Miscellaneous Organisms Many other gram-negative rods have been reported to cause occasional infections in hosts who are immunologically unprepared to deal with relatively avirulent organisms or who are unfortunate enough to encounter an exceptionally large inoculum. Such organisms include *Weeksella* species; various CDC groups, such as EF-4, Ve-2 (*Flavimonas* species), IVc-2, NO-1, WO-1, and Gilardi Group WO-1; *Sphingobacterium* species; *Protomonas* species; *Ochrobactrum anthropi*; *Oligella urethralis*; and *Shewanella putrefaciens*. The reader is advised to consult subspecialty texts and references for further guidance on these organisms.

151. *LEGIONELLA* INFECTION - *Feng-Yee Chang*, *Victor L. Yu*

DEFINITION

Legionellosis refers to the two clinical syndromes caused by bacteria of the genus *Legionella*. *Pontiac fever* is an acute, febrile, self-limited illness that has been serologically linked to *Legionella* species, whereas *Legionnaires' disease* is the designation for pneumonia caused by these species.

HISTORY

Legionnaires' disease was first recognized in 1976, when an outbreak of pneumonia took place at a hotel in Philadelphia during the American Legion Convention. Investigators from the Centers for Disease Control and Prevention (CDC) identified the causative aerobic gram-negative bacterium in lung specimens obtained from the victims at autopsy and named this organism *L. pneumophila*. Retrospective studies of stored serum samples revealed that an epidemic of Legionnaires' disease had occurred in 1957 in Austin, Minnesota. In this epidemic 78 persons were hospitalized with acute respiratory infection. Antibody determinations showed seroconversion to *L. pneumophila* in most cases.

MICROBIOLOGY

At present, the family Legionellaceae comprises 41 species with 64 serogroups. The species *L. pneumophila* causes 80 to 90% of human infections and includes at least 14 serogroups; serogroups 1, 4, and 6 are most commonly implicated in human infections. To date, 17 species other than *L. pneumophila* have been associated with human infections, among which *L. micdadei* (Pittsburgh pneumonia agent), *L. bozemanii*, *L. dumoffii*, and *L. longbeachae* are the most common.

Members of the Legionellaceae are aerobic, thin, gram-negative bacilli that do not grow on routine microbiologic media. Buffered charcoal yeast extract (BCYE) agar is the medium used to grow *Legionella*. This highly enhanced medium contains the amino acid L-cysteine, which is an absolute growth requirement for *Legionella*. Growth of the organism on BCYE medium is usually visible in 3 to 5 days at 35 to 37°C. *L. micdadei* and *L. maceachernii* produce blue colonies on BCYE medium containing bromocresol purple and bromothymol blue dyes, while the other species produce green colonies.

Antimicrobial agents, including polymyxin B, cefamandole, and vancomycin, are used in *Legionella*-selective media to suppress competing components of the microflora. Although *L. pneumophila* is relatively tolerant to these antibiotics, the drugs may inhibit the growth of other legionellae; for example, cefamandole-containing media suppress the growth of *L. micdadei*.

Traditional biochemical tests are not particularly helpful in distinguishing one *Legionella* species from another. Fatty-acid profile determination by gas-liquid chromatography and ubiquinone analysis allow identification to the genus level. The direct fluorescent antibody (DFA) test can definitively identify a number of individual species. In *L. pneumophila*, lipopolysaccharide is a prominent constituent of the outer membrane, and

the serogroup-specific antigen and antibodies detected by immunofluorescence are directed primarily at the lipopolysaccharide. Both polyclonal and monoclonal DFA reagents are commercially available. The monoclonal antibody reagent is less cross-reactive but is specific for *L. pneumophila*. Genetic analysis has been considered the definitive arbiter for the identification of individual species, with the degree of DNA sequence homology the most common criterion employed. A nucleic-acid hybridization probe reactive to *Legionella* ribosomal RNA, used with a single reagent, can identify a member of the genus within hours.

ECOLOGY AND TRANSMISSION

The natural habitats for *L. pneumophila* are aquatic bodies, including lakes and streams; *L. longbeachae* has been isolated from soil. Legionellae can survive under a wide range of environmental conditions; for example, the organisms can live for years in refrigerated water samples. Natural bodies of water contain only small numbers of legionellae. However, once the organisms enter human-constructed aquatic reservoirs (such as cooling towers or water-distribution systems), they can grow and proliferate. Factors known to enhance colonization by and amplification of legionellae include warm temperatures (25° to 42°C), stagnation, and scale and sediment. The presence of symbiotic microorganisms, including algae, amebas, ciliated protozoa, and other water-dwelling bacteria, likewise promotes growth of *L. pneumophila*.

Hot-water tanks colonized with *L. pneumophila* are significantly more likely than uncolonized tanks to be cooler (<60°C), to have a vertical configuration, to be older, and to have higher concentrations of calcium and magnesium. Vertical tanks, especially those that are electric coil-heated rather than gas-heated, have a pronounced temperature stratification and thick sediment accumulation at the bottom. Studies have shown that neither a high degree of outward cleanliness nor routine application of maintenance measures decreases the frequency or intensity of *Legionella* colonization. Thus, engineering guidelines and building codes, although often advocated as preventive measures, have relatively little impact on *Legionella* colonization.

The source of *Legionella* is water, but the mode of transmission from the environmental reservoir to the patient remains controversial. Early investigations that implicated cooling towers antedated the discovery that the organism could also exist in potable water distribution systems. It is now known that, in many outbreaks, cases of Legionnaires' disease continued to occur despite disinfection of cooling towers and the potable water supply was the actual source. Koch's postulates have been fulfilled in epidemiologic studies using molecular fingerprinting methods to link potable water sources (rather than cooling towers) to *Legionella* infection in humans. Community-acquired Legionnaires' disease has been linked to colonization of residential and industrial water supplies.

Multiple modes of transmission of *Legionella* to humans exist, including aerosolization, aspiration, and direct instillation into the lung during respiratory tract manipulations. Aspiration may be the predominant mode of transmission, but it is unclear whether *Legionella* enters the lung via oropharyngeal colonization or directly via the drinking of contaminated water. Nasogastric tubes have been linked to nosocomial Legionnaires' disease in several reports; microaspiration of contaminated water was the hypothesized

mode of transmission. Surgery with general anesthesia is a known risk factor that is consistent with aspiration. Especially compelling is the reported 30% incidence of postoperative *Legionella* pneumonia among patients undergoing head and neck surgery in a hospital with a contaminated water supply; aspiration is a recognized sequela in such cases. Studies of patients with hospital-acquired Legionnaires' disease showed that these individuals underwent endotracheal intubation significantly more often and for a significantly longer duration than patients with nosocomial pneumonia of other etiologies.

Aerosolization of legionellae by devices filled with tap water, including nebulizers and humidifiers, has caused cases of Legionnaires' disease. An ultrasonic mist machine in the produce section of a grocery store was implicated in a community outbreak. Pontiac fever has been linked to *Legionella*-containing aerosols from water-using machinery, a cooling tower, air-conditioners, and whirlpools.

EPIDEMIOLOGY

The incidence of Legionnaires' disease depends on the degree of contamination of the aquatic reservoir, the susceptibility and immune status of the persons exposed to the water from that reservoir, the intensity of exposure, and the availability of specialized laboratory tests on which the correct diagnosis can be based.

Numerous prospective studies have found *Legionella* to rank among the top four microbial causes of community-acquired pneumonia (*Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Chlamydia pneumoniae* usually ranking first, second, and third), accounting for 3 to 15% of cases. On the basis of a multihospital study of community-acquired pneumonia in Ohio, theCDC has estimated that only 3% of sporadic cases of Legionnaires' disease are correctly diagnosed. Legionellae are responsible for 10 to 50% of nosocomial pneumonias when a hospital's water system is colonized with the organisms. One situation in which the diagnosis of Legionnaires' disease should be considered is that in which the presenting patient has been hospitalized within 10 days before the onset of symptoms. In one study, a number of patients had been discharged from the hospital and readmitted with Legionnaires' disease; molecular fingerprinting showed that the isolates obtained from patients and the isolate from the hospital's water supply were similar.

The most common risk factors for Legionnaires' disease are cigarette smoking, chronic lung disease, advanced age, and immunosuppression. The disease most often develops in elderly men; this predilection is probably related to cigarette smoking. Surgery is a prominent predisposing factor in nosocomial infection, with transplant recipients at highest risk. Nosocomial cases are now being recognized among neonates and among children with immunosuppression or underlying pulmonary disease.

Pontiac fever occurs in epidemics. The high attack rate (>90%) reflects airborne transmission.

PATHOGENESIS

Legionellae enter the lungs through aspiration or direct inhalation. The organisms

possess pili that may mediate adherence to respiratory tract epithelial cells. Thus, conditions that impair mucociliary clearance, including cigarette smoking, lung disease, or alcoholism, predispose to Legionnaires' disease.

Cell-mediated immunity is the primary mechanism of host defense against *Legionella*, as it is against other intracellular pathogens, including *Mycobacterium tuberculosis*, *Listeria*, and *Toxoplasma*. Alveolar macrophages readily phagocytose legionellae. The attachment of the bacteria to phagocytes is mediated via complement receptors, which attach to the bacterial major outer-membrane protein. Binding to these receptors promotes phagocytosis but fails to trigger an oxidative burst. Although many legionellae are killed, some proliferate intracellularly until the cells rupture; the bacteria are then phagocytosed again by newly recruited phagocytes, and the cycle begins anew. Legionnaires' disease is more common and the disease manifestations are more severe in patients with depressed cell-mediated immunity, including transplant recipients, patients infected with HIV, and patients receiving glucocorticoids. The disease also occurs with unusual frequency among patients with hairy cell leukemia (which is characterized by monocyte deficiency and dysfunction) but not among patients with other types of leukemia.

The role of neutrophils in immunity appears to be minimal: neutropenic patients are not predisposed to Legionnaires' disease. Although *L. pneumophila* is susceptible to oxygen-dependent microbiologic systems in vitro, it resists killing by neutrophils.

The humoral immune system is active against *Legionella*. Type-specific IgM and IgG antibodies are measurable within weeks of infection. In vitro, antibodies promote killing of legionellae by phagocytes (neutrophils, monocytes, and alveolar macrophages). However, antibodies neither enhance lysis by complement nor inhibit intracellular multiplication within phagocytes. Immunized animals develop a specific antibody response, with subsequent resistance to *Legionella* challenge.

Some *L. pneumophila* strains are clearly more virulent than others, although the precise factors mediating virulence remain uncertain. For example, although multiple strains may colonize water-distribution systems, only a few cause disease in patients exposed to that water. At least one surface epitope of *L. pneumophila* serogroup 1 is associated with virulence. *L. pneumophila* serogroup 6 is more commonly involved in nosocomial Legionnaires' disease and is more likely to be associated with a poor outcome.

PATHOLOGY

The consistent pathologic features of Legionnaires' disease are confined to the lungs. Findings in infected lung tissue range from multifocal pneumonia with patchy lobular inflammation to extensive multilobar consolidation. Visible abscesses with central necrosis were seen in 20% of autopsied cases in one study. On histologic examination, fibrinopurulent pneumonia with intensive alveolitis and bronchiolitis is evident. Lesions of longer standing can have a nodular appearance with a central area of necrosis surrounded by macrophages and other cells. The alveoli are filled with fibrin, neutrophils, and alveolar macrophages.

Usual tissue stains, including Gram's, hematoxylin and eosin, Brown-Brenn, and

methenamine silver, do not reveal the organism. Giminez stain can be used for imprints on fresh or fixed tissue. Dieterle's silver stain or modified Giminez stain, although nonspecific and relatively insensitive, can be used for paraffin-fixed specimens. TheDFAstain is not only specific but also the most sensitive option for visualization of the organism in tissues. Polyvalent DFA stains but not monoclonal DFA stain can be used for formalinized specimens (Fig. 151-CD1). Because the DFA stains are species and serogroup specific, false-negative results can be obtained if the incorrect reagent is used. Thus, culture is the preferred method for diagnosis based on clinical specimens.

CLINICAL AND LABORATORY FEATURES

Pontiac Fever Pontiac fever is an acute, self-limiting, flulike illness with a 24- to 48-h incubation period. Pneumonia does not develop in Pontiac fever. Malaise, fatigue, and myalgias are the most frequent symptoms, occurring in 97% of cases. Fever (usually with chills) develops in 80 to 90% of cases and headache in 80%. Other symptoms (seen in fewer than 50% of cases) include arthralgias, nausea, cough, abdominal pain, and diarrhea. Modest leukocytosis with a neutrophilic predominance is sometimes detected. Complete recovery takes place within only a few days without antibiotic therapy; a few patients may experience lassitude for many weeks thereafter. The diagnosis is established by antibody seroconversion.

Legionnaires' Disease (Pneumonia) Clinical findings that raise the possibility of Legionnaires' disease are summarized in Table 151-1. Although these manifestations may provide clues to the diagnosis, prospective comparative studies have shown that they are generally nonspecific and do not serve to distinguish Legionnaires' disease from pneumonia of other etiologies. Legionnaires' disease is often included in the differential diagnosis of "atypical pneumonia," along with infection due to *Chlamydia pneumoniae*, *C. psittaci*, *Mycoplasma pneumoniae*, *Coxiella burnetii*, and some viruses. The clinical similarities among these types of pneumonia include a relatively nonproductive cough and a low incidence of grossly purulent sputum. However, the clinical manifestations of Legionnaires' disease are usually more severe than those of most "atypical" pneumonias, and the course and prognosis of *Legionella* pneumonia more resemble those of bacteremic pneumococcal pneumonia than those of pneumonia due to other "atypical" pathogens. Patients with community-acquired Legionnaires' disease are significantly more likely than patients with pneumonia of other etiologies to be admitted to an intensive care unit on presentation.

The incubation period for Legionnaires' disease is 2 to 10 days. The symptoms and signs may range from a mild cough and a slight fever to stupor with widespread pulmonary infiltrates and multisystem failure. Nonspecific symptoms -- malaise, fatigue, anorexia, and headache -- are seen early in the illness. Myalgias and arthralgias are uncommon but are unusually marked in a few patients. Upper respiratory symptoms, including coryza, are rare.

The mild cough of Legionnaires' disease is only slightly productive. Sometimes the sputum is streaked with blood. Chest pain -- either pleuritic or nonpleuritic -- can be a prominent feature and, when coupled with hemoptysis, can lead to an incorrect diagnosis of pulmonary embolism. Shortness of breath is reported by one-third to one-half of patients.

Gastrointestinal difficulties are often pronounced; abdominal pain, nausea, and vomiting affect 10 to 20% of patients. Diarrhea (watery rather than bloody) is reported in 25 to 50% of cases. The most common neurologic abnormalities are confusion or changes in mental status; however, the multitudinous neurologic symptoms reported range from headache and lethargy to encephalopathy.

Patients with Legionnaires' disease virtually always have fever. Temperatures in excess of 40.5°C (104.9°F) were recorded in 20% of the cases in one series. Relative bradycardia has been overemphasized as a useful diagnostic finding; it occurs infrequently, primarily affecting older patients with severe pneumonia. Chest examination reveals rales early in the course and evidence of consolidations as the disease progresses. Abdominal examination may reveal generalized or local tenderness.

Diarrhea and hyponatremia occur significantly more often in Legionnaires' disease than in other forms of pneumonia. Hyponatremia is most common in severe cases. The mechanism of hyponatremia does not appear to be related to inappropriate secretion of antidiuretic hormone but instead to salt and water loss. Besides hyponatremia, other laboratory abnormalities include abnormal liver function tests, hypophosphatemia, hematuria, hematologic abnormalities, and thrombocytopenia; although common, these abnormalities are not found significantly more frequently in Legionnaires' disease than in pneumonias of other etiologies.

Extrapulmonary Legionellosis Since the portal of entry for legionellae is the lung in virtually all cases, extrapulmonary manifestations usually result from bloodborne dissemination from the lung. In a prospective survey of patients with Legionnaires' disease diagnosed by isolation of the organism from sputum, legionellae were isolated from the blood by a special culture method in 38% of cases.

Legionella has been identified in the spleen, liver, or kidneys in 50% of autopsied cases of Legionnaires' disease. The organism has also been isolated from intrathoracic and inguinal lymph nodes -- a finding suggesting dissemination by lymphatic pathways. Extrapulmonary involvement, including sinusitis, peritonitis, pyelonephritis, cellulitis, and pancreatitis, has been documented predominantly in immunosuppressed patients.

The most common extrapulmonary site of legionellosis is the heart; numerous reports have described myocarditis, pericarditis, postcardiotomy syndrome, and prosthetic-valve endocarditis. Most cases have been hospital-acquired. Since many of the patients involved have not had overt pneumonia, the lung may not have been the portal of entry. Rather, in these cardiac infections, the organisms may have gained entry through a postoperative sternal wound exposed to contaminated tap water or through a mediastinal-tube insertion site.

Various other sources of or factors promoting *Legionella* infection at various extrapulmonary sites have been postulated, including the presence of foreign bodies, such as sutures and draining tubes (wound infection after cardiothoracic surgery); immersion in a Hubbard tank (superinfection of a hip wound); bloodborne dissemination from a pulmonary infection site (perirectal abscess); and ingestion of contaminated

water (peritonitis).

Chest Radiographic Abnormalities Virtually all patients with Legionnaires' disease have abnormal chest radiographs showing pulmonary infiltrates at the time of clinical presentation. In a few cases of nosocomial disease, fever and respiratory tract symptoms have preceded the appearance of the infiltrate on chest radiography. Findings on chest radiography are nonspecific and do not serve to distinguish Legionnaires' disease from pneumonias of other etiologies. Pleural effusion is evident in one-third of cases, and the diagnosis is often based on culture and antigen testing (by the method designed for use with urine) of pleural fluid obtained by thoracentesis.

In immunosuppressed patients, especially those receiving glucocorticoids, distinctive rounded nodular opacities may be seen; these lesions may expand and cavitate (Fig. 151-1). Likewise, pulmonary abscesses can occur in immunosuppressed hosts. The progression of infiltrates on chest radiography despite appropriate antibiotic therapy is common, and radiographic improvement lags behind clinical improvement by several days. Complete clearing of infiltrates requires 1 to 4 months.

DIAGNOSIS

The diagnosis of Legionnaires' disease requires special microbiologic tests (Table 151-2). The sensitivity of bronchoscopy specimens is approximately the same as that of sputum samples; if sputum is not available, bronchoscopy specimens may yield the organism. Bronchoalveolar lavage fluid gives higher yields than bronchial wash specimens. Thoracentesis should be performed if pleural effusion is found, and the fluid should be evaluated byDFAstaining, culture, and the antigen test designed for use with urine.

Staining Gram's staining of material from normally sterile sites, such as pleural fluid or lung tissue, occasionally suggests the diagnosis; efforts to detect legionellae in sputum by Gram's staining typically reveal numerous leukocytes, but no organisms. When they are visualized, the organisms appear as small, pleomorphic, faint, gram-negative bacilli. *L. micdadei* organisms can be detected as weakly or partially acid-fast bacilli in clinical specimens. Modified acid-fast staining substitutes 1% sulfuric acid for the traditional 3% hydrochloric acid; the less aggressive decolorizer increases the yield of *L. micdadei*. *Legionella*-infected patients have often been treated empirically with antituberculosis medications because of false-positive acid-fast smears.

The DFA test is rapid and highly specific but is less sensitive than culture because large numbers of organisms are required for microscopic visualization. This test is more likely to be positive in advanced than in early disease.

Culture The definitive method for diagnosis of *Legionella* infection is isolation of the organism from respiratory secretions or other specimens. As has been mentioned,BCYEagar supplemented with antibiotics and dyes is the most sensitive medium, and colonies grow slowly, requiring 3 to 5 days to become grossly visible. When culture plates are overgrown with other microflora, pretreatment of the specimen with acid or heat can markedly improve the yield. *L. pneumophila* is often isolated from sputum that is not grossly or microscopically purulent; sputum containing more than 25

epithelial cells per high-power field (a finding that classically suggests contamination) may still yield *L. pneumophila*.

Antibody Detection Antibody testing of both acute- and convalescent-phase sera may be necessary. A fourfold rise in titer is diagnostic; 4 to 12 weeks are often required for the detection of an antibody response, and some patients never seroconvert. A single titer of 1:128 in a patient with pneumonia constitutes presumptive (but not definitive) evidence for Legionnaires' disease. Serology is of use primarily in epidemiologic studies. The specificity of serology for the non-*L. pneumophila* species is uncertain; there is cross-reactivity with *L. pneumophila* and some gram-negative bacilli.

Urinary Antigen The assay for *Legionella* soluble antigen in urine (Binax, Portland, ME) is rapid, relative inexpensive, easy to perform, second only to culture in terms of sensitivity, and highly specific. Its use in every clinical laboratory is recommended. The test is available only for *L. pneumophila* serogroup 1, which, as has been mentioned, causes about 80% of *Legionella* infections. Antigen in urine is detectable 3 days after the onset of clinical disease, even if specific therapy has been started; furthermore, urinary antigen persists for several weeks.

Molecular Methods Polymerase chain reaction (PCR) with DNA probes is theoretically more sensitive and specific than other methods, but results have been disappointing to date. PCR has proved useful in the identification of legionellae from environmental water specimens.

TREATMENT

Controlled evaluations of antibiotic therapy for Legionnaires' disease have never been conducted. In the 1976 American Legion outbreak, patients treated with erythromycin and tetracycline appeared to have a better outcome than those treated with other agents. These two antibiotics also exhibited intracellular activity against legionellae and were effective in animal models. The fact that *Legionella* is an intracellular pathogen provided the biologic basis for the success of erythromycin and tetracycline, given that relatively high intracellular penetration. Antibiotics capable of achieving intracellular concentrations higher than the minimal inhibitory concentration are the most likely to be efficacious in the clinical setting. The dosages for various drugs used in the treatment of *Legionella* infection are listed inTable 151-3.

The newer macrolides (especially azithromycin) and quinolones are now the antibiotics of choice, displacing erythromycin. Compared with erythromycin, the newer agents azithromycin, clarithromycin, and roxithromycin have superior in vitro activity, display greater intracellular activity, and reach higher concentrations in respiratory secretions and in lung tissue. The pharmacokinetics of the newer macrolides and quinolones also allow once- or twice-daily dosing, in contrast to the four-times-daily dosing required for erythromycin. Finally, the large fluid volume required for intravenous administration, symptomatic ototoxicity, and gastrointestinal side effects have rendered erythromycin obsolete for the treatment of *Legionella* infection.

The quinolones (levofloxacin, ciprofloxacin, pefloxacin, gemifloxacin, and moxifloxacin) are more active than any of the macrolides against *Legionella* in in vitro dilution

susceptibility tests, intracellular models, and animal models. Furthermore, in open noncomparative studies of pneumonia, numerous cases of Legionnaires' disease have been successfully treated with quinolones. Quinolones are the preferred antibiotics for transplant recipients because both macrolides (except azithromycin) and rifampin interact pharmacologically with cyclosporine and tacrolimus.

Alternative agents include tetracycline and its analogues doxycycline and minocycline. Anecdotal reports have described both successes and failures with trimethoprim-sulfamethoxazole, imipenem, and clindamycin. For severely ill patients with Legionnaires' disease, the combination of rifampin plus a macrolide or a quinolone can be used for initial treatment.

Initial therapy should be given by the intravenous route. Usually, a clinical response occurs within 3 to 5 days, after which oral therapy can be substituted. The total duration of therapy in the immunocompetent host is 10 to 14 days; a longer course (3 weeks) may be appropriate for immunosuppressed patients and those with advanced disease. In the oral phase, 5 to 10 days of azithromycin is therapy sufficient.

