole. Metabolic acidosis (secondary to shock) and hyperglycemia (resulting from the inhibition of insulin release) may be present. Serum calcium levels, however, remain normal.

Diagnosis These agents can be detected by comprehensive urine screening tests. Serum levels are not generally available or helpful in guiding therapy.

TREATMENT

Activated charcoal is preferred for gastrointestinal decontamination. Symptomatic bradycardia should be treated with atropine, calcium, isoproterenol, glucagon, and electrical (external or internal) pacing. Restoring perfusion is particularly important in patients with organ ischemia. The initial dose of calcium is 10 mL of 10% calcium chloride or 30 mL of the 10% gluconate solution intravenously over 2 min. This dose may be repeated up to four times in patients with a partial, transient, or absent response. High serum calcium levels may be required for a therapeutic effect. A

continuous calcium infusion (0.2 mL/kg body weight per hour up to a maximum of 10 mL/h) may be appropriate when relapse occurs after an initial bolus. Although electrical pacing may be required, glucagon, in the same dose as for beta blocker poisoning, may also be effective. High-dose insulin (0.1-0.2 units/kg body weight of regular insulin as a bolus followed by 0.1-1 units/kg per hour) along with glucose (25-g bolus followed by 1 g/kg per hour of a 20% infusion) and potassium to maintain euglycemia and normokalemia should also be considered. This treatment enhances myocardial metabolism and improves myocardial contactility. It may be particularly effective in verapamil poisoning. Hypotension that persists despite resolution of bradycardia should initially be treated with fluids. Amrinone, dopamine, dobutamine, glucagon, and norepinephrine, alone or in combination, have also been used with success. Intraaortic balloon pump support should be used in patients with refractory shock. Patients with mild toxicity usually recover within a few hours, whereas those with severe toxicity or overdose with sustained-release preparations may remain symptomatic for 24 h or longer.

CARBON MONOXIDE

Carbon monoxide is produced in large amounts in industrial processes as well as by internal combustion engines, fossil-fueled home appliances (generators, heaters, stoves), and the incomplete combustion of nearly all natural materials and synthetic products. Methylene chloride, a solvent in paint removers, is metabolized to carbon monoxide.

Carbon monoxide is absorbed rapidly through the lungs and binds to hemoglobin (forming carboxyhemoglobin) with an affinity 210 times that of oxygen. Its binding reduces oxygen transport by hemoglobin and also decreases the release of oxygen in tissues (the oxygen dissociation curve shifts to the left). Carbon monoxide also binds to myoglobin, decreasing its oxygen-carrying capacity, and to mitochondrial cytochrome oxidase, inhibiting cellular respiration. The net effect is tissue hypoxia with anaerobic metabolism, lactic acidosis, lipid peroxidation, and free radical formation. Once carbon monoxide exposure is discontinued, dissociation of the hemoglobin-carbon monoxide complex occurs, and carbon monoxide is excreted through the lungs. At atmospheric pressure, the carboxyhemoglobin half-life is 4 to 6 h. It decreases to 40 to 80 min when breathing 100% oxygen and to 15 to 30 min with hyperbaric oxygen therapy. The apparent half-life after methylene chloride exposure is considerably longer.

Clinical Toxicity Manifestations of carbon monoxide poisoning include shortness of breath, dyspnea, tachypnea, headache, emotional lability, confusion, impaired judgment, clumsiness, and syncope. Nausea, vomiting, and diarrhea may also occur. Cerebral edema, coma, respiratory depression, and pulmonary edema may be seen in severe poisoning. Cardiovascular manifestations include ischemic chest pain, arrhythmias, heart failure, and hypotension. In comatose patients, blisters and bullae may develop over pressure points. Serum creatine kinase and lactate dehydrogenase levels may be elevated. Myoglobinuria secondary to muscle necrosis may result in renal failure. Visual field defects, blindness, and venous engorgement with papilledema or optic atrophy may be noted. Arterial blood gas analysis may reveal metabolic acidosis, a normal P_{O2}, decreased oxygen saturation (when measured by CO-oximetry, but not when calculated from the P_{O2} or measured by pulse oximetry), and a variable P_{CO2}.

Oxygen saturation measured by pulse oximetry will be falsely elevated but less than normal. A cherry-red color of skin and mucous membranes is rare, and cyanosis is usual.

After brief exposure, carboxyhemoglobin fractions of 15 to 20% are associated with mild symptoms, 20 to 40% with moderate symptoms, and 40 to 50% with severe symptoms. Fractions>60% are often fatal. With prolonged exposure, toxicity occurs at lower fractions. Patients with loss of consciousness are at risk for developing neuropsychiatric sequelae 1 to 3 weeks after exposure. Manifestations vary from subtle personality changes and intellectual impairment to gross neurologic deficits such as blindness, deafness, incoordination, and parkinsonism.

Diagnosis An elevated carboxyhemoglobin fraction confirms exposure, but the result must be interpreted with respect to the time elapsed from exposure to sampling. If the carboxyhemoglobin fraction cannot be measured directly, the difference between the oxygen saturation calculated from the P_{O2} and that measured by CO-oximetry can be used to estimate the carboxyhemoglobin fraction.

TREATMENT

In conscious patients, oxygen should be administered by a non-rebreather mask at 10 L/min until carboxyhemoglobin fraction is <10% and symptoms have resolved. Infants and pregnant women require treatment for several more hours, because fetal hemoglobin has a higher affinity for carbon monoxide than adult hemoglobin. Endotracheal intubation and mechanical ventilation with 100% oxygen are indicated in patients with coma, seizures, or cardiovascular instability. Arrhythmias and hypotension are treated by usual measures. Although hyperbaric oxygen therapy is often recommended for patients with coma, syncope, seizures, and cardiovascular instability, for those with less severe neurologic or cardiovascular dysfunction that does not resolve with oxygen and supportive measures, and for those who develop neurologic sequalae, recent data suggest that it is no more effective than prolonged high-flow normobaric oxygen in reversing acute toxicity and preventing sequelae.

CARDIAC GLYCOSIDES

Poisoning with digitalis and other cardiac glycosides occurs most often during therapeutic or suicidal use of digoxin. It can also occur when plants (foxglove, oleander, squill) or the skin (venom) of *Bufo* toads (Colorado River, Asian, Chinese, European) are ingested. Toad venom also contains hallucinogens and accounts for the practice of toad licking as a form of recreational drug abuse. At therapeutic doses, cardiac glycosides inhibit the enzyme Na^+, K^+-ATPase, leading to increased intracellular levels of Na^+ and Ca^{2+} and decreased intracellular K^+levels. Increased cytosolic Ca^{2+}enhances the excitation-contraction coupling of actin and myosin during systole and improves myocardial contractility. Electrophysiologic effects are due to indirect sympatholytic and vagotonic effects and to direct effects on cardiac muscle, pacemaker, and conduction cells (reduced action potential duration andAV node resting potential, prolongation of the refractory period).ECGmanifestations include prolongation of the PR interval, shortening of the QT interval, scooping and depression of the ST segment, and decreased T-wave amplitude. In toxic doses,SA node automaticity and AV nodal

conduction are decreased. Sympathetic tone; automaticity in muscle, AV nodal, and conduction cells; and afterdepolarizations are increased. ECG manifestations include bradydysrhythmias as well as triggered tachydysrhythmias. Hypokalemia potentiates the electrophysiologic effects of cardiac glycosides, increases their tissue binding, and decreases their renal excretion. Magnesium blocks calcium channels and modulates their sympathetic effects, whereas calcium and hypoxia enhance their activity.

Digoxin is absorbed and distributed slowly. Serum levels may not correlate with clinical effect for up to 8 h following a dose. Digoxin is 25 to 30% protein bound in the plasma, has a large volume of distribution of 5 to 6 L/kg body weight, and is eliminated primarily by renal excretion. The half-life ranges between 36 and 45 h, is prolonged in hepatic failure and in renal failure, and may be shortened in overdose. Therapeutic serum concentrations range from 0.6 to 2.5 nmol/L (0.5 to 2.0 ng/mL).

Clinical Toxicity Symptoms include vomiting, confusion, delirium, and occasionally hallucinations, blurred vision, photophobia, scotomata, and chromotopsia (disturbed color perception). Cardiac manifestations include sinus arrhythmia, sinus bradycardia, and all degrees ofAVblock. Premature ventricular contractions, bigeminy, ventricular tachycardia, and fibrillation also occur. The combination of a supraventricular tachyarrhythmia and AV block (e.g., paroxysmal atrial tachycardia with second-degree AV block, atrial fibrillation with third-degree AV block) or the presence of bidirectional ventricular tachycardia is highly suggestive of cardiac glycoside poisoning. Bradyarrhythmias and hypokalemia are common with chronic intoxication, whereas tachyarrhythmias and hyperkalemia are generally seen with acute poisoning. Similarly, serum digoxin levels may be minimally elevated or even therapeutic in chronic toxicity, whereas they are usually markedly elevated following acute overdose. Since chronic poisoning occurs almost exclusively in patients with underlying heart disease, the incidence, variety, and severity of dysrhythmias tend to be greater than with acute poisoning. In patients taking digoxin, poisoning should be suspected when a normal or fast heart rate becomes slow or the rhythm becomes regularly irregular.

Diagnosis The diagnosis is confirmed by measuring the serum digoxin level. Levels must be interpreted with respect to the time of the last dose. Digoxin assays may cross-react with nondigoxin glycosides and produce a false-positive result. Toxicology screening tests do not detect cardiac glycosides.

TREATMENT

Activated charcoal is preferred for gastrointestinal decontamination. Emesis and gastric intubation may cause vagal stimulation and precipitate or worsen conduction disturbances. Repeated doses of charcoal can enhance the elimination of digoxin. Potassium, magnesium, and calcium abnormalities and hypoxia should be corrected. Sinus bradycardia and second- and third-degree heart block resulting in hypotension can be treated with atropine, dopamine, epinephrine, and possible phenytoin (100 mg intravenously every 5 min up to 15 mg/kg) and isoproterenol. Magnesium sulfate (as for antiarrhythmic poisoning), phenytoin, lidocaine, bretylium, and amiodarone may be given for ventricular tachyarrhythmias. Antidotal therapy with digoxin-specific Fab-fragment antibodies should be administered for potentially life-threatening dysrhythmias. A serum potassium level ³5.5 meq/L following acute overdose is

associated with severe poisoning and is an indication for antibody therapy in the absence of dysrhythmias. Electrical pacing may be necessary as a temporizing measure. Prophylactic pacing is not recommended, as the pacing wire may increase ventricular irritability and precipitate tachydysrhythmias. If defibrillation is necessary, a low energy level (e.g., 50 W×s) should be used initially as the electrical shock may precipitate arrhythmias, which are more malignant and refractory to treatment. Digoxin-specific Fab-fragment antibodies are given intravenously over 15 to 30 min, unless cardiac arrest has occurred, in which case the solution is given as a bolus. Effects are usually apparent within an hour. The drug-antibody complex is excreted in the urine with a half-life of 16 to 20 h. In patients with renal failure, the drug-antibody complex is metabolized over a period of days to weeks. Although free digoxin levels decrease rapidly to zero following antibody administration, routine methods used to measure digoxin do not differentiate between bound and unbound drug, so that drug levels do not correlate with toxicity after antibody therapy.

Each vial (40 mg) of digoxin antibody fragments can neutralize 0.6 mg of digoxin. Formulas and tables for calculating the dose of antibody are available in the package insert. Unfortunately, toxicity may occur before distribution is complete or before levels are available. In addition, the amount of an acute overdose may be unknown, and calculated doses often exceed the effective dose (leading to costly overtreatment). The following empirical dosing guidelines are therefore offered. With chronic intoxication, the total-body drug load and serum drug levels only slightly exceed therapeutic amounts, patients may be dependent on inotropic effects, and a dose of 1 to 4 vials is usually effective. In acute poisoning, drug load is generally quite high, and 5 to 15 vials are usually required. Initial doses can be on the low side and repeated as necessary. Antibodies cross-react with other cardiac glycosides, but larger doses may be needed for toxicity not involving digoxin.

CYANIDE

Cyanide salts are used in photography, metallurgy, electroplating, metal cleaning, and ore refining. Hydrogen cyanide gas, which is used as a fumigant rodenticide and in chemical syntheses, is liberated when they are combined with acids. Cyanide is also produced during the decomposition and metabolism of nitroprusside. Organic cyanides (nitriles) are used in making rubber, in artificial nail removers, and as rodenticides. Cyanogenic glycosides are present in the seeds of the chokeberry, cherry, plum, peach, apricot, pear, bean, apple, and crabapple.

Cyanide inhibits mitochondrial cytochrome oxidase, thereby blocking electron transport and preventing oxygen utilization and oxidative metabolism. Lactic acidosis occurs as a consequence of anaerobic metabolism. Cyanide is rapidly absorbed from the stomach, lungs, mucosal surfaces, and unbroken skin. Ingested salts react with gastric hydrochloric acid to form hydrocyanic acid, which is then absorbed. A dose of 200 mg of potassium or sodium cyanide, or 50 mg of hydrocyanic acid, is potentially lethal. Cyanide is 60% protein bound, concentrated in red cells, and has a volume of distribution of 1.5 L/kg body weight. Mitochondrial rhodanase mediates the transfer of sulfur from thiosulfate to the cyanide ion and converts it to less toxic thiocyanate, which is excreted in the urine. Cyanide poisoning during nitroprusside therapy can be prevented by the prophylactic administration of thiosulfate.

Clinical Toxicity Effects begin within seconds of inhalation and within 30 min of ingestion. Initial manifestations of cyanide poisoning include a burning sensation in the mouth and throat, agitation, anxiety, faintness, headache, nausea, vomiting, diaphoresis, dyspnea, tachycardia, and hypertension. A bitter almond odor may be detected on the breath. Later effects include coma, convulsions, opisthotonus, trismus, paralysis, respiratory depression, pulmonary edema, arrhythmias, bradycardia, and hypotension. A rough correlation exists between blood cyanide levels and symptoms: Levels<8 umol/L (0.02 mg/L) are associated with no symptoms; 20 to 40 umol/L (0.05 to 0.1 mg/dL) with flushing and tachycardia; 40 to 100 umol/L (0.1 to 0.25 mg/dL) with obtundation; 100 to 200 umol/L (0.25 to 0.3 mg/dL) with coma and respiratory depression; and levels >120 umol/L (0.3 mg/dL) with death. With significant poisoning, lactic acidosis is invariably present.ECGabnormalities include both tachyarrhythmias and bradyarrhythmias.

Diagnosis The diagnosis is based on the history and physical examination. Although measurement of the whole-blood cyanide level will confirm the diagnosis, cyanide assays are not routinely available and treatment decisions must be based on clinical findings. Lactate levels have been used as a surrogate marker.

TREATMENT

Management involves supportive therapy, gastrointestinal decontamination, high-dose oxygen, and antidotal therapy with amyl nitrite, sodium nitrite, and sodium thiosulfate (the Lilly cyanide antidote kit). Nitrites convert hemoglobin to methemoglobin, which has a higher affinity for cyanide than does cytochrome oxidase and thus promotes its dissociation from this enzyme. Thiosulfate reacts with cyanide, which is slowly released from cyanomethemoglobin, to form thiocyanate. Oxygen reverses the binding of cyanide to cytochrome oxidase sites and enhances the efficacy of sodium nitrite and sodium thiosulfate, in addition to acting as a substrate for metabolism.

Indications for antidotal therapy include altered mental status, abnormal vital signs, and metabolic acidosis. Amyl nitrite, administered for 30 s of each minute and using a fresh ampule every 3 min, is a first-aid measure and is omitted when intravenous sodium nitrite is available or the patient has been intubated. The ampule is broken between two pads of gauze and placed over the airway while the patient breathes spontaneously or is ventilated by a bag-mask unit. Sodium nitrite is administered as a 3% solution at a dose of 10 to 15 mL (300 to 450 mg) over 1 to 2 min. Sodium thiosulfate is also administered intravenously, as a 25% solution at a dose of 50 mL (12.5 g) given over 1 to 2 min. With recurrent or persistent symptoms, doses of sodium nitrite and sodium thiosulfate can be repeated. Hyperbaric oxygen therapy should be considered in patients who fail to respond to antidotal therapy. Hydroxycobalamin, a vitamin B_{12}precursor that also binds cyanide ion, is an alternative antidote that is not yet widely available.

CYCLIC ANTIDEPRESSANTS

Tricyclic antidepressants (TCAs) such as amitriptyline, imipramine (and their respective active metabolites nortriptyline and desipramine), chlomipramine, doxepin, protriptyline,

and trimipramine and polycyclic agents such as amoxapine, bupropion, maprotiline, mirtazepine, and trazodone (and its metabolite nefazodone) act primarily by blocking the presynaptic reuptake monoamine neurotransmitters in theCNS, most importantly norepinephrine and serotonin, but also dopamine. They also have anticholinergic, a-adrenergic receptor blocking, and quinidine-like (class IA antiarrhythmic) effects as well as variable and selective blocking activity at histamine and monoamine receptors. Bupropion, nefazodone, and trazodone have serotonin agonist activity. Selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine, paroxetine, sertaline, citalopram, and fluvoxamine can enhance the presynaptic release of serotonin and block its receptors in addition to inhibiting its reuptake. The nonselective serotonin reuptake inhibitors such as venlafaxine also inhibit norepinephrine reuptake.

Cyclic antidepressants are well absorbed. Peak serum levels usually occur within 2 to 6 h of ingestion but can sometimes occur later. These agents exhibit high (about 95%) protein binding in the plasma, have large volumes of distribution (20 to 45 L/kg body weight), and are eliminated mainly by hepatic metabolism, with half-lives of 24 h or more.

Clinical Toxicity Effects generally develop within 30 min of ingestion and peak within 6 h. Following low overdosage (about 10 mg/kg) ofTCAs, anticholinergic effects predominate (see "Anticholinergic Agents," above). With larger doses, markedCNSdepression (Table 396-2), cardiotoxicity, seizures, and hypotension occur. Ventricular tachyarrhythmias, atrioventricular and intraventricular conduction delays, terminal bradycardia, decreased cardiac output, and pulmonary edema may be seen. Death can occur within 6 h of ingestion from cardiovascular effects or much later from multiple organ failure or pulmonary complications. Terminal (last 40 ms) QRS right-axis deviation, an R wave greater than the S wave or >3 mm in lead aV_R, and prolongation of the QRS complex (>100 ms) of theECG are sensitive indicators of TCA cardiotoxicity. Increasing duration of the QRS complex correlates with an increased risk of cardiac arrhythmias and seizures.

Although seizures can occur,CNSdepression is typically mild withSSRIsand moderate with the polycyclic agents. Sinus tachycardia is common, but life-threatening cardiovascular effects are virtually nonexistent. An exception is trazodone, which can cause QT-interval prolongation and ventricular tachycardia. The serotonin syndrome (discussed separately) is also a potential complication of SSRI overdose.

Diagnosis The diagnosis is supported by the presence of these drugs in the urine on comprehensive screening tests.TCAserum levels are diagnostic and generally correlate with severity. Serum levels of active metabolites should be summed with that of the parent compound when estimating the serum concentration. Levels 1000 nmol/L (300 ng/mL) are therapeutic. Levels >3300 nmol/L (1000 ng/mL) are associated with severe poisoning.

TREATMENT

Activated charcoal is the preferred method of gastrointestinal decontamination. Repeated doses may enhance the elimination of some agents. Physostigmine (see "Anticholinergic Agents," above) can reverse anticholinergic effects due to

low-doseTCApoisoning and may be used if theECG is normal and deterioration has been excluded by a suitable period of observation. For other toxicity, treatment includes support of respiration and volume expansion and norepinephrine or high-dose dopamine for hypotension. Seizures should be treated with benzodiazepines and barbiturates. Phenytoin is of uncertain benefit. Acidemia increases the likelihood of arrhythmias and should be corrected. Sodium bicarbonate should be given as a bolus following a seizure and as an infusion to maintain a serum pH of 7.45 to 7.50 in patients with QRS prolongation. Treatment of ventricular tachyarrhythmias is similar to that described for antiarrhythmic agents and should include sodium bicarbonate. Phenytoin is often recommended, but its efficacy is not established.b-Adrenergic blockers and class IA, IC, and III antiarrhythmics should be avoided. Cardiac pacing and invasive hemodynamic support may be necessary for severe cardiovascular depression.

ETHYLENE GLYCOL

Ethylene glycol is a colorless, odorless, sweet-tasting, water-soluble liquid used as a solvent for paints, plastics, and pharmaceuticals; in the manufacture of explosives, fire extinguishers, and foams; and as an ingredient in hydraulic fluids, windshield cleaners, radiator antifreeze, and de-icer solutions.

Ethylene glycol produces intoxication similar to that caused by ethanol but is more potent. Peak blood levels occur approximately 2 h after ingestion. The volume of distribution is 0.6 to 0.8 L/kg body weight. Ethylene glycol is oxidized by alcohol dehydrogenase to glycoaldehyde, which is metabolized successively to glycolic acid, glyoxylic acid, and oxalic acid. Pyridoxine and thiamine are cofactors in degradation pathways. As much as 20% is excreted unchanged in the urine. The half-life ranges from 3 to 8 h. Metabolites, primarily glycolic acid, causeCNSdepression, metabolic acidosis with an increased anion gap, and interstitial and tubular damage to the kidney. Oxalic acid may precipitate as calcium oxalate in the brain, heart, kidney, lung, pancreas, and urine and cause hypocalcemia.