Mortality rates for Legionnaires' disease vary, depending on the patient's underlying disease and its severity, the patient's immune status, the severity of pneumonia, and the timing of administration of appropriate antimicrobial therapy. Mortality rates are highest (80%) among immunosuppressed patients who do not receive appropriate antimicrobial therapy. With appropriate and timely antibiotic treatment, mortality from community-acquired Legionnaires' disease among immunocompetent patients ranges from 0 to 11%; without treatment, the figure may be as high as 31%. Pontiac fever requires only symptom-based treatment, not antimicrobial therapy.

PREVENTION

Routine environmental culture of the hospital water supply is recommended as an approach to the prevention of hospital-acquired Legionnaires' disease. Positive cultures from the water supply mandate the use of specialized laboratory tests (especially culture on selective media and urinary antigen assay) for patients with hospital-acquired pneumonia.

Disinfection of the water supply is now feasible. Two methods have proven reliable and cost-effective. The superheat and flush method requires heating of the water so that the distal-outlet temperature is 70 to 80°C and flushing of the distal outlets with hot water for at least 30 min. This method is ideal for emergency situations. A commercial copper and silver ionization method has proved effective in numerous hospitals. Hyperchlorination is no longer recommended because of its expense, carcinogenicity, corrosive effects on piping, and unreliable efficacy.

152. PERTUSSIS AND OTHER *BORDETELLA* INFECTIONS - *Scott A. Halperin*

Pertussis is an acute infection of the respiratory tract caused by *Bordetella pertussis*. The name *pertussis* means "violent cough," which aptly describes the most consistent and prominent feature of the illness. The inspiratory sound made at the end of an episode of paroxysmal coughing gives rise to the common name for the illness, "whooping cough"; however, this feature is variable, being uncommon in infants £6 months of age and frequently absent in older children and adults. The Chinese name for pertussis is "the 100-day cough," which accurately describes the clinical course of the illness. The identification of *B. pertussis* was first reported by Bordet and Gengou in 1906, and vaccines were produced over the following two decades.

MICROBIOLOGY

Six species have been identified in the genus *Bordetella*: *B. pertussis*. *B. parapertussis*, *B. bronchiseptica*, *B. avium*, *B. holmesii*, and *B. hinzii*. *B. pertussis* infects only humans and is the most important *Bordetella* species causing human disease. *B. parapertussis* causes an illness in humans that is similar to pertussis but is typically milder; co-infections with *B. parapertussis* and *B. pertussis* have been documented. *B. bronchiseptica* is an important pathogen of domestic animals that causes kennel cough in dogs, atrophic rhinitis and pneumonia in pigs, and pneumonia in cats. Both respiratory infection and opportunistic infection are occasionally reported in humans. *B. avium* is an important cause of respiratory illness in turkeys. The remaining two species, *B. hinzii* and *B. holmesii*, have been recognized as unusual causes of bacteremia. Both of these species have been isolated from patients with sepsis, most often from those who are immunocompromised.

Bordetella species are gram-negative pleomorphic aerobic bacilli that share common genotypic characteristics. *B. pertussis* and *B. parapertussis* are the most similar of the species but differ in that *B. parapertussis* does not express the gene coding for pertussis toxin. *B. pertussis* is a slow-growing fastidious organism that requires selective medium and forms small glistening bifurcated colonies. Suspicious colonies are presumptively identified as *B. pertussis* by direct fluorescent antibody testing or by agglutination with species-specific antiserum. *B. pertussis* is further differentiated from other *Bordetella* species by biochemical and motility characteristics.

B. pertussis produces a wide array of toxins and biologically active products that are important in its pathogenesis and in immunity. Most of these virulence factors are under the control of a single genetic locus that regulates their production, resulting in antigenic modulation and phase variation. Although these processes occur both in vitro and in vivo, their importance in the pathobiology of the organism is unknown; they may play a role in intracellular persistence and person-to-person spread. The organism's most important virulence factor is *pertussis toxin*, which is composed of a B oligomer-binding subunit and an enzymatically active A protomer that ADP-ribosylates a guanine nucleotide-binding regulatory protein (G protein) in target cells, producing a variety of biologic effects. Pertussis toxin has important mitogenic activity, affects the circulation of lymphocytes, and serves as an adhesin for bacterial binding to respiratory ciliated cells. In animal models, the toxin's effects include histamine sensitization, lymphocytosis promotion, and insulin secretion. Another virulence factor is *filamentous hemagglutinin*,

a component of the cell wall and a bacterial adhesin. *Pertactin* is an outer-membrane protein and another important adhesin. *Fimbriae* are bacterial appendages that also play a role in bacterial attachment; they are the major antigens against which agglutinating antibodies are directed. These agglutinating antibodies have historically been the primary means of serotyping *B. pertussis* strains. Other virulence factors include tracheal cytotoxin, which causes respiratory epithelial damage; adenylate cyclase toxin, which impairs host immune cell function; dermonecrotic toxin, which may contribute to respiratory mucosal damage; and lipo-oligosaccharide, which has properties similar to those of other gram-negative bacterial endotoxins.

PATHOGENESIS

Infection with *B. pertussis* is initiated by attachment of the organism to the ciliated epithelial cells of the nasopharynx. Attachment is mediated by surface adhesins (e.g., pertactin and filamentous hemagglutinin), which bind to the integrin family of cell-surface proteins, probably in conjunction with pertussis toxin. The role of fimbriae in adhesion or maintenance of infection has not been fully delineated. At the site of attachment, the organism multiplies, producing a variety of other toxins that cause local mucosal damage (tracheal cytotoxin, dermatonecrotic toxin). Impairment of host defense by *B. pertussis* is mediated by pertussis toxin and adenylate cyclase toxin. There is local cellular invasion, with intracellular bacterial persistence; however, systemic dissemination does not occur. Systemic manifestations (lymphocytosis) result from the effects of the toxins.

The pathogenesis of the clinical manifestations of pertussis is poorly understood. It is not known what causes the paroxysmal cough that is the hallmark of pertussis. A pivotal role for pertussis toxin has been proposed. Proponents of this position point to the efficacy of preventing clinical symptoms with a vaccine containing only pertussis toxoid. Detractors counter that pertussis toxin is not the critical factor because paroxysmal cough also occurs in patients infected with *B. parapertussis*, which does not produce pertussis toxin. It is thought that the neurologic events observed in pertussis, such as seizures and encephalopathy, are due to hypoxia from coughing paroxysms or apnea rather than to the effects of specific bacterial products. *B. pertussis* pneumonia, which occurs in up to 10% of infants with pertussis, is usually a diffuse bilateral primary infection. In older children and adults with pertussis, pneumonia is often due to secondary bacterial infection with streptococci or staphylococci.

IMMUNITY

Both humoral and cell-mediated immunity are thought to be important in pertussis. Antibodies to pertussis toxin, filamentous hemagglutinin, pertactin, and fimbriae are all protective in animal models. Pertussis agglutinins were correlated with protection in early studies of whole-cell pertussis vaccines. Serologic correlates of protection conferred by acellular pertussis vaccines have not been established, although antibody to pertactin, fimbriae, and (to a lesser degree) pertussis toxin correlated best with protection in two acellular pertussis vaccine efficacy trials. The duration of immunity after whole-cell pertussis vaccination is short-lived, with little protection remaining after 10 to 12 years. Data on the duration of protection after acellular pertussis vaccination are still being collected. Although immunity after natural infection has been said to be

lifelong, seroepidemiologic evidence suggests that it may not be and that subsequent episodes of clinical pertussis are prevented by intermittent subclinical infection.

EPIDEMIOLOGY

Pertussis is a highly communicable disease, with attack rates of 80 to 100% among unimmunized household contacts and 20% within households in well-immunized populations. The infection has a worldwide distribution, with cyclical outbreaks every 3 to 5 years (a pattern that has persisted despite widespread immunization). Pertussis occurs in all months; however, in North America, pertussis activity peaks in the summer and autumn.

Before the institution of widespread immunization programs, pertussis was one of the most common infectious causes of morbidity and death. In the United States prior to the 1940s, between 115,000 and 270,000 cases of pertussis were reported annually, with an average yearly rate of 150 cases per 100,000 population. With universal childhood immunization, the number of reported cases fell by >95%, with even more dramatic decreases in mortality. Only 1010 cases of pertussis were reported in 1976. Since that time, however, rates have slowly increased. In 1994, over 15,000 cases of pertussis were reported in the United States.

Although thought of as a disease of childhood, pertussis can affect people of all ages and is increasingly being identified as a cause of prolonged coughing illness in adolescents and adults. In unimmunized populations, pertussis incidence peaks in the preschool years, and well over half of children have the disease before reaching adulthood. In highly immunized populations such as those in North America, the peak incidence is in infants <1 year of age who have not completed the three-dose primary immunization series. Recent trends, however, show an increasing incidence of pertussis in adolescents and adults. In the United States in 1997, ~30% of patients were £6 months of age, 25% were adolescents, and 20% were adults. The figures for adolescents and adults are probably underestimates because of a greater degree of underrecognition and underreporting in these age groups. A number of studies of prolonged coughing illness suggest that pertussis may be the etiologic agent in 12 to 30% of adults with cough that does not improve within 2 weeks. A seroprevalence study in the United States estimated an annual incidence of pertussis of 176 cases per 100,000 healthy adults. This high incidence undoubtedly includes subclinical and mild cases that would not be readily identified as pertussis; this fact accounts for infection rates similar to those reported before the introduction of routine immunization.

Severe morbidity and mortality, however, are virtually restricted to infants. In Canada, there were 10 deaths from pertussis between 1991 and 1998; all those who died were infants£6 months of age. Although school-age children are the source of infection for most households, adults are the likely source for high-risk infants and may serve as the reservoir of infection between epidemic years. In developing countries, pertussis remains an important cause of infant morbidity and mortality. The World Health Organization estimated that in 1995 over 40 million people worldwide were infected by *B. pertussis* and that 355,000 children died of pertussis.

CLINICAL MANIFESTATIONS

Pertussis is a prolonged coughing illness with clinical manifestations that vary by age (Table 152-1). Classic pertussis is most often seen in preschool and school-age children, although it is not uncommon among adolescents and adults. After an incubation period averaging 7 to 10 days, an illness develops that is indistinguishable from the common cold and is characterized by coryza, lacrimation, mild cough, low-grade fever, and malaise. After 1 to 2 weeks, this *catarrhal phase* evolves into the *paroxysmal phase*: the cough becomes more frequent and spasmodic with repetitive bursts of 5 to 10 coughs, often within a single expiration. Posttussive vomiting is frequent, with a mucous plug occasionally expelled at the end of an episode. The episode may be terminated by an audible whoop, which occurs upon rapid inspiration against a closed glottis at the end of a paroxysm. During a spasm, there may be impressive neck-vein distension, bulging eyes, tongue protrusion, and cyanosis. Paroxysms may be precipitated by noise, eating, or physical contact. Between attacks, the patient's appearance is normal but increasing fatigue is evident. The frequency of paroxysmal episodes varies widely, from several per hour to 5 to 10 per day. Episodes are often worse at night and interfere with sleep. Weight loss is not uncommon as a result of interference with eating. Most complications occur during the paroxysmal stage. Fever is uncommon and suggests bacterial superinfection.

After 2 to 4 weeks, the coughing episodes become less frequent and less severe -- changes heralding the onset of the *convalescent phase*. This phase can last from 1 to 3 months and is characterized by a gradual resolution of the coughing episodes. For 6 months to a year, intercurrent viral infections may be associated with a recrudescence of paroxysmal cough.

Not all children who develop pertussis have classic disease. Although cough (typically paroxysmal) is nearly always present, whoop may occur in only half of cases. In infants, the illness may be atypical; often apnea and cyanosis are the only symptoms at presentation. Seizures, encephalopathy, and pneumonia are all more common in infants£6 months old. Pertussis-associated infant deaths due to apnea may be confused with sudden infant death syndrome. The clinical manifestations in adolescents and adults may be classic but are more often atypical. In a German study of pertussis in adults, over two-thirds had paroxysmal cough and over one-third had whoop. Adult illness in North America differs from this experience: the cough may be severe and prolonged but is less frequently paroxysmal, and a whoop is uncommon. Vomiting with cough is the best predictor of pertussis as the cause of a prolonged cough in adults. Other features predictive of the disease are a cough at night and exposure to other individuals with a prolonged coughing illness.

COMPLICATIONS

Complications are frequently associated with pertussis and are more common among infants than among older children or adults. Subconjunctival hemorrhages, abdominal and inguinal hernias, pneumothoraces, and facial and truncal petechiae can result from increased intrathoracic pressure generated by severe fits of coughing. Weight loss can follow decreased caloric intake. In a series of over 1100 children <2 years of age who were hospitalized with pertussis, 27.1% had apnea, 9.4% had pneumonia, 2.6% had seizures, and 0.4% had encephalopathy; 10 children (0.9%) died. Pneumonia is

reported in fewer than 5% of adolescents and adults and is usually caused by encapsulated organisms such as *Streptococcus pneumoniae* or *Haemophilus influenzae*; in contrast, infants develop primary *B. pertussis* pneumonia. Pneumothorax, severe weight loss, inguinal hernia, rib fracture, and cough syncope have all been reported in adolescents and adults with pertussis.

DIAGNOSIS

If the classic symptoms of pertussis are present, clinical diagnosis is not difficult. However, particularly in older children and adults, it is difficult to differentiate infections caused by *B. pertussis* and *B. parapertussis* from other respiratory tract infections on clinical grounds. Therefore, laboratory confirmation should be attempted in all cases. Lymphocytosis (absolute neutrophil count, >10´10^9/L) is common among young children (in whom it is unusual with other infections) but not among adolescents and adults. Culture of nasopharyngeal secretions remains the "gold standard" of diagnosis; the best specimen is collected by nasopharyngeal aspiration, in which a fine flexible plastic catheter attached to a 10-mL syringe is passed into the nasopharynx and withdrawn while gentle suction is applied. Since *B. pertussis* is highly sensitive to drying, secretions should be inoculated without delay onto appropriate media (Bordet-Gengou or Regan-Lowe) or the catheter should be flushed with a phosphate-buffered saline solution. An alternative is a nasopharyngeal culture with a calcium alginate swab; again, inoculation of culture plates should be immediate or an appropriate transport medium (such as Regan-Lowe charcoal medium) should be used. Cultures become positive by day 5 of incubation, and *B. pertussis* and *B. parapertussis* can be differentiated by agglutination with specific antisera or by direct immunofluorescence.

Nasopharyngeal cultures in untreated pertussis remain positive for a mean of 3 weeks after the onset of illness; these cultures become negative within 5 days of the institution of appropriate antimicrobial therapy. Since much of the period during which the organism can be recovered from the naropharynx falls in the catarrhal phase, when the etiology of the infection is not suspected, there is only a small window of opportunity for culture-proven diagnosis. Cultures from infants and young children are more frequently positive than those from older children and adults; this difference may reflect earlier presentation of the former age group for medical care. The increasing availability of the polymerase chain reaction for pertussis in diagnostic laboratories is enhancing the sensitivity of the organism's detection. This method may further laboratory confirmation but does not solve problems related to the long delays in specimen procurement that often are encountered in pertussis cases. Direct fluorescent antibody tests of nasopharyngeal secretions for direct diagnosis may still be available in some laboratories but should not be used because of poor sensitivity and specificity.

As a result of the difficulties with laboratory diagnosis of pertussis in adolescents, adults, and any patient who has been symptomatic for >4 weeks, increasing attention is being given to serologic diagnosis. Enzyme immunoassays detecting IgA and IgG antibodies to pertussis toxin, filamentous hemagglutinin, pertactin, and fimbriae have been developed and assessed for their reproducibility. Two- or fourfold increases in antibody are suggestive of pertussis, although cross-reactivity of some antigens (such as filamentous hemagglutinin) among *Bordetella* species makes it difficult to depend diagnostically on seroconversion involving a single type of antibody. Late presentation

for medical care and prior immunization also complicate serologic diagnosis because the first sample obtained may in fact be a convalescent-phase specimen. Proposed criteria for serologic diagnosis based on a single serum specimen call for comparison of the patient's antibody levels with established population values; for example, a patient with serologically confirmed pertussis might be required to have a titer greater than two or three standard deviations above the mean titer for a normal population. However, at present, no antibody test is widely or commercially available, and no specific serologic criteria are universally accepted.

DIFFERENTIAL DIAGNOSIS

A child presenting with paroxysmal cough, posttussive vomiting, and whoop is likely to have an infection caused by *B. pertussis* or *B. parapertussis*; lymphocytosis increases the likelihood of a *B. pertussis* etiology. Viruses such as respiratory syncytial virus and adenovirus have been isolated from patients with clinical pertussis but probably represent co-infection. In adolescents and adults, among whom paroxysmal cough and whoop are frequently absent, the differential diagnosis of a prolonged coughing illness is more extensive. Pertussis should be suspected in anyone with a cough that does not improve within 14 days, a paroxysmal cough of any duration, or any respiratory symptoms after contact with a laboratory-confirmed case of pertussis. Other etiologies to consider include infections caused by *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, adenovirus, influenza virus, and other respiratory viruses. Use of angiotensin-converting enzyme (ACE) inhibitors, reactive airway disease, and gastroesophageal reflux disease are well-described noninfectious causes of prolonged cough in adults.

TREATMENT

Antibiotics The purpose of antibiotic therapy for pertussis is to eradicate the infecting bacteria from the nasopharynx; therapy does not substantially alter the clinical course unless given early in the catarrhal phase. Erythromycin (preferably the estolate form) is recommended at a dose of 50 mg/kg (maximum, 2 g/d) in three divided doses and reliably clears *B. pertussis* from the nasopharynx after 5 days. A dose of 1 g/d has also been shown to be effective and may be better tolerated. Although a 14-day course of therapy has been recommended to prevent relapse, one study showed that a 7-day course was equally effective. Erythromycin is also effective against other pathogens implicated in cough illness, such as *Mycoplasma* and *Chlamydia*.

Other macrolide antibiotics, such as azithromycin and clarithromycin, are active against *B. pertussis* in vitro, but data on their clinical efficacy are limited; clinical trials are under way. Trimethoprim-sulfamethoxazole (8/40 mg/kg per day in two divided doses) is recommended as an alternative for individuals who cannot use erythromycin, although good clinical data to support this recommendation are lacking. A macrolide-resistant *B. pertussis* strain has been reported from a single case in an outbreak in Arizona.

Immune Globulin Although immune globulin was used widely to treat pertussis in the preantibiotic era, evidence for its effectiveness was lacking and the commercially available product was removed from the market. There is renewed interest in the therapeutic use of immune globulin, particularly for infants who develop pertussis while

still too young to have completed their primary immunization series. A high-titer pertussis toxin immune globulin for intravenous use is undergoing clinical trials.

Supportive Care Infants have the highest rates of complication and death from pertussis; therefore, most infants and older children with severe disease should be hospitalized. Monitoring for apnea and cyanosis, administration of supplemental oxygen, management of secretions, hydration, and nutritional support are the mainstays of care. A quiet environment may decrease the stimulation that can trigger paroxysmal episodes. Assisted ventilation may be required for management of apnea or pneumonia. Use ofb-adrenergic agonists and/or glucocorticoids has been advocated by some but has not been proved to be effective. Cough suppressants are not effective and play no role in the management of pertussis.

Infection Control Measures Hospitalized patients with pertussis should be placed in respiratory isolation, with the use of precautions appropriate for pathogens spread by large respiratory droplets. Isolation should continue for 5 days after initiation of erythromycin therapy or for 3 weeks (i.e., until nasopharyngeal cultures are consistently negative) in those individuals unable to tolerate antimicrobial therapy.

PREVENTION

Chemoprophylaxis Because the risk of transmission of *B. pertussis* within households is high, chemoprophylaxis is widely recommended for household contacts of pertussis cases. The effectiveness of chemoprophylaxis, although unproven, is supported by several epidemiologic studies of institutional and community outbreaks of pertussis. In the only randomized placebo-controlled study, erythromycin estolate (50 mg/kg per day in three divided doses; maximum dose, 1 g/d) was effective in reducing bacteriologically confirmed pertussis by 67%; however, there was no decrease in the incidence of clinical disease. Despite these disappointing results, many authorities continue to recommend chemoprophylaxis, particularly in households with members at high risk of severe disease (children<1 year of age). Data are not yet available on use of the newer macrolides for chemoprophylaxis.

Immunization (See alsoChap. 122) The mainstay of pertussis prevention is active immunization. Pertussis vaccine has been available for over 70 years and became widely used in North America after 1940; reported cases of pertussis have since fallen by >90%. Whole-cell pertussis vaccines are prepared through the heating, chemical inactivation, and purification of whole *B. pertussis* organisms. Although effective (average efficacy estimate, 85%, with results in various studies of different products ranging from 30 to 100%), whole-cell pertussis vaccines are associated with adverse events -- both common (fever; injection site pain, erythema, and swelling; irritability) and uncommon (febrile seizures, hypotonic hyporesponsive episodes). Alleged associations of whole-cell pertussis vaccine with encephalopathy, sudden infant death syndrome, and autism, although not substantiated, have spawned an active anti-immunization lobby. The development of acellular pertussis vaccines, which are effective but less reactogenic, has greatly alleviated concerns about the inclusion of pertussis vaccine in the combined infant immunization series. In some countries (Canada, Sweden, Germany), acellular pertussis vaccines are used exclusively for childhood immunization; in the United States, acellular pertussis vaccines are now the preferred product but

whole-cell vaccine is still considered acceptable. In North America, both whole-cell and acellular pertussis vaccines are given as a three-dose primary series at 2, 4, and 6 months of age, with a reinforcing dose between 15 and 18 months of age and a booster dose at 4 to 6 years of age.

A wide variety of acellular pertussis vaccines have been developed, although not all are available in every country. All acellular pertussis vaccines currently available contain pertussis toxoid. Only one monovalent pertussis toxoid vaccine has been licensed in the United States; the remainder of the fully developed vaccines contain filamentous hemagglutinin as well as toxoid. At least four acellular pertussis vaccines also contain pertactin, and two products also contain one or more types of fimbriae. All of the licensed acellular pertussis vaccines have undergone phase 3 efficacy testing. Although differences in study design make direct comparisons difficult, an effort to standardize case definitions and the similarity of some of the studies, which used common vaccine arms to allow "bridging" of the data between studies, have permitted some general conclusions. Even though some would still disagree, most experts have concluded that two-component acellular pertussis vaccines are more effective than monocomponent vaccines and that the addition of pertactin further increases efficacy. The further addition of fimbriae appears to provide some additional protective efficacy against milder disease. In two studies, protection against pertussis by vaccines correlated best with the production of antibody to pertactin, fimbriae, and pertussis toxin.

The development of acellular pertussis vaccines has sparked interest in the potential for control of pertussis in adolescents and adults and in the possibility that pertussis control in those groups will enhance the protection of infants too young to be immunized. Whole-cell pertussis vaccine is contraindicated in individuals³7 years of age because of their poor toleration of possible adverse events. However, adult formulations of acellular pertussis vaccines, both alone and in combination with adult-formulation diphtheria-tetanus toxoid, have been demonstrated to be safe and immunogenic in clinical trials in adolescents and adults. Further epidemiologic studies and an efficacy study are under way to better delineate the scope of pertussis illness in adolescents and adults as well as the efficacy of a single dose of acellular pertussis vaccine. These data, along with the results of other studies characterizing the spectrum of pertussis disease in adolescents and adults, will help public health authorities and advisory committees to determine the role of adolescent and adult pertussis immunization.

153. DISEASES CAUSED BY GRAM-NEGATIVE ENTERIC BACILLI - *Thomas A. Russo*

GENERAL FEATURES AND PRINCIPLES

EPIDEMIOLOGY

This chapter discusses gram-negative bacilli (GNB) belonging to the medically important genera of the family Enterobacteriaceae (*Escherichia*, *Klebsiella*, *Proteus*, *Enterobacter*, *Serratia*, *Citrobacter*, *Morganella*, *Providencia*, and *Edwardsiella*) as well as the genus *Actinetobacter* from the family Neisseriaceae. These bacteria are members of normal animal and human colonic flora and/or residents of a variety of environmental habitats, including long-term-care facilities and hospitals. In healthy humans, *Escherichia coli* is the predominant species of GNB in the colonic flora. GNB (primarily *E. coli*, *Klebsiella*, and *Proteus*) only transiently colonize the oropharynx and skin. In contrast, in the long-term-care and hospital settings, a variety of GNB emerge as the dominant components of the colonizing flora of both mucosal and skin surfaces, particularly with antimicrobial use and increasing severity of disease. Acquisition of these GNB from a variety of reservoirs leads to infection.