Ethanol and fomepizole bind to alcohol dehydrogenase with a higher affinity than ethylene glycol and hence block the production of toxic metabolites. Ethanol is metabolized by alcohol dehydrogenase, but fomepizole is not. Ethanol and fomepizole prolong the half-life of ethylene glycol to 15 to 20 h.

Clinical Toxicity As little as 120 mg/kg body weight or 0.1 mL/kg body weight (one swallow) of pure ethylene glycol can result in a potentially toxic serum concentration of 3 mmol/L (20 mg/dL). Effects begin about 30 min after ingestion and include nausea, vomiting, slurred speech, ataxia, nystagmus, and lethargy. A faint, sweet aromatic odor may be detected on the breath, and the serum osmolality may be elevated. Effects caused by metabolites begin 3 to 12 h after ingestion (longer if ethanol has also been ingested) and include tachypnea, agitation, confusion, lethargy, back pain, hypotension, coma, and seizures. In severe cases,ARDS, cyanosis, pulmonary edema, and cardiomegaly may be seen. Laboratory findings include metabolic acidosis, an increased anion gap (low bicarbonate and chloride), hypocalcemia, leukocytosis, increasedBUN and creatinine, calcium oxalate crystalluria, and proteinuria. Acute tubular necrosis with oliguria or anuria typically becomes evident 12 to 24 h following ingestion. Renal failure is usually reversible but may last days to weeks.

Diagnostic Evaluation The diagnosis is established by measuring serum ethylene glycol and glycolate levels. The diagnosis is suggested by an elevated serum osmolality and ethanol-like effects soon after ingestion and by an increased anion-gap metabolic acidosis and crystalluria later on. If laboratory confirmation is not immediately available, the osmolal gap can also be used to estimate the serum ethylene glycol concentration (Table 396-3).

TREATMENT

Gastric aspiration is the decontamination procedure of choice. Activated charcoal should also be administered. Supportive measures include protection of the airway, ventilatory and circulatory support, and anticonvulsants for seizures. Metabolic acidosis will not resolve spontaneously and should be corrected with sodium bicarbonate; large doses may be required. Sodium bicarbonate should also be given to alkalinize the urine as this will enhance the excretion of acid metabolites. Fluids and diuretics can be used to treat oliguria but they do not increase the excretion of ethylene glycol. Hypocalcemia is treated with intravenous calcium salts. Supplemental pyridoxine (50 mg qid) and thiamine (100 mg qid) may be beneficial.

Indications for ethanol or fomepizole therapy include an ethylene glycol concentration>3 mmol/L (20 mg/dL); an elevated osmolal gap, an increased anion-gap metabolic acidosis, back pain, laboratory evidence of renal toxicity, or ethanol-like intoxication in a patient with a history of ethylene glycol ingestion and a low or undetectable ethanol level; an elevated osmolal gap not accounted for by the presence of ethanol, isopropyl alcohol, acetone, or propylene glycol in a patient with ethanol-like intoxication; and an increased anion-gap metabolic acidosis with a low lactate level not explained by alcoholic or diabetic ketoacidosis, uremia, or salicylate, formaldehyde, paraldehyde, or toluene exposure. A serum ethanol level of ^{3}20 mmol/L (100 mg/dL) is required to inhibit the metabolism of ethylene glycol (higher levels may be needed with very high ethylene glycol concentrations). The loading dose of ethanol is 10 mL/kg of 10% ethanol intravenously or 1 mL/kg of 95% ethanol by mouth; the maintenance dose is 1.5 mL/kg per hour of 10% ethanol intravenously or 3 mL/kg per hour of 10% ethanol intravenously during hemodialysis. Maintaining a therapeutic concentration is often difficult; levels must be monitored frequently and the dose adjusted as necessary. Ethanol induces its own metabolism and progressively higher doses may be required as time passes. Fomepizole is diluted in 100 mL of intravenous fluid and administered over 30 min in a loading dose of 15 mg/kg followed by 10 mg/kg every 12 h for four doses and 15 mg/kg thereafter. Additional doses are required in patients undergoing dialysis. Although expensive (about $1000 U.S. per 1.5-g vial), fomepizole has a number of advantages over ethanol: it does not causeCNSdepression, hypoglycemia, or fluid, electrolyte, and serum osmolality derangements; it has a longer duration of action; and does not require monitoring of serum drug levels. Although seizures have occurred after fomepizole, their etiology is unclear, and side effects have generally been limited to headache, nausea, dizziness, rash, eosinophilia, and mild self-limited hepatotoxicity. Serum ethylene glycol concentrations should be monitored frequently. Ethanol or fomepizole should be continued until the ethylene glycol level falls below 1.5 mmol/L (10 mg/dL).

Hemodialysis enhances the elimination of ethylene glycol and its toxic metabolites so

that it is complete in about 3 h. Indications for hemodialysis include an ethylene glycol concentration>8 mmol/L (50 mg/dL) and metabolic acidosis not readily correctable with bicarbonate and antidotal therapy, lack of clinical improvement despite treatment, and laboratory evidence of renal toxicity (regardless of the ethylene glycol level). This therapy should be continued (repeated intermittently) until acidemia resolves and the ethylene glycol level is <3 mmol/L (20 mg/dL).

HYDROCARBONS

Aromatic hydrocarbons, such as xylene and toluene, halogenated hydrocarbons, such as carbon tetrachloride and trichloroethane, and petroleum distillate hydrocarbons, such as gasoline, lacquer thinner, mineral seal oil, kerosene, and lighter fluid, areCNSdepressants and gastrointestinal and respiratory tract irritants. They are absorbed rapidly following inhalation or pulmonary aspiration. Aromatic and halogenated hydrocarbons are also absorbed following ingestion and are toxic to the heart, liver, and kidneys. Aromatic hydrocarbons can cause bone marrow suppression and skeletal muscle damage. Petroleum distillate hydrocarbons are poorly absorbed following ingestion.

Clinical Toxicity Hydrocarbons produceCNSexcitation in low doses and depression in high doses. Rarely, coma and seizures occur. Psychosis, cerebral and cerebellar atrophy, encephalopathy, and peripheral neuropathy can result from chronic inhalation. Other effects include nausea, vomiting, abdominal pain, hepatitis, renal tubular acidosis, acute hepatic or renal failure, and rhabdomyolysis. Sudden death due to myocardial irritability and ventricular fibrillation may occur following hydrocarbon sniffing. After ingestion, hydrocarbons cause burning of the mouth and throat with subsequent nausea, vomiting, and diarrhea. Aspiration into the lungs may occur with ingestion or as a result of vomiting and cause pneumonia. Following aspiration, chest x-ray abnormalities include infiltrates, atelectasis, effusions, pneumothorax, and pneumatoceles. Renal tubular acidosis with decreased serum bicarbonate, calcium, phosphate, and potassium and increased serum chloride may result from chronic aromatic hydrocarbon inhalation.

Diagnosis The diagnosis is based on the clinical presentation. Assays for hydrocarbons are not routinely available.

TREATMENT

The ingestion of aromatic and halogenated hydrocarbons requires prompt gastric lavage. More than one episode of ipecac-induced emesis is contraindicated, and the role of activated charcoal is controversial. Since the ingestion of other types of hydrocarbons is unlikely to result in systemic toxicity and since the risk of aspiration during gastric decontamination is greater than the potential benefit, decontamination is contraindicated for these ingestions. Supportive therapy includes oxygen, respiratory support, and monitoring of liver, renal, and myocardial function. Metabolic abnormalities should be corrected, and patients with aspiration pneumonitis should be monitored for superimposed bacterial infection. Glucocorticoids are ineffective.

HYDROGEN SULFIDE

Hydrogen sulfide is a rapidly acting, malodorous ("rotten eggs"), colorless, irritating gas. It is encountered in the petroleum and mining industries, tanning of leather, vulcanization of rubber, the production of synthetic fabrics, metal refining, the production of heavy water for atomic reactors, and glue and felt manufacturing. It is also found in sewers, sulfur springs, and the holds of fishing vessels and as a byproduct of manure storage.

Sulfide anion inhibits electron transport in the cytochrome oxidase system, thereby inhibiting aerobic metabolism with resultant cellular anoxia and lactic acidosis. Hydrogen sulfide is rapidly detoxified by oxidation to sulfate products, which are excreted by the kidneys.

Clinical Toxicity Exposure to low concentrations of hydrogen sulfide results in rhinitis, conjunctivitis, and pharyngitis. Inhalation of large amounts causes headache, vertigo, nausea, vomiting, confusion, seizures, and coma. Hypoventilation, hypoxia, cyanosis, metabolic acidosis, pneumonia, and pulmonary edema can occur.

Diagnosis The diagnosis is based on the characteristic clinical features, including the characteristic odor, exposure setting, and rapidity of onset. Sulfide levels have been used to confirm the diagnosis but are not routinely available.

TREATMENT

Treatment includes prompt removal of the victim from the site of exposure, assisted ventilation, and 100% oxygen. Although controversial, amyl and sodium nitrite, in the same dose as for cyanide poisoning, should be considered for patients with coma or cardiac arrest who fail to respond to oxygen therapy. Nitrites promote the dissociation of sulfide ions from cytochrome oxidase by providing an alternative binding site (methemoglobin). They also enhance detoxification by acting as a catalyst for sulfide oxidation. Hyperbaric oxygen should be considered in patients who do not respond to the preceding measures.

IRON

Non-transferring-bound plasma iron catalyzes the formation of free radicals, which then cause mitochondrial injury, lipid peroxidation, increased capillary permeability, vasodilation, and intestinal, renal, hepatic, myocardial, and pulmonary toxicity. Ingestion of 20 mg/kg body weight of elemental iron typically produces gastrointestinal symptoms, and 60 mg/kg body weight may cause systemic toxicity. Ferrous sulfate, fumarate, gluconate, and succinate contains 20, 33, 12, and 35% elemental iron, respectively.

Ferrous iron is absorbed by duodenal and jejunal cells, oxidized to ferric iron, and bound to ferritin. It is then slowly released, binds to plasma transferrin (an iron-specific globulin) and other proteins, and is transported to tissues. Serum iron levels usually peak 4 to 6 h after overdosage (later for delayed-release formulations). Iron bound to transferrin is nontoxic.

Clinical Toxicity Initial manifestations include vomiting and diarrhea (often bloody).

X-rays may reveal iron tablets in the stomach or small bowel. Systemic effects include lethargy, hypotension, and metabolic acidosis. Seizures, coma, pulmonary edema, and vascular collapse may occur with severe poisoning. Jaundice, elevated hepatic enzyme levels, prolongation of prothrombin time, and hyperammonemia are indicative of liver injury. Proteinuria and cells in the urine indicate renal injury. In the recovering patient, gastric ulcerations and scars may cause outlet obstruction. Overgrowth of *Yersinia enterocolitica* with sepsis is a rare complication of iron overload.

Diagnosis The diagnosis is primarily based on clinical findings. A serum iron concentration>50 umol/L (300 ug/dL) is potentially toxic. A positive x-ray, fever>38.5°C, hyperglycemia >8.5 mmol/L (150 mg/dL), and leukocytosis (white blood cell count >15,000/uL) have also been associated with potential toxicity. Serious poisoning is generally associated with levels >80 umol/L (500 ug/dL). A positive urine deferoxamine provocative challenge test (see below) is also diagnostic.

TREATMENT

Gastric lavage and whole-bowel irrigation are the preferred methods of gastrointestinal decontamination. When iron tablets are visible on x-ray, serial films can be used to assess their success. Endoscopic removal and gastrostomy may be necessary when these procedures are ineffective (e.g., large ingestions, concretions). Complexation of ingested iron with orally administered activated charcoal, bicarbonate, phosphate, deferoxamine, or magnesium hydroxide has not been shown to reduce toxicity.

Intravenous sodium bicarbonate should be used to correct metabolic acidosis. Nearly all patients are volume depleted and should be given intravenous crystalloid. Coagulation abnormalities should be treated with vitamin K or blood products.

Parenteral deferoxamine should be given to patients with elevated serum iron levels or clinical manifestations of poisoning. If the iron level is mildly elevated or not immediately available or if the patient has mild clinical toxicity, an intravenous challenge dose of 15 mg/kg per hour can be given. Urine becomes a vin rose or rusty orange color in the presence of the iron-deferoxamine complex (ferrioxamine), indicating that free iron is present. Patients with a positive challenge test or significant clinical toxicity should be given intravenous deferoxamine at a rate of 10 to 15 mg/kg per hour. When iron levels exceed 180 umol/L (1000 ug/dL), larger deferoxamine doses (up to 30 mg/kg per hour) can be given initially. Once the patient is asymptomatic or improved, deferoxamine therapy should be discontinued. Rapid infusion of deferoxamine can cause hypotension. Pulmonary edema is a complication of prolonged, high-dose therapy, and renal failure can occur if it is administered to hypovolemic patients. Exchange transfusion or plasmapheresis should be reserved for patients with renal failure or who fail to respond to the preceding therapy.

ISONIAZID

Toxic doses of isoniazid decrease the synthesis of the inhibitoryCNSneurotransmitterGABA by interfering with the activation and supply of pyridoxal-5-phosphate, a cofactor for the enzyme glutamic acid decarboxylase, which converts glutamic acid to GABA. Isoniazid also causes pyridoxine depletion by

complexing with pyridoxine to form hydrazides that are then excreted, and it forms hydrazones that inhibit the production and activity of pyridoxal phosphate enzymes. The resultant decrease in GABA can cause seizures with increased lactate production by muscle. Since isoniazid also inhibits the metabolism of lactate to pyruvate, profound and intractable lactic acid acidosis may ensue.

Isoniazid is rapidly absorbed, with peak serum concentrations noted within 1 to 2 h. The volume of distribution is approximately 0.7 L/kg body weight. Serum protein binding is slight. Elimination is primarily by hepatic acetylation to acetylisoniazid followed by hydrolysis to isonicotinic acid. The rate of acetylation is genetically determined and characterized as either slow or fast with corresponding half-lives of 0.5 to 1.5 and 2 to 4 h.

Clinical Toxicity Nausea, vomiting, dizziness, slurred speech, lethargy, and confusion begin within 30 min of ingestion of doses greater than 20 mg/kg body weight. Severe poisoning results in coma, respiratory depression, generalized seizures, and lactic acid acidosis. Seizures may be protracted and relatively unresponsive to standard anticonvulsant therapy. Acidosis does not occur when seizures are prevented.

Diagnosis The diagnosis is primarily based on clinical findings. It can be confirmed by measuring isoniazid in blood, but isoniazid assays are not routinely available. Urine screening tests do not detect the drug.

TREATMENT

Activated charcoal adsorbs isoniazid quite well and is the preferred method of gastrointestinal decontamination. Ipecac-induced vomiting should be avoided because of the potential for rapid deterioration with coma and seizures. Seizures are sometimes responsive to benzodiazepines and barbiturates, but pyridoxine (vitamin B_6), which reverses isoniazid-induced enzyme inhibition, is often also necessary. Diazepam and pyridoxine are synergistic. Bicarbonate may be necessary to correct acidosis. Intravenous pyridoxine is given intravenously (over 5 min in patients with seizures and over 30 min in those without) in an amount equal to the ingested dose of isoniazid. When the ingested dose is not known, 5 g of pyridoxine should be administered. Seizures are usually promptly controlled, but the patient may not awake for several hours. The dose may be repeated if the response is partial or if symptoms recur. Saline diuresis enhances the excretion of isoniazid, and the drug is efficiently removed by hemodialysis. Because pyridoxine therapy is highly effective, these procedures are rarely necessary.

ISOPROPYL ALCOHOL AND ACETONE

Isopropyl alcohol is a component of rubbing alcohol, solvents, aftershave solutions, antifreeze, and window cleaners. Acetone is found in cleaners, solvents, and nail polish removers. Both are absorbed rapidly from the stomach and the lungs and distributed in body water with volumes of distribution of about 0.6 L/kg body weight. Isopropyl alcohol is metabolized to acetone in the liver by the enzyme alcohol dehydrogenase. Up to 20% is excreted unchanged in urine. Its half-life ranges from 3 to 6 h. Acetone is excreted by the kidneys and lungs with a half-life of 20 to 30 h. Isopropyl alcohol and acetone

areCNSdepressants and have about twice the potency of ethanol.

Clinical Toxicity Effects begin within 30 min of ingestion and include vomiting, abdominal discomfort, and sometimes hematemesis as well as headache, dizziness, and ethanol-like intoxication. Obtundation, coma, respiratory depression, hypothermia, and hypotension may be seen with severe poisoning. Their characteristic odors may be detected on the breath or gastric contents. Both hypoglycemia and hyperglycemia can occur. Increased serum osmolality, mild ketoacidosis, and a falsely elevated serum creatinine with a normalBUN (due to the interference with creatinine assays by acetone) may be present.

Diagnosis Characteristic clinical and laboratory findings suggest the diagnosis. Direct measurement of serum levels will confirm it. Routine urine screening tests do not detect these agents. If laboratory confirmation is not readily available, the osmolal gap can be used to estimate the serum concentration (Table 396-3).

TREATMENT

Gastric aspiration is the preferred method of gastrointestinal decontamination. Activated charcoal is ineffective. Intravenous fluids and possibly bicarbonate should be given for dehydration, hypotension, and acidosis. Ventilatory support may be necessary. Hemodialysis is effective for removing isopropyl alcohol and acetone and should be considered in patients with high serum levels who do not respond to conservative therapy.

LITHIUM

Lithium, an alkali metal like sodium and potassium, appears to act by substituting for endogenous cations, thereby intefering with cell membrane ion transport and excitability, adenylate cyclase activation, neurotransmitter (norepinephrine) release, and Na^+, K^+-ATPase activity. It is available as the carbonate salt in pill form and as the liquid citrate salt. These preparations contain 8 mmol (meq) of lithium per 300 mg and 5 mL, respectively.

Lithium is absorbed slowly, with peak serum levels occurring 2 to 4 h after ingestion (later with overdosage and with sustained-release preparations). Lithium is not bound to plasma proteins. It has an initial volume of distribution of 0.3 to 0.4 L/kg body weight and a final one of 0.7 to 1 L/kg. Therapeutic serum levels are 0.6 to 1.2 mmol/L. An increase in the postdistribution lithium level of 1 to 1.5 mmol/L for each mmol/kg ingested can be predicted following acute overdose. Levels obtained prior to complete distribution will be higher than those in tissue and not correlate with clinical effects. Elimination is primarily (95%) by renal excretion (glomerular filtration with significant reabsorption in the proximal tubule). Renal excretion is increased by diuresis and urinary alkalinization and decreased by hypovolemia and hyponatremia. The serum half-life ranges from 18 to 36 h and can be prolonged in patients with chronic intoxication.

Clinical Toxicity Effects begin 1 to 4 h after acute ingestion. Onset can be delayed following overdose of sustained-release preparations. It typically occurs insidiously during chronic therapy, often resulting from an intercurrent illness that causes

dehydration and decreased lithium elimination. Gastrointestinal effects include nausea, vomiting, and diarrhea; neuromuscular effects include weakness, confusion, ataxia, tremors, fasciculations, myoclonus, choreoathetosis, coma, and seizures; and cardiovascular effects include arrhythmias and hypotension. Hyperthermia can occur. Leukocytosis, hyperglycemia, albuminuria, glycosuria, nephrogenic diabetes insipidus, and a falsely elevated serum chloride level (due to interference by lithium with its assays) resulting in a low anion-gap may be present.ECGchanges include sinus tachycardia or bradycardia, flattened or inverted T waves,AVblock, and a prolonged QT interval. Prolonged or permanent encephalopathy and movement disorders can occur in patients with severe poisoning.

Diagnosis Since lithium is not detected by routine screening tests, a serum level must be requested specifically. Because of slow absorption and distribution, serial drug levels should be obtained following acute overdosage. In chronic poisoning, severe toxicity may occur at serum levels of 3 to 4 mmol/L. Following acute overdose, only mild effects may be present despite serum levels that rise to³8 mmol/L. As distribution occurs and levels fall, progressive toxicity may ensue.

TREATMENT

Gastric lavage and whole-bowel irrigation are the procedures of choice for gastrointestinal decontamination. Whole-bowel irrigation is preferred for sustained-release formulations because intact pills will not fit through a lavage tube. Endoscopy should be considered if a concretion is suspected (persistently high or rising drug levels 2 or more days following ingestion). Activated charcoal does not adsorb lithium. Experimentally, oral administration of the ion-exchange resin sodium polystyrene sulfonate (Kayexalate) can bind lithium, prevent its absorption, and enhance its elimination, but the clinical effectiveness of this therapy is unproven. Supportive therapy includes standard treatments for seizures, CNS depression, hypotension, and arrhythmias. Symptomatic patients should be given an intravenous saline bolus and infusion to correct dehydration, to achieve a normal urine output, and to replace fluid losses in those with diabetes insipidus. Although diuresis can enhance renal excretion of lithium, there is little evidence that this therapy is more effective than simply maintaining a normal urine output. Hemodialysis, however, is highly effective in enhancing lithium elimination. It is recommended for patients with coma, seizures, and severe, persistent or progressive confusion, CNS depression, or movement disorders; lesser toxicity in the presence of renal failure; and when the peak lithium level exceeds 8 mmol/L following acute overdose (because of the likelihood of severe postdistribution toxicity). Because of slow redistribution, drug levels typically rise following dialysis. Dialysis should be repeated until the postredistribution level is<1 mmol/L. Despite dialysis, clinical recovery may take days to weeks. There is no conclusive evidence that dialysis decreases the incidence of permanent sequelae.

METHANOL

Methanol is a component of shellacs, varnishes, paint removers, canned fuel (Sterno), windshield-washer solutions, and copy machine fluid. It is also used to denature ethanol and render it unfit for consumption. It is aCNSdepressant with a potency about half of that of ethanol. Methanol is initially metabolized by alcohol dehydrogenase to

formaldehyde, with subsequent oxidation to formic acid, and then to carbon dioxide and water. Formic acid is responsible for metabolic acidosis and retinal toxicity. Its detoxification utilizes tetrahydrofolate as a cofactor.

Methanol is readily absorbed, with peak serum levels occurring 1 to 2 h after ingestion. It is distributed throughout body water, with a volume of distribution of 0.7 L/kg body weight. Protein binding is negligible. Elimination occurs mainly by hepatic metabolism, with up to 10% excreted unchanged by the lungs and kidneys. Elimination follows first-order kinetics, with a half-life of 2 to 4 h at low serum levels (9 mmol/L or 30 mg/dL). At higher levels, it changes to zero-order kinetics, with an elimination rate of about 3 mmol/L per hour (10 mg/dL per hour) and an apparent half-life of up to 30 h. As with ethylene glycol, ethanol and fomepizole block the production of methanol metabolites, by competitively inhibiting alcohol dehydrogenase, and increase its elimination half-life to 30 to 60 h.

Clinical Toxicity As with ethylene glycol, as little as one swallow of pure methanol is potentially toxic. Effects begin within an hour of ingestion. Initial manifestations are caused by methanol itself and include nausea, vomiting (sometimes bloody), abdominal pain, headache, vertigo, and an ethanol-like intoxication. An increased osmolal gap may be present. Pancreatitis has been reported. Later effects are due to formic acid and include coma, seizures, an increased anion-gap metabolic acidosis, and retinal injury. Ophthalmologic manifestations occur 15 to 30 h after ingestion and include clouding and diminished vision, dancing and flashing spots, dilated or fixed pupils, hyperemia of optic disks, retinal edema, and blindness. These changes are potentially reversible with prompt institution of therapy. With severe poisoning, myocardial depression, bradycardia, and shock may occur.

Diagnosis The diagnosis is confirmed by measurement of serum methanol and formate levels. Early in the course, the diagnosis is suggested by ethanol-like intoxication and an elevated serum osmolality. Later, the diagnosis is suggested by an increased-anion-gap metabolic acidosis and visual complaints. If laboratory confirmation is not immediately available, the osmolal gap can also be used to estimate the serum methanol concentration (Table 396-3).

TREATMENT

Gastric aspiration is the treatment of choice for gastrointestinal decontamination. Supportive measures should include volume replacement, respiratory care, and treatment of seizures. Acidosis should be corrected with sodium bicarbonate; large amounts may be required. Sodium bicarbonate should also be given to alkalinize the urine as this will enhance the excretion of formic acid. Supplemental folate (50 mg qid) is recommended.

Indications for ethanol or fomepizole therapy include a methanol concentration>6 mmol/L (20 mg/dL); an elevated osmolal gap, an increased anion-gap metabolic acidosis, visual symptoms, or ethanol-like intoxication in a patient with a history of methanol ingestion and a low or undetectable ethanol level; an elevated osmolal gap not accounted for by the presence of ethanol, isopropyl alcohol, acetone, or propylene glycol in a patient with ethanol-like intoxication; and an increased anion-gap metabolic

acidosis with a low lactate level not explained by alcoholic or diabetic ketoacidosis or uremia or by salicylate, formaldehyde, paraldehyde, or toluene exposure. Doses and treatment considerations are the same as for ethylene glycol. Serum methanol concentrations should be monitored frequently. Ethanol or fomepizole should be continued until the methanol level falls below 3 mmol/L (10 mg/dL).

Hemodialysis enhances the elimination of methanol and formic acid. Indications for hemodialysis include methanol levels >15 mmol/L (50 mg/dL) and metabolic acidosis not readily correctable with bicarbonate and antidotal therapy, lack of clinical improvement despite treatment, or visual symptoms (regardless of the methanol level). This therapy should be continued or repeated intermittently until acidemia resolves and the methanol level is <6 mmol/L (20 mg/dL).

METHEMOGLOBINEMIA

Methemoglobinemia results from exposure to chemicals that oxidize the ferrous (Fe^{2+}) iron in hemoglobin to the ferric (Fe^{3+}) state. Concomitant oxidation of hemoglobin protein may cause its precipitation in erythrocytes and consequent hemolytic anemia, manifest as Heinz bodies and "bite cells," respectively, on peripheral blood smear. Oxidizing agents include aniline and its derivatives, aminophenols, aminophenones, chlorates, dapsone, local anesthetics (particularly benzocaine), nitrites, nitrates, naphthalene, nitrobenzene and related chemicals, oxides of nitrogen, phenazopyridine, primaquine and related antimalarials, and sulfonamides.

Methemoglobin (ferric hemoglobin) cannot carry oxygen and causes a functional anemia. It also shifts the oxygen-dissociation curve to the left, limiting the release of oxygen to tissues. Symptoms are due to hypoxia and anaerobic metabolism.

Various systems normally operate to keep methemoglobin at physiologic levels (1% of the total hemoglobin concentration). Oxidizing agents are inactivated by enzymes that utilize ascorbic acid and sulfhydryl agents such as glutathione. Methemoglobin is reduced to hemoglobin by NADH-methemoglobin reductase (responsible for 95% of baseline reducing capacity), NADPH-methemoglobin reductase, and the ascorbic acid and glutathione enzyme systems. When supplied with the cofactor methylene blue, the activity of NADPH-methemoglobin reductase is greatly increased. Because this enzyme is dependent on NADPH, individuals with glucose-6-phosphate dehydrogenase (G6PD) deficiency have profound impairment in the ability to reduce methemoglobin after oxidant exposure.

Clinical Toxicity Onset may be immediate or delayed depending on whether the parent compound or a metabolite is the oxidant. Cyanosis with a gray-brown hue that is unresponsive to oxygen occurs when the fraction of hemoglobin existing as methemoglobin exceeds 15% (about 15 g/L or 1.5 g/dL of absolute methemoglobin). Most patients are asymptomatic until the methemoglobin fraction is>20 to 30%, at which point fatigue, headache, tachycardia, dizziness, and weakness develop. At fractions>45%, dyspnea, bradycardia, hypoxia, metabolic (lactic) acidosis, seizures, coma, and cardiac arrhythmias may occur. Fractions>70% are rapidly fatal. Hemolytic anemia is typically delayed in onset and may cause hyperkalemia and renal failure.

Diagnosis The diagnosis is confirmed by measuring the methemoglobin level by CO-oximetry. If CO-oximetry is not available, the methemoglobin fraction can be estimated by the difference between the oxygen saturation calculated from the P_{O2} and that measured directly. Oxygen saturation measured by pulse oximetry will be subnormal but either falsely depressed or elevated with respect to the true value. Blood with high levels of methemoglobin is chocolate-colored when placed on filter paper and compared with normal blood. Urine toxicology testing may detect the oxidizing agent.

TREATMENT

Activated charcoal is the preferred method of gastrointestinal decontamination. Supplemental oxygen should be administered. Methylene blue is indicated for methemoglobin fractions >30% and at lower fractions in patients with anemia or cardiovascular disease, particularly if manifestations of hypoxia or organ ischemia are present. Methylene blue is given at a dose of 1 to 2 mg/kg body weight as a 1% solution over 5 min. If a clinical response is not observed within 1 h, the dose may be repeated. As long as the oxidizing agent is present, methemoglobin will continue to be generated, and additional doses may be necessary. Side effects of methylene blue include anxiety, dysuria, precordial pain, and blue or green discoloration of the urine. It is contraindicated in patients withG6PDdeficiency in whom it may induce hemolysis. In doses>7 mg/kg of body weight, methylene blue itself can cause methemoglobinemia. Exchange transfusion and hyperbaric oxygen therapy may be of benefit in patients with very high methemoglobin fractions or severe clinical toxicity that is refractory to the above and those with G6PD deficiency. Erythrocyte transfusion may be necessary if hemolysis is severe. Hemodialysis may be useful for removing the offending agent.

MONOAMINE OXIDASE INHIBITORS

The antidepressants isocarboxazid, phenelzine, and tranylcypromine and the chemotherapeutic agent procarbazine irreversibly and nonselectively block monoamine oxidase (MAO) isoenzymes in the brain, gut, and liver, thus inhibiting the catabolism of endogenous MAO substrates such as epinephrine, dopamine, norepinephrine, and serotonin and exogenous ones such as ingested tyramine. Clorgyline and moclobemide selectively inhibit MAO-A, which preferentially deaminates serotonin, and pargyline and selegiline selectively inhibit MAO-B. Toxicity results from the accumulation and effects of MAO substrates. A tyramine reaction can occur when foods with high tyramine content such as aged cheese, aged, pickled, or smoked meat and fish, and red wine are ingested by individuals taking MAO inhibitors. Interactions with sympathomimetics can result in exaggerated sympathetic effects, and interactions with serotonergic agents can cause the serotonin syndrome (discussed subsequently).

MAOinhibitors are absorbed and appear to have relatively large volumes of distribution (>1 L/kg body weight). They are eliminated primarily by hepatic metabolism and have half-lives ranging from several hours to >24 h.

Clinical Toxicity Onset following overdose is typically delayed and insidious. Effects may not begin until 6 to 24 h after ingestion and progress slowly. Initial manifestations include dilated pupils, agitation, diaphoresis, tachycardia, hypertension, and tachypnea. Nausea and vomiting may also occur. Later, confusion,CNSdepression, fasciculations,

twitching, tremor, muscle rigidity, rhabdomyolysis, hyperthermia, and lactic acidosis may be noted. Terminal bradycardia and cardiovascular collapse may ensue.

Tyramine and sympathomimetic reactions occur within 30 to 90 min of food or drug ingestion and resolve within a few hours. Manifestations are similar to overdose. Reflex bradycardia, seizures, and intracranial hemorrhage have also been described.

Diagnosis The diagnosis is based on the history and clinical presentation. Serum assays are not available, and urine screening tests do not usually detect these agents.

TREATMENT

Activated charcoal is the preferred method of gastrointestinal decontamination. Benzodiazepines should be given for neuromuscular hyperactivity. Therapeutic paralysis is recommended for refractory or progressive neuromuscular hyperactivity, particularly if concomitant rhabdomyolysis and hyperthermia are present. The treatment of hyperthermia should include external cooling measures. Replacement of insensible fluid losses is also important. Severe hypertension and tachycardia should be treated with labetalol or nitroprusside and esmolol. Hypotension should first be treated with intravenous fluids and then with pressors. Pressors should initially be given at lower than normal doses because of the possibility of an exaggerated response. In fact, before any drug is given, potential interaction withMAOinhibitors should be investigated. Because MAO inhibition may persist for up to 2 weeks after discontinuing therapy, drug and dietary precautions should be maintained during this period.

MUSCLE RELAXANTS AND MISCELLANEOUS SEDATIVE-HYPNOTICS

Muscle relaxants (baclofen, carisoprodol, chlorphenesin, chlorzoxazone, cyclobenzaprine, methocarbamol, and orphenadrine) and nonbarbiturate, nonbenzodiazepine sedative-hypnotics (buspirone, chloral hydrate, ethchlorvynol, glutethimide, meprobamate, methaqualone, methyprylon, zolpidem) including the street drugsg-butyrolactone (GBL) and its metaboliteg-hydroxybutyrate (GHB) are primarilyCNSdepressants. Most interact withGABAreceptor complexes, enhancing the effects of this inhibitory neurotransmitter. Some muscle relaxants also depress spinal synaptic reflexes. Cyclobenzaprine and orphenadrine have anticholinergic activity. Orphenadrine also has sodium channel blocking activity.

These agents are readily absorbed, with peak blood levels occurring 1 to 2 h after ingestion. They are eliminated primarily by hepatic metabolism. Baclofen, an exception, is largely excreted unchanged in the urine. Chloral hydrate is rapidly metabolized to trichloroethanol, an active compound with a much longer half-life than the parent drug. Carisoprodol is metabolized to meprobamate. Glutethimide also has an active metabolite. Half-lives are >20 h for cyclobenzaprine, ethchlorvynol, and methaqualone; 10 to 20 h for glutethimide, meprobamate, methyprylon, and orphenadrine; and <6 h for other agents.

Clinical Toxicity Effects begin within an hour of ingestion. All muscle relaxants causeCNSdepression (Table 396-2). Nystagmus is usually present. Carisoprodol, chloral hydrate, chlorphenesin, chlorzoxazone, and methocarbamol also cause nausea

and vomiting. Cyclobenzaprine and orphenadrine cause anticholinergic toxicity, and orphenadrine can cause ventricular tachyarrhythmias, including torsades de pointes. Baclofen can produce hypothermia, excitability, delirium, myoclonus, seizures, cardiac conduction abnormalities, tachycardia, bradycardia, and hypotension. Intrathecal baclofen overdose can lead to precipitous and profound effects. Supraventricular and ventricular tachycardia can occur in chloral hydrate poisoning.GBL andGHB can cause paradoxical agitation, seizures, miosis, and bradycardia in addition to CNS depression. The effects of GBL and GHB typically last only a few hours; the duration of toxicity from other agents is substantially longer. Coma from ethchlorvynol and glutethimide, which are highly lipophilic, and from meprobamate, which can form concretions, can last for several days. With glutethimide, erratic absorption can result in cyclic coma.

Diagnosis The clinical diagnosis is supported by detecting the drugs on comprehensive urine screening. Quantitative measurements of serum levels are not routinely available.

TREATMENT

Activated charcoal is preferred for gastrointestinal decontamination. Repetitive doses may enhance their elimination. The treatment of anticholinergic poisoning is discussed in the section pertaining to these agents. Although arrhythmias due to orphenadrine have responded to physostigmine, they are more likely due to sodium channel blockade than to anticholinergic effects and should probably be treated as described above for class I antiarrhythmics. Cerebrospinal fluid drainage may enhance the elimination of intrathecal baclofen.CNSdepression from zolpidem may respond to flumazenil (see "Benzodiazepines," above). Treatment is otherwise supportive. Extracorporeal hemodynamic support and enhanced elimination procedures should be considered for patients with cardiovascular depression unresponsive to standard therapy.

NEUROLEPTIC AGENTS

Clozapine, chlorprothixene, droperidol, haloperidol, loxapine, molindone, olanzapine, pimozide, quetiapine, risperidone, sertindole, thiothixene, trimethobenzamide, ziprasidone, and the phenothiazines (chlorpromazine, fluphenazine, perphenazine, prochlorperazine, promazine, promethazine, thiethylperazine, thioridazine and its metabolite mesoridazine, trifluoperazine, triflupromazine, trimeperazine) primarily act by blocking type 2 dopamine receptors in theCNS. They also have variable inhibitory activity ata-adrenergic, histaminergic, muscarinic, serotonergic, and other dopamine receptor subtypes. Some phenothiazines have a quinidine-like activity. Acute extrapyramidal effects (dystonia, akathisia, Parkinsonism) result from an imbalance of cholinergic and dopaminergic activity in the basal ganglia. These effects are idiosyncratic rather than dose-related and can be delayed in onset. The neuroleptic malignant syndrome (Chaps. 17 and363) rarely, if ever, occurs following acute overdose.

Neuroleptic agents are well absorbed, exhibit 90 to 95% protein binding in plasma, have large apparent volumes of distribution (10 to 40 L/kg body weight), and are eliminated slowly by hepatic metabolism with half-lives of 10 to 40 h.

Clinical Toxicity Toxic effects begin within 30 to 60 min of ingestion and

includeCNSdepression (Table 396-2), respiratory depression, hypotension, pulmonary edema, and hypothermia. Pupils are often constricted, and the skin is usually warm and dry. Anticholinergic manifestations may be the predominant effect of low overdosage (see "Anticholinergic Agents," above). Cardiac effects include tachycardia, atrioventricular block, and atrial and ventricular arrhythmias. Torsade de pointes; prolonged PR, QRS, and QT intervals; and U- and T-wave abnormalities may be seen with pimozide, mesoridazine, respiridone, thioridazine ingestions and high-dose intravenous droperidol and haloperidol.

Acute dystonic reactions are characterized by sustained muscle contractions resulting in abnormal posturing of the eyes, face, tongue, jaw, neck, back, abdomen, and pelvis. Akathisia is the subjective sensation of motor restlessness, and Parkinsonism is manifest by akinesia and rigidity. Patients may be anxious but remain alert and oriented during these reactions.

Diagnosis The diagnosis is supported by detecting the presence of these agents on toxicologic screening of the urine. Quantitative measurement is not helpful.

TREATMENT

Activated charcoal is the preferred method of gastrointestinal decontamination. Supportive care includes airway protection and mechanical ventilation forCNS and respiratory depression, fluid resuscitation followed by pressors for hypotension, and anticonvulsants for seizures. Diuresis and dialysis are ineffective. Seizures should be treated with benzodiazepines, and hypotension should be managed with volume expanders and pressor agents. Physostigmine may be useful for anticholinergic toxicity (see "Anticholinergic Agents," above). Treatment of ventricular dysrhythmias is the same as described above for class I antiarrhythmics.

Acute extrapyramidal reactions usually respond rapidly to antimuscarinic therapy such as intravenous diphenhydramine (1 mg/kg body weight given over 2 min) or benztropine (1 to 2 mg). Doses may be repeated in 20 min if the response is incomplete. Treatment should be continued with an oral formulation for 2 to 3 days since these reactions can recur in the absence of additional exposure.

NONSTEROIDAL ANTI-INFLAMMATORY DRUGS

Diclofenac, diflunisal, etodolac, fenoprofen, flurbiprofen, ibuprofen, indomethacin, ketoprofen, ketorolac, meclofenamate, mefenamic acid, naproxen, oxaprozin, piroxicam, phenylbutazone, sulindac, and tolmetin inhibit prostaglandin and thromboxane synthesis by blocking cyclooxygenase (COX) isoenzymes: COX-1, the constitutive form in the gastrointestinal tract, kidney, and platelets, and COX-2, an inducible form that becomes expressed in response to bacterial toxins and cytokines (tissue inflammation). They are absorbed rapidly, and blood concentrations peak 1 to 2 h after ingestion. They are highly protein bound (>90%) and have volumes of distribution of less than 1.0 L/kg body weight. They are primarily eliminated by hepatic metabolism. Half-lives range from 1 to 16 h except for phenylbutazone, which has a half-life of 2 to 4 days.

Clinical Toxicity Effects are usually mild and include nausea, vomiting, abdominal pain,

drowsiness, headache, glycosuria, hematuria, and proteinuria. Acute renal failure and hepatitis occur rarely. Diflunisal can cause hyperventilation, tachycardia, and sweating. Coma, respiratory depression, seizures, and cardiovascular collapse may occur with mefenamic acid and phenylbutazone. Ibuprofen can cause metabolic acidosis, coma, and seizures. Metabolic acidosis is relatively common in phenylbutazone poisoning and occurs rarely with naproxen. Seizures can also occur with ketoprofen and naproxen. Preliminary data indicates that selectiveCOX-2 inhibitors, such as celecobix and rofecobix, do not share the toxicity of these nonselective inhibitors.

Diagnosis Comprehensive toxicology screening will identify these drugs in the urine, but quantitative analysis is not useful.

TREATMENT

Activated charcoal is the preferred method of gastrointestinal decontamination. Repeated doses may enhance the elimination of indomethacin, phenylbutazone, and piroxicam. Renal excretion is not increased by diuresis, and protein binding limits the efficacy of hemodialysis. Hemoperfusion might be useful in patients with hepatic or renal failure and severe clinical toxicity. Treatment is otherwise supportive.

ORGANOPHOSPHATE AND CARBAMATE INSECTICIDES

Organophosphorus compounds such as the insecticides chlorpyrifos, phosphorothioic acid (Diazinon), dichlorvos, fenthion, malathion, and parathion and the chemical warfare "nerve gases" such as sarin irreversibly inhibit acetylcholinesterase and cause accumulation of acetylcholine at muscarinic and nicotinic synapses and in theCNS. Carbamates such as the insecticides aldicarb, propoxur (Baygon), carbaryl (Sevin), and bendiocarb (Ficam) and the therapeutic agents ambenonium, neostigmine, physostigmine, and pyridostigmine reversibly inhibit this enzyme. Agents that directly stimulate cholinergic receptors such as arecholine (from betel nuts), bethanechol, pilocarpine, and urecholine have the same effect.

Organophosphates are absorbed through the skin, lungs, and gastrointestinal tract; are distributed widely in tissues; and are slowly eliminated by hepatic metabolism. Oxidative metabolites of parathion and malathion (paraoxon, malaoxon) are the active forms of these agents. Carbamates are eliminated rapidly by serum and liver enzymes.