STRUCTURE AND FUNCTION

Structurally, these organisms possess an extracytoplasmic outer membrane, a feature shared among gram-negative bacteria. The outer membrane consists of a lipid bilayer and associated proteins, lipoproteins, and polysaccharides [capsule, lipopolysaccharide (LPS)]. This structure interfaces with the environment, including the human host. A variety of components of the outer membrane are critical determinants in mediating the pathogenesis of infection and antimicrobial resistance.

INFECTIOUS SYNDROMES

Depending on both the host and the pathogen, nearly every organ and body cavity can be infected withGNB. *Escherichia* and, to a lesser degree, *Klebsiella* and *Proteus* account for the majority of infections and are the most virulent pathogens of this group. However, the other genera are becoming increasingly important, particularly in long-term-care or hospitalized patients, in large part because of the organisms' innate or acquired resistance to antimicrobial agents and the increasing number of immunocompromised hosts. The mortality rate is significant in many GNB infections and correlates with the severity of illness. Especially problematic are pneumonitis and bacteremia from any source complicated by shock, which have associated mortality rates of 20 to 50%.

DIAGNOSIS

Isolation of GNBfrom sterile sites almost always implies infection. Their isolation from nonsterile sites, particularly from soft tissue and respiratory cultures, requires clinical correlation to differentiate colonization from infection.

TREATMENT AND PREVENTION

The antimicrobial resistance ofGNB is variable and is influenced by both location and regional antibiotic use. Empirical antimicrobial choices should be based on local susceptibility patterns, but it is critical to be cognizant of emerging resistance. The acquisition of transferable plasmids that possess genes for extended-spectrumb-lactamases (ESBLs) is increasing. To date, these plasmids are most prevalent in *Klebsiella* and *E. coli*, but they have also been described (albeit less frequently) in most of the enteric GNB. The plasmids confer resistance to third-generation cephalosporins and aztreonam and frequently contain linked resistance determinants for aminoglycosides, tetracyclines, and trimethoprim-sulfamethoxazole (TMP-SMZ). In some outbreaks, strains with ESBLs also exhibit associated fluoroquinolone resistance. Derepression of inducible chromosomal b-lactamases, another important resistance mechanism, may be preexisting or may develop during therapy. This determinant confers resistance to second- and third-generation cephalosporins, to aztreonam, and often tob-lactam/b-lactamase inhibitor combinations. Of the enteric GNB, *Enterobacter*, *Serratia*, *Citrobacter*, *Proteus vulgaris*, *Proteus penneri*, *Providencia*, and *Morganella* possess this determinant. Although relevant data are suboptimal or conflicting, combination therapy may increase antimicrobial efficacy (particularly in serious infections, such as pneumonitis) and diminish the emergence of resistance. Further, drainage of abscesses and removal of infected foreign bodies are often needed for cure. GNB are commonly part of a polymicrobial infection in which it is difficult to determine the role of each specific pathogen. Although some species are more pathogenic than others, it is usually prudent, if possible, to design an antimicrobial regimen that includes activity against all of the GNB identified, since each is capable of pathogenicity in its own right. Diligent hand washing by health care personnel and avoidance of inappropriate antimicrobial use are the two most important measures for the prevention of infection.

PATHOGENESIS

Multiple bacterial traits are required for various aspects of the pathogenesis ofGNB. The possession of specialized virulence genes is what defines pathogens and enables them to infect the host efficiently. As more is learned about these genes, it is becoming clear that hosts and their cognate pathogens have been coadapting throughout evolutionary history. In fact, it has been speculated that infection is just a point on the spectrum of evolutionary development between microbes and the host. At one end of this spectrum is a commensal/symbiotic interaction (e.g., mitochondria -- formerly bacteria -- within eukaryotic cells); at the other is a lethal outcome that results in a "dead-end relationship" (e.g., Ebola virus). During this host-pathogen "chess match" over time, a variety and redundancy of solutions have emerged in both pathogens and hosts that enable the partners to maintain their coexistence (Table 153-1).

Intestinal Infection Intestinal pathogenic strains of *E. coli* cause gastroenteritis by a variety of unique pathogenic mechanisms. Their virulence traits are for the most part distinct from those of *E. coli* strains that cause disease outside the bowel. This difference is not surprising in light of site-dependent differences in host environments and defense mechanisms.

Extraintestinal Infection Extraintestinal pathogenic strains of *E. coli* (ExPEC) and the

other genera discussed in this chapter cause infection outside the bowel. All are extracellular pathogens and therefore share certain pathogenic features. Innate defense systems (complement, phagocytes) and humoral immunity are the most critical host defense components. As a result, both susceptibility to and severity of infection are increased with dysfunction or deficiencies of these components (e.g., neutrophils). A given pathogen usually possesses multiple adhesins for binding to a variety of host cells (e.g., in *E. coli*: type I, Sfa/Foc, P pili). Nutrient acquisition (e.g., iron via siderophores) requires many genes that are necessary but not sufficient for pathogenesis. The ability to resist the bactericidal activity of complement and professional phagocytes in the absence of antibody (e.g., conferred by capsule or O antigen ofLPS) is one of the defining traits of an extracellular pathogen. Tissue damage (e.g., hemolysis in the case of *E. coli*) may facilitate spread. However, many important virulence genes await identification, and our understanding of many aspects of the pathogenesis ofGNB is in its infancy (Chap. 120). The ability to induce septic shock is another defining feature of these genera. GNB are the most common cause of this dangerous complication. The lipid A moiety of LPS and probably other bacterial factors as well (e.g., capsule) stimulate a proinflammatory host response, which, if overexuberant, results in shock (Chap. 124). Lastly, a large number of serotypes (e.g., in *E. coli*, >100 O-specific and>80 capsular antigens) exist within most genera of GNB. This antigenic variability enables immune evasion and successful recurrent infection by strains of the same species and has also impeded vaccine development (Chap. 122).

ESCHERICHIA COLI INFECTIONS

From a clinical perspective, *E. coli* can be divided into three categories: commensal strains, intestinal pathogenic (enteric or diarrheagenic) strains, andExPEC.

ETIOLOGY, EPIDEMIOLOGY, AND MANIFESTATIONS

Commensal Strains Commensal strains of *E. coli* constitute the bulk of the facultative fecal flora in most healthy humans. Such strains appear to be adapted for peaceful coexistence with the host and appear not to cause disease within the intestinal tract. Further, in humans, these microorganisms do not usually cause disease outside the intestinal tract except in the presence of precipitating factors, such as an indwelling foreign body or an impairment of host defenses. Commensal *E. coli* strains typically lack the specialized virulence traits of intestinal andExPECstrains.

Intestinal Pathogenic Strains In contrast to commensal *E. coli*, intestinal pathogenic strains of *E. coli* are rarely encountered in the fecal flora of healthy hosts and instead appear to be essentially obligate pathogens, causing gastroenteritis or colitis whenever ingested in sufficient quantities by a naive host. At least six distinct "pathotypes" of intestinal pathogenic *E. coli* exist: (1) enterotoxigenic *E. coli* (ETEC); (2) Shiga toxin-producing *E. coli* (STEC)/enterohemorrhagic *E. coli* (EHEC); (3) enteropathogenic *E. coli* (EPEC); (4) enteroinvasive *E. coli* (EIEC); (5) enteroaggregative *E. coli* (EAEC); and (6) diffusely adherent *E. coli* (DAEC). Organisms of these pathotypes are acquired via the fecal-oral route. Transmission occurs predominantly via contaminated food and water for ETEC, STEC, EIEC, EAEC, and DAEC and by person-to-person spread for EPEC (and occasionally STEC). Humans appear to be the major reservoir (except for STEC), since the host range appears to be dictated by species-specific attachment

factors. Although there is some overlap, each pathotype possesses a unique combination of virulence traits that results in a distinctive intestinal pathogenic mechanism; however, these strains are largely incapable of causing disease outside the intestinal tract.

*ETEC*In tropical or developing countries, several separate episodes of ETEC infection occur in children over the first 3 years of life. The incidence of disease diminishes with age, a pattern suggesting the development of immunity. In industrialized countries, infection usually follows travel to endemic areas. ETEC is the most common cause of traveler's diarrhea (Chap. 123), being responsible for 25 to 75% of cases. Cases usually develop within the first few weeks of travel. The incidence of infection is decreased by the prudent avoidance of potentially contaminated fluids and foods. ETEC infection is uncommon in the United States, but outbreaks have taken place secondary to contamination of domestic food products. A high inoculum (10^6 to 10^{10}CFU) is needed to cause disease. After ingestion of contaminated water or food (particularly items poorly cooked, unpeeled, or unrefrigerated), the small bowel is colonized during a 1- to 7-day incubation period. Disease is mediated in part by heat-labile (LT) and/or heat-stable (STa) toxin encoded by genes present on transferable plasmids. These toxins stimulate fluid secretion via activation of adenylate cyclase (LT) and/or guanylate cyclase (STa); the result is watery diarrhea accompanied by cramps. Characteristically absent are histopathologic changes of the small bowel; mucus, blood, and inflammatory cells in stool; and fever. The disease spectrum ranges from mild illness to a life-threatening cholera-like illness. Although symptoms are usually self-limited (2 to 6 days), infection may result in significant morbidity and mortality when health care is poor and small and/or undernourished children are affected.

STEC/*EHEC*STEC strains constitute an emerging group of pathogens that have received substantial media attention as a result of several large outbreaks attributable to the consumption of undercooked ground beef and other foods. Serotype O157:H7 is the most prominent of the more than 30 serotypes associated with the STEC syndrome (see below). Other common serogroups include O26, O39, O103, O104, and O111. The ability to produce Shiga-like toxin (Stx2 and/or Stx1) or related toxins is the critical factor dictating whether a bacterium can cause the clinical syndrome associated with STEC. *Citrobacter* isolates that produce Stx2 and *Shigella* strains that produce related toxins can cause the same syndrome.

A combination of factors are responsible for the emergence ofSTECdisease. A number of animals, including cattle and young calves, serve as a major reservoir for these strains. Ground beef, the most common food source, is frequently contaminated during processing. Further, cattle or other animal manure used as fertilizer can contaminate produce (potatoes, lettuce, sprouts, fallen apples) and water (fecal runoff). It is estimated that$<10^3$CFU of STEC can cause disease. Therefore, not only can low levels of food or environmental contamination (e.g., water swallowed when swimming) result in disease, but person-to-person transmission becomes an important vehicle for secondary spread (e.g., at day-care centers and in institutions). Because of the low infective dose (which is similar to that of *Shigella*), laboratory-associated infections also take place. Both outbreaks and sporadic disease occur with this group of pathogens, with a seasonal peak in the summer.

In contrast to infection with the other five pathotypes, infection withSTECoccurs more frequently in developed countries, where consumption of processed foods is more common than in developing regions. FoodNet data indicate that O157 strains are the fourth most common reported cause of bacterial diarrhea in the United States (behind *Campylobacter*, *Salmonella*, and *Shigella*). Colonization of the colon and perhaps of the ileum results in symptoms after an incubation period of 3 or 4 days. Maximal disease expression requires Stx2 (produced by most O157 isolates) and/or Stx1 (more commonly produced by non-O157 isolates) as well as other virulence genes (e.g., *eaeA*). Colonic edema and an initial secretory diarrhea may develop into the syndrome's hallmark trait of grossly bloody diarrhea (detected by history or examination) in >90% of cases. Significant abdominal pain and fecal leukocytes are commonly present (70% of cases), but fever is usually absent. Occasionally, *Clostridium difficile*, *Campylobacter*, and *Salmonella* infection present in a similar fashion, as do noninfectious diseases (e.g., appendicitis, inflammatory bowel disease). STEC disease is usually self-limited, lasting 5 to 10 days. This infection can be complicated by the hemolytic-uremic syndrome (HUS), which occurs 2 to 14 days after diarrhea in 2 to 8% of cases, most often in the very young and the elderly. An estimated 50% of all cases of HUS in the United States are caused by STEC infection. This complication is probably mediated by the systemic translocation of Shiga-like toxins and subsequent cellular damage, particularly to endothelial cells in the renal and cerebral microvasculature. HUS is characterized by microangiopathic hemolytic anemia, thrombocytopenia, and renal failure. Neurologic symptoms, with or without fever, can also occur. Although mortality with dialysis support is <10%, residual renal dysfunction and neurologic sequelae may persist.

*EPEC*EPEC causes disease primarily in young children, including neonates. This *E. coli* group was recognized as a cause of diarrheal disease when it was found in outbreaks of infantile diarrhea (some in hospital nurseries) in industrialized countries in the 1940s and 1950s. Presently, however, infection due to EPEC is uncommon in developed countries. In contrast, EPEC is an important cause of infant diarrhea (both sporadic and epidemic) in developing countries. Breast-feeding diminishes the incidence of infection. Rapid person-to-person spread may occur. Upon colonization of the small bowel, symptoms develop after an incubation period of 1 or 2 days. Disease is not toxin-mediated. Studies have identified a variety of virulence traits responsible for adherence and a characteristic effacement of microvilli with formation of cuplike, actin-rich pedestals to which the bacteria attach. Diarrheal stool often contains mucus but not blood. Although usually self-limiting, EPEC diarrhea may persist for weeks.

*EIEC*EIEC is a relatively uncommon cause of diarrhea and is rarely identified in the United States, although a few food-related outbreaks have been described. In less developed countries, sporadic disease is infrequently recognized in children and travelers. EIEC shares many features with *Shigella* infection; however, unlike *Shigella*, EIEC causes disease only at a high inoculum (10^8 to 10^{10}CFU). Invasion of and replication within the colonic mucosa result in the development of symptoms after an incubation period of 1 to 3 days. Secretory diarrhea may evolve into inflammatory colitis characterized by fever, abdominal pain, tenesmus, and scant stool containing mucus, blood, and inflammatory cells. Symptoms are usually self-limited, lasting 7 to 10 days.

*EAEC*and*DAEC*These pathotypes have been described primarily in developing countries and mostly affect young children. These strains may also cause some cases

of traveler's diarrhea. A high inoculum is required for infection. In vitro, the organisms exhibit a diffuse or "stacked-brick" adherence pattern. Clinical disease has been associated with persistent diarrhea.

DIAGNOSIS

A practical approach in evaluating diarrhea is to distinguish noninflammatory from inflammatory cases (Chap. 131).ETEC,EPEC,EAEC, and DAECare uncommon causes of noninflammatory diarrhea in the United States. Their diagnosis requires specialized assays that are not routinely available and whose use is rarely indicated since these diseases are self-limiting. ETEC causes the majority of cases of noninflammatory traveler's diarrhea; EAEC and DAEC cause a minority of these cases. Definitive diagnosis generally is not necessary, and empirical antimicrobial treatment is a reasonable approach. If diarrhea persists with treatment, *Giardia* or *Cryptosporidium* should be sought. The diagnosis of infection withEIEC, a rare cause of inflammatory diarrhea in the United States, also requires specialized assays. However, evaluation forSTEC, particularly when bloody diarrhea is reported or observed, is appropriate. Although screening for *E. coli* strains that do not ferment sorbitol and subsequent serotyping for O157 constitute the most common method presently used to detect STEC, testing for Shiga-like toxins or toxin genes is more sensitive, specific, and rapid. The latter approach offers another advantage: it detects both non-O157 strains and sorbitol-fermenting strains of O157, which otherwise are difficult to identify. DNA-based, enzyme-linked immunosorbent, and cytotoxicity assays are in various stages of development and will probably become the diagnostic standards in time.

Extraintestinal Pathogenic Strains From both pathogenic and clinical viewpoints,ExPECstrains are distinct from commensal and intestinal pathogenic strains of *E. coli*. ExPEC strains also make up part of the normal human fecal flora, but, in contrast to commensal strains, possess specialized genes that encode virulence factors enabling the organisms to cause extraintestinal infections (Table 153-1). ExPEC (as opposed to commensal *E. coli*) causes the majority of cases of urinary tract infection (UTI), bacteremia, and neonatal meningitis. It is likely that ExPEC also causes the majority of other extraintestinal infections due to *E. coli*. Entry into an extraintestinal site (e.g., the urinary tract or the peritoneum) -- not acquisition -- is the limiting factor for infection. All age groups, all types of hosts, and nearly every organ and site are susceptible to infection by ExPEC. Normal, previously healthy hosts infected with ExPEC can become severely ill and die. However, adverse outcomes are more prevalent in the presence of coincidental disease and abnormalities in host defenses. Typical extraintestinal infections include UTI, diverse intraabdominal infections, pneumonia (particularly in hospitalized and institutionalized patients), meningitis (mainly in neonates and patients who have undergone neurosurgery), intravascular device infection, osteomyelitis, and soft tissue infection (which usually occurs in the setting of tissue compromise). Bacteremia can accompany infection at any of these sites. Although *E. coli* is considered to be primarily a community-acquired pathogen, it is the most frequently isolated of theGNB in the ambulatory, long-term-care, and hospital settings. The scope and magnitude of infection caused by ExPEC are as great as for any other invasive bacterial pathogen. Although these isolates do not make headlines, billions of health care dollars, millions of workdays, and thousands of lives are lost to this group of pathogens each year.

URINARY TRACT INFECTION (UTI) The urinary tract is the site most frequently infected byExPEC. About 90% of ambulatoryUTIs and 25 to 35% of long-term-care and hospital UTIs are due to *E. coli*. The majority of UTIs occur in seven epidemiologically defined groups: children<1 year of age, school-age girls, premenopausal women, men with prostatic or other causes of urinary tract obstruction, postmenopausal women, individuals with neurogenic bladders, and patients with indwelling urinary catheters. In premenopausal women, diaphragm-spermicide use, sexual activity, and a history of UTI are risk factors for infection; 20% of women with an initial infection have frequent recurrences (0.3 to>20 per year). In postmenopausal women, estrogen replacement decreases the incidence of UTI. Acceptance of the diagnosis of UTI in males (beyond the first year of life) requires clear documentation since this infection is unusual in the absence of a history of instrumentation or anal intercourse. UTI in premenopausal women alone accounts for an estimated 7 million office visits and >$1 billion in direct medical costs annually. UTI is the second most common infection (behind lower respiratory tract infection) responsible for hospitalization.

Uncomplicated urethritis or cystitis occurs most commonly and is characterized by symptoms of dysuria, frequency, and suprapubic pain. Fever and/or back pain suggests progression to pyelonephritis. Pregnant women are at unusually high risk for this complication, which can adversely affect the outcome of pregnancy. As a result, prenatal screening for bacteriuria, with treatment when the results are positive, is the standard of care. Fever may take 5 to 7 days to resolve completely in appropriately treated patients with pyelonephritis but should fall over time. Persistently elevated or increasing fever and neutrophil counts should prompt evaluation for intrarenal or perinephric abscess and/or obstruction. Renal parenchymal damage and loss of renal function occur primarily in the setting of obstruction. Prostatic infection is generally a complication ofUTI in men with a history of instrumentation and/or prostatic hypertrophy. The diagnosis and treatment of UTI are detailed inChap. 280 and are tailored according to the host, the nature and site of infection, and the local pattern of antimicrobial susceptibility.

ABDOMINAL INFECTION The abdomen is the second most frequent site of extraintestinal infection due to *E. coli*. The majority of abdominal *E. coli* infections develop outside the hospital. Any inciting event that results in disruption of the bowel mucosa (particularly the colonic mucosa) often leads to acute peritonitis (secondary peritonitis; Chap. 130). This process is usually polymicrobial, but *E. coli* is isolated in most cases. Bacteremia often complicates this acute stage of infection. Abscess formation within the peritoneum may follow the acute stage or may develop as a consequence of subclinical fecal spillage (e.g., diverticulitis, chronic appendicitis). Intraperitoneal abscesses are almost always polymicrobial, with *E. coli* as the most commonGNBisolated. *E. coli* is also the GNB most often responsible for primary hepatic abscesses, hepatic abscesses in the setting of biliary disease and obstruction, septic cholangitis/cholecystitis, pancreatic abscesses, and infected pancreatic pseudocysts. This organism is the leading cause of spontaneous bacterial peritonitis, usually seen in patients who have ascites associated with cirrhosis or occasionally with malignancy. *E. coli* occasionally causes splenic abscesses and peritoneal dialysis-associated peritonitis

(Chap. 130).

PNEUMONIA E. coli is not usually considered a cause of pneumonia (Chap. 255). EntericGNB are responsible for only 2 to 5% of cases of community-acquired pneumonia, in part because these organisms only transiently colonize the oropharynx in a minority of healthy individuals. In contrast, oral colonization with *E. coli* and other GNB increases with the severity of illness and with antibiotic use. Thus, GNB are a common cause of pneumonia acquired by residents of long-term-care institutions and are the most frequent cause of hospital-acquired pneumonia (Chap. 135), particularly in postoperative and intensive care patients. Despite significant institutional variation, *E. coli* is generally the third or fourth most commonly isolated GNB in these settings, behind *Pseudomonas* and *Klebsiella*. Regardless of the host, severe disease and high mortality rates (20 to 60%) are usually seen when GNB cause pneumonia. Tissue necrosis, probably due to cytotoxins produced by GNB, is common. Infection is usually acquired by small-volume aspiration but occasionally occurs via hematogenous spread, in which case multifocal nodular infiltrates can be seen.

MENINGITIS (SeeChap. 372) ExPECare a leading cause of meningitis in the first month of life. The majority of responsible strains possess the K1 capsular serotype. Outside this setting, meningitis due to *E. coli* is uncommon, occurring predominantly with cirrhosis (Chap. 299) or disruption of the meninges due to surgery or trauma.

CELLULITIS/MUSCULOSKELETAL INFECTION Infections of decubitus ulcers and the lower extremities in diabetic patients (or other hosts with neurovascular compromise) are usually polymicrobial. *E. coli* frequently contributes to infection of decubiti and occasionally to lower-extremity infections in these patients. It may occasionally cause cellulitis or burn site or surgical wound infection, particularly when the infection originates close to the perineum. Osteomyelitis secondary to contiguous spread can occur in these settings. Hematogenously acquired osteomyelitis, particularly of vertebral bodies, is more common than is appreciated, accounting for 10% of cases in some series (Chap. 129). *E. coli* occasionally causes orthopedic device-associated infection and is a rare cause of hematogenously acquired myositis. Myositis or fasciitis of the upper leg should prompt an evaluation for an abdominal source with contiguous spread.

ENDOVASCULAR INFECTION Extraintestinal isolates of *E. coli* cause a significant minority of intravascular device-associated infections (Chap. 135). Despite being one of the most common causes of bacteremia, however, *E. coli* rarely seeds native heart valves and is an uncommon cause of prosthetic valve endocarditis. Likewise, *E. coli* infections of aneurysms and vascular grafts are uncommon.

MISCELLANEOUS INFECTIONS E. coli can cause infection in nearly every organ and site. This organism causes a minority -- but still a significant number -- of surgical site infections (e.g., mediastinitis) and cases of complicated sinusitis. It uncommonly causes endophthalmitis.