Clinical Toxicity The time from exposure to the onset of toxicity varies from minutes to hours but is usually between 30 min and 2 h. Muscarinic effects include nausea, vomiting, abdominal cramps, urinary and fecal incontinence, increased bronchial secretions, cough, wheezing, dyspnea, sweating, salivation, miosis, blurred vision, lacrimation, and urinary frequency and incontinence. In severe poisoning, bradycardia, conduction block, hypotension, and pulmonary edema may occur. Nicotinic signs include twitching, fasciculations, weakness, hypertension, tachycardia, and in severe cases paralysis and respiratory failure.CNSeffects include anxiety, restlessness, tremor, confusion, weakness, seizures, and coma. Toxicity due to carbamates is shorter in duration and usually less severe than that due to organophosphates. Most patients recover within 24 to 48 h, but fat-soluble organophosphates may cause effects for weeks to months. Death is most often due to pulmonary toxicity.

Diagnosis A reduction of cholinesterase activity in plasma and in red blood cells to<50% of normal confirms the diagnosis. A reduction in red blood cell cholinesterase activity is more specific; however, this test is less readily available, and some organophosphates inhibit only one type of cholinesterase. With carbamates, depression in plasma or red blood cell cholinesterase levels is transient because of the rapid reversibility of the inhibition. Since cholinesterase assays are not routinely or rapidly available, the initial diagnosis is clinical.

TREATMENT

Contaminated clothing should be removed, and the skin should be washed with soap and water. Gastrointestinal decontamination should include use of activated charcoal. Supportive measures include oxygen administration, ventilatory assistance, and treatment of seizures. Atropine, a muscarinic receptor antagonist, should be administered for muscarinic effects. A dose of 0.5 to 2 mg is given intravenously every 5 to 15 min until bronchial and other secretions have dried. Repeated doses or a constant infusion may be necessary for recurrent toxicity. Pralidoxime (2-PAM) reactivates cholinesterases and is indicated for nicotinic symptoms due to organophosphate poisoning. The use of pralidoxime in carbamate poisoning is controversial. It is usually unnecessary, but its use is safe, particularly if it is administered in conjunction with atropine. A dose of 1 to 2 g is given intravenously over 5 to 30 min (depending on severity). It can be repeated in 30 min if the response is incomplete. Rapid injection can cause tachycardia, laryngospasm, muscle rigidity, and weakness. Repeated doses (every 4 to 6 h) or a continuous infusion (500 mg/h) are indicated for recurrent effects. Neither atropine nor pralidoxime is particularly effective at reversingCNSeffects; seizures should be treated aggressively with benzodiazepines.

SALICYLATES

Aspirin (acetylsalicyclic acid) and salicylate salts have activity similar to that of other nonsteroidal anti-inflammatory drugs described above. Aspirin, but not other salicylates, also inhibits platelet aggregation. Toxic doses increase the sensitivity of respiratory centers in the brain to changes in oxygen and carbon dioxide concentrations. They also uncouple oxidative phosphorylation, increase the rate of metabolism (oxygen consumption, glucose utilization, and carbon dioxide and heat production), and inhibit the Krebs cycle and carbohydrate and lipid metabolism. Metabolic effects lead to respiratory center stimulation and respiratory alkalosis early in the course of poisoning and lactic and ketoacidosis in later stages. Salicylates can also inhibit the hepatic synthesis of clotting factors.

With therapeutic doses, peak serum levels of 0.7 to 1.4 mmol/L (10 to 20 mg/dL) occur 1 to 2 h after ingestion, 50 to 80% is bound to albumin, the volume of distribution is small (0.2 L/kg body weight), and the half-life is 2 to 3 h. Being a weak acid, the unbound portion in the serum exists mainly in an ionized state. Elimination occurs primarily by hepatic metabolism, with about 10% being excreted unchanged.

Although salicylates are absorbed rapidly, absorption may continue for 24 h or longer after an overdose. Acidosis increases the nonionized (diffusable) fraction, and unbound

salicylate promotes its tissue distribution (i.e., increases the volume of distribution). Saturation of metabolic pathways results in a prolonged half-life (20 to 36 h), and renal excretion becomes the most important route of elimination. Alkalinization of the urine enhances renal excretion by converting urinary salicylate to the ionized form, which cannot be reabsorbed.

Clinical Toxicity Initial manifestations occur 3 to 6 h after an overdose of³150 mg/kg and include vomiting, sweating, tachycardia, hyperpnea, fever, tinnitus, lethargy, confusion, respiratory alkalosis with compensatory bicarbonate excretion resulting in an alkaline urine (pH >6). Increases in the rate or depth of respirations may be subtle. Vomiting, diaphoresis, and hyperventilation may lead to dehydration and decreased renal function. As acid products of intermediary metabolism accumulate, increased anion-gap metabolic acidosis and ketosis develop, and their excretion results in the urine becoming acidic (pH<6). In moderate poisoning, both respiratory alkalosis and metabolic acidosis are present, usually with alkalemia and paradoxical aciduria, although the serum pH can be normal. Elevation of the hematocrit, white blood cell count, and platelet count; hypernatremia; hyperkalemia; hypoglycemia; and prolongation of the prothrombin time may be seen. Severe poisoning is manifest by coma, respiratory depression, seizures, cardiovascular collapse, and cerebral and pulmonary edema (both noncardiogenic and cardiogenic). At this stage, metabolic evaluation reveals acidemia (metabolic acidosis with respiratory alkalosis or acidosis) and aciduria.

Diagnosis The diagnosis should be suspected in anyone with an unexplained acid-base disorder. Salicylates are identified by a positive urine ferric chloride test (purple color), which is usually included in routine screening procedures, or quantitative serum analysis. Following acute overdose, a peak level of<2.2 mmol/L (30 mg/dL) is associated with little or no toxicity, one of 2.2 to 7 mmol/L (30 to 100 mg/dL) with mild to moderate effects, and one of >7 mmol/L (100 mg/dL) with severe poisoning. Because of delayed and prolonged absorption, serial levels should be obtained. In chronic poisoning, symptoms may occur at levels only slightly above the therapeutic range.

TREATMENT

Activated charcoal is the preferred method of gastrointestinal decontamination. Repeated doses may enhance elimination. Because of delayed absorption, decontamination may be helpful 12 to 24 h after ingestion. Gastric lavage and whole-bowel irrigation should be considered in patients with ingestions of>500 mg/kg, particularly when toxicity progresses and drug levels continue to rise following charcoal administration. Endoscopy may be useful for the diagnosis and removal of gastric bezoars. A bedside glucose level should be determined in patients with altered mental status. Intravenous saline should be given to replace fluid losses and to produce a brisk urine flow. The degree of dehydration is often underestimated; several liters or more may be necessary. Supplemental glucose and oxygen should also be given. Electrolyte and metabolic abnormalities should be corrected. Coagulopathy should be treated with intravenous vitamin K. Seizures and heart failure are treated with standard therapies. Saline diuresis and urinary alkalinization (to a pH of 8) enhance the elimination of salicylate and should be instituted in symptomatic patients and those with salicylate levels>2.2 mmol/L (30 mg/dL). Depending on severity, 50 to 150 mmol of bicarbonate (along with potassium) can be added to a liter of dextrose-containing saline solution

(such that the final sodium concentration is nearly isotonic) and administered at a rate of 2 to 6 mL/kg per hour. Electrolytes, calcium, acid-base status, urine pH, and fluid balance must be monitored carefully during such therapy. When acidemia is present, bicarbonate should also be given to correct the serum pH, increase the ionization of serum salicylate, and limit its tissue distribution. Diuresis is contraindicated when cerebral or pulmonary edema and renal failure are present. Salicylates are effectively removed by hemodialysis. Indications for hemodialysis include severe clinical toxicity, levels that approach or exceed 7 mmol/L (100 mg/dL) following acute overdose, and contraindications or failure to respond to other treatment modalities.

SEROTONIN SYNDROME

This syndrome is due to excessiveCNS and peripheral serotonergic (5HT-1a and possibly 5HT-2) activity and results from the concomitant use of agents that promote the release of serotonin from presynaptic neurons (e.g., amphetamines, cocaine, codeine, methylenedioxy-methamphetamine or MDMA, reserpine, someMAOinhibitors), inhibit its reuptake (e.g., cyclic antidepressants, particularly theSSRIs, ergot derivatives, dextromethorphan, meperidine, pentazocine, sumatriptan and related agents, tramadol, some MAO inhibitors) or metabolism (e.g., cocaine, MAO inhibitors), or stimulate postsynaptic serotonin receptors (e.g., bromocryptine, bupropion, buspirone, levodopa, lithium, L-tryptophan, lysergic acid diethylamide or LSD, mescaline, trazodone). Less often, it results from the use or overdose of a single serotonergic agent or when one agent is taken soon after another has been discontinued (up to 2 weeks for some agents). Serotonergic effects also appear to have been responsible for pulmonary hypertension and valvulopathy associated with the anorexiants dexfenfluramine and fenfluramine (withdrawn from U.S. markets in 1997).

Clinical Toxicity Onset occurs as early as an hour after single or multiple drug overdose or the addition of another serotonergic agent to current therapy and as a long as several days after increasing the dose of one or more agents. Manifestations include altered mental status (agitation, confusion, delirium, mutism, coma, and seizures), neuromuscular hyperactivity (restlessness, incoordination, hyperreflexia, myoclonus, rigidity, and tremors), and autonomic dysfunction (abdominal pain, diarrhea, diaphoresis, fever, elevated and fluctuating blood pressure, flushed skin, mydriasis, tearing, salivation, shivering, and tachycardia). Complications include hyperthermia, lactic acidosis, rhabdomyolysis, kidney and liver failure,ARDS, and disseminated intravascular coagulation. Effects last from 6 to 48 h, depending on severity.

Diagnosis The diagnosis is based on clinical manifestations and the history of drug exposure. Toxicology testing is useful only for confirming an exposure or detecting an unsuspected one. In contrast to the neuroleptic malignant syndrome (Chap. 363), with which its shares many features, the serotonin syndrome becomes maximal and later resolves over a period of hours rather than days, and there is myclonus and hyperreflexia in contrast to "lead-pipe" rigidity.

TREATMENT

Gastrointestinal decontamination may be indicated for acute overdose. Supportive measures include hydration with intravenous fluids, airway protection and mechanical

ventilation, benzodiazepines (and paralytics, if necessary) for neuromuscular hyperactivity, and mechanical cooling measures for hyperthermia.

The administration of serotonin-receptor antagonists may hasten the resolution of this syndrome. Cyproheptadine (Periactin), an antihistamine with 5HT-1a and 5HT2 receptor blocking activity, and chlorpromazine (Thorazine), a nonspecific serotonin receptor antagonist, have been used with success. Cyproheptadine is given orally or by gastric tube in an initial dose of 4 to 8 mg and repeated as necessary every 2 to 4 h up to a maximum of 32 mg in 24 h. A response is usually noted in 1 to 2 h but may be absent in severe cases. Chlorpromazine has the advantage that it can be given parenterally (intramuscularly or by slow intravenous injection in doses of 50 to 100 mg). Since it can cause hypotension, its use should be preceded by adequate fluid hydration. The use of chlorpromazine for the neuroleptic malignant syndrome misdiagnosed as the serotonin syndrome, and conversely, the use of bromocriptine for the serotonin syndrome misdiagnosed as the neuroleptic malignant syndrome may result in worsening of symptoms. Other medications with variable success in treating the serotonin syndrome include propranolol, methysergide, and dantrolene.

SYMPATHOMIMETICS

Amphetamines (amphetamine itself, benzphetamine, dextroamphetamine, diethylpropion, methamphetamine, phendimetrazine, phentermine), cathinone (from khat, or the plant *Catha edulis*), ephedrine, mazindol, methylphenidate, and pemoline directly stimulate a- andb-adrenergic receptors. Some also induce the release of dopamine and norepinephrine. Phenylephrine, pseudoephedrine, and phenylpropanolamine primarily stimulate a receptors, whereas mephentermine and bronchodilators such as albuterol, bitoterol, isoetherine, etaproterenol, pirbuterol, and salmeterol primarily stimulateb receptors.

These agents are readily absorbed, with peak serum levels occurring 1 to 2 h after ingestion (sooner after nasal insufflation and with the "ice" or crystalline form of methamphetamine, which, like crack cocaine, can be smoked). They are weak bases with volumes of distribution of 2 to 6 L/kg body weight. Elimination occurs by a combination of hepatic metabolism and renal excretion of unchanged drug. Half-lives range from 2 to 34 h. Excretion is enhanced in an acid urine and slowed in an alkaline one.

Clinical Toxicity Effects are seen within 30 to 60 min after ingestion and include nausea, vomiting, abdominal cramps, and headache as well as manifestations of adrenergic andCNSstimulation (Table 396-2). Although hypertension and tachycardia occur with nonselective agents, hypertension with reflex bradycardia, and evenAVblock, may occur with agents that have predominantly alpha effects. Tachycardia with hypotension (as a result of vasodilation) can be seen with selectiveb agonists. Other findings may include combativeness, auditory and visual hallucinations, dilated pupils, dry mouth, pallor, and tachypnea. Complications include lactic acidosis, rhabdomyolysis, and intracranial hemorrhage. b-Adrenergic stimulation causes potassium to move into cells and may result in hypokalemia.

Diagnosis The diagnosis is supported by finding these agents in the urine by toxicology

screening. Quantitative measurement is not useful.

TREATMENT

Activated charcoal is the preferred method of gastrointestinal decontamination. Benzodiazepines or barbiturates should be used to control neuromuscular hyperactivity and to treat seizures. A nonselective adrenergic blocker such as labetalol or the selective a-adrenergic antagonist phentolamine (1 to 5 mg intravenously every 5 min until the desired response is achieved) with or without a cardioselective beta blocker such as esmolol are recommended for severe or symptomatic hypertension; propranolol or a cardioselective beta blocker is recommended for severe or symptomatic tachycardia. Lidocaine and propranolol are preferred for the treatment of ventricular tachyarrhythmias. Hyperthermia should be treated with external cooling measures along with sedation and, if necessary, paralyzing agents. Although theoretically effective for enhancing drug elimination, acid diuresis is not recommended due to lack of documented clinical efficacy and risks of side effects such as worsening of acidosis and potential triggering of myoglobinuric renal failure.

THEOPHYLLINE

Theophylline, caffeine, and other methylxanthines are phosphodiesterase inhibitors that reduce the degradation of intracellular cyclic AMP, thereby enhancing the actions of endogenous catecholamines and leading to b-adrenergic stimulation. Theophylline is absorbed rapidly from the stomach and upper small bowel. Following overdose, serum levels peak 1 to 2 h after ingestion of liquid preparations, 2 to 4 h after ingestion of tablets, and 6 to 24 h after ingestion of sustained-release preparations. Theophylline is approximately 60% bound to albumin and has a low volume of distribution (0.6 L/kg body weight). Therapeutic serum levels are 55 to 110 umol/L (10 to 20 mg/L). Elimination occurs primarily by hepatic metabolism, which is saturable at levels in the high therapeutic range. The serum half-life, normally 4 to 6 h, is therefore prolonged in overdoses. Elimination is also decreased with impaired liver function, congestive heart failure, viral infections, and concomitantly administered drugs such as cimetidine, erythromycin, fluoroquinolones, and tetracycline.

Clinical Toxicity Effects begin 30 min to 2 h following overdose and include nausea, vomiting, psychomotor excitation, pallor, diaphoresis, tachypnea, tachycardia, and muscle tremors. Severe poisoning is characterized by coma, seizures, respiratory depression, cardiac arrhythmias, hypotension, and rhabdomyolysis. Seizures can be focal and are often protracted, repetitive, and resistant to therapy. Both atrial and ventricular tachyarrhythmias, including ventricular fibrillation, can occur. Hypotension develops only after acute overdose. Ketosis, metabolic acidosis, hyperamylasemia, hyperglycemia, hypokalemia, hypocalcemia, and hypophosphatemia may also be seen in acute poisoning.

Diagnosis The diagnosis is confirmed by measuring a serum drug level. Theophylline is not readily detected by routine urine screening. Wtih chronic exposure, arrhythmias and seizures occur at lower serum levels (200 to 300 umol/L, or 40 to 60 mg/L) than the levels seen after acute overdose (400 to 500 umol/L, 80 to 100 mg/L). Because of prolonged and delayed absorption after overdosage, particularly with sustained-release

preparations, levels should be measured serially to determine the peak concentration.

TREATMENT

Activated charcoal is the preferred method of gastrointestinal decontamination. With sustained-release forms, whole-bowel irrigation should also be considered. Antiemetics are often required for vomiting. Seizures and neuromuscular hyperactivity should be treated with benzodiazepines and barbiturates and pharmacologic paralysis in refractory cases; phenytoin is ineffective. Intravenous propranolol is preferred for the treatment of tachyarrhythmias. It can also reverse hypotension, which results from b_2-adrenergic stimulation. Although b_2 receptor blockade can potentially cause bronchospasm in those with reactive or obstructive airway disease, this has not been reported when propranolol has been used in this setting. The selective beta$_1$ blocker esmolol can also be used for supraventricular tachycardias, and ventricular tachycardias can be treated with lidocaine or other antiarrhythmics. Volume expansion and an a agonist such as norepinephrine can be given for hypotension. Repeated doses of charcoal shorten the serum half-life of theophylline by approximately 50% and are recommended for all patients. Hemodialysis and hemoperfusion are effective in removing theophylline and are indicated for patients with severe clinical toxicity or a serum drug level equal to or greater than that associated with such toxicity.

397. DISORDERS CAUSED BY REPTILE BITES AND MARINE ANIMAL EXPOSURES - *Robert L. Norris, Paul S. Auerbach*

Few topics in medicine are as controversial or as influenced by tradition as the management of bites and stings from venomous creatures. Because the incidence of serious bites and stings is relatively low in developed nations, there remains a paucity of relevant clinical research and literature, and therapeutic decision-making is often based on anecdotal information. Furthermore, the responses of different species to various toxins make it difficult to extrapolate data from animal studies to clinical application. This chapter outlines general principles for the evaluation and management of victims of venom poisoning or intoxication by certain reptiles and marine creatures and presents a clinical approach to these emergencies.

VENOMOUS SNAKEBITE

EPIDEMIOLOGY

The venomous snakes of the world are grouped into the families Viperidae (subfamily Viperinae: the Old World vipers; subfamily Crotalinae: the New World and Asian pit vipers), Elapidae (including the cobras, coral snakes, and all Australian venomous snakes), Hydrophiidae (the sea snakes), Atractaspididae (the burrowing asps), and Colubridae (a large group of which only a few species are dangerously toxic to humans). The highest bite rates occur in temperate and tropical regions where people subsist by manual agriculture. Global estimates suggest that 30,000 to 40,000 persons die each year from venomous snakebite, but this range is likely an underestimate because of incomplete reporting.

SNAKE ANATOMY/IDENTIFICATION

The typical snake-venom apparatus consists of bilateral venom glands -- one on each side of the head, below and behind the eye -- connected by ducts to hollow, anterior maxillary teeth. In viperids (vipers and pit vipers), these teeth are long, mobile fangs that retract against the roof of the mouth when the animal is at rest. In elapids and sea snakes, the fangs are less enlarged and are fixed in an erect position. Venomous snakes can bite without injecting venom. Approximately 20% of pit viper bites and an even higher percentage of bites inflicted by some other snake families (e.g., up to 75% for sea snakes) are "dry."

Differentiation of venomous from nonvenomous snake species can be difficult. Viperids are characterized by somewhat triangular heads (a feature shared with many harmless snakes); elliptical pupils (also seen in some nonvenomous snakes, such as boas and pythons); enlarged maxillary fangs; subcaudal scalation that involves a single scale running the full width of the ventral surface of the tail for several rows just distal to the anal plate (as opposed to two scales in each subcaudal row for most nonvenomous snakes); and, in the case of pit vipers, the heat-sensing pits (foveal organs located slightly inferior and anterior to the eyes on each side) for which they are named. Color pattern is notoriously misleading in identifying most venomous snakes except for the coral snakes, whose other body characteristics are similar to those of harmless colubrids. The American coral snakes can be identified by red, yellow (or white), and

black bands completely encircling the body; a few species have red and black bands only. North of Mexico City, the immediate contiguity of red and yellow bands is fairly reliable for distinguishing a coral snake from its many harmless mimics. Further south, differentiation by color pattern is more problematic.

In many areas of the world, enzyme-linked immunoassay (ELISA) kits are available to aid in determining the specific snake species involved in a bite. These kits identify venom in the victim's blood, urine, or wound aspirate. No such kit is commercially available in the United States, however.

VENOMS AND CLINICAL MANIFESTATIONS

Snake venoms are complex mixtures of enzymes, low-molecular-weight polypeptides, glycoproteins, and metal ions. Among the deleterious components are hemorrhagins that promote vascular leaking and cause both local and systemic bleeding. Various proteolytic enzymes cause local tissue necrosis, affect the coagulation pathway at various steps, and impair organ function. Myocardial depressant factors reduce cardiac output, and neurotoxins act either pre- or postsynaptically to inhibit peripheral nerve impulses. Most snake venoms have multisystem effects in their victims.