BACTEREMIA E. coli bacteremia can result from extraintestinal infection of any site. The incidences of community-acquired and long-term-care/hospital-acquired bacteremia are roughly equal. Overall, it has been amply documented that *E. coli* and *Staphylococcus aureus* are the most common blood isolates (range for *E. coli*, 16 to

37%). *E. coli* is theGNB most frequently isolated from blood in the ambulatory setting and in most long-term-care and hospital settings. When *E. coli* is isolated from the blood, it is almost always clinically significant. Approximately 15% of bacteremias are complicated by septic shock. Two-thirds of bacteremias arise from the urinary tract; these infections are particularly common in the setting of pyelonephritis or obstruction (including kinked urinary catheters) or instrumentation of the urinary tract in the presence of *E. coli*. However, one should be cautious in identifying the urinary tract as the source of *E. coli* bacteremia in the absence of appropriate symptoms, despite a positive urine culture. Asymptomatic bacteriuria is common, particularly in women, even in the absence of an indwelling bladder catheter, with a prevalence of 15 to 25% after the age of 60. Therefore, occult abdominal or other sources should be considered. The abdomen is the second most common source, accounting for 25% of episodes. Although obstructive biliary tract disease (stones, tumor) and overt disruption of the bowel are responsible for many cases of *E. coli* bacteremia, some abdominal sources, such as abscesses, are remarkably silent clinically and require identification via imaging studies (e.g., computed tomography). Soft tissue, bone, and pulmonary infection are the next most frequent sources for bacteremia. As stated above, endocarditis is uncommon, occurring in only 2 of 861 bacteremias in a recent series. In the setting of chemotherapy-induced fever and neutropenia, *E. coli* is a common cause of bacteremia, usually secondary to intestinal mucositis. It is prudent in this situation, however, to exclude perirectal infection or typhlitis (Chap. 89).ExPECstrains are among the most common causes of sepsis in neonates.

Diagnosis Strains of *E. coli* that cause extraintestinal infections usually grow both aerobically and anaerobically within 24 h on standard diagnostic media and are easily identified by the clinical microbiology laboratory using standard biochemical criteria (Chap. 121). More than 90% of these strains are rapid lactose fermenters.

TREATMENT

Although *E. coli* is generally perceived as an "antibiotic-friendly" pathogen, resistance has increased over the past decade. In general, the frequency of ampicillin resistance precludes its empirical use, even in community-acquired infections. Rates of resistance to first-generation cephalosporins andTMP-SMZin community-acquired strains are increasing in the United States (5 to 25%) and are even higher in Europe and developing countries. Not surprisingly, long-term-care and hospital isolates are more resistant than community isolates. Significant resistance (30 to 40%) to amoxicillin/clavulanic acid and piperacillin has been increasingly reported. Fortunately, resistance to second- and third-generation cephalosporins [mean rate, 3.2% according to 1998 National Nosocomial Infections Study (NNIS) data], fourth-generation cephalosporins, quinolones, monobactams (e.g., aztreonam), carbapenems (e.g., imipenem), and aminoglycosides is generally found in <10% of strains. An exception is in settings where quinolone prophylaxis is used extensively (patients with leukemia, transplant recipients); in these settings, significant quinolone resistance has emerged. Acquisition of plasmids containingESBLsand other resistance determinants is likely to increase.

The mainstay of treatment for all diarrheal syndromes is the appropriate replacement of water and electrolytes (Chap. 159). The use of prophylactic antibiotics to prevent

traveler's diarrhea should be discouraged, especially in light of high rates of antibiotic resistance. When diarrhea is free of mucus and blood, early patient-initiated treatment with a quinolone significantly decreases the duration of illness, and the use of loperamide may halt symptoms in a few hours (Chap. 123). Treatment ofSTEC is controversial since antibiotics may increase the incidence ofHUS, perhaps via increased release of Shiga-like toxin.

INFECTIONS CAUSED BY OTHER GRAM-NEGATIVE ENTERIC BACILLI

KLEBSIELLA INFECTIONS

K. pneumoniae is the most important *Klebsiella* species medically, causing community-acquired, long-term-care, and hospital infections. *K. oxytoca* is primarily a pathogen in long-term-care and hospital settings. *K. rhinoscleromatis* and *K. ozaenae* are usually isolated from patients in tropical climates. *Klebsiella* species are broadly prevalent in the environment and colonize mucosal surfaces of mammals. In healthy humans, *K. pneumoniae* colonization rates range from 5 to 35% in the colon and from 1 to 5% in the oropharynx; the skin is usually colonized only transiently. In long-term-care facilities and hospitals, colonization occurs with *K. oxytoxa* as well, and carriage rates are significant among both workers and patients. Person-to-person spread is thought to be the predominant mode of acquisition. Classically, *Klebsiella* is associated with community-acquired pneumonia, primarily in alcoholics. However, the majority of *Klebsiella* infections now occur in long-term-care facilities and hospitals. *Klebsiella* causes a spectrum of extraintestinal infections similar to that caused by *E. coli*. However, extraintestinal infections due to *Klebsiella* occur at a lower incidence in all sites except the respiratory tract. These variances in infection rates are probably due to differences in colonization and site-specific virulence traits. Antibiotic-resistant strains have been responsible for a number of nosocomial outbreaks of infection in intensive care units (ICUs) and neonatal nurseries. The most common clinical syndromes are pneumonia,UTI, abdominal infection, surgical site infection, soft tissue infection, and subsequent bacteremia. *K. rhinoscleromatis* is the causative agent of rhinoscleroma, a slowly progressive (months to years) mucosal upper respiratory infection that causes necrosis and occasional obstruction of the nasal passages. *K. ozaenae* has been implicated as a cause of chronic atrophic rhinitis.

Infectious Syndromes

Pneumonia K. pneumoniae causes only a small proportion of cases of community-acquired pneumonia (Chap. 255). This infection occurs primarily in hosts with underlying disease, such as alcoholics, diabetics, and individuals with chronic lung disease. As in all pneumonias due to entericGNB, purulent sputum production and "airspace" disease on x-ray are typical. Presentation with earlier, less extensive infection is more common than that with the classic lobar infiltrate with a bulging fissure. Pulmonary necrosis, pleural effusion, and empyema occur with progression. Pulmonary infection in residents of long-term-care facilities and in hospitalized patients is especially frequent because of increased oropharyngeal colonization rates. Mechanical ventilation is an important risk factor.

*UTI*The incidence of *K. pneumoniae* UTI among healthy adults is only 1 to 2%.

However, in complicated UTIs (including those associated with indwelling bladder catheters), the incidence of *Klebsiella* infection increases to 5 to 17%.

Abdominal Infection Klebsiella causes a spectrum of abdominal infections similar to that caused by *E. coli* but is less frequently isolated from these infections.

Other Infections Klebsiella cellulitis or soft tissue infection occurs most frequently in devitalized tissue (e.g., decubitus ulcers, diabetes, burn sites) or in immunocompromised hosts. *Klebsiella* causes a significant minority of surgical site infections and nosocomial sinusitis cases as well as occasional cases of osteomyelitis contiguous to soft tissue infection, temperate myositis, and neonatal meningitis or meningitis associated with neurosurgery.

Bacteremia Klebsiella infection at any site can result in bacteremia. Infections of the urinary tract, respiratory tract, and abdomen each account for 15 to 30% of *Klebsiella* bacteremias. Intravascular device-related infection is another important source (5 to 15%). Surgical site infection and other miscellaneous infections account for the rest. *Klebsiella* is one of the agents that causes sepsis neonatorum and bacteremia with fever and neutropenia. Like entericGNB in general, *Klebsiella* rarely causes endocarditis or endovascular infection.

Diagnosis Except for *K. rhinoscleromatis* and *K. ozaenae*, klebsiellae are readily isolated and identified by the laboratory and usually ferment lactose.

TREATMENT

K. pneumoniae and *K. oxytoca* have similar antibiotic resistance profiles. They are intrinsically resistant to ampicillin and ticarcillin.NNISdata from 1998 indicated that 10.7% ofICUpatients were infected with strains resistant to third-generation cephalosporins. This increasing degree of resistance is primarily mediated by transferable plasmids containing genes that encodeESBLs. In addition, these plasmids usually possess linked resistance determinants for aminoglycosides, tetracyclines, andTMP-SMZ. Resistance tob-lactam/b-lactamase inhibitor combinations and second-generation cephalosporins independent of ESBL-containing plasmids has also been increasingly described. In some outbreaks, ESBL-containing strains have displayed associated fluoroquinolone resistance. At this time, resistance to quinolones, cephamycins (e.g., cefoxitin), fourth-generation cephalosporins (e.g., cefepime), and amikacin is generally <10% but will probably increase. Carbapenems (e.g., imipenem) remain the most active antibiotic class against *Klebsiella*.

PROTEUS INFECTIONS

P. mirabilis causes 90% of *Proteus* infections. These infections occur in the community, in long-term-care facilities, and in hospitals. *P. vulgaris* and *P. penneri* are isolated primarily from infections contracted in long-term-care facilities or hospitals. *Proteus* species are part of the colonic flora of a wide variety of mammals, birds, fish, and reptiles. Their ability to generate histamine from contaminated fish has implicated theseGNB in the pathogenesis of scombroid (fish) poisoning (Chap. 131). *P. mirabilis* colonizes healthy humans (prevalence, 50%), but *P. vulgaris* and *P. penneri* are isolated

primarily from individuals with underlying disease. The urinary tract is overwhelmingly the favored site of *Proteus* infection, in part because of unique pathogenic properties of the organisms. However, *Proteus* less commonly causes infection in a variety of extraintestinal sites.

Infectious Syndromes

UTIP. mirabilis causes only 1 to 2% of cases ofUTI in healthy women, and *Proteus* species cause only 5% of cases of hospital-acquired UTI. However, *Proteus* is responsible for 10 to 15% of cases of complicated UTI, primarily those associated with catheterization; in the setting of long-term catheterization, their prevalence rate ranges from 20 to 45%. This high prevalence is due to the ability of *Proteus* to produce high levels of urease, which hydrolyzes urea to ammonia and results in alkalization of the urine. This situation, in turn, leads to precipitation of organic and inorganic compounds, with the formation of struvite and carbonate-apatite crystals, biofilm formation on catheters, and/or the development of calculi. *Proteus* becomes associated with the stones and usually can be eradicated only by complete stone removal. Over time, staghorn calculi may form and lead to obstruction and renal failure. Therefore, an unexplained alkaline urine should be cultured for *Proteus*, and identification of a *Proteus* species should prompt an evaluation for calculi.

Other Infections Although the majority of *Proteus* infections arise from the urinary tract, these bacteria occasionally cause pneumonia (primarily in long-term-care or hospitalized patients), nosocomial sinusitis, intraabdominal abscesses, biliary tract infection, surgical site infection, soft tissue infection (especially decubitus and diabetic ulcers), and osteomyelitis (primarily contiguous); they rarely cause temperate myositis. In addition, *Proteus* occasionally causes neonatal meningitis (with the umbilicus often implicated as the source), and cerebral abscess is a common complication.

Bacteremia The majority of *Proteus* bacteremias originate from the urinary tract; however, any of the less common sites of infection are also potential sources. Infection of intravascular devices should also be considered. Endovascular infection is rare. *Proteus* species are occasional agents of sepsis neonatorum and bacteremia with fever and neutropenia.

Diagnosis *Proteus* is readily isolated and identified by the laboratory. The majority of strains are lactose negative, and most demonstrate characteristic "swarming" motility on agar plates.

TREATMENT

P. mirabilis remains susceptible to most antimicrobial agents except tetracycline. Resistance to ampicillin and first-generation cephalosporins has been acquired by 10 to 20% of strains. Acquisition ofESBLsremains uncommon. *P. vulgaris* and *P. penneri* are more resistant. Resistance to ampicillin and first-generation cephalosporins is the rule for these species. Derepression of an inducible chromosomalb-lactamase (not present in *P. mirabilis*) occurs in up to 30% of strains. Imipenem, fourth-generation cephalosporins (e.g., cefepime), aminoglycosides,TMP-SMZ, and quinolones have excellent activity (90 to 100%).

ENTEROBACTER INFECTIONS

E. cloacae and *E. aerogenes* are responsible for most *Enterobacter* infections (65 to 75% and 15 to 25%, respectively); *E. agglomerans*, *E. sakazakii*, and *E. gergoviae* are less commonly isolated (5%, 1%, and<1%, respectively). These organisms cause primarily health care- or hospital-related infections. They are prevalent in foods, environmental sources (including health care facility equipment), and a wide variety of animals. Only a minority of healthy humans are colonized, but the percentage increases significantly in the setting of long-term care or hospitalization. Although colonization is an important prelude to infection, direct introduction via intravenous lines (e.g., contaminated intravenous fluids, pressure monitors) also occurs. Significant antibiotic resistance has developed in *Enterobacter* species and has contributed to their emergence as prominent nosocomial pathogens. Individuals who have received prior antibiotic treatment, who have comorbid disease, and who are patients inICUs are at greatest risk for infection. *Enterobacter* causes a spectrum of extraintestinal infections similar to that described for otherGNB in this chapter.

Infectious Syndromes Pneumonitis,UTI(particularly catheter-related), intravascular device-related infection, surgical wound/site infection, and abdominal infection (primarily postoperative or device-related -- e.g., biliary stents) are the most common syndromes encountered. Nosocomial sinusitis, meningitis related to neurosurgical procedures (including use of pressure monitors), osteomyelitis, and endophthalmitis after eye surgery are less frequent. *E. sakazakii* is commonly responsible for neonatal meningitis/sepsis (particularly in premature infants), and contaminated formula has been implicated as a source of this infection. Neonatal meningitis is frequently associated with brain abscesses. Bacteremia can result from infection at any of these sites. In the setting of *Enterobacter* bacteremia, contamination of intravenous fluids, blood products, catheter-flushing fluids, pressure monitors, and dialysis equipment should always be considered, particularly with epidemic infection. *Enterobacter* can also cause bacteremia in patients with fever and neutropenia. *Enterobacter* endocarditis is rare, primarily affecting abnormal native or prosthetic valves.

Diagnosis *Enterobacter* is readily isolated and identified by the laboratory. Most strains are lactose positive.

TREATMENT

Significant antimicrobial resistance exists among *Enterobacter* strains. Ampicillin and the first- and second-generation cephalosporins have little or no activity. The extensive use of third-generation cephalosporins has resulted in the selection of strains that produce high levels ofb-lactamase (i.e., derepression ofb-lactamase), which confers resistance to second- and third-generation cephalosporins, monobactams (e.g., aztreonam), and (frequently)b-lactam/b-lactamase inhibitor combinations. Resistant isolates may emerge during therapy; their presence should be considered a possibility when clinical deterioration follows several days of improvement. A 34% resistance rate to third-generation cephalosporins was reported inICUisolates in 1998 (NNISdata). Imipenem, fourth-generation cephalosporins (e.g., cefepime), aminoglycosides (amikacin > gentamicin),TMP-SMZ, and quinolones have retained excellent activity (90

to 99%). However, increasing resistance to quinolones, in conjunction with the increased use of these agents, is a concern.

ACINETOBACTER INFECTIONS

A. baumannii is responsible for the majority of *Acinetobacter* infections; a minority are due to *A. calcoaceticus* and *Acinetobacter* genospecies 3 and 13TU. *Acinetobacter* is highly prevalent in the environment. It is found in most water and soil samples and has a wide habitat. *Acinetobacter* has been cultured from the moist skin of healthy humans; increased colonization of the skin and the respiratory and gastrointestinal tracts occurs in individuals in long-term-care facilities and hospitals. Reservoirs for acquisition in these settings include health care personnel, medical equipment, food, and the surrounding environment. Infections in healthy people in the community are unusual, but a few reports of pneumonia have been published. The overwhelming majority of infections are acquired in the hospital and long-term-care facilities. The spectrum of extraintestinal infections caused by *Acinetobacter* is similar to that caused by otherGNB. *Acinetobacter* species account for 1 to 3% of hospital-acquired infections and affect primarily immunocompromised hosts and patients with comorbid disease.ICUs are a prominent site of *Acinetobacter* infection. In some centers, the incidence of *Acinetobacter* infections, particularly those due to antibiotic-resistant strains, is increasing. Both sporadic and epidemic infection occurs, usually after the first week of hospitalization.

Infectious Syndromes The respiratory tract (particularly in ventilated patients) and intravascular devices (particularly for non-*A. baumannii* species) are the favored sites of infection. A catheterized urinary tract, postoperative sites, burn sites, biliary stents, sinuses (with tube-related ostial obstruction), and neurosurgical infections (site- or device-associated -- e.g., pressure monitors) are less common. Uncommon infections include contiguous osteomyelitis, peritonitis associated with continuous ambulatory peritoneal dialysis, and ophthalmic infection. The respiratory tract and intravascular devices are the most common sources for bacteremia.

Diagnosis On Gram's stain, *Acinetobacter* organisms usually appear as shortGNB or coccobacilli. They are strictly aerobic, nonfermenting, and readily isolated and identified.

TREATMENT

Many strains of *Acinetobacter* are highly resistant to antimicrobial agents. Empirical combination therapy is prudent pending susceptibility studies. Ampicillin, aztreonam, and the first- and second-generation cephalosporins possess little or no activity against these species. The activity of mezlocillin, piperacillin, quinolones, third- and fourth-generation cephalosporins, aminoglycosides, andb-lactam/b-lactamase inhibitor combinations is variable. Imipenem is presently the most active antimicrobial (>95% sensitivity), andb-lactam/sulbactam combinations are often active. Amikacin, third- and fourth-generation cephalosporins, quinolones, and combinations consisting of a b-lactam other than sulbactam plus a b-lactamase inhibitor retain significant activity in some centers, while highly resistant strains are more common in other centers.

SERRATIA INFECTIONS

S. marcescens causes the majority of *Serratia* infections (>90%), and *S. liquefaciens* is occasionally isolated. Serratiae are found primarily in the environment, including health care institutions and particularly in moist foci. Although strains have been isolated from a variety of animals, healthy humans are rarely colonized. In long-term-care facilities or hospitals, diverse reservoirs for the organisms include the hands of health care personnel, food, sinks, respiratory and other hospital equipment, intravenous solutions, blood products (e.g., platelets), lotions, irrigation solutions, and even disinfectants. Infection results from either direct inoculation (e.g., via intravenous fluid) or colonization (primarily of the respiratory tract) and subsequent infection. Sporadic infection is most common, but occasional epidemics and common-source outbreaks occur. The spectrum of extraintestinal infections caused by *Serratia* is similar to that for otherGNB. *Serratia* species account for 1 to 3% of hospital-acquired infections.

Infectious Syndromes The respiratory tract, the genitourinary tract, intravascular devices, and surgical wounds and sites are the most common sites of *Serratia* infection and sources of *Serratia* bacteremia. Soft tissue infections, including myositis, osteomyelitis, abdominal and biliary tract infection (postprocedural), contact lens-associated infection, endophthalmitis, septic arthritis (primarily with intraarticular injections), and infusion-related bacteremias occur less commonly. Serratiae are uncommon causes of neonatal or postsurgical meningitis and bacteremia associated with fever and neutropenia. Endocarditis is rare.

Diagnosis Serratiae are readily cultured and identified by the laboratory and are usually lactose negative. A minority of *S. marcescens* strains are red-pigmented.

TREATMENT

A high proportion of *Serratia* strains (>80%) are resistant to ampicillin and the first-generation cephalosporins. Significant resistance to ticarcillin, piperacillin, gentamicin, second- and third-generation cephalosporins,b-lactam/b-lactamase inhibitor combinations, and aztreonam has developed and may evolve during therapy. Imipenem, amikacin, cefepime, and quinolones are the most active agents, with >90% of strains susceptible.

CITROBACTER INFECTIONS

C. freundii and *C. koseri* (formerly *C. diversus*) cause the majority of human *Citrobacter* infections, which are similar epidemiologically and clinically to *Enterobacter* and *Acinetobacter* infections. *Citrobacter* organisms are commonly present in water, food, soil, and the intestinal tracts of animals. *Citrobacter* is part of the normal fecal flora in a minority of healthy humans, but colonization rates increase in long-term care facilities and hospitals -- the settings in which nearly all infections occur. *Citrobacter* species account for 1 to 2% of nosocomial infections. The affected hosts are usually immunocompromised or have comorbid disease. *Citrobacter* causes extraintestinal infections whose spectrum is similar to that described for otherGNB.

Infectious Syndromes The urinary tract is the site of 40 to 50% of infections due to *Citrobacter*. Less commonly infected sites include the biliary tree (particularly with

stones or obstruction), the respiratory tract, surgical sites, soft tissue (e.g., decubitus ulcers), the peritoneum, and intravascular devices. Osteomyelitis (usually contiguous), neurosurgery-related infection, and myositis occur rarely. *Citrobacter* is also an uncommon cause of neonatal meningitis; *C. koseri* accounts for 90% of cases due to this genus. A frequent and devastating complication of this infection (occurring in 50 to 80% of cases) is the development of brain abscesses. Bacteremia is most commonly due to UTI, biliary or abdominal infection, or intravascular devices. *Citrobacter* is an uncommon cause of bacteremia in the setting of fever and neutropenia. Endocarditis or endovascular infection is rare.

Diagnosis *Citrobacter* species are readily isolated and identified, often as part of a polymicrobial culture; 35 to 50% of isolates are lactose positive.

TREATMENT

C. freundii is generally more resistant to antibiotics than *C. koseri*. Ampicillin and the first- and second-generation cephalosporins display poor activity against *Citrobacter*. Resistance is variable but increasing to ticarcillin, mezlocillin, piperacillin, aztreonam, quinolones, gentamicin, and third-generation cephalosporins; such resistance may evolve during therapy. Theb-lactamase inhibitors usually do not improve susceptibility to b-lactam agents. Imipenem, amikacin, and the fourth-generation cephalosporins are most active, with>90% of strains sensitive.

MORGANELLA AND *PROVIDENCIA* INFECTIONS

M. morganii (formerly *Proteus morganii*), *P. stuartii*, and (to a lesser degree) *P. rettgeri* (formerly *Proteus rettgeri*) are the members of these genera that are responsible for human infections. The epidemiologic, pathogenic, and clinical manifestations of these organisms are similar to those of *Proteus* species; however, *Morganella* and *Providencia* are almost exclusively pathogens of persons in long-term-care facilities and, to a lesser degree, hospitalized patients.

Infectious Syndromes These species are primarily urinary tract pathogens, most often associated with long-term (>30-day) catheterization.UTI in uncatheterized or short-term-catheterized individuals is uncommon. Biofilm formation or encrustation of the catheter usually develops and may lead to catheter obstruction. Likewise, infection may result in the development of struvite bladder or renal stones, which, in turn, may lead to renal obstruction and serve as foci for relapse. Other infectious syndromes occur less commonly but include surgical wound/site infections, soft tissue infection (primarily decubitus and diabetic ulcers), burn site infection, pneumonia (particularly ventilator-associated), intravascular device infection, and intraabdominal infection. Rarely, the other extraintestinal infections described forGNB also occur. Bacteremia is uncommon; although any infected site can serve as the source, the urinary tract accounts for the majority of cases, with surgical wound/site and soft tissue infections less frequently responsible.

Diagnosis *M. morganii* and *Providencia* are readily isolated and identified. Nearly all isolates are unable to ferment lactose.

TREATMENT

Morganella and *Providencia* may be highly resistant to antimicrobial agents. Ampicillin and the first-generation cephalosporins exhibit poor activity against these organisms. Variable resistance is emerging (and may evolve during therapy) against ticarcillin, mezlocillin, piperacillin, aztreonam, gentamicin,TMP-SMZ, and the second- and third-generation cephalosporins and quinolones. Theb-lactamase inhibitor tazobactam (but not sulbactam or clavulanic acid) improves susceptibility to b-lactam agents somewhat. Imipenem, amikacin, and the fourth-generation cephalosporins are most active, with >90% of strains susceptible. Removal of an infected catheter or stones is critical for eradication of the organisms from the urinary tract.

EDWARDSIELLA INFECTION

E. tarda is the only member of this genus associated with human disease. This organism is found predominantly in both freshwater and marine environments and in the animals that live in these environments. Human acquisition occurs primarily during interaction with these reservoirs. *E. tarda* infection is rare in the United States; most recently reported cases are from Southeast Asia. This pathogen shares some of the clinical features of both *Salmonella* species and *Vibrio vulnificus*.