TREATMENT

Field Management Initial (prehospital) measures should focus on rapidly delivering the victim to definitive medical care while keeping him/her as inactive as possible to limit systemic spread of venom. Any other measures employed should at least do no further harm to the victim.

After viperid bites, local mechanical suction applied to the site within 3 to 5 min may remove a small percentage of deposited venom. A useful device is the Extractor (Sawyer Products, Safety Harbor, FL), which delivers one atmosphere of negative pressure to the wound. Suction should be continued for at least 30 min. Mouth suction should be avoided as it inoculates the wound with oral flora and theoretically can also result in the absorption of venom by the rescuer through lesions of the upper digestive tract. If the victim is >60 min from medical care, a proximal lympho-occlusive constriction band may limit the spread of venom when applied within 30 min. To avoid worsening tissue damage, however, the band should not interrupt arterial blood flow. The bitten extremity should be splinted if possible and kept at approximately heart level. Measures to be avoided include incising or cooling the bite site, giving the victim an alcoholic beverage, or applying electric shocks.

For elapid or sea snake bites, the Australian pressure-immobilization technique, in which the entire bitten extremity is wrapped with an elastic or crepe bandage and then splinted, is highly effective. The bandage is applied with the same snugness used for a sprained ankle. This technique greatly restricts absorption and circulation of venom. The utility of this method in viperid poisoning requires further research, as it theoretically could compound local tissue damage by restricting venom to the local tissues.

Hospital Management In the hospital, the victim should be closely monitored (vital signs, cardiac rhythm, and oxygen saturation) while a history is quickly obtained and a

brief but thorough physical examination is performed. The level of erythema and/or swelling in a bitten extremity should be marked and limb circumferences measured in several locations every 15 min until swelling has stabilized. Large-bore intravenous access in unaffected extremities should be established. Early hypotension is due to pooling of blood in the pulmonary and splanchnic vascular beds. Hours later, hemolysis and loss of intravascular volume into soft tissues may play important roles. Fluid resuscitation with normal saline or Ringer's lactate should be initiated for clinical shock. If the blood pressure response is inadequate after administration of 20 to 40 mL/kg of body weight, then a trial of 5% albumin (10 to 20 mL/kg) is in order. If tissue perfusion fails to respond to volume resuscitation and antivenom infusion (see below), vasopressors (e.g., dopamine) should be administered. Invasive hemodynamic monitoring (central venous and/or pulmonary arterial pressures) can be helpful in such cases, although obtaining access is riskier if coagulopathy is present.

Blood should be drawn for laboratory evaluation as soon as possible. Blood typing and cross-matching procedures can be affected over time by circulating venom. Also important are a complete blood count to evaluate the degree of hemorrhage or hemolysis, studies of renal and hepatic function, coagulation studies to identify signs of consumptive coagulopathy, and testing of urine for blood or myoglobin. In severe cases or in the face of significant comorbidity, arterial blood gas studies, electrocardiography, and chest radiography are indicated.

Attempts to locate a source of appropriate antivenom should begin early in all cases of known venomous snakebite, regardless of symptoms. In the event that signs and symptoms progress rapidly, any delay in the administration of antivenom is dangerous. Antivenoms rarely offer cross-protection against snake species other than those used in their production unless the species are closely related. An example of good cross-protection is that of Australian tiger snake (*Notechis scutatus*) antivenom for sea snake bites (see below). The package insert accompanying a particular antivenom should be consulted for information regarding the spectrum of coverage. In the United States, assistance in finding antivenom can be obtained 24 hours a day from the University of Arizona Poison and Drug Information Center (telephone: 520-626-6016).

Rapidly progressive or severe local findings (soft tissue swelling, ecchymosis, petechiae, etc.) or manifestations of systemic toxicity (signs and symptoms or laboratory abnormalities) are indications for the administration of intravenous antivenom. The package insert outlines techniques for reconstitution of antivenom (when necessary), skin-testing procedures (for potential allergy), and appropriate starting doses. Most commercial antivenoms are of equine origin and carry a risk of anaphylactic, anaphylactoid, and delayed-hypersensitivity reactions. Skin testing does not reliably predict which patients will have an allergic reaction to equine antivenom; false-negative and false-positive results are common. Before antivenom infusion, the patient should receive appropriate loading doses of intravenous antihistamines (e.g., diphenhydramine, 1 mg/kg to a maximum of 100 mg; and cimetidine, 5 to 10 mg/kg to a maximum of 300 mg) in an effort to limit acute reactions. Modest expansion of the patient's intravascular volume with crystalloids may also be beneficial in this regard. Epinephrine should be immediately available, and the antivenom dose to be administered should be diluted (e.g., in 1000 mL of normal saline for adults or in 20 mL/kg for children). This volume can be decreased if necessary (e.g., if the victim has a history of congestive heart

failure). The antivenom should be started slowly, with the physician at the bedside to intervene in the event of an acute reaction. The rate of infusion can be increased gradually in the absence of allergic phenomena until the total starting dose has been administered (over a total period of 1 to 4 h). Further antivenom may be necessary if the patient's clinical condition worsens. Laboratory values should be rechecked hourly, particularly if abnormal, until stability is apparent.

The management of a life-threatening envenomation in a victim with an apparent allergy to antivenom requires significant expertise. Consultation with a poison specialist, an intensive care specialist, and/or an allergist is recommended. Often antivenom can still be administered in these situations under closely controlled conditions and with intensive premedication (e.g., with epinephrine, antihistamines, and steroids).

Care of the bite wound should include application of a dry sterile dressing and splinting of the extremity with padding between the digits. Once the administration of an indicated antivenom has been initiated, the extremity should be elevated above heart level to relieve edema. Tetanus immunization should be updated as appropriate. The use of prophylactic antibiotics is controversial, as the incidence of secondary infection following venomous snakebite appears to be low. Many authorities, however, prescribe a broad-spectrum antibiotic (such as ampicillin or a cephalosporin) for the first few days.

If swelling in the bitten extremity raises concern that subfascial muscle edema may be impeding tissue perfusion (muscle-compartment syndrome), intracompartmental pressures should be checked by any minimally invasive technique (e.g., the wick catheter). If pressures are elevated and remain so despite antivenom administration, prompt surgical consultation for possible fasciotomy should be obtained. This complication, fortunately, is rare after snakebites.

Whether or not antivenom is given, any patient with signs of venom poisoning should be observed in the hospital for at least 24 h. A patient with an apparently "dry" bite should be watched for at least 6 to 8 h before discharge, as significant toxicity occasionally develops after a delay of several hours. The onset of systemic symptoms is commonly delayed for a number of hours after bites by several of the elapids (including the coral snakes) and sea snakes. Patients bitten by these reptiles should be observed in the hospital for 24 h.

Significant work is being done in several regions of the world to produce safer, more effective antivenoms. Much of this work involves production of ovine-based antivenoms that are further purified and enzymatically cleaved to yield functional F(ab) fragments of the immunoglobulin molecules. These antivenoms are currently in clinical use in many countries, and trials of one product are under way in the United States.

MORBIDITY AND MORTALITY

The overall mortality rates for venomous snakebite are low in areas of the world with rapid access to medical care and appropriate antivenom. In the United States, for example, the mortality rate is <1% for victims who receive antivenom. Eastern and western diamondback rattlesnakes (*Crotalus adamanteus* and *C. atrox*, respectively) are responsible for most snakebite deaths in the United States. Snakes responsible for

large numbers of deaths in other regions of the world include the cobras (*Naja* spp.) of Asia and Africa, the carpet and saw-scaled vipers (*Echis* spp.) of the Middle East and Africa, Russell's viper (*Daboia russelli*) of the Middle East and Asia, the large African vipers (*Bitis* spp.), and the lancehead pit vipers (*Bothrops* spp.) of Central and South America.

The incidence of morbidity in terms of permanent functional loss in a bitten extremity is difficult to estimate but is probably substantial. Such loss may be due to muscle, nerve, or vascular injury or to scar contracture. In the United States, such loss due to snakebite tends to be much more common and severe after rattlesnake bites than after bites by copperheads or water moccasins.

LIZARD BITES

Bites from the two species of venomous lizards (the gila monster, *Heloderma suspectum*, of the southwestern United States and the Mexican beaded lizard, *H. horridum*) are infrequent and usually follow attempts to capture or handle these creatures. The wounds are characterized by soft tissue trauma with surrounding local edema and occasionally local cyanosis and ecchymosis. Broken teeth may be embedded in the wounds. The venom contains proteases and phospholipases. Systemic effects may include hypotension, weakness, dizziness, and diaphoresis.

Prehospital care measures for these bites should follow the guidelines listed above for viperid bites. If the biting lizard is still attached to the victim, its jaws may need to be manually pried apart for removal.

The sparseness of data on the pathophysiologic effects of helodermatid venom precludes specific recommendations regarding laboratory evaluation, but routine studies (complete blood count, coagulation studies, electrolyte analysis, blood typing and cross-matching, urinalysis, and electrocardiography) are prudent in anything other than a trivial bite. Wounds should be cleansed thoroughly and irrigated when possible. Tetanus immunization should be updated as indicated. Soft tissue radiography of the bite site and sterile probing under local anesthesia may identify retained teeth. The extremity should be splinted and elevated, but antibiotic treatment is not usually required. Systemic care is supportive (e.g., crystalloid infusion for hypotension). No commercial antivenom exists. Pain due to local venom effects and mechanical trauma can be treated with opiates and regional nerve blocks. The mortality rate is extremely low.

MARINE ENVENOMATIONS

Management of venom poisoning by marine creatures is similar to that of venomous snakebite in that much of the treatment administered is supportive in nature. A few specific marine antivenoms can be used when appropriate.

INVERTEBRATES

Hydroids, fire coral, jellyfish, Portuguese man-of-war, and *sea anemones* possess specialized stinging cells called nematocysts. The venoms from these organisms are

mixtures of proteins, carbohydrates, and other components. The clinical syndrome following envenomation by any of these species is similar but of variable severity. Victims usually report immediate prickling or burning, pruritus, paresthesia, and painful throbbing with radiation. A legion of neurologic, cardiovascular, respiratory, rheumatologic, gastrointestinal, renal, and ocular symptoms have been described. Victims in unstable condition with hypotension or respiratory distress should be treated supportively. During stabilization, the skin should be immediately decontaminated with a forceful jet of vinegar (5% acetic acid) or rubbing alcohol (40 to 70% isopropyl alcohol), which inactivates nematocysts. For the venomous *box-jellyfish* (*Chironex fleckeri*;Plate IID-53), vinegar should be used. Perfume, aftershave lotion, and high-proof ethanol are less efficacious and may be detrimental. Shaving the skin helps remove remaining nematocysts. Freshwater irrigation and rubbing lead to further stinging by adherent nematocysts and should be avoided. After decontamination, application of anesthetic ointments (lidocaine, benzocaine), antihistamine creams (diphenhydramine), or steroid lotions (hydrocortisone) may be helpful. Persistent pain following decontamination may be treated with morphine or meperidine. Muscle spasms may respond to 10% calcium gluconate (5 to 10 mL) or diazepam (2 to 5 mg, titrated upwards as necessary) given intravenously. An antivenom is available from Commonwealth Serum Laboratories (see section on antivenom sources, below) for stings from the box-jellyfish found in Australian waters.

Touching a *sea sponge* may result in dermatitis. If contact occurs, the skin should be gently dried and adhesive tape used to remove embedded spicules. Vinegar should be applied immediately and then for 10 to 30 min three or four times a day. Rubbing alcohol may be used if vinegar is unavailable. After spicule removal and skin decontamination, a steroid or antihistamine cream may be applied to the skin. Severe vesiculation should be treated with a 2-week course of systemic glucocorticoids.

Annelid worms (bristleworms) possess rows of soft, cactus-like spines capable of inflicting painful stings. Contact results in symptoms similar to those of nematocyst envenomation. Without treatment, pain usually subsides over several hours, but inflammation may persist for up to a week. Victims should resist the urge to scratch, since scratching may fracture retrievable spines. Visible bristles should be removed with forceps and adhesive tape, a commercial facial peel, or a thin layer of rubber cement. Use of vinegar, rubbing alcohol, or dilute ammonia or a brief application of unseasoned meat tenderizer (papain) may provide additional relief. Local inflammation should be treated with topical or systemic glucocorticoids.

Sea urchins possess either hollow, venom-filled, calcified spines or triple-jawed, globiferous pedicellariae with venom glands. Their venom contains several toxic components, including steroid glycosides, hemolysins, proteases, serotonin, and cholinergic substances. Contact with either venom apparatus produces immediate and intensely painful stings. The affected part should be immersed immediately in hot water (see below). Accessible embedded spines should be removed but may break off and remain lodged in the victim. Residual dye from the surface of a spine remaining after the spine's removal may mimic a retained spine but is otherwise of no consequence. Soft tissue radiography or magnetic resonance imaging can confirm the presence of retained spines; this finding may warrant referral for attempted surgical removal if the spines are located near vital structures (e.g., joints, neurovascular bundles). Retained spines may

cause the formation of granulomas that are amenable to excision or to intralesional injection with triamcinolone hexacetonide (5 mg/mL).

Cone shells are predatory, carnivorous mollusks. The most dangerous of these creatures are found in the Indian and Pacific oceans. A neurotoxic venom comprising multiple peptides is delivered through harpoon-like darts propelled from an extensible proboscis. Clinically, the sting is like that of a bee. The victim may report wound, perioral, and generalized paresthesias. Bulbar dysfunction and systemic muscular paralysis indicate severe envenomation. The sting of the geographer cone (*Conus geographus*) can cause cerebral edema, coma, and death due to respiratory or cardiac failure. Immediately after envenomation, a circumferential pressure-immobilization dressing 15 cm wide should be applied over a gauze pad measuring approximately 7 ´ 7´ 2 cm that has been placed directly over the sting. The dressing should be applied at venous-lymphatic pressure with the preservation of distal arterial pulses. Once the victim has been transported to the nearest medical facility, the bandage can be released. Provision should be made for cardiovascular and respiratory support.

Serious envenomations and deaths have followed bites of the *Australian blue-ringed octopuses* (*Octopus maculosus* and *O. lunulata*). Although these animals rarely exceed 20 cm in length, their venom contains a potent neurotoxin (maculotoxin) that inhibits peripheral nerve transmission by blocking sodium conductance. Within several minutes of a serious envenomation, oral and facial numbness develops and rapidly progresses to total flaccid paralysis, including failure of respiratory muscles. If respirations are assisted, the victim may remain awake although completely paralyzed. Since there is no antidote, treatment is supportive. Immediately after envenomation, attempts should be made to limit the dispersion of venom by application of a pressure-immobilization or venous-lymphatic pressure dressing. Hot-water immersion and cryotherapy are ineffective. Artificial respiration should be provided. Even with serious envenomations, significant recovery often takes place within 4 to 10 h. Sequelae are uncommon unless related to hypoxia.

VERTEBRATES

A number of marine vertebrates, including stingrays, scorpionfish, catfish, surgeonfish, and weeverfish, can envenom humans. The management of most of these stings is similar.

A *stingray* injury is both an envenomation and a traumatic wound. The venom, which contains serotonin, 5¢-nucleotidase, and phosphodiesterase, causes immediate and intense pain that may last up to 48 h. Systemic effects include weakness, diaphoresis, nausea, vomiting, diarrhea, dysrhythmias, syncope, hypotension, muscle cramps, fasciculations, paralysis, and (in rare cases) death.

The designation *scorpionfish* encompasses members of the family Scorpaenidae and includes not only scorpionfish but also lionfish and stonefish. A complex venom with neuromuscular toxicity is delivered through 12 or 13 dorsal, two pelvic, and three anal spines. Pectoral spines do not contain venom. The severity of envenomation depends on the species of fish, the number of stings, and the amount of venom released. In general, the sting of a stonefish is regarded as the most serious (severe to

life-threatening); that of the scorpionfish is of intermediate seriousness; and that of the lionfish is the least serious. Like that of a stingray, the sting of a scorpionfish is immediately and intensely painful. Pain from a stonefish envenomation may last for days. The systemic manifestations are similar to those of stingray envenomations but may be more pronounced, particularly in the case of a stonefish sting. The rare deaths following stonefish envenomation usually occur within 6 to 8 h.

Two species of marine *catfish*, *Plotosus lineatus* (the oriental catfish) and *Galeichthys felis* (the common sea catfish), as well as several species of freshwater catfish are capable of stinging humans. Venom is delivered through a single dorsal spine and two pectoral spines. Clinically, a catfish sting is comparable to that of a stingray, although marine catfish envenomations are generally more severe than those of their freshwater counterparts. *Surgeonfish* (doctorfish, tang), *weeverfish*, and *horned venomous sharks* have also been implicated in human envenomations.

The stings of all these marine vertebrates are treated in a similar fashion. Except for stonefish and serious scorpionfish envenomations (see below), no antivenom is available. The affected part should be immersed immediately in nonscalding hot water (113°F/45°C) for 30 to 90 min or until there is significant relief of pain. This measure also helps inactivate the heat-labile components of the venoms. Recurrent pain may respond to repeated hot-water treatment. Cryotherapy is contraindicated. Opiates will help alleviate the pain, as will local wound infiltration or regional nerve block with 1% lidocaine, 0.5% bupivacaine, and sodium bicarbonate mixed in a 5:5:1 ratio. After soaking and anesthetic administration, the wound must be explored and debrided. Radiography may be helpful in the identification and location of foreign bodies. After exploration and debridement, the wound should be vigorously irrigated with warm sterile water, saline, or 1% povidone-iodine in solution. Bleeding can usually be controlled by sustained local pressure for 10 to 15 min. In general, wounds should be left open to heal by secondary intention or be treated by delayed primary closure. Tetanus immunization should be updated. Antibiotic treatment should be considered for serious wounds and for envenomation in immunocompromised hosts. The initial antibiotics should cover *Staphylococcus* and *Streptococcus* spp. If the victim is immunocompromised or an infection develops, antibiotic coverage should be broadened to include *Vibrio* spp.

Approach to the Patient

It is not uncommon for a physician to encounter a patient who has been envenomed by a marine creature that cannot be positively identified at the scene of the envenomation. Therefore, it is useful to be familiar with the local marine fauna and to recognize patterns of injury.

A large puncture wound or jagged laceration, particularly on the lower extremity, that is more painful than one would expect from the size and configuration of the wound is likely a stingray envenomation. Smaller punctures, as described above, represent the activity of a sea urchin or starfish. Stony corals cause rough abrasions and, in rare instances, lacerations or puncture wounds.

Coelenterate (marine invertebrate) stings sometimes create diagnostic skin patterns. A diffuse urticarial rash on exposed skin is often indicative of exposure to fragmented

hydroids or larval anemones. A linear, whiplike print pattern appears where a jellyfish tentacle has contacted the skin. In the case of the dreaded box-jellyfish (Plate IID-53), a frosted cross-hatched appearance followed by dark purple coloration within a few hours of the sting heralds skin necrosis. An encounter with fire coral causes immediate pain and a red, swollen skin irritation in the pattern of contact, similar to but more severe than the imprint left by exposure to an intact feather hydroid. Seabather's eruption, caused by thimble jellyfishes and larval anemones, may cause a diffuse rash that consists of clusters of erythematous macules or raised papules, accompanied by intense itching. Toxic sponges (exposure to which usually occurs during handling) create a burning and painful red rash on exposed skin, which may blister and later desquamate. Virtually all marine stingers invoke the sequelae of inflammation, so that local erythema, swelling, and adenopathy are fairly nonspecific.

SOURCES OF ANTIVENOMS AND OTHER ASSISTANCE

An antivenom for stonefish (and severe scorpionfish) envenomation, made in Australia by the Commonwealth Serum Laboratories (CSL; 45 Poplar Road, Parkville, Victoria, Australia 3052; 61-3-389-1911; fax: 61-3-389-1434), is available in the United States through the pharmacies of Sharp Cabrillo Hospital Emergency Department, San Diego, CA, at (619) 221-3429, and Community Hospital of Monterey Peninsula (CHOMP) Emergency Department, Monterey, CA, at (408) 625-4900.

Polyvalent sea snake antivenom is available from CSL or CHOMP. If sea snake antivenom is unavailable, tiger snake (*N. scutatus*) antivenom should be used.

Divers Alert Network, a nonprofit organization designed to assist in the care of injured divers, may also help with the treatment of marine injuries. The network can be reached 24 h a day at (919) 684-8111 or on the Internet athttp://www.dan.ycg.org.

MARINE POISONINGS

CIGUATERA

Ciguatera poisoning is the most common nonbacterial food poisoning associated with fish in the United States. The poisoning involves almost exclusively tropical and semitropical marine coral reef fish. Of reported cases, 75% (except in Hawaii) involve the barracuda, snapper, jack, or grouper. The ciguatera syndrome is associated with at least five toxins, all of which are unaffected by freeze-drying, heat, cold, and gastric acid and none of which affects the odor, color, or taste of fish.