Infectious Syndromes Gastroenteritis is the predominant infectious syndrome reported (50 to 80% of infections). Self-limiting watery diarrhea is most frequent; however, cases of severe colitis responding to therapy have also been described. The most common extraintestinal infection is wound infection due to direct inoculation, which is often associated with freshwater, marine, or snake-related injuries. Other infectious syndromes appear to be due to invasion of the gastrointestinal tract and subsequent bacteremia. The majority of afflicted hosts have either liver disease or an iron-overload state (e.g., sickle cell disease). A primary bacteremic syndrome, sometimes complicated by meningitis, has been described and has a 40% case-fatality rate. Visceral (primarily hepatic) or intraperitoneal abscesses have also been reported.

Diagnosis Although *E. tarda* can readily be isolated and identified, most laboratories do not routinely identify it from stool.

TREATMENT

E. tarda is sensitive to mostGNB-appropriate antimicrobial agents. Gastroenteritis is generally self-limiting, but treatment withTMP-SMZor a quinolone may expedite its resolution. In the setting of overwhelming sepsis, quinolones, third- or fourth-generation cephalosporins, imipenem, and aminoglycosides -- alone or in combination -- are the safest choices pending susceptibility information.

INFECTIONS CAUSED BY MISCELLANEOUS GENERA

Species from genera ofGNB such as *Hafnia*, *Kluyvera*, *Cedecea*, *Pantoea*, and *Ewingella* are occasionally isolated from a variety of clinical specimens, including blood, sputum, cerebrospinal fluid, joint fluid, biliary drainage, wounds, and sputum. Although their role in disease has not always been defined, these strains appear to be rare and

usually opportunistic human pathogens. The primary medical literature should be consulted for details on their potential role as infectious agents.

154. *HELICOBACTER PYLORI* INFECTIONS - *John C. Atherton*, *Martin J. Blaser*

DEFINITION

Helicobacter pylori colonizes the human stomach and is of etiologic importance in peptic ulcer disease and gastric malignancy. Other gastric *Helicobacter* species colonize animals, some with a narrow range and others with a broad range of host species specificity. Those with broad specificity are occasionally found in humans, possibly as zoonoses. It is unclear whether *Helicobacter heilmanii* (formerly known as *Gastrospirillum hominis*), the most common of these species among isolates from humans, is associated with human disease. Numerous species of nongastric helicobacters are found in animals, and some have been isolated from human stool and gall bladder; whether these species cause disease is unknown.

ETIOLOGIC AGENT

H. pylori is a gram-negative, spiral, flagellate bacillus that naturally colonizes humans and monkeys. It is noninvasive, living in gastric mucus; a small proportion of the bacterial cells are adherent to the mucosa. Its spiral shape and flagellae render *H. pylori* motile in the mucous environment, and its efficient urease protects it against acid by catalyzing urea hydrolysis to produce buffering ammonia. In vitro, *H. pylori* is microaerophilic and slow-growing and requires complex growth media. In 1997, the complete genomic sequence of *H. pylori* was published, and this information has greatly advanced the understanding of metabolic pathways and other aspects of the organism's biology. *H. heilmanii* is a longer, more tightly coiled spiral than *H. pylori* and cannot easily be cultured in vitro at present.

EPIDEMIOLOGY

The prevalence of *H. pylori* colonization is about 30% in the United States and other developed countries as opposed to >80% in most developing countries. In the United States, prevalence varies with age; around 50% of 60-year-old persons as opposed to 25% of 30-year-old persons are colonized. Spontaneous acquisition or loss of the bacterium in adulthood is uncommon. *H. pylori* is usually acquired in childhood. (The age association is mostly due to a birth-cohort effect.) Other than age, the main risk factor for colonization is low socioeconomic status; crowding and low family income in childhood are especially strong correlates of colonization.

Humans are the only important reservoir of *H. pylori*. Members of a family may carry the same strain, and colonization is particularly common in childhood institutions. These findings imply direct person-to-person spread, but whether transmission takes place by the fecal-oral or oral-oral route is unknown. *H. pylori* DNA has been found in water sources, and indirect epidemiological evidence indicates that contaminated water may lead to human colonization in developing countries. Much research is focused on determining which of these possible routes of acquisition is most important.

CLINICAL MANIFESTATIONS

Essentially all *H. pylori*-colonized persons have gastric inflammation, but this condition

in itself is asymptomatic (Fig. 154-1). Symptoms are due to illnesses such as peptic ulceration or gastric malignancy, which develop in fewer than 10% of individuals colonized with *H. pylori*. More than 80% of peptic ulcers are related to *H. pylori* colonization, most of the remainder being due to damage caused by aspirin or nonsteroidal anti-inflammatory drugs (NSAIDs). The main lines of evidence for an ulcer-promoting role of *H. pylori* are (1) that the presence of the organism is a risk factor for the development of ulcers, (2) that (non-NSAID-induced) ulcers rarely develop in the absence of *H. pylori*, (3) that eradication of *H. pylori* results in a dramatic drop in the rate of ulcer relapse (from about 80% to 15% in the first year), and (4) that experimental infection of gerbils and mice causes gastroduodenal injury.

Prospective case-control studies have shown that *H. pylori* colonization is a risk factor for adenocarcinomas of the stomach (other than those arising in the gastric cardia). However, persons who have had documented duodenal ulcers are less likely than other persons to develop gastric adenocarcinoma later in life; the implication is that, whereas *H. pylori* colonization increases risk for both duodenal ulcerogenesis and gastric carcinogenesis, other factors determine which disease path is taken. The presence of *H. pylori* is strongly associated with gastric lymphoma. Low-grade B-cell mucosa-associated lymphoid tissue (MALT) lymphomas, which are antigen driven, often regress following *H. pylori* eradication. Whether all such diagnosed cases represent true malignancies remains to be determined.

Most *H. pylori* colonization is asymptomatic. Whether colonization occasionally causes symptoms (nonulcer dyspepsia) in the absence of ulcers or malignancy is controversial. Some but not all trials of *H. pylori* eradication in nonulcer dyspepsia have shown a reduction of symptoms in a small proportion of patients. As there is no prospective method for identifying this small group, eradication of *H. pylori* in patients with nonulcer dyspepsia is not currently indicated.

Much interest has focused on a possible protective role for *H. pylori* in gastroesophageal reflux disease (GERD) and adenocarcinoma of the esophagus and gastric cardia. The main lines of evidence for this role are that (1) there is a temporal relationship between a falling prevalence of *H. pylori* colonization and a rising incidence of these conditions; (2) in most studies, the prevalence of *H. pylori* colonization, especially with *cagA*$^+$strains, is lower among patients with these esophageal diseases than among control subjects; and (3) eradication of *H. pylori* often leads to the development or worsening of GERD or its symptoms. Although there are plausible mechanisms for a protective effect of *H. pylori* against these diseases, none has yet been definitively identified. Thus a causal link remains probable but unproven.

Several extra-gastrointestinal pathologies have been linked epidemiologically with *H. pylori* colonization. The most notable are ischemic heart disease and cerebrovascular disease. The associations have been found more commonly in small than in large studies, and most authorities consider them to be noncausal and due to confounding factors.

PATHOLOGY AND PATHOGENESIS

H. pylori colonization induces chronic superficial gastritis, which includes both

mononuclear and polymorphonuclear cell infiltration of the mucosa. (The term *gastritis* should be used specifically to describe histologic features; it also has been used to describe endoscopic appearances and even symptoms, neither of which have been linked to microscopic findings or to the presence of *H. pylori*.) The immune response to *H. pylori* includes both the production of antibody (local and systemic) and a cell-mediated response but is ineffective in clearing the bacterium. *H. pylori* and associated inflammation are most evident in the stomach but are also found in areas of gastric metaplasia and heterotopia (e.g., the duodenal bulb).The pattern of gastric inflammation is associated with disease risk: antral-predominant gastritis is most closely linked with duodenal ulceration and is common in the United States and other developed countries, whereas the predominant form in developing countries is pangastritis, which is epidemiologically linked with gastric ulceration and adenocarcinoma. Longitudinal analyses of gastric biopsy specimens taken years apart from the same patient show that inflammation may progress to atrophy, intestinal metaplasia, and dysplasia and then (by implication) to carcinoma. Patients with atrophic gastritis are at risk for vitamin B_{12}deficiency and its associated hematologic and neurologic sequelae. Continuous omeprazole therapy (for example, forGERD) may speed progression to atrophy when *H. pylori* is present.

Most *H. pylori*-colonized persons do not develop clinical sequelae. That some persons develop overt disease whereas others do not is probably due to a combination of bacterial strain differences, host susceptibility to disease, and environmental factors; of these, bacterial factors are best studied.

The two major disease-associated *H. pylori* virulence factors described so far are a vacuolating cytotoxin, VacA, and a group of genes termed the *cag* pathogenicity island (*cag* PaI). VacA occurs in several forms, and its level of production varies between strains; thus, although all strains have the gene (*vacA*) encoding the protein, not all exhibit vacuolating activity in vitro. Cytotoxic strains are more commonly isolated from patients with peptic ulcer disease than from persons without ulcers. The *cag* PaI includes genes that confer enhanced virulence on *H. pylori* strains, at least partly by inducing epithelial cells to produce proinflammatory cytokines. The gene *cagA*, an imperfect marker for the *cag* PaI, is useful for epidemiologic studies because it encodes a highly immunogenic protein, CagA. Patients with peptic ulcers or gastric adenocarcinoma are more likely to have CagA antibodies than persons without these conditions. However, patients with esophageal dysplasia or adenocarcinoma or with the premalignant condition Barrett's esophagus are less likely to harbor *cagA*$^+$strains than are *H. pylori*-positive controls. Thus, eradication of *cagA*$^+$strains from asymptomatic persons to prevent disease is not recommended.

How does gastric *H. pylori* colonization increase risk for duodenal ulceration? One explanation is that antral *H. pylori* colonization diminishes the number of somatostatin-producing cells; somatostatin-mediated inhibition of gastrin release leads to hypergastrinemia. Individuals with antral-predominant gastritis (and thus a normally functioning acid-producing gastric corpus) develop increased acid secretion, which may increase the risk of duodenal ulceration per se or may induce gastric metaplasia in the duodenum, which becomes colonized by *H. pylori*, then inflamed, and finally ulcerated. After eradication of *H. pylori* from patients with duodenal ulcer disease, the level of acid secretion often falls.

DIAGNOSIS

Tests for *H. pylori* can be divided into two groups: invasive tests, which require upper gastrointestinal endoscopy and are based on the analysis of gastric biopsy specimens, and noninvasive tests (Table 154-1). Invasive tests are preferred for (1) the initial management of dyspeptic patients, because the decision of whether or not to eradicate *H. pylori* depends on ulcer disease status, and (2) follow-up after treatment of patients with gastric ulceration to be certain that the ulcer was not malignant. Follow-up endoscopy should be performed at least 4 weeks after cessation of all anti-*Helicobacter* drugs, since at earlier points the *H. pylori* load may be low and tests may be falsely negative. The most convenient endoscopy-based test is the biopsy urease test, in which two antral biopsy specimens are put into a gel containing urea and an indicator. The presence of *H. pylori* urease elicits a color change, which often takes place within minutes but can require up to 24 h. Histologic examination of biopsy specimens is accurate, provided that a special stain (e.g., a modified Giemsa or silver stain) permitting optimal visualization of *H. pylori* is used. Histologic study yields additional information, including the degree and pattern of inflammation, atrophy, metaplasia, and dysplasia, although these details are rarely of clinical use. Microbiologic culture is most specific but may be insensitive due to difficulty with *H. pylori* isolation. Once cultured, the identity of *H. pylori* can be confirmed by its typical appearance on Gram's stain and its positive reactions in oxidase, catalase, and urease tests. Antibiotic sensitivities also can be determined. Specimens containing *H. heilmanii* are only weakly positive in the biopsy urease test. The diagnosis is based on visualization of the characteristic long, tight spiral bacteria in histologic sections.

The simplest tests for *H. pylori* infection are serologic, involving the assessment of specific IgG levels in serum. The best of these tests are as accurate as other diagnostic methods, but many commercial tests, especially rapid office tests, perform poorly. In quantitative tests, a defined drop in antibody titer between matched serum samples taken before and 6 months after treatment (no sooner because of the slow decline in antibody titer) accurately indicates that *H. pylori* infection has been eradicated. The other major noninvasive tests are the ^{13}C and ^{14}C urea breath tests. In these simple tests, the patient drinks a labeled urea solution and then blows into a tube. The urea is labeled with either the nonradioactive isotope ^{13}C or a minute dose of the radioactive isotope ^{14}C (which exposes the patient to less radiation than a standard chest x-ray). If *H. pylori* urease is present, the urea is hydrolyzed and labeled carbon dioxide is detected in breath samples. Unlike serologic tests, urea breath tests can be used to assess the outcome of treatment 1 month after its completion and thus may replace endoscopy for this purpose in the follow-up of duodenal ulcer patients. As for endoscopic tests, all anti-*Helicobacter* drugs should be avoided in this period or the test may be falsely negative.

TREATMENT

At present, the only clear indications for treatment are *H. pylori*-related duodenal and gastric ulceration and the rare low-grade B-cell MALT lymphoma. *H. pylori* should be eradicated in patients with documented ulcer disease, whether or not the ulcers are currently active, to reduce the likelihood of relapse. At present, treatment is not

recommended for nonulcer dyspepsia or for prophylaxis against ulcers or gastric adenocarcinoma (although it may be reasonable to eradicate *H. pylori* in persons with a strong family history of gastric cancer). Reasons for avoiding treatment for these other potential indications include the expense, the induction of morbidity in otherwise healthy people, the risk of inducing widespread antibiotic resistance in *H. pylori* and in other colonizing bacteria, and the risk of inducing or worseningGERD.

H. pylori is susceptible to a wide range of antibiotics in vitro, but monotherapy has been disappointing in vivo, probably because of inadequate antibiotic delivery to the full locus of colonization. Failure of monotherapy has led to the development of multidrug regimens, the most successful of which are triple and quadruple combinations that achieve *H. pylori* eradication rates of >90% in many trials and>75% in clinical practice. Current 7- to 14-day drug regimens consisting of a proton pump inhibitor and two or three antimicrobial agents often require only twice-daily dosing (Table 154-2).

The two most important goals in *H. pylori* eradication are to obtain the patient's compliance with the dosing regimen and to use drugs to which *H. pylori* has not acquired resistance. Treatment failure following minor lapses in compliance is common and often leads to acquired resistance to metronidazole or clarithromycin. To stress the importance of compliance, written instructions should be given to the patient, and minor side effects of the regimen should be explained. Resistance to metronidazole and clarithromycin is of growing concern; however, in multidrug regimens, the clinical significance of single-drug resistance is diminished. Assessment of antibiotic susceptibilities before treatment would be optimal but is not usually undertaken. In the absence of susceptibility information, a history of antibiotic use should be obtained, and, if resistance is likely, metronidazole-containing regimens should be avoided. Metronidazole resistance is common among persons who have taken the agent previously, even years earlier, for other conditions such as giardiasis or trichomoniasis. If initial *H. pylori* treatment fails, compliance should be checked and re-treatment should be based on known antibiotic susceptibilities. When this information cannot be obtained, the recommended course is quadruple therapy without clarithromycin (if a clarithromycin-containing regimen was given first) or triple therapy with omeprazole/clarithromycin/amoxicillin (if clarithromycin has not been used) (Table 154-2).

Given the high efficacy of treatment regimens, it is unclear whether the success of attempted *H. pylori* eradication should be checked. For gastric ulceration, the opportunity to retest for *H. pylori* is present at the repeat endoscopy, which is performed to evaluate healing. For duodenal ulceration, although many clinicians prefer to retest only if symptoms recur, a urea breath test or endoscopy should be performed no sooner than 1 month after treatment. This test will provide reassurance if treatment has been successful and will prompt re-treatment in cases of persistence.

Clearance of *H. heilmanii* has been described following the use of bismuth compounds alone or triple-therapy regimens. However, in the absence of trials, it is unclear whether this result represents successful treatment or natural clearance of the bacterium.

PREVENTION

Carriage of *H. pylori* has public health significance in developing countries, where gastric adenocarcinoma is a common cause of cancer death. However, *H. pylori* has co-evolved with its human host over millennia, and there may be disadvantages in preventing or eliminating colonization. For example, as has been mentioned, the absence of *H. pylori* appears to increase the risk of developingGERD and esophageal adenocarcinoma. If mass prevention were contemplated, vaccination would be preferred, and experimental immunization of animals has given promising results. However, in the United States and other developed countries, the incidences of *H. pylori* carriage, peptic ulceration, and gastric adenocarcinoma are dropping. Thus, prevention of colonization in these countries may be unnecessary or even unwise.

155. INFECTIONS DUE TO *PSEUDOMONAS* SPECIES AND RELATED ORGANISMS

- Christopher A. Ohl*, *Matthew Pollack

Pseudomonas species and phylogenetically related bacteria are ubiquitous, free-living, opportunistic gram-negative pathogens. *P. aeruginosa*, the most common human pathogen in this group, is the primary subject of this chapter. Also discussed are two pathogens of increasing importance: *Burkholderia cepacia* (formerly *P. cepacia*), primarily an opportunistic pathogen, and *Stenotrophomonas maltophilia* (formerly *Xanthomonas maltophilia*), which principally infects hospitalized patients. In addition, melioidosis, a tropical systemic disease with acute and chronic manifestations caused by *B. pseudomallei* (formerly *P. pseudomallei*), will be considered.

INFECTIONS DUE TO *P. AERUGINOSA*

P. aeruginosa is a small, nonsporulating, aerobic gram-negative rod belonging to the family Pseudomonadaceae. It is motile by virtue of its single polar flagellum. More than half of all clinical isolates produce the blue-green pigment pyocyanin; this pigment is helpful in the identification of the organism and accounts for the species name *aeruginosa*, which refers to the distinctive color of copper oxide.

EPIDEMIOLOGY

P. aeruginosa is widespread in nature, inhabiting soil, water, plants, and animals (including humans). It has a predilection for moist environments. This organism occasionally colonizes the skin, external ear, upper respiratory tract, or large bowel of healthy humans. Rates of carriage are relatively low, however, except among patients who have serious underlying disease, whose host defenses have been naturally or iatrogenically compromised, who have previously received antibiotic therapy, and/or who have been exposed to the hospital environment. Under these circumstances, colonization with *P. aeruginosa* frequently precedes infection, and factors that predispose to the former also increase the likelihood of the latter.

Most *P. aeruginosa* infections are acquired in the hospital, where intensive care units account for the highest rates of infection. According to the National Nosocomial Infections Surveillance (NNIS) system, between 1992 and 1999, *P. aeruginosa* was the second most common cause of pneumonia, the fourth most common cause of urinary tract infection, and the sixth most frequent bloodstream isolate in intensive care units. Many potential reservoirs of infection have been identified in the hospital environment, including respiratory equipment, cleaning solutions, disinfectants, sinks, vegetables, flowers, endoscopes, and physiotherapy pools. Most reservoirs are associated with moisture. It is assumed that the organism is transmitted to patients via the hands of hospital personnel or via fomites. While some infecting strains of *P. aeruginosa* appear to be endemic within the hospital, others are traced to a common source associated with a specific outbreak or epidemic. Epidemiologic investigation is facilitated by serotyping (immunotyping) of strains on the basis of differences in lipopolysaccharide (LPS) structure and by the use of molecular techniques such as pulsed-field gel electrophoresis.

PATHOGENESIS

That the pathogenesis of infections due to *P. aeruginosa* is complex is evidenced by the clinical diversity of the diseases related to this organism and by the multiplicity of virulence factors it produces. *P. aeruginosa* rarely causes disease in the healthy host. Relative risk for infection is greatly increased, however, when normal cutaneous or mucosal barriers have been breached or bypassed, when immunologic defense mechanisms have been compromised, or when the protective function of the normal bacterial flora has been disrupted (Table 155-1). The ubiquity of the organism, its flexible nutritional and metabolic requirements, its environmental resiliency, and its relative resistance to antibiotics help account for the frequency and success with which it acts as an opportunistic pathogen.

Infections caused by *P. aeruginosa* usually begin with bacterial attachment and superficial colonization of cutaneous or mucosal surfaces and progress to localized bacterial invasion and damage to underlying tissues. The infection may remain anatomically localized or may spread by direct extension to contiguous structures. This process may continue with bloodstream invasion, dissemination, the systemic inflammatory-response syndrome (SIRS), multiple-organ dysfunction, and ultimately death. Not only is local infection more likely to occur in immunocompromised hosts, such as those with profound neutropenia, but it is more likely to culminate in bloodstream invasion and dissemination.LPS(endotoxin), which is a structural component of the bacterial outer membrane, is thought to play a pivotal role in the pathogenesis of the sepsis syndrome or SIRS.

The initial attachment of *P. aeruginosa* to the respiratory epithelium and other epithelial surfaces appears to be mediated by bacterial organelles called *pili* or *fimbriae* and facilitated by *alginate*, a mucoid exopolysaccharide produced by most strains of the bacterium under appropriate environmental conditions. Alginate plays an important role in colonization and infection of the respiratory tract in patients with cystic fibrosis and in the formation of biofilms within which sessile colonies of *P. aeruginosa* enjoy relative protection from host defenses and antimicrobial agents.

P. aeruginosa produces a number of extracellular virulence factors, including alkaline protease, elastase, phospholipase, cytotoxin, and exoenzymes (or exotoxins) A and S. The breakdown of host tissues by these bacterial products creates conditions conducive to enhanced bacterial proliferation, invasion, and tissue injury. Production and secretion of many of these extracellular virulence factors are under the regulatory control of a cell-to-cell signaling system that has been termed *quorum sensing*. Through lactones and other signal molecules secreted by individual *P. aeruginosa* bacteria, the entire bacterial population is able to sense its environment, communicate, and discern its own cell density. This regulatory system conceivably allows *P. aeruginosa* to produce extracellular virulence factors in a coordinated manner dependent on cell density and may give the pathogen an appreciable advantage over host defense mechanisms.

The extracellular enzyme exotoxin A -- a diphtheria-like toxin -- is produced by most clinical isolates of *P. aeruginosa*. Exotoxin A inhibits mammalian protein synthesis by transferring the adenosine diphosphate (ADP) ribose moiety of the nicotinamide adenine dinucleotide into covalent linkage with elongation factor 2, inactivating this factor's ability to catalyze the elongation step in polypeptide assembly. Another

extracellular cytotoxin, exoenzyme S, is also an adenosine diphosphate ribosyltransferase but, unlike exotoxin A, preferentially ribosylates guanosine triphosphate-binding proteins, resulting in disruption of host cell actin cytoskeletons. Exoenzyme S is one of several extracellular virulence factors of *P. aeruginosa* that is directly introduced from the bacterial cytosol into the host cell cytoplasm via a complex array of transmembrane proteins termed the *type III secretion apparatus*. This process requires direct cell contact and allows the injection of virulence factors from the bacterium into host cells without interference from humoral immune defenses.

CLINICAL MANIFESTATIONS AND DIAGNOSIS

Respiratory Tract Infections *Primary pneumonia*, or *nonbacteremic pneumonia*, results from aspiration of upper respiratory tract secretions; often develops in patients with chronic lung disease, congestive heart failure, or AIDS; and is most common in an intensive care setting in association with mechanical ventilator use. Fever, chills, severe dyspnea, cyanosis, productive cough, apprehension, confusion, and other signs of severe systemic toxicity characterize this acute, often life-threatening infection. Chest roentgenograms typically show bilateral bronchopneumonia with nodular infiltrates and small areas of radiolucency; pleural effusions are common; empyema is relatively uncommon; and lobar consolidation is occasionally seen. Cavitary lesions are particularly common in AIDS patients with *P. aeruginosa* pneumonia. Pathologic lesions include alveolar necrosis, focal hemorrhages, and microabscesses.

Bacteremic pneumonia due to *P. aeruginosa* begins as a respiratory infection but, in contrast to primary pneumonia, is typically associated with neutropenia, subsequent bloodstream invasion, and metastatic spread that produces characteristic lesions in the lungs and other viscera. Alveolar hemorrhage and necrosis are common. The signs and symptoms of this fulminant disease include those described for nonbacteremic pneumonia caused by this organism as well as those associated with gram-negative sepsis. Chest roentgenograms characteristically demonstrate a rapid progression from pulmonary vascular congestion to interstitial edema, then to pulmonary edema, and finally to diffuse necrotizing bronchopneumonia with cavity formation. The patient typically dies 3 or 4 days after initial presentation.

Chronic infection of the lower respiratory tract with *P. aeruginosa* is caused almost exclusively by mucoid strains, which produce alginate. Such infection is prevalent among older children and young adults with cystic fibrosis and also develops in some patients with AIDS. In patients with cystic fibrosis, mucoid strains invariably colonize and infect patients with increasing prevalence over time, contributing to the acute exacerbations and chronic progression that characterize pulmonary disease in these individuals. Airway obstruction appears to begin with bronchiolitis, which causes mucus plugging and predisposes to *P. aeruginosa* infection. The infection produces more mucus plugging, chronic suppuration, bronchiectasis, atelectasis, and ultimately fibrosis. This process progresses to pulmonary insufficiency, hypoxemia, and alterations in cardiopulmonary dynamics resulting in pulmonary hypertension and cor pulmonale.

Clinical manifestations of lower respiratory tract infections due to *P. aeruginosa* in patients with cystic fibrosis vary with the severity and duration of underlying lung disease, the frequency and intensity of acute episodes, and the presence of coinfecting

pathogens such as *B. cepacia* (Chap. 257). Soon after colonization, patients may experience recurrent upper respiratory symptoms followed by a lingering cough. Episodes of pneumonia develop later, with persistent cough between acute episodes. Eventually, patients exhibit a chronic productive cough, wheezing, diminished appetite, weight loss, growth retardation, and decreased activity. Acute exacerbations are typically accompanied by low-grade fever and heightened respiratory symptoms. Physical signs include evidence of malnutrition, an increase in anteroposterior diameter, intercostal retractions, cyanosis, inspiratory and expiratory wheezing, rhonchi, moist rales, abdominal distention, and clubbing of the fingers and toes. Laboratory abnormalities include leukocytosis with a left shift and hypoxemia with or without hypercarbia. Tests of pulmonary function demonstrate obstructive and restrictive defects. Chest roentgenograms reveal overaeration, patchy atelectasis, peribronchial fibrosis, and patchy infiltrates associated with pneumonia. In more advanced disease, there may be evidence of severe overaeration, depressed diaphragm, further increased anteroposterior diameter, extensive peribronchial infiltration, generalized bronchiectasis, and cyst formation.

Bacteremia *P. aeruginosa* remains an important cause of life-threatening bloodstream infection in immunocompromised patients. Bacteremia is frequently iatrogenic and is usually seen in hospitalized patients with various comorbid conditions (Table 155-1). Bloodstream infection can be either primary (with no identifiable source) or secondary to a discrete focus of infection.

The clinical features of *P. aeruginosa* bacteremia are similar to those of other forms of bacteremia. Common primary sites of infection include the urinary tract, gastrointestinal tract, lungs, skin and soft tissues, and intravascular foci, including indwelling central venous catheters. Fever, tachypnea, tachycardia, and prostration are common. Disorientation, confusion, or obtundation may be evident. Hypotension can progress to refractory shock. Renal failure, adult respiratory distress syndrome, and disseminated intravascular coagulation occur as complications.

Pathognomonic skin lesions termed *ecthyma gangrenosum* (Fig. 19-CD1) develop in a relatively small minority of patients with *P. aeruginosa* bacteremia. The lesions begin as small hemorrhagic vesicles surrounded by a rim of erythema and undergo central necrosis with subsequent ulceration (seePlate IID-57C). They occur singly or in small numbers on the perineum, buttocks, and extremities; in the axillae; or elsewhere. Histologically, these lesions contain numerous bacteria invading blood vessels but few inflammatory cells. Bacteria are readily visible on Gram's staining and may be cultured from aspirated material.

Endocarditis *P. aeruginosa* infects native heart valves in injection drug users as well as prosthetic heart valves. The source of *P. aeruginosa* strains infecting drug users appears to be standing water contaminating drug paraphernalia. Foreign materials mixed with heroin may cause injury to valve leaflets or mural endocardium, with resulting fibrosis and an increased risk for valve infection. Exposure of the tricuspid valve to both trauma and bacteria apparently accounts for the high incidence of tricuspid involvement in association with injection drug use.

The pulmonic, mitral, or aortic valve and the mural endocardium of either atrium may be

affected in *P. aeruginosa* endocarditis. Multiple-valve infections are common. Tricuspid or right-sided involvement is often associated with septic pulmonary emboli. Right-sided *P. aeruginosa* endocarditis usually presents subacutely, while the appearance of left-sided disease is likely to be more acute or even fulminant. Fever is virtually invariable, and murmurs are usually detectable at initial presentation or shortly thereafter. Septic pulmonary emboli associated with right-sided disease result in cough, pleuritic chest pain, sputum production, pulmonary infiltration (with or without abscess formation), and pleural effusion. Left-sided infections may present as intractable heart failure or large systemic emboli. Mycotic aneurysms, cerebritis, or brain abscess may occur; septic infarcts are occasionally found in the spleen. Skin and soft tissue manifestations, including Janeway lesions, Osler's nodes, and ecthyma gangrenosum, are relatively uncommon.

The diagnosis of *P. aeruginosa* endocarditis is based on positive blood culture in the absence of an extracardiac source; an indication of valvular dysfunction or vegetation on an echocardiogram; evidence of septic pulmonary lesions on a chest roentgenogram (in right-sided disease); and the actual demonstration of infected heart valves at the time of surgery.

Central Nervous System Infections *P. aeruginosa* infections of the central nervous system include meningitis and brain abscess. These infections follow extension from a contiguous parameningeal structure such as the ear, mastoid, or paranasal sinus; direct inoculation into the subarachnoid space or brain through head trauma, surgery, or diagnostic procedures; or bacteremic spread from infection at a distant site. Like *P. aeruginosa* infections at other anatomic sites, central nervous system infections are documented almost exclusively in patients with compromised local or systemic immune-defense mechanisms.

The clinical signs of *P. aeruginosa* meningitis, like those of other forms of acute bacterial meningitis, include fever, headache, stiff neck, confusion, and obtundation. The onset of illness may be acute or even fulminant, particularly in bacteremic patients, with a precipitous downhill course, shock, coma, and early death. In nonbacteremic patients, *P. aeruginosa* meningitis or brain abscess may present more insidiously, with a paucity of systemic symptoms. This presentation is especially common in infections resulting from recent neurosurgery, cancer of the head and neck, or direct extension from a parameningeal focus of chronic infection. Occasionally, *P. aeruginosa* meningitis runs a subacute or relapsing course that is thought to be related to the intermittent release of bacteria from a loculated site of infection.

Ear Infections *P. aeruginosa* is often found in the external auditory canal, particularly under moist conditions and in the presence of inflammation or maceration (as in "swimmer's ear"). Moreover, this organism is the predominant pathogen associated with external otitis, a usually benign inflammatory process affecting the external auditory canal. The ear is painful or merely itchy, there is a purulent discharge, and pain is elicited by pulling on the pinna. The external canal appears edematous and is filled with detritus that often prevents visualization of the tympanic membrane.

P. aeruginosa occasionally penetrates the epithelium overlying the floor of the external auditory canal at the junction between bone and cartilage and invades underlying soft

tissue. The ensuing invasive process, which involves soft tissue, cartilage, and cortical bone, is typically slow but destructive. Termed *malignant external otitis*, this condition occurs predominantly in elderly diabetic patients but is reported occasionally in infants with other underlying diseases and rarely in elderly nondiabetic patients. Virtually all cases of malignant external otitis are caused by *P. aeruginosa*. From the external ear, the infection advances to the retromandibular area or parotid space and enters the mastoid air cells and temporal bone. Advancing osteomyelitis at the base of the skull often involves the seventh, ninth, tenth, and eleventh cranial nerves. The cavernous sinus can become involved, as can the contralateral petrous apex. The middle ear is commonly spared; meningitis and brain abscess are relatively rare complications.

Otorrhea and severe otalgia are common presenting symptoms of malignant external otitis. Facial-nerve paralysis tends to occur early, while other cranial-nerve palsies appear later. There may be a loss of hearing. Constitutional symptoms such as fever and weight loss are relatively uncommon. Physical examination almost always reveals remarkable tenderness of the pinna of the ear and abnormalities of the external auditory canal, including swelling, erythema, purulent discharge, debris, and granulation tissue in the canal wall. The tympanic membrane is often hidden from view and is sometimes perforated. Inflammation may involve the pinna as well as the periauricular, retromandibular, and mastoid areas.

Peripheral leukocytosis is relatively infrequent in malignant external otitis, while the erythrocyte sedimentation rate is usually markedly elevated. Cerebrospinal fluid occasionally exhibits pleocytosis and an elevation in the protein level. Computed tomography (CT) or magnetic resonance imaging (MRI) of the mastoid or temporal bone typically reveals bony erosions and new bone formation, while the floor of the skull may have soft tissue densities associated with areas of cellulitis. In addition, technetium 99m bone scans and gallium 67 scans frequently give positive results. Cultures of samples from the external auditory canal and of surgical specimens are almost always positive for *P. aeruginosa*.

Eye Infections (See alsoChap. 28) *P. aeruginosa* causes bacterial keratitis or corneal ulcer and endophthalmitis in the human eye. Keratitis due to *P. aeruginosa* may result from even minor corneal injury, which interrupts the integrity of the superficial epithelial surface and permits bacterial access to the underlying stroma. Corneal ulcer may complicate contact lens use, particularly when extended-wear soft contact lenses are involved. Contact lens solutions or the lenses themselves may be the source of the organism, which is probably inoculated into the eye at sites of minor lens-induced corneal damage. Patients who have sustained serious burns, have undergone ocular irradiation or tracheostomy, have been exposed to the intensive care environment, and/or are in a coma are also susceptible to *P. aeruginosa*-associated corneal ulcers. *P. aeruginosa* keratitis usually starts as a small central ulcer; spreads concentrically to involve a large portion of the cornea, sclera, and underlying stroma; and in some cases progresses to posterior corneal perforation.

The clinical manifestations of *P. aeruginosa* keratitis include a rapidly expanding, necrotic stromal infiltrate in the bed of an epithelial injury; surrounding epithelial edema; an anterior chamber reaction; and mucopurulent discharge adherent to the ulcer's surface. Corneal ulcer due to *P. aeruginosa* may advance rapidly to involve the entire

cornea in £2 days or may evolve subacutely over several days. Systemic symptoms are uncommon. Complications include corneal perforation, anterior chamber involvement, and endophthalmitis.

P. aeruginosa endophthalmitis is typically a rapidly progressive, sight-threatening condition that demands immediate therapeutic intervention. It may complicate penetrating injuries of the eye, intraocular surgery, hematogenous spread from other sites of *Pseudomonas* infection, or posterior perforation of corneal ulcers. Clinical manifestations may include eye pain, conjunctival hyperemia, chemosis, lid edema, decreased visual acuity, hypopyon, severe anterior uveitis, and signs of possible vitreous involvement. Panophthalmitis may result from this intraocular infection.

Bone and Joint Infections Vertebral osteomyelitis due to *P. aeruginosa* is associated with complicated urinary tract infection, genitourinary instrumentation or surgery, and injection drug use. Vertebral infections that are associated with a urinary tract source most often develop in the elderly and usually affect the lumbosacral spine. Presumably the route of infection in these patients is a shared venous plexus between the pelvis and spine. Injection drug use-related infections typically occur in younger patients and may affect the cervical or lumbosacral spine. *P. aeruginosa* vertebral osteomyelitis is usually an indolent disease. Accordingly, symptoms may develop weeks or even months before diagnosis. Back or neck pain is generally reported, while fever and systemic symptoms are relatively uncommon. Local tenderness and decreased range of motion of the affected spine are typical. Leukocytosis may be noted, the erythrocyte sedimentation rate is almost always markedly elevated, and blood cultures are sometimes positive. Roentgenograms reveal loss of bone density, narrowed intervertebral space, destruction of vertebral end plates, lytic lesions of vertebral bodies, sclerosis, and occasionally osteophyte formation.CT andMRI are the most sensitive and specific means of defining lesions. Technetium bone scans and gallium scans usually yield positive results. An etiologic diagnosis requires the culture of material obtained by needle aspiration or biopsy of the affected spine under fluoroscopic guidance; open biopsy is sometimes needed.

Sternoclavicular pyarthrosis caused by *P. aeruginosa* is another complication of injection drug use; in some cases it is associated with *P. aeruginosa* endocarditis, but more often it is not. Joint involvement is usually monoarticular, with the sternoclavicular joint more often affected than sternochondral joints. Patients present with acute or chronic pain in the anterior chest wall, often associated with fever and restricted movement of the homolateral shoulder. Physical examination reveals tenderness, erythema, and swelling over the affected joint. Leukocytosis is common, and the erythrocyte sedimentation rate is almost invariably elevated. Roentgenograms show soft tissue edema; bone demineralization; lytic lesions; and periosteal elevation of the clavicular head, rib, or sternum. Material obtained by arthrocentesis or synovial biopsy yields *P. aeruginosa* in culture.

P. aeruginosa infections of the symphysis pubis are associated with pelvic surgery and injection drug use. The symphysis pubis, like other fibrocartilaginous joints, exhibits a peculiar susceptibility to bloodborne infection with *P. aeruginosa*. Affected patients report pain in the groin, hip, thigh, and/or lower abdomen that is made worse by walking. Fever is variable, and the duration of symptoms before diagnosis ranges from days to

months. The erythrocyte sedimentation rate is markedly elevated. Roentgenography orCT shows irregularities of the pubic margins, separation of the symphysis pubis, and osteomyelitic abnormalities of the pubic rami that may be extensive. Bone scans are usually positive. Needle aspiration or biopsy is necessary to obtain material for culture. A positive culture is particularly important for the discrimination of *P. aeruginosa* infections and other pyogenic infections from osteitis pubis, which is thought to be a noninfectious condition complicating pelvic surgery, childbirth, or trauma.

P. aeruginosa osteochondritis of the foot follows puncture wounds of the foot, primarily in children. The organism infects the small joints and bones, including the proximal phalanges, metatarsals, metatarsophalangeal joints, tarsal bones, and calcaneus. On average, local pain and swelling last for several weeks, and systemic symptoms are usually lacking. There may be plantar cellulitis over the involved area or tenderness upon deep palpation. Results of roentgenograms and bone scans are generally positive. Aspiration of the affected joint frequently yields purulent material in which *P. aeruginosa* can be demonstrated by Gram's staining and by culture.

P. aeruginosa is one of the most common causative agents in a variety of other, less specific syndromes involving nonhematogenous infections of bones and joints and collectively referred to as *chronic contiguous osteomyelitis*. These infections may result, for example, from compound fractures, contamination associated with open reduction and fixation of closed fractures, sternotomy performed in conjunction with cardiac surgery, contiguous spread from infected ischemic ulcers related to peripheral vascular disease or diabetes mellitus, and cellulitis in general. The chronicity, indolence, and heterogeneity of these infections explain their varied clinical manifestations and the frequent need for complicated long-term management.

Urinary Tract Infections *P. aeruginosa* is one of the most common causes of complicated and nosocomial infections of the urinary tract. These infections may result from urinary tract catheterization, instrumentation, surgery, or obstruction; they may arise from persistent foci (e.g., the prostate or stones) and may be chronic or recurrent. The urinary tract may be a target for bloodborne infection in patients with *P. aeruginosa* bacteremia but more often is the source of bacteremia. Chronic *P. aeruginosa* infections of the urinary tract are relatively common among patients with indwelling urinary catheters, altered urinary tract anatomy secondary to diversionary procedures, and paraplegia.

The clinical features of urinary tract infections due to *P. aeruginosa* are usually indistinguishable from those of other bacterial infections. However, *P. aeruginosa* infections exhibit a propensity for persistence, chronicity, resistance to antibiotic therapy, and recurrence. More unusual forms of urinary tract involvement peculiar to *P. aeruginosa* include (1) ulcerative lesions of the renal pelvis, ureters, and bladder that cause sloughing of vesical membranes in the urine; and (2) ecthyma-like lesions of the renal cortex that are seen in association with *Pseudomonas* sepsis.

Skin and Soft Tissue Infections As indicated above, *P. aeruginosa* bacteremia may be associated with the disseminated skin lesions of ecthyma gangrenosum (seePlate IID-57C). Less common skin manifestations of *P. aeruginosa* sepsis include vesicular or pustular lesions, bullae, subcutaneous nodules, deep abscesses, and cellulitis.

Metastatic lesions of the skin or mucous membranes complicate *Pseudomonas* sepsis and occasionally produce massive necrosis or gangrene of the extremities, perineum, face, or oropharynx.

Primary *P. aeruginosa* pyoderma occurs when the skin breaks down secondary to trauma, burn injury, dermatitis, or ulcers related to peripheral vascular disease or pressure sores. Moist conditions and neutropenia may predispose to this condition. The clinical appearance of primary *P. aeruginosa* pyoderma, which frequently includes hemorrhage and necrosis, resembles that of metastatic *P. aeruginosa* skin lesions. Histologic studies document vascular invasion by bacteria in both diseases. A rare distinguishing feature of *P. aeruginosa* pyoderma is its association with a blue-green exudate and a characteristic fruity odor.

P. aeruginosa wound sepsis complicating extensive third-degree burn injuries is associated with an extremely high mortality rate. This infection results from colonization of the burn site or burn eschar, invasion of the subeschar space and underlying dermis, vascular invasion, and systemic spread. The development and progression of *P. aeruginosa* burn wound sepsis are facilitated by the injury-associated breakdown of normal skin, selection of empirical antibiotics with inadequate coverage for this pathogen, and burn-related immune defects. Local manifestations include black, dark brown, or violaceous discoloration of the burn eschar; degeneration of underlying granulation tissue, hemorrhage, and premature eschar separation; edema, hemorrhage, and necrosis of skin adjacent to the burn site; and erythematous nodular lesions in unburned skin. Systemic manifestations include fever or hypothermia and other signs of sepsis,SIRS, or multiple-organ system failure. The diagnosis of *P. aeruginosa* burn sepsis is based on these local and systemic clinical manifestations and on a burn wound biopsy that reveals both>10^5colony-forming units of *P. aeruginosa* per gram of tissue and histologic evidence of bacterial invasion of unburned tissue, vasculitis, or intense inflammation at the burn margin.

P. aeruginosa causes diffuse pruritic maculopapular and vesiculopustular rashes associated with exposure to contaminated hot tubs (Fig. 128-CD4), spas, whirlpools, and swimming pools. Many cases of *P. aeruginosa* dermatitis have occurred in conjunction with a common-source outbreak. At least two nosocomial common-source outbreaks -- one related to a physiotherapy pool -- have been reported. Skin rashes may be limited to areas covered by swimsuits or may be more diffuse, sparing only the head and neck. Low-grade fever or other associated symptoms are uncommon. The illness is usually self-limited, and the rash resolves without specific therapy after cessation of exposure.

***P. aeruginosa* Infections in Patients with AIDS** During the 1980s and 1990s, *P. aeruginosa* infections were increasingly associated with AIDS. The vast majority of these infections are currently seen in patients with advanced AIDS, previous opportunistic infections, and CD4+ lymphocyte counts<100/uL (often<50/uL). The specific immunologic factors that lead to *P. aeruginosa* infections in patients with AIDS are not well understood but are speculated to be a loss of mucosal integrity, defects in cellular and humoral immunity, and qualitative leukocyte abnormalities. Of note is that the majority of *P. aeruginosa* infections in this population are community-acquired, in contrast to the nosocomial transmission documented for most *P. aeruginosa* infections

in non-AIDS patients.

Pneumonia accounts for a substantial proportion of the *P. aeruginosa* infections in patients with AIDS. In most instances, pneumonia presents as a necrotizing infection of the pulmonary parenchyma, frequently with cavitary lesions, or as a chronic relapsing bronchopulmonary infection reminiscent of the bronchopulmonary disease seen in patients with cystic fibrosis. Also frequent are bloodstream infections, including those associated with indwelling central venous catheters, and infections of the paranasal sinuses, skin and soft tissue, and urinary tract. Bacteremia, either primary or secondary to infection at a remote site, is often recurrent, associated with high mortality, and occasionally accompanied by skin manifestations similar to those seen in non-AIDS patients.

Because *P. aeruginosa* infections occur in patients with advanced AIDS, survival after recovery from the initial infection may be limited to a few months. However, with the widespread use of highly active antiretroviral therapy and the consequent increase in CD4+ cell counts, the incidence of *P. aeruginosa* infection in patients with AIDS is likely to decline and the natural history of infection to change. For example, a few patients with recalcitrant, relapsing *P. aeruginosa* bronchopulmonary infections have reportedly experienced the resolution of infection soon after initiation of intensive antiretroviral therapy.

TREATMENT

Table 155-2 lists antimicrobial agents available in the United States that are generally active against *P. aeruginosa*.Table 155-3 outlines suggested antibiotic choices and an approach to therapy for selected sites of infection. The initial antibiotic selection should take into account the local patterns of antimicrobial susceptibility, while the susceptibilities of the isolate from a particular case should guide definitive antibiotic therapy.

In most severe or life-threatening infections due to *P. aeruginosa*, two antipseudomonal antibiotics to which the infecting strain is (or is likely to be) sensitive should be administered together. The benefits of this combined therapy, as determined by in vitro studies, are to increase efficacy, to achieve additive or synergistic killing, and to prevent the emergence of antibiotic resistance. Despite widespread acceptance of combination therapy for *P. aeruginosa* infections, there are few clinical data since the advent of newerb-lactam antibiotics documenting that combination therapy is more efficacious than monotherapy or that it actually forestalls the acquisition of antimicrobial resistance. Nevertheless, combination therapy continues to be recommended for most acute or fulminant infections, as outlined in Table 155-3.

The appropriate duration of antibiotic therapy for disease caused by *P. aeruginosa* depends on the type, location, and severity of infection. In general, chronic infections associated with extensive tissue injury, disruption of normal anatomy, foreign or prosthetic material, or suboptimal antibiotic accessibility require therapy for weeks or even months rather than days. More acute infections may be treated aggressively but for shorter periods.

P. aeruginosa infections of the lower respiratory tract in cystic fibrosis pose a special challenge because of their long-standing nature. In general, antibiotic therapy for acute exacerbations results in short-term clinical improvement, while periodic expectant courses of antimicrobial therapy may limit disease progression. A more novel approach utilizing intermittent, cyclical administration of inhaled tobramycin has been shown to improve pulmonary function, decrease the risk of hospitalization, and reduce the density of *P. aeruginosa* in sputum of older patients with cystic fibrosis. Lung transplantation has also been employed with good results in selected cystic fibrosis patients with severe, progressive lower respiratory tract infections due to *P. aeruginosa*.

ANTIMICROBIAL RESISTANCE

Antibiotic resistance in *P. aeruginosa* is both intrinsic, as reflected by the relative paucity of antibiotics with inherent antimicrobial activity against wild-type strains, and acquired, as defined by high-level resistance to agents that would be expected to exhibit antimicrobial activity. Acquired resistance is rapidly increasing among *P. aeruginosa* isolates, particularly those associated with cystic fibrosis and with intensive care units. Escalating resistance among intensive care unit isolates is especially alarming. Data from theNNISsystem show an increase in rates of resistance to imipenem and fluoroquinolones from 12% during previous years to 18.5% and 23.0%, respectively, during 1999. Factors responsible for this increase may include expanding use of immunosuppressive therapies, increased severity of illness in hospitalized patients, inadequate infection control procedures, and growing antibiotic use. Resistant organisms can be transmitted directly to patients from the hospital staff, other patients, or the environment, or they may arise de novo during therapy with any given agent. Emergence of multi-drug-resistant strains has been associated with increases in secondary bacteremia and mortality and has led in some cases to longer hospital stays and increased hospitalization costs. Therapy for patients with resistant *P. aeruginosa* infections should consist of antimicrobial agents selected on the basis of extended susceptibility testing. Increased treatment duration and surgical drainage or removal of infected tissues may be necessary.