The onset of symptoms may come within 15 to 30 min of ingestion and typically takes place within 1 to 3 h. Symptoms then increase in severity over the ensuing 4 to 6 h. Most victims develop symptoms within 12 h of ingestion, and virtually all are afflicted within 24 h. The more than 150 symptoms reported include abdominal pain, nausea, vomiting, diarrhea, chills, paresthesias, pruritus, tongue and throat numbness or burning, sensation of "carbonation" during swallowing, odontalgia or dental dysesthesias, dysphagia, dysuria, dyspnea, weakness, fatigue, tremor, fasciculations, athetosis, meningismus, aphonia, ataxia, vertigo, pain and weakness in the lower extremities, visual blurring, transient blindness, hyporeflexia, seizures, nasal congestion

and dryness, conjunctivitis, maculopapular rash, skin vesiculations, dermatographism, sialorrhea, diaphoresis, headache, arthralgias, myalgias, insomnia, bradycardia, hypotension, central respiratory failure, and coma. Death is rare.

Diarrhea, vomiting, and abdominal pain usually develop 3 to 6 h after ingestion of a ciguatoxic fish. Symptoms may persist for 48 h and then generally resolve (even without treatment). A pathognomonic symptom is the reversal of hot and cold tactile perception, which develops in some persons after 3 to 5 days and may last for months. Tachycardia and hypertension have been described, in some cases after potentially severe transient bradycardia and hypotension. More severe reactions tend to occur in persons previously stricken with the disease. Persons who have ingested parrotfish (scaritoxin) may suffer from classic ciguatera poisoning as well as a "second-phase" syndrome (after 5 to 10 days' delay) of disequilibrium with locomotor ataxia, dysmetria, and resting or kinetic tremor. This affliction may persist for 2 to 6 weeks.

The differential diagnosis of ciguatera includes paralytic shellfish poisoning, eosinophilic meningitis, type E botulism, organophosphate insecticide poisoning, tetrodotoxin poisoning, and psychogenic hyperventilation. At present, the diagnosis of ciguatera poisoning is made on clinical grounds because no routinely used laboratory test detects ciguatoxin in human blood. A ciguatoxin enzyme immunoassay or radioimmunoassay may be used to test small portions of the suspected fish.

Therapy is supportive and based on symptoms. Although not of proven efficacy, gastric lavage or syrup of ipecac-induced emesis followed by the administration of a slurry of activated charcoal (100 g) in sorbitol may be of limited value if performed within 3 h after ingestion. Nausea and vomiting may be controlled with an antiemetic, such as prochlorperazine (2.5 to 5 mg intravenously). Hypotension may require the administration of intravenous crystalloid and, in rare cases, a pressor drug. Bradyarrhythmias that lead to cardiac insufficiency and hypotension generally respond well to atropine (0.5 mg intravenously, up to 2 mg). Cool showers or the administration of hydroxyzine (25 mg orally every 6 to 8 h) may relieve pruritus. Amitriptyline (25 mg orally twice a day) reportedly ameliorates pruritus and dysesthesias. In three cases unresponsive to amitriptyline, tocainide appeared to be efficacious. Intravenous infusion of mannitol may be beneficial in moderate or severe cases, particularly for the relief of distressing neurologic or cardiovascular symptoms. The infusion is rendered initially as 1 g/kg per day over 45 to 60 min during the acute phase (days 1 to 5). The mechanism of the benefit against ciguatera intoxication is hyperosmotic water-drawing action, which reverses ciguatoxin-induced Schwann cell edema. Mannitol may also act in some fashion as a "hydroxyl scavenger."

During recovery from ciguatera poisoning, the victim should exclude the following from the diet: fish (fresh or preserved), fish sauces, shellfish, shellfish sauces, alcoholic beverages, and nuts and nut oils. Consumption of fish in ciguatera-endemic regions should be avoided. All oversized fish of any predacious reef species should be suspected of harboring ciguatoxin. Neither moray eels nor the viscera of tropical marine fish should ever be eaten.

PARALYTIC SHELLFISH POISONING

Paralytic shellfish poisoning (PSP) is induced by the ingestion of any of a variety of feral or aquacultured filter-feeding organisms, including clams, oysters, scallops, mussels, chitons, limpets, starfish, and sand crabs. The origin of their toxicity is the chemical toxin they accumulate and concentrate by feeding on various planktonic dinoflagellates and protozoan organisms. The unicellular phytoplanktonic organisms form the foundation of the food chain, and in warm summer months these organisms "bloom" in nutrient-rich coastal temperate and semitropical waters. A number of dinoflagellates produce a variety of toxins. These planktonic species can release massive amounts of toxic metabolites into the water and cause enormous mortality in bird and marine populations. The paralytic shellfish toxins are water-soluble as well as heat- and acid-stable; they cannot be destroyed by ordinary cooking. The best-characterized and most frequently identified paralytic shellfish toxin is saxitoxin, which takes its name from the Alaska butter clam *Saxidomus giganteus*. A toxin concentration of >75 ug/100 g of foodstuff is considered hazardous to humans. In the 1972 New England "red tide," the concentration of saxitoxin in blue mussels exceeded 9000 ug/100 g of foodstuff. Saxitoxin appears to block sodium conductance, inhibiting neuromuscular transmission at the axonal and muscle membrane levels.

Within minutes to a few hours after ingestion of contaminated shellfish, there is the onset of intraoral and perioral paresthesias, notably of the lips, tongue, and gums, that progress rapidly to involve the neck and distal extremities. The tingling or burning sensation later changes to numbness. Other symptoms rapidly develop and include lightheadedness, disequilibrium, incoordination, weakness, hyperreflexia, incoherence, dysarthria, sialorrhea, dysphagia, thirst, diarrhea, abdominal pain, nausea, vomiting, nystagmus, dysmetria, headache, diaphoresis, loss of vision, chest pain, and tachycardia. Flaccid paralysis and respiratory insufficiency may follow 2 to 12 h after ingestion. In the absence of hypoxia, the victim often remains alert but paralyzed.

Treatment is supportive and based on symptoms. If the victim comes to medical attention within the first few hours after poison ingestion, the stomach should be emptied by gastric lavage and then irrigated with 2 L (in 200-mL aliquots) of a solution of 2% sodium bicarbonate. The administration of activated charcoal (50 to 100 g) and a cathartic (sorbitol, 20 to 50 g) makes empirical sense but has not been proved effective. Some authors advise against administration of magnesium-based solutions, such as certain cathartics, cautioning that hypermagnesemia may contribute to suppression of nerve conduction.

The most serious problem is respiratory paralysis. The victim should be closely observed in a hospital for at least 24 h for respiratory distress. With prompt recognition of ventilatory failure, endotracheal intubation and assisted ventilation prevent anoxic myocardial and brain injury.

DOMOIC ACID INTOXICATION

In late 1987 in eastern Canada, an outbreak of gastrointestinal and neurologic symptoms (amnestic shellfish poisoning) occurred after consumption of mussels found to be contaminated with domoic acid. A heat-stable neuroexcitatory amino acid whose biochemical analogs are kainic acid and glutamic acid, domoic acid binds to the kainate type of glutamate receptor with three times the affinity of kainic acid and is 20 times as

powerful a toxin. Mussels can be tested for domoic acid by mouse bioassay and high-performance liquid chromatography. The regulatory limit for domoic acid in shellfish is 20 parts per million.

The abnormalities noted within 24 h of ingesting contaminated mussels *(Mytilus edulis*) include arousal, confusion, disorientation, and memory loss. The median time of onset is 5.5 h. Other prominent symptoms include severe headache, nausea, vomiting, diarrhea, abdominal cramps, hiccoughs, arrhythmias, hypotension, seizures, ophthalmoplegia, hemiparesis, mutism, grimacing, agitation, emotional lability, coma, copious bronchial secretions, and pulmonary edema. Histologic study of brain tissue taken at autopsy has shown neuronal necrosis or cell loss and astrocytosis, most prominently in the hippocampus and the amygdaloid nucleus -- findings similar to those in animals poisoned with kainic acid. Several months after the primary intoxication, victims still demonstrate chronic residual memory deficits and motor neuronopathy or axonopathy. Nonneurologic illness does not persist.

Therapy is supportive and based on symptoms. Since kainic acid neuropathology seems to be nearly entirely seizure mediated, an emphasis should be placed on anticonvulsive therapy, for which diazepam appears to be as effective as any other drug.

SCOMBROID

Scombroid (mackerel-like) fish include the albacore, bluefin, and yellowfin tuna; mackerel; saury; needlefish; wahoo; skipjack; and bonito. Nonscombroid fish that produce scombroid poisoning include the dolphinfish (mahimahi, *Coryphaena*), kahawai, sardine, black marlin, pilchard, anchovy, herring, amberjack, and Australian ocean salmon. In the northeastern and mid-Atlantic United States, bluefish has been linked to scombroid poisoning. Because greater numbers of nonscombroid fish are being recognized as scombrotoxic, the syndrome may more appropriately be called *pseudoallergic fish poisoning*.

Under conditions of inadequate preservation or refrigeration, the musculature of these dark- or red-fleshed fish undergoes bacterial decomposition, which includes the decarboxylation of the amino acid L-histidine to histamine, histamine phosphate, and histamine hydrochloride. Histamine levels of >20 to 50 mg/100 g are noted in toxic fish, with levels in excess of 400 mg/100 g on occasion. The toxin is heat stable and is not destroyed by domestic or commercial cooking. Affected fish typically have a sharply metallic or peppery taste; however, they may be normal in appearance, color, and flavor.

Symptoms occur within 15 to 90 min of ingestion and include flushing (sharply demarcated; exacerbated by ultraviolet exposure; particularly pronounced on the face, neck, or upper trunk), a sensation of warmth without elevated core temperature, conjunctival hyperemia, pruritus, urticaria, angioneurotic edema, bronchospasm, nausea, vomiting, diarrhea, epigastric pain, abdominal cramps, dysphagia, headache, thirst, pharyngitis, burning of the gingiva, palpitations, tachycardia, dizziness, and hypotension. Without treatment, the symptoms generally resolve within 8 to 12 h. The reaction may be more severe in a person who is concurrently ingesting isoniazid

because of blockade of gastrointestinal tract histaminase.

Therapy is directed at reversing the histamine effect with antihistamines, either H-1 or H-2. If bronchospasm is severe, an inhaled bronchodilator -- or in rare, extremely severe circumstances, injected epinephrine -- may be used. Glucocorticoids are of no proven benefit. Protracted nausea and vomiting, which may empty the stomach of toxin, may be controlled with a specific antiemetic, such as prochlorperazine. The persistent headache of scombroid poisoning may respond to cimetidine or a similar antihistamine if standard analgesics are not effective.

PFIESTERIA

In the summer of 1997, reports of adverse reactions after casual exposure to Maryland waters infested with the fish-eating dinoflagellate *Pfiesteria* prompted the Centers for Disease Control and Prevention (CDC) to undertake multistate surveillance and to establish a case definition. As defined by the CDC, the human disease syndrome associated with *Pfiesteria* is characterized by either of two groups of signs and symptoms: (1) memory loss, confusion, or acute skin burning on direct contact with infested water; or (2) at least three of the following: headache, rash (flat red sores), eye irritation, upper respiratory irritation, muscle cramps, and gastrointestinal symptoms. Since the initial reports from Maryland, many such cases have followed both casual exposure to infested water and laboratory work with *Pfiesteria* (which is currently conducted in biohazard III facilities).

Research on *Pfiesteria* has been complicated by a variety of factors, including the lack of a test for detection of its toxins, which have yet to be purified, and the organism's complex life cycle, which includes at least two dozen stages. In nature, the proximity of a school of fish elicits *Pfiesteria's* transformation into a flagellated zoospore that releases at least two toxins: a water-soluble, neuroactive toxin that kills fish within minutes, and a fat-soluble toxin that causes epidermal delamination. Polluted environments appear to favor *Pfiesteria*.

For the treatment of *Pfiesteria*-associated syndromes, one teaspoon of milk of magnesia followed by one scoop of cholestyramine in 8 ounces of water and 70% sorbitol solution is administered daily for 2 weeks.

398. ECTOPARASITE INFESTATIONS, ARTHROPOD BITES AND STINGS - *James H. Maguire*, *Andrew Spielman*

Ectoparasites are arthropods or helminths that *infest* the skin of other animals from which they derive sustenance. They may penetrate beneath the surface of the host or attach superficially by their mouthparts. These organisms damage their hosts by inflicting direct injury, by eliciting a hypersensitivity reaction, or by inoculating toxins or pathogens. The main medically important ectoparasites are arachnids (including mites and ticks), insects (including lice, fleas, and flies), pentastomes (tongue worms), and leeches. Arthropods may also harm humans through brief encounters in which they take a blood meal or attempt to defend themselves by biting, stinging, or inoculating venoms. Various arachnids (spiders, scorpions), insects (including bees, hornets, wasps, ants, flies, bugs, caterpillars, and beetles), millipedes, and centipedes produce ill effects in this manner, as do certain ectoparasites of animals, including ticks, biting mites, and fleas (discussed in this chapter as biting arthropods). More people in the United States die each year as a consequence of arthropod stings than from poisonous snake bites.

ECTOPARASITE INFESTATIONS

SCABIES

The human itch mite, *Sarcoptes scabiei* (Fig. 398-CD1), which infests some 300 million persons each year, is one of the most common causes of itching dermatoses throughout the world. Gravid female mites measuring 0.3 to 0.4 mm in length burrow superficially beneath the stratum corneum for a month, depositing two or three eggs a day. Nymphs that hatch from these eggs mature in about 2 weeks through a series of molts and then emerge as adults to the surface of the skin, where they mate and subsequently reinvade the skin of the same or another host. Transfer of newly fertilized female mites from person to person occurs by intimate personal contact and is facilitated by crowding, uncleanliness, and multiple sexual partners. Medical practitioners are at particular risk of infestation. Transmission via sharing of contaminated bedding or clothing is infrequent because these mites cannot survive much more than a day without host contact. In the United States, scabies may account for 2 to 5% of visits to dermatologists; involved particularly often are children, immigrants from developing countries, and close household contacts. Outbreaks occur in nursing homes, mental institutions, and hospitals.

The itching and rash associated with scabies derive from a sensitization reaction directed against the excreta that the mite deposits in its burrow (Plate IID-52). For this reason, an initial infestation remains asymptomatic for 4 to 6 weeks, and a reinfestation produces a hypersensitivity reaction without delay. Scratching generally destroys the burrowing mite, but symptoms remain even in its absence. Burrows become surrounded by infiltrates of eosinophils, lymphocytes, and histiocytes, and a generalized hypersensitivity rash later develops in remote sites. By destroying these pathogens, immunity and associated scratching limit most infestations to fewer than 15 mites per person. Hyperinfestation with thousands or millions of mites, a condition known as *crusted scabies* or *Norwegian scabies*, may result from glucocorticoid use, immunodeficiency diseases (including AIDS and infection with human T-lymphotropic virus type I), and neurologic and psychiatric illnesses that interfere with itching and

scratching.

Patients with scabies report intense itching that worsens at night and after a hot shower. Typical burrows may be difficult to find because they are few in number and may be obscured by excoriations. Burrows appear as dark wavy lines in the epidermis, measure 3 to 15 mm, and end in a small pearly bleb that contains the female mite. Such lesions generally develop on the volar wrists, between the fingers, on the elbows, and on the penis. Small papules and vesicles, often accompanied by eczematous plaques, pustules, or nodules, are symmetrically distributed in these sites (Fig. 398-CD2) and in skin folds under the breasts and around the navel, axillae, belt line, buttocks, upper thighs, and scrotum. Except in infants, the face, scalp, neck, palms, and soles are spared. Burrows and other typical lesions may be sparse in persons who wash frequently, and topical glucocorticoid treatment and bacterial superinfection may alter the appearance of the rash. Atypical presentations of scabies include bullous lesions, which resemble those of bullous pemphigoid, and vesicular lesions, which resemble those of dermatitis herpetiformis. Superinfection with nephritogenic strains of streptococci has led to acute glomerulonephritis. Crusted scabies resembles psoriasis in its typical widespread erythema, thick keratotic crusts, scaling, and dystrophic nails. Characteristic burrows are not seen in crusted scabies, and patients usually do not itch, although their infestations are highly contagious and have been responsible for outbreaks of classic scabies in hospitals. Bacteremia occurs frequently in AIDS patients with crusted scabies and prominent fissures. Persons with massive infestations occasionally present with diffuse pruritus and generalized papules or with minimal or no cutaneous signs.

A diagnosis of scabies should be considered in patients with pruritus and symmetric polymorphic skin lesions in characteristic locations, particularly if there is a history of household contact with a case. Burrows should be sought and unroofed with a sterile needle or scalpel blade, and the scrapings should be examined microscopically for the mite, its eggs, and its fecal pellets. A drop of mineral oil facilitates removal of the sample. Biopsies or scrapings of papulovesicular lesions may also be diagnostic. In the absence of identifiable mites or mite products, the diagnosis is based on clinical presentation and history. The possibility of other sexually transmitted diseases should be excluded in adults with scabies.

TREATMENT

For the treatment of scabies, 5% permethrin cream is less toxic than the once commonly used 1% lindane preparations and is effective against lindane-tolerant infestations. Both scabicides are applied thinly but thoroughly behind the ears and from the neck down after bathing and are removed 8 h later with soap and water. Lindane is absorbed through the skin, and its overuse has led to seizures and aplastic anemia. It should not be applied to pregnant women or infants. Alternatives include topical crotamiton cream, benzyl benzoate, and sulfur ointments. Successful treatment of crusted scabies requires the application first of a keratolytic agent such as 6% salicylic acid (to improve the penetration of scabicides) and then of scabicides to the scalp, face, and ears (with care to avoid the eyes). Repeated treatments or the sequential use of several agents may be necessary. A single oral dose of ivermectin (200 ug/kg) effectively treats scabies in otherwise healthy persons. Patients with crusted scabies

may require two or more doses of ivermectin. Although ivermectin may become the agent of choice for treating crusted scabies, it has not yet received approval by the U.S. Food and Drug Administration (FDA) for any form of scabies. Its use should be reserved for persons who fail to respond to topical scabicides, the elderly, persons with generalized eczema, and other persons who may not tolerate topical therapy.

Although effectively treated scabies infestations become noninfectious within a day, itching and rash due to hypersensitivity frequently persist for weeks or months. Unnecessary re-treatment of the affected patients may provoke contact dermatitis. Antihistamines, salicylates, and calamine lotion relieve itching during treatment, and topical glucocorticoids are useful for the pruritus that lingers after effective treatment. An oral antibiotic may be necessary for bacterial superinfections that fail to resolve with antiscabietic therapy. Relapses of scabies may be due to infestations of the scalp when topical therapy is applied only from the neck down. To prevent reinfestations, bedding and clothing should be washed in hot water, and close contacts, even if asymptomatic, should be treated simultaneously.

OTHER MITE INFESTATIONS

Species of *Demodex*, the follicle mite, live in hair follicles and sebaceous glands of the face and ears. The wormlike mites measure up to 0.4 mm in length and, if carefully sought, can be found on almost all persons. They appear not to cause disease, although their density is high in persons with rosacea. House dust mites of the genus *Dermatophagoides* infest houses throughout the world, living on furniture and rugs and feeding on shed human dander. Exposure to their allergens causes asthma, rhinitis, conjunctivitis, and eczema in persons with house dust allergies. Management includes immunotherapy with mite extracts and environmental interventions such as frequent vacuuming and removal of rugs from bedrooms to reduce mite density.

PEDICULOSIS (LOUSE INFESTATIONS)

All three species of human louse feed at least once a day on human blood. *Pediculus humanus* var. *capitis* (Fig. 398-CD3) infests the head (Fig. 398-CD4), *P. humanus* var. *corporis* the clothing (Fig. 398-CD5), and *Phthirus pubis* (Fig. 398-CD6) mainly the hair of the pubis (Fig. 398-CD7). Females cement their eggs (nits) firmly to hair or clothing. The saliva of lice produces an intensely irritating maculopapular or urticarial rash in sensitized persons.

Head lice, which infest an estimated 6 to 12 million people in the United States, are transmitted directly from person to person and occasionally by shared headgear and grooming implements. The prevalence is highest among school-aged girls who wear long hair; in the United States, black children are less frequently infested than other children. Excoriations of pruritic lesions on the scalp, neck, and shoulders lead to oozing, crusting, matting of hair, bacterial infections, and regional lymphadenopathy. Adult lice are frequently seen crawling in the hair with a velocity that approaches 25 mm/min.

Body lice remain in clothing except when feeding and cannot survive more than a few hours away from the human host. It follows, therefore, that *P. humanus* var. *corporis*

mainly infests disaster victims or indigent persons who do not change their clothes. Transmission by direct contact or by sharing of clothing and beds is enhanced under crowded conditions. The fact that the body louse leaves febrile persons or corpses as they become cold facilitates the transmission of typhus, louse-borne relapsing fever, and trench fever (Chap. 177). Trench fever and endocarditis due to *Bartonella quintana* have emerged as diseases of homeless persons living in large cities of the United States and Europe. Pruritic lesions are particularly common around the neckline. Chronic infestations result in the postinflammatory hyperpigmentation and thickening of skin known as *vagabonds' disease*.

The cosmopolitan crab or pubic louse is transmitted mainly by sexual contact but can infest eyelashes, axillary hair, and hair in other sites as well as pubic hair. Children with pubic lice generally acquire their infestations from parents rather than via sexual transmission. Polymerase chain reaction (PCR) analysis of the blood meal of lice permits identification of host DNA in cases of child abuse or rape. Intensely pruritic lesions and 2- to 3-mm blue macules (maculae ceruleae) develop at the site of bites. Blepharitis commonly accompanies infestations of the eyelashes.