INFECTIONS CAUSED BY OTHER *PSEUDOMONAS* SPECIES OR RELATED BACTERIA

Burkholderia cepacia *B. cepacia*, like *P. aeruginosa*, is primarily an opportunistic pathogen that is implicated in both sporadic endemic infections and occasional nosocomial outbreaks. Hospital epidemics are most frequently associated with a liquid reservoir or a moist environmental surface. Colonization by *B. cepacia* precedes infection, and distinction between the two is often difficult. *B. cepacia* has been reported to cause pneumonia, urinary tract infections, meningitis, peritonitis, surgical and burn wound infections, bacteremia, and endocarditis related to injection drug use. In addition, *B. cepacia* has been implicated as a cause of chronic lower respiratory tract infections in patients with chronic granulomatous disease, in patients with sickle cell hemoglobinopathies, and -- together with *P. aeruginosa* -- in patients with cystic fibrosis. In some patients with cystic fibrosis, the appearance of *B. cepacia* has been associated with fulminant necrotizing pneumonia, bacteremia, and a rapid downhill course.

TREATMENT

The treatment of *B. cepacia* infections is complicated by intrinsic resistance of the organism to aminoglycosides and many b-lactam agents. Although trimethoprim-sulfamethoxazole and chloramphenicol have been used successfully in the treatment of *B. cepacia* infections, resistance to these two antimicrobial agents has been reported. Carbapenems, third-generation cephalosporins, and fluoroquinolones may offer activity against sensitive strains, but relevant clinical experience is limited. Some but not all cystic fibrosis centers segregate patients infected with *B. cepacia* in an attempt to reduce horizontal transmission to uninfected patients. In addition, many centers consider lung transplantation contraindicated in these patients because of an unacceptably high mortality rate after surgery.

Stenotrophomonas maltophilia *S. maltophilia* is a ubiquitous, free-living opportunistic bacterium that has emerged as an important pathogen in hospitalized patients, particularly in cancer centers and intensive care units. Factors that lead to colonization and infection include prolonged hospitalization, malignancy, instrumentation (including urinary, peritoneal, and central venous catheterization), and prior administration of broad-spectrum antibiotics. This organism has most commonly been associated with pneumonia but also causes bacteremia, urinary tract infection, wound infection, peritonitis, cholangitis, meningitis, and (rarely) endocarditis. Acute *S. maltophilia* pneumonia -- an often devastating disease associated with bacteremia -- is being seen with increasing frequency in debilitated patients on intensive care units. Antibiotic resistance in *S. maltophilia*, based on both low outer-membrane permeability and inducible b-lactamases, is at least partly responsible for the emergence of this organism as a nosocomial pathogen under the selective pressure of antibiotic treatment.

TREATMENT

Trimethoprim-sulfamethoxazole (at a trimethoprim dose of 15 to 20 mg/kg per day for patients with normal renal function) is the drug of choice for treatment of most *S. maltophilia* infections. Alternative agents include ticarcillin/clavulanate, minocycline, and doxycycline. The third-generation cephalosporins cefoperazone and ceftazidime are occasionally active against *S. maltophilia*, but in vitro susceptibilities may not reflect clinical efficacy. The aminoglycosides and imipenem are almost always inactive. Indwelling catheters or appliances that are associated with infection should be removed.

Melioidosis Infections caused by *B. pseudomallei* constitute a broad spectrum of acute and chronic, local and systemic, clinical and subclinical disease processes collectively called *melioidosis*. *B. pseudomallei* and the infections it causes are found mainly in the tropics and are endemic in Southeast Asia and surrounding areas. *B. pseudomallei* is a free-living, small, motile, aerobic, gram-negative bacillary saprophyte normally found in soil, ponds, and rice paddies and on produce from endemic areas. It is occasionally a pathogen for animals. Humans contract the disease through soil contamination of abrasions, ingestion, or inhalation. In contrast to *B. cepacia*, *B. pseudomallei* does not establish colonization without causing infection and is rarely transmitted from person to person.

Melioidosis presents in different forms. High rates of seropositivity in endemic areas such as Vietnam, Thailand, and Malaysia suggest that many infections are clinically

inapparent. The occasional diagnosis based solely on abnormal routine chest roentgenograms represents asymptomatic pneumonitis. Acute pulmonary infections may originate in the respiratory tract or result from hematogenous spread, their severity varying from mild bronchitis to extensive necrotizing pneumonia. Onset may be sudden or gradual. Fever, productive cough, and marked tachypnea are frequent. Chest roentgenograms typically reveal upper-lobe infiltrates or thin-walled cavities that may mimic tuberculosis. Acute, localized, suppurative skin infections associated with nodular lymphangitis and regional lymphadenitis result from direct inoculation at sites of minor skin trauma. Recrudescent disease arising from inactive sites of infection and perhaps triggered by intercurrent illness or other events may present in an acute or chronic form.

Either acute suppurative infections or pulmonary disease may give rise to hematogenous dissemination and the acute septicemic form of melioidosis. This progression is more likely in chronically debilitated patients, such as those with diabetes mellitus or alcoholism. Septicemic patients may present with severe tachypnea, confusion, headache, pharyngitis, diarrhea, and pustular lesions of the head, trunk, and extremities. The skin may be flushed or cyanotic, signs of meningitis or arthritis may be apparent, the liver and spleen may be enlarged, and muscle tenderness may be striking. Chest roentgenograms show diffuse nodular densities that may expand, coalesce, and finally cavitate. The acute septicemic form of melioidosis usually follows a rapid downhill course, ending in early death. Mortality remains high despite optimal therapy.

The diagnosis of melioidosis should be entertained when a febrile patient who has been in an endemic area presents with an acute lower respiratory tract illness associated with tachypnea, exhibits unusual skin or subcutaneous lesions, or has a chest roentgenogram suggesting tuberculosis in the absence of sputum-associated tubercle bacilli. An etiologic diagnosis may be made by microscopic demonstration of small, irregularly staining, gram-negative rods in exudate material; by characteristic bipolar ("safety-pin") staining of organisms with methylene blue; and by a culture positive for *B. pseudomallei* and/or a fourfold or greater rise in the titer of serum antibody to the organism.

TREATMENT

The mainstay of treatment for melioidosis is antibiotic administration combined with appropriate surgical drainage of abscesses and aggressive support for patients with septicemic forms of the disease. The guidelines for antibiotic therapy are somewhat imprecise. Subclinical infection or mere seropositivity does not usually require specific therapy. Ceftazidime or imipenem appears to be the agent of choice for clinical disease, including severe infections, while trimethoprim-sulfamethoxazole, cefotaxime, and amoxicillin/clavulanate are possible alternatives. Combination therapy with ceftazidime or imipenem plus trimethoprim-sulfamethoxazole may be indicated in severe forms of melioidosis, including septicemia. Unfortunately, increasing resistance of many strains of *B. pseudomallei* to trimethoprim-sulfamethoxazole, particularly in Southeast Asia, is of concern. Patients with acute pulmonary infections who are treated with either ceftazidime or imipenem should receive antibiotics until they show definite evidence of clinical improvement (often after 10 to 30 days), at which time therapy can be switched to an oral maintenance regimen -- a combination of chloramphenicol,

trimethoprim-sulfamethoxazole, and doxycycline or the single agent amoxicillin/clavulanate -- and continued for 12 to 20 weeks. Chronic disease associated with persistently positive sputum cultures and extrapulmonary suppurative disease may require treatment for up to 1 year.

Other Species *Pseudomonas fluorescens* occasionally causes human disease; it is implicated particularly often in infections related to the administration of contaminated (stored) blood products and in pseudoinfections. Additional species that are associated only rarely with human infections include *P. putida*, *P. stutzeri*, *P. pseudoalcaligenes*, and (all formerly *Pseudomonas* species) *Burkholderia gladioli*, *B. pickettii*, *Comamonas acidovorans*, *C. testosteroni*, *Brevundimonas diminuta*, and *B. vesicularis*.

156. SALMONELLOSIS - *Cammie F. Lesser*, *Samuel I. Miller*

The salmonellae constitute a genus of over 2300 serotypes that are highly adapted for growth in both human and animal hosts and cause a wide spectrum of disease. A subset of *Salmonella* serotypes that includes *S. typhi* and *S. paratyphi* causes enteric (typhoid) fever and is restricted to growth in human hosts. The remainder of *Salmonella* serotypes, referred to as nontyphoidal *Salmonella*, are prevalent in the gastrointestinal tracts of a broad range of animals, including mammals, reptiles, birds, and insects. Over 200 of these serotypes are pathogenic to humans; these pathogenic serotypes cause gastroenteritis and can be associated with localized infections and/or bacteremia.

ETIOLOGY

Salmonella is a large genus of gram-negative bacilli within the family Enterobacteriaceae. The nomenclature and classification of these bacteria have undergone numerous revisions, most recently in 1983 when -- on the basis of a high degree of DNA similarity between the bacterial genomes -- over 2000 bacterial strains were grouped into one species, *S. choleraesuis*. This species was further divided into seven subgroups based on host range specificity and additional DNA similarity. Almost all the strains pathogenic for humans are in subgroup 1 (*enterica* or *choleraesuis*) except for those causing rare infections (subgroups 3a and 3b). The nomenclature of this large species is quite complex. For example, the correct taxonomic name for the organism that causes enteric fever is *Salmonella choleraesuis* ssp. *choleraesuis* (or subgroup 1), serovar *typhi*. Given the cumbersome nature of this nomenclature system, a simplified system is in widespread use, in which the common species name that existed before the reclassification of the species is accepted. For example, *S. choleraesuis* ssp. *choleraesuis*, serovar *typhi*, is referred to by its common name, *S. typhi*.

The initial identification of this genus in the clinical laboratory relies on growth characteristics. Like other Enterobacteriaceae, salmonellae produce acid on glucose fermentation, reduce nitrates, and do not produce cytochrome oxidase. They are non-spore-forming and facultatively anaerobic. With few exceptions, salmonellae are motile by means of peritrichous flagella (exception: *S. gallinarum-pullorum*) and produce gas (H_2S) on sugar fermentation (exception: *S. typhi*). Since 99% of clinical isolates are lactose nonfermenters, rare clinical isolates may not be detected if a high level of suspicion is not maintained.

Salmonella can be further divided into serovars based on the detection of three major antigenic determinants: the somatic O antigen [lipopolysaccharide (LPS) cell-wall components], the surface Vi antigen (restricted to *S. typhi* and *S. paratyphi* C), and the flagellar H antigen. In general, clinical laboratories initially divide *Salmonella* into serogroups (A, B, C_1, C_2, D, and E) based on reactivity to somatic O-antigen antisera. These initial groupings provide only limited clinical information, given their high degree of cross-reactivity. Thus, additional biochemical and serologic tests are needed to determine serotype. For the epidemiologic evaluation of *Salmonella* outbreaks, specific *Salmonella* strains within serovars can be distinguished by bacteriophage typing, plasmid profile determination, and restriction length polymorphism analysis.

PATHOGENESIS

Salmonellae are transmitted to humans orally by contaminated food or water. The bacteria traverse the gastrointestinal tract, including the acidic environment of the stomach, to colonize the small intestines. In the case of enteric fever (a systemic illness), salmonellae cross the intestinal barrier, where phagocytosis by macrophages results in their dissemination throughout the reticuloendothelial system. In nontyphoidal salmonellosis, the bacteria generally cause a localized infection resulting in an influx of neutrophils to the intestines and self-limited gastroenteritis.

Numerous attempts have been made to determine the infectious dose (ID_{50}) of *Salmonella*, both in the laboratory and in the field. Controlled experiments, in which healthy volunteers were exposed to laboratory-grown strains of *S. typhi*, concluded that the ID_{50} was 10_6colony-forming units (CFU); increases in the ID_{50}corresponded to decreases in incubation time. However, analyses of salmonellosis outbreaks with a known source indicate that the ID_{50} can be as low as 10_3 CFU. Host defenses, the most important of which appears to be the acidity of the stomach, most likely account for variations in the ID_{50}. Conditions that decrease stomach acidity (an age of<1 year, antacid ingestion, or achlorhydric disease) increase susceptibility to *Salmonella* infection, as do conditions that decrease intestinal integrity (inflammatory bowel disease, history of gastrointestinal surgery, or alteration of the intestinal flora by antibiotic administration).

Once salmonellae reach the small intestine, the bacteria resist a variety of innate immune factors (including bile salts, lysozyme, complement, and cationic antimicrobial peptides) before penetrating the mucus layer. The organisms enter the intestines through phagocytic microfold or M cells overlying the Peyer's patches. Salmonellae also enter normally nonphagocytic epithelial cells by a process known as *bacteria-mediated endocytosis*, whose mechanism is not entirely clear but depends on the direct translocation of *Salmonella* proteins into the host cell cytoplasm by a specialized secretion apparatus (type III secretion).

In enteric (typhoid) fever, salmonellae (*S. typhi* or *S. paratyphi*) undergo phagocytosis by macrophages after crossing the epithelial layer of the small intestine. Once phagocytosed, the bacteria are protected from polymorphonuclear leukocytes (PMNs), the complement system, and the acquired immune response (antibodies). Salmonellae have evolved mechanisms to avoid or delay killing by macrophages. Upon phagocytosis, the bacteria form a "spacious phagosome" and alter the regulation of ~200 bacterial proteins. The best-characterized regulatory system is PhoP/PhoQ, a two-component regulon that senses changes in bacterial location and alters bacterial protein expression. The alterations mediated by PhoP/PhoQ include modifications inLPS and in the synthesis of outer-membrane proteins; these changes presumably remodel the bacteria's outer surface such that the organisms can resist microbicidal activities and possibly alter host cell signaling. PhoP/PhoQ also mediates the synthesis of divalent cationic transporters that scavenge magnesium. By a second type III secretion mechanism, salmonellae can directly translocate bacterial proteins into the macrophage, a phenomenon that is believed to promote survival within phagocytes.

After phagocytosis, salmonellae disseminate throughout the body in macrophages via

the lymphatics and colonize reticuloendothelial tissues (liver, spleen, lymph nodes, and bone marrow). During this initial incubation stage, patients are relatively asymptomatic. Signs and symptoms, including fever and abdominal pain, probably result from secretion of cytokines by macrophages when a critical number of organisms have replicated. For example, the observed hepatosplenomegaly is likely to be related to the recruitment of mononuclear cells and the development of a cell-mediated immune response to *S. typhi* colonization. The recruitment of additional mononuclear cells and lymphocytes to Peyer's patches during the several weeks after initial colonization/infection can result in marked enlargement and necrosis of the Peyer's patches, with right-lower-quadrant abdominal pain.

It is not known why *S. typhi* and *S. paratyphi* cause systemic disease while the vast majority of pathogenic *Salmonella* strains cause gastroenteritis. In contrast to enteric fever, which is characterized by an infiltration of mononuclear cells into the small-bowel mucosa, nontyphoidal *Salmonella* gastroenteritis is characterized by massivePMNinfiltration into both the large- and the small-bowel mucosa. This response appears to depend on the induction of interleukin (IL) 8, a strong neutrophil chemotactic factor, which is secreted by intestinal cells. The degranulation and release of toxic substances by neutrophils may result in damage to the intestinal mucosa, causing inflammatory diarrhea.

ENTERIC (TYPHOID) FEVER

Typhoid fever is a systemic disease characterized by fever and abdominal pain caused by dissemination of *S. typhi* or *S. paratyphi*. The disease was initially called *typhoid fever* because of its clinical similarity to typhus. However, in the early 1800s, typhoid fever was clearly defined pathologically as a unique illness on the basis of its association with enlarged Peyer's patches and mesenteric lymph nodes. In 1869, given the anatomic site of infection, the term *enteric fever* was proposed as an alternative designation to distinguish typhoid fever from typhus. However, to this day, the two designations are used interchangeably.

EPIDEMIOLOGY

In contrast to other *Salmonella* serotypes, the etiologic agents of enteric fever -- *S. typhi* and *S. paratyphi* -- have no known hosts other than humans. Thus, enteric fever is transmitted only through close contact with acutely infected individuals or chronic carriers. While direct person-to-person transmission through the fecal-oral route has been documented, it is quite rare. Rather, most cases of disease result from ingestion of contaminated food or water. Health care workers occasionally acquire enteric fever after exposure to infected patients, while laboratory workers can acquire the disease after laboratory accidents.

Over the past four decades, with the advent of improvements in food handling and water/sewage treatment, enteric fever has become a rare occurrence in developed nations. Over the past 10 years, ~400 cases of typhoid fever and even fewer cases of paratyphoid fever have been reported annually in the United States. In contrast, enteric fever continues to be a global health problem, with an estimated 13 to 17 million cases worldwide resulting in ~600,000 deaths per year. Children<1 year of age appear to be

most susceptible to initial infection and to the development of severe disease.

Enteric fever is endemic in most developing regions, especially the Indian subcontinent, South and Central America, and Asia, and is related to rapid population growth, increased urbanization, inadequate human waste treatment, limited water supply, and overburdened health care systems. These conditions most likely account for the recent epidemics of typhoid fever in eastern Europe. Antibiotic resistance among salmonellae is also a rising concern and has recently been linked to antibiotic use in livestock. Many *S. typhi* strains contain plasmids encoding resistance to chloramphenicol, ampicillin, and trimethoprim -- the antibiotics that have long been used to treat enteric fever. In addition, resistance to ciprofloxacin, either chromosomally or plasmid encoded, has been observed in Asia. Morbidity and mortality are increased in outbreaks associated with antibiotic-resistant strains, presumably because of inadequate or delayed appropriate treatment.

The high worldwide prevalence of enteric fever serves as a reservoir for cases in the United States. Over 70% of U.S. cases are related to international travel within 30 days before onset. Only 3% of travelers diagnosed with enteric fever give a history of vaccination against *S. typhi* within the previous 2 years. Of U.S. cases of internationally acquired enteric fever, 80% can be linked to travel in six countries: Mexico (28%), India (25%), the Philippines (10%), Pakistan (8%), El Salvador (5%), and Haiti (4%). While the percentage of cases associated with travel to Mexico is declining, travel to the Indian subcontinent is becoming much riskier, with an incidence 18 times higher than for any other area. The recent trend toward an increased incidence of multidrug-resistant (MDR) *Salmonella* (see "Treatment," below) in developing countries is reflected by the increase in the proportion of U.S. cases caused by MDR strains from 0.6% in 1985-1989 to 12% in 1990-1994.

Almost 30% of the reported cases of enteric fever in the United States are domestically acquired. Although the majority of these cases (80%) are sporadic, large outbreaks do occur. In the most notable outbreak in the past 15 years, 47 culture-proven and 24 potential cases were linked to contaminated orange juice at a resort in New York. Evaluation of this outbreak led to the identification of a previously unknown chronic carrier. Similarly, evaluation of 25% of the 571 cases of domestically acquired enteric fever reported between 1985 and 1994 led to the identification of previously unknown chronic carriers.

CLINICAL COURSE

Enteric fever is a misnomer, in that the hallmark features of this disease -- fever and abdominal pain -- are variable. While fever is documented at presentation in >75% of cases, abdominal pain is reported in only 20 to 40%. Thus, a high index of suspicion for this potentially lethal systemic illness is necessary when a person presents with fever and a history of recent travel to a developing country.

The incubation period for *S. typhi* ranges from 3 to 21 days. This variability is most likely related to the size of the initial inoculum and the health and immune status of the host. The most prominent symptom of this systemic infection is prolonged fever (38.8° to 40.5°C, or 101.8° to 104.9°F). A prodrome of nonspecific symptoms often precedes

fever and includes chills, headache, anorexia, cough, weakness, sore throat, dizziness, and muscle pains. Gastrointestinal symptoms are quite variable. Patients can present with either diarrhea or constipation; diarrhea is more common among patients with AIDS and among children<1 year of age. As stated above, only 20 to 40% of patients present with abdominal pain, although the majority have abdominal tenderness over the course of the disease. In general, the symptoms associated with *S. typhi* are more severe than those associated with *S. paratyphi*.

Early physical findings of enteric fever include rash ("rose spots"), hepatosplenomegaly, epistaxis, and relative bradycardia. Rose spots make up a faint, salmon-colored, blanching, maculopapular rash located primarily on the trunk and chest. The rash is evident in ~30% of patients at the end of the first week and resolves after 2 to 5 days without leaving a trace. Patients can have two or three crops of lesions, and *Salmonella* can be cultured from punch biopsies of these lesions. The faintness of the rash makes it difficult to detect in dark-skinned patients. On occasion, patients who remain toxic manifest neuropsychiatric symptoms described as a "muttering delirium" or "coma vigil," with picking at bedclothes or imaginary objects.

Late complications, occurring in the third and fourth weeks of infection, are most common in untreated adults and include intestinal perforation and/or gastrointestinal hemorrhage. These complications can develop despite clinical improvement and presumably result from necrosis at the initial site of *Salmonella* infiltration in the Peyer's patches of the small intestine. Both complications are life-threatening and require immediate medical and surgical interventions, with broadened antibiotic coverage for polymicrobial peritonitis (Chap. 130) and treatment of gastrointestinal hemorrhages, including bowel resection.

Rare complications whose incidences are reduced by prompt antibiotic treatment include pancreatitis, hepatic and splenic abscesses, endocarditis, pericarditis, orchitis, hepatitis, meningitis, nephritis, myocarditis, pneumonia, arthritis, osteomyelitis, and parotitis. Despite prompt antibiotic treatment, relapse rates remain at ~10% in immunocompetent hosts.

Approximately 1 to 5% of patients with enteric fever become long-term, asymptomatic, chronic carriers who shed *S. typhi* in either urine or stool for >1 year. The incidence of chronic carriage is higher among women and among persons with biliary abnormalities (e.g., gallstones, carcinoma of the gallbladder) and gastrointestinal malignancies. The anatomic abnormalities associated with these conditions presumably allow prolonged colonization.

DIAGNOSIS

Other than a positive culture, no specific laboratory test is diagnostic for enteric fever. In 15 to 25% of cases, leukopenia and neutropenia are detectable. In the majority of cases, the white blood cell count is normal despite high fever. However, leukocytosis can develop in typhoid fever (especially in children) during the first 10 days of the illness, or later if the disease course is complicated by intestinal perforation or secondary infection. Other nonspecific laboratory results include moderately elevated values in liver function tests (aminotransferases, alkaline phosphatase, and lactate

dehydrogenase). In addition, nonspecific ST and T wave abnormalities can be seen on electrocardiograms.

The diagnostic "gold standard" is a culture positive for *S. typhi* or *S. paratyphi*. The yield of blood cultures is quite variable: it can be as high as 90% during the first week of infection and decrease to 50% by the third week. A low yield is related to low numbers of *Salmonella* (<15 organisms per milliliter) in infected patients and/or to recent antibiotic treatment. Centrifugation to isolate and culture the buffy coat, which contains abundant blood mononuclear cells associated with the bacteria, decreases time to isolation but does not affect culture sensitivity.

A diagnosis can also be based on positive cultures of stool, urine, rose spots, bone marrow, and gastric or intestinal secretions. Unlike blood cultures, bone marrow cultures remain highly (90%) sensitive despite £5 days of antibiotic therapy. Culture of intestinal secretions (best obtained by a noninvasive duodenal string test) can be positive despite a negative bone marrow culture. If blood, bone marrow, and intestinal secretions are all cultured, the yield of a positive culture is >90%. Stool cultures, while negative in 60 to 70% of cases during the first week, can become positive during the third week of infection in untreated patients. Although the majority of patients (90%) clear bacteria from the stool by the eighth week, a small percentage become chronic carriers and continue to have positive stool cultures for at least 1 year.