A suspected diagnosis of pediculosis is confirmed by the finding of nits or adult lice on hairs or in clothing. The dorsoventrally flattened adult lice measure 2 to 4 mm in length and have three pairs of legs ending in claws that enable them to grasp hair shafts or clothing. Oval nits measure 0.8 mm in length and are opaque white or cream-colored (body and head lice) or dark brown (pubic lice).

TREATMENT

The preferred treatment is a 10-min application of 1% permethrin creme rinse, which kills both lice and eggs and is available without prescription. An alternative, 0.5% malathion, requires a prescription and must be left in place for 8 to 12 h. Other agents, such as the more toxic 1% lindane and pyrethrins with piperonyl butoxide, are not ovicidal and require a second application 1 week after the first to kill hatching nymphs. Dead or hatched nits, which remain attached to hair sheaths and become translucent or opalescent, may falsely suggest an active infection. Resistance of head lice to permethrin, malathion, and lindane has been reported. When a properly applied treatment fails, a higher concentration (5%) of permethrin may be tried or the class of pediculicide changed (e.g., by switching from permethrin to malathion). Ivermectin may be useful in cases of resistance to both malathion and permethrin but has not been approved for this purpose by theFDA.

After louse infestations have been treated with insecticide, the hair should be combed with a fine-toothed nit comb to remove nits. Combs and brushes should be disinfected in hot water at 65°C for 5 min or soaked in insecticide for 1 h. Body lice can be eliminated by bathing and application of topical pediculicides from head to foot. Clothes and bedding are deloused by heat sterilization in a dryer at 65°C for 30 min or by fumigation. Infestations with pubic lice are treated with topical pediculicides except for eyelid infestations (*phthiriasis palpebrum*), which respond to a coating of petroleum applied for 3 to 4 days or 1% yellow oxide of mercury ointment applied four times daily for 2 weeks.

TUNGIASIS

Tunga penetrans, like other fleas, is a wingless, laterally flattened insect measuring 2 to 4 mm in length that feeds on blood. Also known as the chigoe flea, sand flea, or jigger, it occurs in tropical regions of Africa and the Americas. Adults live in sandy soil and burrow under the skin between toes, under nails, or on the soles of bare feet. The fleas engorge on blood and grow from pinpoint to pea size over a 2-week period. The lesions resemble a white pustule with a central black depression and may be pruritic or painful. Occasional complications include tetanus, bacterial infections, and autoamputation of toes. Tungiasis is treated by removal of the intact flea with a sterile needle or scalpel, tetanus vaccination, and topical antibiotics.

MYIASIS

Myiasis refers to infestations by maggots, mainly due to the larvae of metallic-colored screw-worm flies or botflies. Maggots invade living or necrotic tissue or body cavities and produce different clinical syndromes depending on the species of fly.

Furuncular Myiasis (Fig. 398-CD8) In forested parts of Central and South America, larvae of *Dermatobia hominis* (the human botfly) produce boil-like subcutaneous nodules 2 to 3 cm in diameter. The adult female captures a mosquito or other bloodsucking insect and deposits her eggs beneath its abdomen. When the carrier insect attacks a human or bovine host several days later, the warmth and moisture of the host's surface stimulate the larvae to hatch and penetrate the skin. After 6 to 12 weeks, the larvae mature and drop to the ground, where they pupate. The African tumbu fly, *Cordylobia anthropophaga*, produces similar lesions. Dozens of eggs are deposited on sand or drying laundry that is contaminated with urine or sweat. Larvae hatch on contact with the body, penetrate the skin, and produce boils from which they emerge 8 or 9 days later. A diagnosis of furuncular myiasis is suggested by uncomfortable lesions with a central breathing pore that emits bubbles when submerged in water. There is often a sensation of movement under the skin that may lead to severe emotional distress. Tumbu fly larvae can be removed by manual expression after the air pore is coated with petroleum to suffocate the larvae and induce them to emerge. Removal of *Dermatobia* larvae is facilitated by injection of a local anesthetic into the surrounding tissue, but surgical excision is often necessary because up-pointing spines hold the larva firmly in place.

Creeping Dermal Myiasis Maggots of the horse botfly, *Gasterophilus intestinalis*, do not mature after penetrating human skin but migrate for weeks in the epidermis. The resulting pruritic and serpiginous eruption resembles cutaneous larva migrans caused by *Ancylostoma braziliense*. Horseback riders become infested when eggs deposited on the flank of the horse hatch against their bare legs. The black spines of the larvae can be identified after mineral oil is smeared over the lesion. Larva are removed with a needle. The larvae of the cattle botfly (*Hypoderma* species) invade more deeply and produce boil-like swellings.

Wound (Fig. 398-CD9) and Body Cavity Myiasis Certain flies are attracted to blood and pus, and their newly hatched larvae enter wounds or diseased skin. Larvae of species such as *Phaenicia sericata*, the green-bottle fly, remain superficial and confined to necrotic tissue and were used in the past to debride purulent wounds. Other species,

including the screw-worms (*Chrysomyia bezziana* in Asia and Africa and *Cochliomyia hominivorax* in Latin America) and the flesh fly (*Wohlfahrtia vigil* in northern North America), invade more deeply into viable tissue and produce large suppurating lesions. Larvae that infest wounds also may infest body cavities such as the mouth, nose, ears, sinuses, anus, vagina, and lower urinary tract, particularly in unconscious or otherwise debilitated patients. The consequences range from harmless colonization to destruction of the nose, meningitis, and deafness. Treatment involves removal of maggots and debridement of tissue.

Other Forms of Myiasis The maggots responsible for furuncular and wound myiasis may also cause ophthalmomyiasis. Sequelae include nodules in the eyelid, retinal detachment, and destruction of the globe. In addition, the adult sheep botfly, *Oestrus ovis*, may deposit larvae in the eyes of persons tending sheep and goats, and the larvae may produce a conjunctival infestation and acute conjunctivitis. True intestinal myiasis occurs when eggs or larvae of the drone fly (*Eristalis tenax*) are ingested with contaminated food, mature in the gut, and cause enteritis. Most instances in which maggots are found in human feces are the result of larviposition by flesh flies on recently passed stools.

PENTASTOMIASIS

Pentastomids, or tongue worms, are parasites with characteristics of both helminths and arthropods and are classified in a separate phylum. The wormlike adults inhabit the respiratory passages of reptiles and carnivorous mammals. Human infestation with *Linguatula serrata* is common in the Middle East and occurs in the Sudan following ingestion of encysted larval stages in raw liver or lymph nodes of sheep and goats, the intermediate hosts. The larvae migrate to the nasopharynx and produce an acute self-limiting syndrome known as *halzoun* (*Marrara* in the Sudan), which is characterized by pain and itching of the throat and ears, coughing, hoarseness, dysphagia, and dyspnea. Severe edema may cause obstruction and necessitate tracheostomy, and ocular invasion has been described. Diagnostic larvae measuring 5 to 10 mm in length are found in the copious nasal discharge or vomitus. Human beings become infected with *Armillifer armillatus* by ingesting eggs in contaminated food or drink or after handling the definitive host, the African python. Larvae encyst in various organs but rarely cause symptoms unless they compress vital structures or perforate an organ during migration. Cysts occasionally require surgical removal as they enlarge during molting, but they are usually encountered as an incidental finding at autopsy. There are reports of the cutaneous larva migrans syndrome due to other pentastomes (*Reighardia* and *Sebekia* species) in Southeast Asia and Central America.

LEECH INFESTATIONS

Medically important leeches are annelid worms that attach to their hosts with chitinous cutting jaws and draw blood with muscular suckers. The medicinal leech, *Hirudo medicinalis*, is still used occasionally to reduce venous congestion in surgical flaps or replanted body parts. This practice has been complicated by wound infections, myonecrosis, and sepsis due to *Aeromonas hydrophila*, which colonizes the gullets of commercially available leeches.

Ubiquitous aquatic leeches that parasitize fish, frogs, and turtles readily attach to the skin of human beings and avidly suck blood. More notorious are the land leeches (*Haemadipsa*) that live in moist vegetation of tropical rain forests. Attachment is usually painless. Hirudinin, a powerful anticoagulant secreted by the leech, causes continued bleeding after the leech has detached. Healing of the wound is slow, and bacterial infections are not uncommon. Several species of aquatic leeches in Africa, Asia, and southern Europe can enter through the mouth, nose, and genitourinary tract and attach to mucosal surfaces at sites as deep as the esophagus and trachea. Bleeding may be intense. Externally attached leeches are removed by steady gentle traction. Removal is hastened by application of alcohol, salt, vinegar, or a flame to the leech. Internally attached leeches may detach on exposure to gargled saline or may be removed by forceps.

DELUSIONAL INFESTATIONS

The groundless conviction that one is infested with arthropods or other parasites is an extremely difficult disorder to treat and unfortunately is not rare. Patients report infestations of their skin, clothing, or homes and describe sensations of something moving in or on their skin. Excoriations often accompany complaints of pruritus or insect bites. Patients bring in as evidence of infestation specimens that are identified microscopically as plant-feeding or peridomestic arthropods, pieces of skin, vegetable matter, or inanimate objects. In suspected cases, it is imperative to rule out true infestations and neuropathies, environmental irritants such as fragments of fiberglass, and other causes of tingling or prickling sensations. Pharmacotherapy with pimozide, which blocks dopamine receptors, has been more helpful than psychotherapy in treating this disorder.

ARTHROPOD BITES AND STINGS

SPIDER BITES

Of the>30,000 recognized species of spider, only about 100 defend themselves aggressively and have fangs sufficiently long to penetrate human skin. The venom that spiders use to immobilize and digest their prey can cause necrosis of skin and systemic toxicity. While the bites of most spiders are painful but not harmful, envenomations of the brown or fiddle spiders (*Loxosceles* species), widow spiders (*Latrodectus* species), and other species may be life-threatening. Identification of the offending spider should be attempted, since specific treatments exist for bites of widow and brown recluse spiders and since injuries attributed to spiders are frequently due to other causes.

Recluse Spider Bites and Necrotic Arachnidism Severe necrosis of skin and subcutaneous tissue follows envenomation by *Loxosceles reclusa*, the brown recluse spider, and by at least four other species of *Loxosceles* in the southern and midwestern United States. Other spiders that produce necrotic ulceration include the hobo spider (*Tegenaria agrestis*) in the Pacific Northwest, the sac spiders (*Chiracanthium* species) throughout the United States and abroad, the South American brown spider *Loxosceles laeta* in Central and South America, and other *Loxosceles* species in Africa and the Middle East. All these spiders measure 7 to 15 mm in body length and 2 to 4 cm in leg span. Recluse spiders are brown and have a dark violin-shaped spot on their dorsal

surface; hobo spiders are brown with gray markings; and sac spiders may be pale yellow, green, or brown.

These spiders are not aggressive toward human beings and bite only if threatened or pressed against the skin. They hide under rocks and logs or in caves and animal burrows, and they emerge at night to hunt other spiders and insects. They invade homes, particularly in the fall, and seek dark and undisturbed hiding spots in closets, in folds of clothing, or under furniture and rubbish in storage rooms, garages, and attics. Bites often occur while the victim is dressing and are sustained primarily to the arms, neck, and lower abdomen.

The clear viscous venoms of these spiders contain an esterase, alkaline phosphatase, protease, and other enzymes that produce tissue necrosis and hemolysis. Sphingomyelinase B, the most important dermonecrotic factor, binds cell membranes and promotes chemotaxis of neutrophils, leading to vascular thrombosis and an Arthus-like reaction. Initially, the bite is painless or produces a stinging sensation. Within the next few hours, the site becomes painful and pruritic, with central induration surrounded by a pale zone of ischemia and a zone of erythema. In most cases, the lesion resolves without treatment over 2 to 3 days. In severe cases, the erythema spreads, and the center of the lesion becomes hemorrhagic and necrotic with an overlying bulla. A black eschar forms and sloughs several weeks later, leaving an ulcer that may be ^{3}25 cm in diameter and eventually a depressed scar. Healing usually takes place within 3 to 6 months but may take as long as 3 years if adipose tissue is involved. Local complications include injury to nerves and secondary infection. Fever, chills, weakness, headache, nausea, vomiting, myalgia, arthralgia, maculopapular rash, and leukocytosis may develop within 72 h of the bite. In rare instances, acute complications such as hemolytic anemia, hemoglobinuria, and renal failure are fatal.

TREATMENT

Initial management includes local cleansing, application of sterile dressings and cold compresses, and elevation and loose immobilization of the affected limb. Analgesics, antihistamines, antibiotics, and tetanus prophylaxis should be administered if indicated. Within the first 48 to 72 h, the administration of dapsone, a leukocyte inhibitor, may halt the progression of lesions that are becoming necrotic. Dapsone is given in oral doses of 50 to 100 mg twice daily after glucose-6-phosphate dehydrogenase deficiency has been ruled out. The efficacy of locally or systemically administered glucocorticoids has not been demonstrated, and a potentially useful *Loxosceles*-specific antivenin has not been approved for use in the United States. Debridement and later skin grafting may be necessary after signs of acute inflammation have subsided, but immediate surgical excision of the wound is detrimental. Patients should be monitored closely for signs of hemolysis, renal failure, and other systemic complications.

Widow Spider Bites The bite of the female widow spider is notorious for the effect of its potent neurotoxin. *Latrodectus mactans*, the black widow, has been found in every state of the United States except Alaska and is most abundant in the southeast. It measures up to 1 cm in body length and 5 cm in leg span, is shiny black, and has a red hourglass marking on the ventral abdomen. Other dangerous North American *Latrodectus* species include *L. geometricus* (the brown widow), *L. bishopi* (the red widow), *L. variolus*, and *L.*

hesperus, and there are related species in other temperate and subtropical parts of the world.

Widow spiders spin their webs under stones, logs, plants, or rock piles or in dark spaces in barns, garages, and outhouses. Bites are most common in the summer and early autumn and occur when the web is disturbed or when the spider is trapped or provoked. The buttocks or genitals are sites of bites incurred by humans while sitting in an outdoor privy.

The initial bite goes unnoticed or is perceived as a sharp pinprick. Two small red marks, mild erythema, and edema develop at the fang entrance site. The oily yellow venom that is injected does not produce local necrosis, and some persons experience no other symptoms. However, a-latrotoxin, the most active component of the venom, binds irreversibly to nerves and causes release and eventual depletion of acetylcholine, norepinephrine, and other neurotransmitters from presynaptic terminals. Within 30 to 60 min, painful cramps spread from the bite site to large muscles of the extremities and the trunk. Extreme rigidity of the abdominal muscles and excruciating pain may suggest peritonitis, but the abdomen is not tender on palpation. Other features include salivation, diaphoresis, vomiting, hypertension, tachycardia, labored breathing, anxiety, headache, weakness, fasciculations, paresthesia, hyperreflexia, urinary retention, uterine contractions, and premature labor. Rhabdomyolysis and renal failure have been reported, and respiratory arrest, cerebral hemorrhage, or cardiac failure may end fatally, especially in very young, elderly, or debilitated persons. The pain begins to subside during the first 12 h but may recur during several days or weeks before resolving spontaneously.

TREATMENT

Treatment consists of local cleansing, application of ice packs, and tetanus prophylaxis. Hypertension that does not respond to analgesics and antispasmodics, such as benzodiazepines or methocarbamol, requires specific antihypertensive medication. Intravenous administration of one or two vials of a widely available equine antivenin rapidly relieves pain and can be life-saving. Because of the risk of anaphylaxis and serum sickness, antivenin should be reserved for severe cases involving respiratory arrest, uncontrollable hypertension, seizures, or pregnancy.

Envenomations by Tarantulas and Other Spiders Tarantulas are long-lived, hairy spiders of which 30 species are found in the United States, primarily in the southwest. The tarantulas that have become popular household pets are usually imported species with bright colors and a leg span of up to 25 cm. Tarantulas bite only when threatened and cause no more harm than a bee sting, but the venom occasionally provokes deep pain and swelling. Several species are covered with urticating hairs that are launched in the thousands when a threatened spider rubs its hind legs across the dorsal abdomen. These hairs penetrate human skin and produce pruritic papules that last for weeks. Failure to wear gloves or to wash the hands after handling the Chilean Rose tarantula, the most popular pet spider, has resulted in transfer of hairs to the eye and devastating ocular inflammation. Treatment of bites includes local washing and elevation of the bitten area, tetanus prophylaxis, and analgesic administration. Antihistamines and topical or systemic glucocorticoids are given for exposure to urticating hairs.

Atrax robustus, the Sydney funnel-web spider of Australia, and *Phoneutria* species, the South American banana spiders, are among the most dangerous spiders in the world because of their aggressive behavior and potent neurotoxins. Envenomation by *A. robustus* causes a rapidly progressive neuromotor syndrome that can be fatal within 2 h. The bite of the banana spiders causes severe local pain followed by profound systemic symptoms and respiratory paralysis that can lead to death within 2 to 6 h. Specific antivenins for envenomation by each of these spiders are available. *Lycosa* species (wolf spiders) are found throughout the world and may produce painful bites and transient local inflammation.

SCORPION STINGS

Scorpions are crablike arachnids that feed on ground-dwelling arthropods and small lizards, which they grasp with a pair of frontal pinchers and paralyze by injecting venom from a stinger on the tip of the tail. Painful but relatively harmless scorpion stings need to be distinguished from the potentially lethal envenomations that are produced by about 30 of the approximately 1000 known species and cause more than 5000 deaths worldwide each year. Scorpions feed at night and remain hidden during the day in crevices or burrows or under wood, loose bark, or rocks on the ground. They seek cool spots under buildings and often enter houses, where they get into shoes, clothing, or bedding or enter bathtubs and sinks in search of water. Scorpions sting human beings only when disturbed.

Scorpions of the United States Of the 40 or so scorpion species in the United States, only the bark scorpion (*Centruroides sculpturatus* or *C. exilicauda*) produces a venom that can be lethal. Stings of the other species, such as the common striped scorpion *C. vittatus* and the large *Hadrurus arizonensis*, cause immediate sharp local pain followed by edema, ecchymosis, and a burning sensation. Symptoms typically resolve within a few hours, and skin does not slough. Allergic reactions to the venom sometimes develop.

The deadly *C. sculpturatus* of the southwestern United States and northern Mexico measures about 7 cm in length and is yellow-brown in color. Its venom contains neurotoxins that cause sodium channels to remain open and neurons to fire repetitively. In contrast to the stings of nonlethal species, *C. sculpturatus* envenomations are usually associated with little swelling, but prominent pain, paresthesia, and hyperesthesia can be accentuated by tapping on the affected area (the tap test). These symptoms soon spread to other locations; dysfunction of cranial nerves and hyperexcitability of skeletal muscles develop within hours. Patients present with restlessness, blurred vision, abnormal eye movements, profuse salivation, lacrimation, rhinorrhea, slurred speech, difficulty in handling secretions, diaphoresis, nausea, and vomiting. Muscle twitching, jerking, and shaking may be mistaken for a seizure. Complications include tachycardia, arrhythmias, hypertension, hyperthermia, rhabdomyolysis, and acidosis. Symptoms progress to maximal severity in about 5 h and subside within a day or two, although pain and paresthesia can last for weeks. Fatal respiratory arrest is most common among young children and the elderly.

Other Dangerous Scorpions Envenomations by *Leiurus quinquestriatus* in the Middle

East and North Africa, by *Mesobuthus tamulus* in India, by *Androctonus* species along the Mediterranean littoral and in North Africa and the Middle East, and by *Tityus serrulatus* in Brazil cause massive release of endogenous catecholamines with hypertensive crises, arrhythmias, pulmonary edema, and myocardial damage. Acute pancreatitis occurs with stings of *Tityus trinitatis* in Trinidad, and central nervous toxicity complicates stings of *Parabuthus* and *Buthotus* scorpions of South Africa. Tissue necrosis and hemolysis may follow stings of the Iranian *Hemiscorpius lepturus*.

TREATMENT

Identification of the offending scorpion aids in planning therapy. Stings of nonlethal species require at most ice packs, analgesics, or antihistamines. Because most victims of dangerous envenomations (such as those produced by *C. sculpturatus*) experience only local discomfort, they can be managed at home with instructions to return to the emergency department if signs of cranial-nerve or neuromuscular dysfunction develop. Aggressive supportive care and judicious use of antivenin can reduce or eliminate mortality from more severe envenomations. Keeping the patient calm and applying pressure dressings and cold packs to the sting site decrease the absorption of venom. A continuous intravenous infusion of midazolam controls the agitation, flailing, and involuntary muscle movements produced by scorpion stings. Close monitoring during treatment with this drug and other sedatives or narcotics is necessary for persons with neuromuscular symptoms because of the risk of respiratory arrest. Hypertension and pulmonary edema respond to nifedipine, nitroprusside, hydralazine, or prazosin, and bradyarrhythmias can be controlled with atropine.

Commercially prepared antivenins are available in several countries for some of the most dangerous species. A caprine *C. sculpturatus* antivenin (not yetFDAapproved) is available as an investigational drug from the Arizona State University for use only in Arizona. Because of the risk of anaphylaxis or serum sickness following administration of goat serum, use of the antivenin is controversial. Intravenous administration of antivenin rapidly reverses cranial-nerve dysfunction and muscular symptoms but does not affect pain and paresthesia. The benefit of scorpion antivenin has not been established in controlled trials.

Prevention In scorpion-infested areas, shoes, clothing, bedding, and towels should be shaken and inspected before being used. Removal of wood, stones, and debris from yards and campsites eliminates hiding places for scorpions, and household spraying of insecticides can deplete their source of food.

CHIGGERS AND OTHER BITING MITES

Chiggers are the larvae of trombiculid (harvest) mites that normally feed on mice in grassy or brush-covered sites in the tropics and subtropics and (less frequently) in temperate areas during warm months. They wait for hosts on low vegetation and attach themselves to passing animals or to people. The larva then pierces the skin of its host and deposits a tubelike structure in the dermis through which it imbibes lymph and tissue juices. This highly antigenic "stylostome" serves as the focus of an exceptionally pruritic papular, papulovesicular, or papulourticarial lesion that may be 2 cm in diameter and that develops within hours of attachment in persons previously sensitized to mite

antigen. Feeding mites appear as tiny red vesicles in hair follicles. Scratching invariably destroys the body of a mite attached to a person. These lesions generally vesiculate and develop a hemorrhagic base. Itching and burning last for weeks. The rash is most common on the ankles or near tight-fitting clothes that obstruct the mites' movements. Chiggers are the vectors of scrub typhus in tropical and subtropical parts of Asia. Repellents are useful for preventing chigger bites.

Certain mesostigmatid mites that infest the nests of mice or birds feed on human beings when their usual hosts have been displaced. For example, intense episodes of itching dermatitis in humans may follow the removal of trash from a human residence or the departure of pigeons that have been nesting on a window air-conditioner. Other mites that infest grain, straw, cheese, or other animal products occasionally produce similar episodes. Persons who have close contact with dogs -- and, to a lesser extent, cats -- may develop a self-limited pruritic papulovesicular rash from bites of cheyletiellid mites that cause a mangelike condition in these animals. Mouse mites are the vectors of rickettsialpox in cities of the northeastern United States. Fowl and chicken mites transmit the viruses of St. Louis encephalitis and western equine encephalitis. Although sanitary measures effectively prevent rickettsialpox, removal of accumulated refuse may result in a transient period of elevated risk.

Diagnosis of mite-induced dermatitides (including those caused by chiggers) relies heavily on a history of exposure to the source of the mite, since the tiny mite may escape notice or may already have fallen off or been scratched off the lesions. Antihistamines or topical steroids effectively reduce mite-induced pruritus.

HYMENOPTERA STINGS

Insects that sting to defend their colonies or subdue their prey belong to the order Hymenoptera, which includes apids (bees and bumblebees), vespids (wasps, hornets, and yellow jackets), and ants. Their venoms contain a wide array of amines, peptides, and enzymes that are responsible for local and systemic reactions. Although the toxic effect of multiple stings can be fatal, nearly all of the 50 or more deaths due to hymenopteran stings in the United States each year are the result of allergic reactions.

Bee and Wasp Stings Bees lose their venom apparatus in the act of stinging and subsequently die, while vespids can sting numerous times in succession. The familiar honeybees (*Apis mellifera*) and bumblebees (*Bombus* and other genera) attack when a colony is disturbed, but the extremely aggressive Africanized honeybees respond to minimal intrusions rapidly and in large numbers. Since their introduction into Brazil in 1957, these "killer bees" have spread through South and Central America to the southern and western United States.

The common vespids in the United States include the yellow jacket, notable for the yellow and black bands on its abdomen; the bald-faced hornet, with a black body and a white face; the brown hornet, measuring 2.5 to 3.5 cm in length; and the paper wasps, which have variously colored elongate bodies. Vespids sting in defense of their nests, which they often build near human dwellings and suspend from eaves or shubbery, plaster onto walls, or burrow into wood or soil. Yellow jackets feed on sugary substances and decaying meat and are annoyingly abundant at recreation sites and

around garbage, particularly in the late summer and fall.

Venom is produced in glands at the posterior end of the abdomen and is expelled rapidly by contraction of muscles of the venom sac, which has a capacity of up to 0.1 mL in large insects. The venoms of different species of hymenopterans are biochemically and immunologically distinct. Direct toxic effects are mediated by mixtures of low-molecular-weight compounds such as serotonin, histamine, and acetylcholine and several kinins. Polypeptide toxins in honeybee venom include mellitin, which damages cell membranes; mast cell-degranulating protein, which causes histamine release; apamin, a neurotoxin; and adolapin, which has anti-inflammatory action. Enzymes in venom include hyaluronidase, which allows the spread of other venom components, and phospholipases, which may be among the major venom allergens. There appears to be little cross-sensitization between honeybee and wasp venoms.

Uncomplicated stings cause immediate pain, a wheal-and-flare reaction, and local edema and swelling that subside in a few hours. Stings from accidentally swallowed insects may induce life-threatening edema of the upper airways. Multiple stings can lead to vomiting, diarrhea, generalized edema, dyspnea, hypotension, and collapse. Rhabdomyolysis and intravascular hemolysis may cause renal failure. Death from the direct effects of venom has followed 300 to 500 honeybee stings.

Large local reactions that spread³10 cm around the sting site over 24 to 48 h are not uncommon. These reactions may resemble cellulitis but are caused by hypersensitivity rather than secondary infection. Such reactions tend to recur on subsequent exposure but are seldom accompanied by anaphylaxis and are not prevented by venom immunotherapy.

An estimated 0.4 to 4.0% of the U.S. population exhibits clinical immediate-type hypersensitivity to insect stings, and 15% may have asymptomatic sensitization manifested by positive skin tests. Persons who experience severe allergic reactions are likely to have similar reactions after subsequent stings; occasionally, adults who have had mild reactions later experience serious reactions. Mild anaphylactic reactions from insect stings, as from other causes, consist of nausea, abdominal cramping, generalized urticaria, flushing, and angioedema. Serious reactions, including upper airway edema, bronchospasm, hypotension, and shock, may be rapidly fatal. Severe reactions usually begin within 10 min of the sting and only rarely develop after 5 h. Unusual complications, including serum sickness, vasculitis, neuritis, and encephalitis, develop several days or weeks after a sting.

TREATMENT

Stingers embedded in the skin should be scraped or brushed off with a blade or a fingernail but not removed with forceps, which may squeeze more venom out of the venom sac. The site should be cleansed and disinfected and ice packs used to slow the spread of venom. Elevation of the affected site and administration of analgesics, oral antihistamines, and topical calamine lotion relieve symptoms; application of meat tenderizer containing papain is of no proven value. Large local reactions may require a short course of oral therapy with glucocorticoids. Patients with numerous stings should be monitored for 24 h for evidence of renal failure or coagulopathy.

Anaphylaxis is treated with subcutaneous injection of 0.3 to 0.5 mL of epinephrine hydrochloride in a 1:1000 dilution; treatment is repeated every 20 to 30 min if necessary. Intravenous epinephrine (2 to 5 mL of a 1:10,000 solution administered by slow push) is indicated for profound shock. A tourniquet may slow the spread of venom. Parenteral antihistamines, fluid resuscitation, bronchodilators, oxygen, intubation, and vasopressors may be required. Patients should be observed for 24 h for recurrent anaphylaxis.

Prevention Persons with a history of allergy to insect stings should carry a sting kit with a preloaded syringe containing epinephrine for self-administration in case of a sting. These patients should seek medical attention immediately after using the kit. To avoid stings when outdoors, individuals can wear shoes and protective clothing and avoid attracting insects with sweet foods, bright-colored clothes, perfumes, or cosmetics.

Venom Immunotherapy Repeated injections of purified venom produce a blocking IgG antibody response to venom and reduce the incidence of recurrent anaphylaxis from between 50 and 60% to <5%. Honeybee, wasp, yellow jacket, and mixed vespid venoms are commercially available for desensitization and for skin testing. Adults with a history of anaphylaxis should undergo desensitization. Results of skin tests and venom-specific radioallergosorbent tests aid in the selection of patients for immunotherapy and guide the design of such treatment. The risk of a systemic reaction to a sting is ~5 to 10% after discontinuation of a ^{3}5-year course of immunotherapy.

Stings of Fire Ants and Other Ants All ants that are large enough can bite human beings, and some can secrete repugnant substances when handled. Stinging fire ants are an important medical problem in the United States. The imported fire ants *Solenopsis richteri* and *S. invicta* were introduced from South America into Alabama in 1918 and now infest urban and rural areas of southern states from Texas to North Carolina, with colonies in California, New Mexico, Arizona, and Virginia. They excavate open fields and yards to build tall mounds that can harbor 200,000 worker ants. Slight disturbances of the mounds have provoked massive outpourings of ants and as many as 10,000 stings on a single person. Each year fire ants sting up to 60% of the inhabitants of some cities. Waterborne ants bite on contact during times of flooding. The elderly and immobile persons are at high risk for attacks when fire ants invade dwellings.

Red-brown or brown-black fire ants attach to human skin with powerful mandibles and rotate their bodies around their heads while repeatedly injecting venom with posteriorly situated stingers. The alkaloid venom consists of cytotoxic and hemolytic piperidines and several proteins with enzymatic activity. The initial wheal-and-flare reaction, burning, and itching resolve in about 30 min, and a sterile pustule develops within 24 h. The pustule ulcerates over the next 48 h and then heals a week or 10 days later unless it becomes secondarily infected. Large areas of erythema and edema lasting several days are not uncommon and in extreme cases may compress nerves and blood vessels. Anaphylaxis occurs in ~1 to 2% of persons, and seizures and mononeuritis have been reported. Stings are treated with ice packs, topical glucocorticoids, and oral antihistamines. Covering pustules with bandages and antibiotic ointment may prevent bacterial infection. Epinephrine and supportive measures are indicated for anaphylactic

reactions. Whole-body extracts are available for skin testing and immunotherapy, which appears to lower the rate of anaphylactic reactions.

The western United States is home to harvester ants (*Pogonomyrmex* species) as well as to less aggressive fire ants not yet displaced by the introduced species. The painful local reaction following harvester ant stings often extends to lymph nodes and may be accompanied by anaphylaxis. Large Australian bulldog ants and the aggressive South American *Paranopera* ants deliver extremely painful stings and may cause systemic symptoms. Velvet ants that inhabit sandy beaches in the United States and sting the bare feet of bathers are actually wingless female wasps of the genus *Dasymutilla*.

TICK BITES AND TICK PARALYSIS

In the United States, hard ticks (Ixodidae) have increased in abundance since the mid-1900s to become the most common carriers of vector-borne diseases. Deer ticks of the genus *Ixodes* transmit the pathogens of Lyme disease, babesiosis, and human granulocytic ehrlichiosis. Other ticks, such as *Dermacentor variabilis* (the dog tick), *D. andersoni* (the wood tick), and *Amblyomma americanum* (the Lone Star tick), are vectors of tularemia, Rocky Mountain spotted fever, Colorado tick fever, and human monocytic ehrlichiosis. Outside the United States, hard ticks transmit pathogenic rickettsiae and arboviruses as well. Soft ticks (Argasidae) of the genus *Ornithodoros* transmit tick-borne relapsing fever (Chap. 175). Except in parts of Africa, soft ticks rarely attack human beings, and relapsing fever occurs only sporadically in the United States. Hard ticks differ from soft ticks by virtue of a dorsal scutum or plate and their preference for wooded, brushy, or weedy habitats. Soft ticks, which are nonscutate and leathery, are generally found in animal burrows and bird nests.

Ticks attach and feed painlessly; blood is their only food. Their secretions, however, produce local reactions, a febrile illness, or paralysis. Soft ticks attach for<1 h and produce erythematous macular lesions up to 2 to 3 cm in diameter. Some species in Africa, the western United States, and Mexico produce painful hemorrhagic lesions. At the site of hard-tick bites, small areas of induration with surrounding erythema and occasionally necrotic ulcers develop. Chronic nodules, or "tick granulomas," reach several centimeters in diameter and may require surgical excision. Tick-induced fever, associated with headache, nausea, and malaise, usually resolves within 24 to 36 h after the tick is removed. Tick paralysis is an ascending flaccid paralysis believed to be caused by a toxin in tick saliva that causes neuromuscular block and decreased nerve conduction. Throughout the world, this rare complication has followed the bites of more than 40 kinds of tick -- most commonly, dog and wood ticks in the United States. Children, especially girls with long hair, are most often affected. Weakness begins in the lower extremities 5 to 6 days after the tick's attachment and ascends symmetrically over several days to result in complete paralysis of the extremities and cranial nerves. Deep tendon reflexes are diminished or lacking altogether, but sensory examination and findings on lumbar puncture are typically normal. Removal of the tick results in improvement within a few hours and usually in complete recovery after several days. Failure to remove the tick may lead to dysarthria, dysphagia, and ultimately death from aspiration or respiratory paralysis. Diagnosis depends on finding the tick, which often is hidden beneath hair and which, when engorged, may resemble a pedunculated nevus.

An antiserum to the saliva of *Ixodes holocyclus*, the usual cause of tick paralysis in Australia, effectively reverses paralysis caused by these ticks. Ticks should be removed by firm traction with a forceps placed near their point of attachment. The site of attachment should be disinfected (e.g., with tincture of iodine). Mouthparts remaining in the skin may cause persistent irritation or lead to secondary infection. Removal of ticks during the first 48 h of attachment nearly always prevents transmission of the agents of Lyme disease, babesiosis, and erhlichiosis. Gentle handling to avoid rupture of ticks and use of gloves may avert accidental contamination with tick fluids containing pathogens. Protective measures against ticks include avoidance of brushy vegetation, removal of ticks from pet dogs and cats, use of protective clothing sprayed with 0.5% permethrin, and application of a repellent containing *N*,*N*-diethyl-*m*-toluamide (DEET). The cuffs of trousers should be tucked inside the socks.

OTHER ARTHROPOD BITES AND ENVENOMATIONS

Dipteran (Fly and Mosquito) Bites In the process of feeding on vertebrate blood, adults of certain fly species inflict painful bites, produce local allergic reactions, or transmit infectious diseases. Unlike insect stings, insect bites rarely cause anaphylaxis. Mosquitoes are ubiquitous pests and are the vectors of malaria, filariasis, yellow fever, dengue, and viral encephalitides. Female mosquitoes require a blood meal to produce eggs and an environment of standing water in which to deposit them. Their bite typically produces a wheal and later a pruritic papule. In the United States, a similar reaction follows the bite of tiny but aggressive midges known as "no-see-ums," which attack in swarms during warm months, or of other *Culicoides* species that transmit "nonpathogenic" filariae in tropical climates. Nodular lesions at the site of midge bites may last for months. The bite of the small humpbacked blackfly of the genus *Simulium* leaves a large bleeding puncture and painful and pruritic sores that are slow to heal; regional lymphadenopathy, fever, or anaphylaxis occasionally ensues. Blackflies are common summertime nuisances in the United States and Canada and are vectors of onchocerciasis in Africa and Latin America. The widely distributed tabanids, including deerflies (*Chrysops* species) and horseflies (*Tabanus* species), are stout flies measuring 10 to 25 mm in length that attack during the day and produce large and painful bleeding punctures. Deerflies transmit loiasis in African equatorial rain forests and tularemia in the United States and elsewhere. Tsetse flies of the genus *Glossina* transmit African trypanosomiasis in sub-Saharan Africa. Tiny phlebotomine sandflies are the vectors of leishmaniasis, bartonellosis (Carrion's disease), sandfly fever, and other arboviral infections in warm climates. *Stomoxys calcitrans*, the stable fly, which resembles a large housefly, is a fierce biter of human beings and domestic animals and a major pest in seacoast areas. Houseflies do not bite.

TREATMENT

Treatment of fly bites is symptom-based. Topical application of antipruritic agents, glucocorticoids, or antiseptic lotions may relieve the itching and pain. Allergic reactions may require oral antihistamines. Antibiotics may be necessary for large bite wounds that become secondarily infected. Personal protection measures against biting flies include avoidance of infested areas, application of a DEET-containing repellent to exposed skin, and use of protective clothing and bed nets treated with permethrin. Higher concentrations of DEET provide longer-lasting protection, and 10 to 35% DEET

provides adequate protection under most conditions. Repellents used on children should contain£10% DEET to avoid absorption of toxic levels that provoke encephalopathy and seizures. Permethrin applied to clothing maintains its potency for at least 2 weeks, even with laundering. It should not be applied to the skin.

Flea Bites Common human-biting fleas include the dog and cat fleas (*Ctenocephalides* species) and the rat flea (*Xenopsylla cheopis*), which inhabit the nests and resting sites of their hosts. Larval fleas feed on pellets of dried host blood that the adult fleas eject from their rectums while feeding. The high-jumping adults attack human beings or other available warm-bodied animals when the usual host abandons or is driven from its nest. The human flea (*Pulex irritans*) infests human bedding and furniture but mainly in relatively humid buildings that lack central heating. Sensitized persons develop erythematous pruritic papules, urticaria, and occasionally vesicles and bacterial superinfection at the site of the bite. Treatment consists of antihistamines and antipruritics.

Fleas transmit plague, murine typhus, a typhus-like illness due to *Rickettsia felis*, the rat and dog tapeworms, and *B. henselae*. Flea infestations are eliminated by frequent cleaning of the nesting sites and bedding of the host or judicious dusting or spraying of insecticides such as pyrethrin, DDT, or malathion.

Hemipteran (True Bug) Bites Several true bugs of the family Reduviidae inflict bites that produce allergic reactions and are sometimes painful. The cosmopolitan bedbug (*Cimex* species) hides in mattresses, behind bedboards, and under loose wallpaper during the day and takes its blood meal at night. The bite is painless, but sensitized persons develop erythema, itching, and wheals around a central hemorrhagic punctum. The cone-nose bugs, so called because of their elongated heads, include the assassin and wheel bugs, which feed on other insects and bite human beings only in self-defense, and the kissing bugs, which routinely feed on vertebrate blood. Assassin and wheel bugs inhabit many parts of the world, including the southwestern and southern United States, where they are notorious for their painful bites. The bites of the nocturnally feeding kissing bugs are painless and occur commonly in groups on the face and other exposed parts of the body. Reactions to such bites depend on prior sensitization and include tender and pruritic papules, vesicular or bullous lesions, giant urticaria, fever, lymphadenopathy, and anaphylaxis. *Triatoma infestans* and other species of kissing bug are the vectors of *Trypanosoma cruzi* in South and Central America and Mexico, but transmission of *T. cruzi* to human beings by species indigenous to the United States is exceedingly rare. Bug bites are treated with topical antipruritics or oral antihistamines. Persons with anaphylactic reactions to reduviid bites should keep an epinephrine kit available.

Centipede Bites and Millipede Dermatitis The fangs of centipedes of the genus *Scolopendra* can penetrate human skin and deliver a venom that produces intense burning pain, swelling, erythema, and lymphangitis. Dizziness, nausea, and anxiety are occasionally described, and rhabdomyolysis and renal failure have been reported. Treatment includes washing of the site, application of cold dressings, oral analgesic administration or local lidocaine infiltration, and tetanus prophylaxis. Species of *Scolopendra*, measuring up to 25 cm, occur widely in the southern United States and other areas with warm climates worldwide. The smaller house centipede *Scutigera*

coleopatrata, which is common throughout the United States, is harmless.

Millipedes, unlike centipedes, do not bite but rather secrete and in some cases eject defensive fluids that burn and discolor human skin. Affected skin turns brown overnight and may blister and exfoliate. Secretions in the eye cause intense pain and inflammation that may lead to corneal ulceration and blindness. Management includes irrigation with copious amounts of water or saline, use of analgesics, and local care of denuded skin. Millipedes are found throughout the world in leaf litter and under rocks.

Caterpillar Stings and Dermatitis The surface of caterpillars of several moth species is covered with hairs or spines that produce mechanical irritation and may contain or be coated with venom. Contact with these caterpillars causes an immediate burning sensation followed by local swelling and erythema and occasionally by regional lymphadenopathy, nausea, vomiting, and headache; shock, seizures, and coagulopathy are rare complications. In the United States, stings are most often caused by io moth larvae and puss as well as saddleback and brown-tail moth caterpillars as they cling to leaves and branches. Contact with even detached hairs of other caterpillars, such as gypsy moth larvae (*Lymantria dispar*) in the northeastern United States, can produce a pruritic urticarial or papular rash hours later. Spines may be deposited on tree trunks and drying laundry or may be airborne and cause irritation of the eyes and upper airways. Treatment of caterpillar stings consists of repeated application of adhesive or cellophane tape to remove the hairs, which can then be identified microscopically. Local ice packs, topical steroids, and oral antihistamines relieve symptoms.

Beetle Vesication When disturbed, blister beetles extrude cantharidin, a low-molecular-weight toxin that produces thin-walled blisters measuring up to 5 cm in diameter 2 to 5 h after contact with the beetle. The blisters are not painful or pruritic unless broken, and they resolve without treatment in a week to 10 days. Nephritis may follow unusually heavy cantharidin exposure. In the southern United States, blister beetles of several *Epicauta* species are abundant in the summer months. Contact occurs when people sit on the ground, work in the garden, or deliberately handle the beetles. In other countries, different species of beetle produce different vesicants. No treatment is necessary, although ruptured blisters should be kept clean and bandaged until healing is complete.