Several serologic tests, including the classic Widal test for "febrile agglutinins," are available; however, given high rates of false-positivity and false-negativity, these tests are not clinically useful. Polymerase chain reaction and DNA probe assays are being developed.

TREATMENT

In the preantibiotic era, the mortality rate from typhoid fever was as high as 15%. The introduction of treatment with chloramphenicol in 1948 greatly altered the disease course, decreasing mortality to <1% and the duration of fever from 14-28 days to 3-5 days. Chloramphenicol remained the standard treatment for enteric fever until the emergence of plasmid-mediated resistance to this drug in the 1970s. Given the increased mortality associated with resistance to chloramphenicol and the rare chloramphenicol-induced bone marrow toxicity, ampicillin (1 g orally every 6 h) and trimethoprim-sulfamethoxazole (TMP-SMZ; one double-strength tablet twice daily) became the mainstays of treatment.

In 1989,MDR*S. typhi* emerged. These bacteria are resistant to chloramphenicol, ampicillin, trimethoprim, streptomycin, sulfonamides, and tetracycline. Like chloramphenicol resistance, resistance to ampicillin and trimethoprim is plasmid-encoded. In 1994, 12% of *S. typhi* isolates in the United States were MDR. Thus either quinolones or third-generation cephalosporins are currently recommended for empirical antibiotic treatment. Despite efficient in vitro killing of *Salmonella*, first- and second-generation cephalosporins as well as aminoglycosides are ineffective in treating clinical infections.

Ceftriaxone (1 to 2 g intravenously or intramuscularly) for 10 to 14 days is equivalent to

oral or intravenous chloramphenicol in the treatment of susceptible strains. Preliminary studies indicate that a 5- to 7-day course of ceftriaxone is likely to be sufficient for treatment of uncomplicated cases. However, one recent report describes a ceftriaxone-resistant *Salmonella* strain isolated from a child with diarrhea and apparently acquired from antibiotic-treated cattle.

Quinolones are the only available oral antibiotics for the treatment ofMDR*S. typhi* infections. The greatest experience has been gained for ciprofloxacin (500 mg orally twice a day for 10 days). Shorter courses of ofloxacin (10 to 15 mg/kg in divided doses twice daily for 2 to 3 days) have also been successful. However, quinolone resistance is emerging. In 1993, an outbreak of nalidixic acid-resistant *S. typhi* (NARST) infections in Vietnam was linked to chromosomal mutations in the gene encoding DNA gyrase (the target of the quinolones). NARST strains have also been isolated in India. Thus, all strains of *S. typhi* must be screened for resistance to nalidixic acid and tested for sensitivity to a clinically appropriate quinolone. Patients infected with NARST strains need to be treated with higher doses of ciprofloxacin (10 mg/kg twice a day for 10 days) or longer courses of ofloxacin (10 to 15 mg/kg in divided doses twice daily for 7 to 10 days) or with other antibiotics to which the strains are sensitive.

In cases of severe typhoid fever (fever; an abnormal state of consciousness -- i.e., delirium, obtundation, stupor, or coma -- or septic shock; and a positive culture for *S. typhi* or *S. paratyphi* A), dexamethasone treatment should be considered. In a single trial in Jakarta in the early 1980s in chloramphenicol-treated patients, treatment with dexamethasone (a single dose of 3 mg/kg followed by eight doses of 1 mg/kg, given every 6 h) decreased mortality from 56% to 10%.

The 1 to 4% of patients who develop chronic carriage of *Salmonella* can be treated for 6 weeks with an appropriate antibiotic. Treatment with oral amoxicillin,TMP-SMZ, ciprofloxacin, or norfloxacin has been shown to be ~80% effective in eradicating chronic carriage of susceptible organisms. However, in cases of anatomic abnormality (e.g., biliary or kidney stones), eradication of the infection often cannot be achieved by antibiotic therapy alone but also requires surgical correction of the abnormalities.

PREVENTION AND CONTROL

Theoretically, it is possible to eliminate salmonellae that cause enteric fever since the bacteria survive only in human hosts and are spread by contaminated food and water. However, given the high prevalence of the disease in developing countries that lack good facilities for sewage disposal and water treatment, this goal is currently unrealistic. Thus, travelers to developing countries should be advised to monitor their food and water intake carefully and to consider vaccination.

Three vaccine alternatives are available: (1) a heat-killed, phenol-extracted, whole-cell vaccine (two parenteral doses); (2) Ty21a, an attenuated *S. typhi* vaccine (four oral doses); and (3) ViCPS, consisting of purified Vi polysaccharide from the bacterial capsule (one parenteral dose). In addition, an acetone-killed whole-cell vaccine is available only for use by the U.S. military. The minimal ages for vaccination with the whole-cell, Ty21a, and ViCPS vaccines are 6 years, 2 years, and 6 months, respectively. A large-scale meta-analysis of vaccine trials in populations of endemic

areas indicates that, while all three vaccines have similar efficacy for the first year, the 3-year cumulative efficacy of the whole-cell vaccine (73%) exceeds that of both Ty21a (51%) and purified Vi (55%). In addition, the heat-killed whole-cell vaccine maintains its efficacy for 5 years, while Ty21a and ViCPS most likely maintain their efficacy for 4 and 2 years, respectively. However, the whole-cell vaccine is associated with a much higher incidence of side effects than the other two vaccines: 16% of whole-cell vaccine recipients develop fever and 10% miss a day of work or school, while only 1 to 2% of persons receiving the alternative vaccines have any fever.

Although data on typhoid vaccines in travelers are limited, some evidence suggests that efficacy may be substantially lower than those for populations in endemic areas. The Centers for Disease Control and Prevention (CDC) currently recommends vaccination for persons traveling to developing countries who will have prolonged exposure to contaminated food and water or close contact with indigenous populations in rural areas. The only recommendations for domestic vaccination include people who have intimate or household contact with a chronic carrier or laboratory workers who frequently work with *S. typhi*. Given the decreased incidence of side effects and the similar short-term efficacy, the current bias is toward vaccination of travelers with either Ty21a or ViCPS.

Enteric fever is a reportable disease in the United States. This reporting system enables public health departments to track down potential source patients and thus to identify and treat chronic carriers in order to prevent further outbreaks. In addition, since 1 to 4% of patients with *S. typhi* infection become chronic carriers, it is important to monitor patients (especially those employed in child care or food handling) for chronic carriage and to treat this condition if indicated.

NONTYPHOIDAL SALMONELLOSIS

EPIDEMIOLOGY

The incidence of nontyphoidal salmonellosis has doubled in the United States over the past two decades. Currently, theCDCestimates that there are 2 million cases annually, with 500 to 2000 deaths. Although over 200 serovars of *Salmonella* are considered to be human pathogens, the majority of the reported cases in the United States is caused by *S. typhimurium* or *S. enteritidis*. The incidence of salmonellosis is highest during the rainy season in tropical climates and during the warmer months in temperate climates, coinciding with the peak in food-borne outbreaks. Morbidity and mortality associated with salmonellosis are highest among the elderly, infants, and immunocompromised individuals, including those with hemoglobinopathies and those infected with HIV or with pathogens that cause blockade of the reticuloendothelial system (e.g., patients with bartonellosis, malaria, schistosomiasis, or histoplasmosis).

Unlike *S. typhi* and *S. paratyphi*, whose only reservoir is humans, nontyphoidal salmonellosis is acquired from multiple animal reservoirs. The main mode of transmission is from food products contaminated with animal products or waste -- most commonly eggs and poultry but also undercooked meat, unpasteurized dairy products, seafood, and fresh produce.

S. enteritidis associated with chicken eggs is emerging as a major cause of food-borne disease. *S. enteritidis* causes infection of the ovaries and upper oviduct tissue of hens, resulting in contamination of the contents of eggs prior to shell deposition. Approximately 1 in 20,000 eggs is thought to be infected with *S. enteritidis*. Between 1974 and 1994, there was a fivefold increase (from 5% to 25%) in the isolation of *S. enteritidis* from eggs in the United States; in 1998, the U.S. Department of Agriculture estimated that 80% of all salmonellosis cases were caused by infected eggs. Eradication of *S. enteritidis* from hens has proven difficult, given that infection is spread to egg-laying hens both vertically from breeding flocks and horizontally through contact with rodents and manure. Transmission via contaminated eggs can be prevented by cooking of eggs such that the liquid yolk is solidified or through pasteurization of egg products.

Another factor in the increasing incidence of nontyphoidal salmonellosis in developed countries, including the United States, is related to the centralization of food processing and widespread distribution. For example, a 1994 outbreak of ~250,000 cases was linked to a pasteurized ice-cream premix most likely contaminated in tanker trucks that had previously carried unpasteurized eggs. Similar outbreaks have been traced to manufactured foods including pasteurized milk, infant formula, powdered-milk products, paprika-powdered potato chips, and a ready-to-eat savory snack. In addition, large outbreaks have been linked to fresh produce, including alfalfa sprouts, cantaloupe, fresh-squeezed orange juice, and sliced tomatoes, contaminated by manure or water at a single site and then broadly distributed.

A less common source of nontyphoidal *Salmonella* infections is exposure to exotic pets, especially reptiles. Fecal carriage rates in reptiles can be>90%. In the 1970s, 14% of cases of salmonellosis were attributed to small turtles; the distribution of these pets was subsequently prohibited by the U.S. Food and Drug Administration, with a resultant decline in rates of reptile-associated salmonellosis. However, since 1986, an increase in the popularity of nonbanned reptiles, including iguanas, has been followed by increases in rates of *Salmonella* infections. Other pets, including African hedgehogs, snakes, birds, rodents, baby chicks, ducklings, dogs, and cats, can also serve as potential vectors.

Antibiotic resistance is an increasing phenomenon among nontyphoidal *Salmonella* serovars. In particular, *S. typhimurium* of definitive phage type 104 (DT104) -- a serotype resistant to ampicillin, chloramphenicol, streptomycin, sulfonamides, and tetracyclines -- has become prominent in the United Kingdom. This serotype is associated with greater mortality and morbidity than other nontyphoidal *Salmonella* serotypes. Its acquisition is associated with exposure to ill farm animals and to a variety of meat products. The prevalence of *S. typhimurium* DT104 in the United States increased from 0.6% in 1979-1980 to 34% in 1996. Of concern is the isolation in the United Kingdom in 1996 of *S. typhimurium* DT104 strains resistant to ciprofloxacin (14%) or trimethoprim (24%).

CLINICAL MANIFESTATIONS

Gastroenteritis Infection with nontyphoidal *Salmonella* most often results in gastroenteritis indistinguishable from that caused by other bacterial and viral pathogens.

Nausea, vomiting, and diarrhea occur 6 to 48 h after the ingestion of contaminated food or water. Patients often experience abdominal cramping and fever (38 to 39°C, or 100.5 to 102.2°F). The diarrhea is usually characterized as loose, nonbloody stools of moderate volume. However, large-volume watery stools, bloody stools, or symptoms of dysentery do not rule out the diagnosis. Rarely, *Salmonella* causes a syndrome of pseudoappendicitis or an illness that mimics inflammatory bowel disease.

Gastroenteritis caused by nontyphoidal *Salmonella* is usually self-limited. Diarrhea resolves within 3 to 7 days and fever within 72 h. Stool cultures remain positive for 4 to 5 weeks after infection and -- in rare cases of chronic carriage (<1%) -- remain positive for >1 year. Antibiotic treatment is usually not recommended and in some studies has prolonged carriage of *Salmonella*. Neonates, the elderly, and the immunosuppressed (e.g., HIV-infected patients) with nontyphoidal *Salmonella* gastroenteritis are especially susceptible to dehydration and dissemination and may require hospitalization and antibiotic therapy.

Bacteremia and Endovascular Infections Up to 5% of patients with nontyphoidal *Salmonella* gastroenteritis have positive blood cultures, and 5 to 10% of these bacteremic persons develop localized infections. Bacteremia is particularly common and persistent among infants, the elderly, and patients with severe underlying infection or immunosuppression (e.g., transplant recipients, HIV-infected patients). Salmonellae have a propensity for infection of vascular sites; if>50% of three or more blood cultures are positive, an endovascular infection should be suspected. Preexisting valvular heart disease is a strong risk factor for the development of endocarditis, while atherosclerotic plaque, prosthetic grafts, and aortic aneurysms are associated with arteritis. Arteritis should be suspected in elderly patients who have a history of prolonged fever with associated back, chest, or abdominal pain preceded by gastroenteritis. Endocarditis and arteritis are rare (<1% of cases) but are associated with potentially morbid complications. Endocarditis can be complicated by cardiac valve perforation or by ring or septal abscesses, while arteritis can be associated with mycotic aneurysms, ruptured aneurysms, or vertebral osteomyelitis.

Unlike most nontyphoidal *Salmonella* serotypes, *S. choleraesuis* and *S. dublin* are frequently associated with sustained bacteremia and fever, often in the absence of a history of gastroenteritis. Similarly, these serotypes appear to be especially invasive and are often associated with metastatic infection.

Localized Infections

Intraabdominal Infections Intraabdominal infections due to nontyphoidal *Salmonella* are rare and usually manifest as hepatic or splenic abscesses or as cholecystitis. Involvement of the pancreas and adrenals and even an infected pheochromocytoma have been reported. Risk factors include anatomic abnormalities of the hepatobiliary system, including gallstones; abdominal malignancy; and sickle cell disease (especially with splenic abscesses). Eradication of the infection often requires surgical correction of anatomic abnormalities and drainage of abscesses.

Central Nervous System Infections Salmonella infections of the central nervous system usually manifest as meningitis, although cerebral abscesses have been found.

Meningitis is usually seen in neonates (<4 months old) and is associated with severe sequelae, including residual seizures, hydrocephalus, ventriculitis, abscess formation, subdural empyema, and permanent disability (e.g., mental retardation and paralysis).

Pulmonary Infections Nontyphoidal *Salmonella* pulmonary infections usually present as lobar pneumonia, sometimes complicated by lung abscesses, empyemas, pleural effusions, and bronchopleural fistulas. The majority of cases occur in patients with a preexisting abnormality of lung or pleura, including malignancy. Additional risk factors include sickle cell disease and glucocorticoid use. It is important to determine whether the pulmonary infection is in fact due to *Salmonella* or whether it is a secondary infection.

Urinary and Genital Tract Infections Urinary tract infections caused by nontyphoidal salmonellae present as either cystitis or pyelonephritis, usually in association with malignancy, urolithiasis, structural abnormalities, or immunosuppression (HIV infection, renal transplantation). Genital infections due to these bacteria are rare and present as ovarian and testicular abscesses, prostatitis, or epididymitis. Like other focal infections, both genital and urinary tract infections can be complicated by abscess formation.

Bone, Joint, and Soft Tissue Infections Salmonella osteomyelitis most commonly affects the femur, tibia, humerus, or lumbar vertebrae and is most often seen in association with sickle cell disease, hemoglobinopathies, or preexisting bone disease (e.g., fractures). Prolonged antibiotic treatment is recommended to decrease the incidence of relapse and chronic osteomyelitis. Septic arthritis occurs in the same patient population as osteomyelitis and usually presents in the knee, hip, or shoulder joints. Reactive arthritis (Reiter's syndrome) can follow *Salmonella* gastroenteritis and is seen most frequently in persons with the HLA-B27 histocompatibility antigen. *Salmonella* can cause rare soft tissue infections, usually at sites of local trauma in immunosuppressed patients.

DIAGNOSIS

Nontyphoidal *Salmonella* gastroenteritis is diagnosed when *Salmonella* is cultured from stool. All salmonellae isolated in clinical laboratories should be sent to local public health departments. In cases where there is concern about bacteremia (i.e., those including prolonged or recurrent fever), blood cultures are indicated. Once bacteremia is documented, it is important to determine whether it is high-grade (>50% of three or more blood cultures positive); if so, endovascular infection is possible and further evaluation to identify the source is indicated. In addition, depending on clinical symptoms and on whether metastatic disease is suspected, other body fluids, such as joint fluid or cerebrospinal fluid, should be cultured.

TREATMENT

Antibiotic treatment is not generally recommended for *Salmonella* gastroenteritis. The symptoms are usually self-limited and have not been demonstrated to be altered by short courses of antibiotics. In addition, in case-control and double-blind placebo-controlled trials, antibiotic treatment has been associated with increased rates of relapse and prolonged gastrointestinal carriage. Dehydration secondary to diarrhea

should be treated with fluid and electrolyte replacement.

However, preemptive antibiotic treatment should be considered in patients at increased risk for metastatic infection. These patients include neonates (probably up to 3 months of age); persons >50 years old (because of the high risk of atherosclerotic plaque or aneurysm); transplant recipients; and patients with lymphoproliferative disease, HIV infection, prosthetic joints, vascular grafts, significant joint disease, or underlying sickle cell disease. This group should receive a course of oral or intravenous antibiotics lasting for 2 or 3 days or until defervescence. Longer courses of antibiotics are not recommended because they have been associated with higher rates of chronic carriage and relapse. Rare cases of chronic nontyphoidal *Salmonella* carriage should be treated with a prolonged antibiotic course, as described above for chronic carriage of *S. typhi*.

Focal infections or life-threatening bacteremia with nontyphoidal *Salmonella* should be treated with antibiotics (at the same doses used for enteric fever). Given the increasing prevalence of antibiotic resistance, empirical therapy should include a third-generation cephalosporin and/or a quinolone. If the bacteremia is low-grade (<50% of blood cultures positive), the patient should be treated for 7 to 14 days. Patients with AIDS and *Salmonella* bacteremia should receive 1 to 2 weeks of intravenous antibiotic therapy followed by 4 weeks of oral therapy with quinolones. Patients who relapse after this regimen should receive long-term suppressive therapy with a quinolone orTMP-SMZ, as indicated by bacterial sensitivities.

If the patient has an endovascular infection or endocarditis, treatment for 6 weeks with intravenous b-lactam antibiotics is indicated. Chloramphenicol treatment has been associated with high failure rates and is not recommended. Limited case reports have described the successful treatment of *Salmonella* endovascular infections with quinolones, which may prove an alternative approach in cases caused by sensitive strains. However, concern remains about the development of quinolone resistance during prolonged therapy. Surgical resection of infected aneurysms or other infected endovascular sites is often required. If surgical resection is not possible, lifelong suppressive antibiotic therapy may be indicated. For extraintestinal nonvascular infections, 2 to 4 weeks of antibiotic therapy (depending on the site) are usually recommended. In cases of chronic osteomyelitis, abscesses, and urinary or biliary tract abnormality, surgical interventions may be required in addition to prolonged antibiotic therapy to eradicate infection.

PREVENTION AND CONTROL

The incidence of nontyphoidal salmonellosis continues to rise along with rates of emergence of antibiotic-resistant strains. The increased centralization of food production plays a prominent role in the growing incidence, as one oversight can result in rapid, widespread distribution of contaminated food. Thus, it is important to monitor every step of food production, from handling of raw products to preparation of finished foods. In particular, with the increasing prevalence of *S. enteritidis* in egg-laying hens, it is recommended that pasteurized eggs be substituted for bulk-pooled eggs at all nursing homes, hospitals, and commercial food-service establishments. All cases of nontyphoidal salmonellosis should be reported to public health departments, since tracking and monitoring of these cases result in the identification of the sources of local

outbreaks and help authorities anticipate large-scale international outbreaks. Lastly, the prudent use of antimicrobial agents in both humans and animals is necessary to minimize the further emergence of antibiotic-resistant strains.

157. SHIGELLOSIS - *Gerald T. Keusch*

DEFINITION

Shigellosis is an acute infectious inflammatory colitis due to one of the members of the genus *Shigella*. Although the disease is often referred to as "bacillary dysentery," many patients have only mild watery diarrhea and never develop dysenteric symptoms. Less severe illness predominates in industrialized countries such as the United States, whereas more severe, often fatal dysentery occurs in patients in developing countries.

ETIOLOGIC AGENT

Shigellae are slender, gram-negative, nonmotile bacilli and are members of the family Enterobacteriaceae and the tribe Escherichieae. They are so closely related to *Escherichia coli* that the two genera cannot be distinguished by DNA hybridization methods. In fact, *Shigella* can be thought of as a differentiated pathogenic *E. coli*. The four *Shigella* species (*S. dysenteriae*, *S. flexneri*, *S. boydii*, and *S. sonnei*) are defined on the basis of surface somatic O antigens and carbohydrate fermentation patterns. Most are lactose-negative (*S. sonnei* is a late lactose fermenter) and produce acid but not gas from glucose, resulting in a typical acid butt and alkaline slant in triple sugar iron agar without H_2S production. The genus is characterized by its ability to invade intestinal epithelial cells and to cause infection and illness in humans, even when the inoculum is small (a few hundred to a few thousand organisms).

EPIDEMIOLOGY

Worldwide, it is estimated that at least 140 million cases of shigellosis and almost 600,000 deaths due to shigellosis occur annually among children under the age of 5 years, primarily in developing countries. The organism is found everywhere in the world but is most common where poor environmental sanitation and crowding facilitate transmission from person to person. A major outbreak took place in the makeshift camps for refugees fleeing the Rwandan civil war in 1994, with thousands of cases and high mortality.

Data collected by the Centers for Disease Control and Prevention in the United States from 1967 through 1988 suggest an average annual incidence of 6 *Shigella* infections per 100,000 population, with periodic hyperendemic increases (primarily due to large outbreaks of *S. sonnei* infection) raising the rate to between 9 and 10 per 100,000. On the basis of these data, the annual number of episodes of shigellosis in the United States is estimated at 25,000 to 30,000. Incidence rates approximate 27 per 100,000 among children 1 to 4 years of age but are only 2.6 per 100,000 among persons 20 years of age or older. Cases are detected most commonly in counties with a relatively high proportion of low-income minority-group residents, including African Americans, Hispanics, and Native Americans; rates are especially high in poor urban communities, in day-care centers, and among retarded children in custodial care.

A comparison with rates among rural Guatemalan Indian children during the same period puts this disease burden into perspective. A prospective surveillance study among 321 such children revealed an annual incidence of nearly 10,000 per 100,000.

Since the description of the genus *Shigella*, major global shifts in the prevalence of its four species have been noted. Until World War I, *S. dysenteriae* type 1 was the predominant isolate, frequently causing devastating epidemics with high mortality until it was replaced by *S. flexneri*. Since World War II, however, *S. flexneri* has been steadily replaced by *S. sonnei* in the industrialized countries. The reasons for these shifts are not clear. *S. boydii*, the fourth species, has remained largely confined to the Indian subcontinent.

Shigella is highly host-adapted and is a natural pathogen only of humans and a few other primates. Transmission from person to person takes place by the fecal-oral route, generally via direct contact but sometimes through contaminated vectors such as food, water, flies, and fomites. Contaminated imported parsley from Mexico was responsible for one multistate outbreak of *S. sonnei* diarrhea. The organism can even be transmitted during participation in recreational water sports in fecally contaminated pools or lakes and can spread rapidly among confined populations in close contact -- for example, in day-care centers, in institutions for the mentally retarded, on cruise ships, or among military personnel. *Shigella* can be transmitted by anal-oral sexual practices among gay men; these cases are almost always due to *S. flexneri*. Rates of *Shigella* infection among HIV-infected individuals greatly exceed those in the non-HIV-infected population (Chap. 309).

Shigellosis is associated with a high rate of secondary household transmission. As many as 40% of children and 20% of adults who are household contacts of a case (generally a preschool child) will develop *Shigella* infection; the infection is often symptomatic in children but asymptomatic in adults, who seem to have an acquired immunity. In contrast, epidemic disease affects all ages, with clusters of severe and fatal cases in the very young and the very old. Since 1969, epidemic *S. dysenteriae* type 1 has reappeared in Latin America, in the Indian subcontinent and elsewhere in Asia, and in central and southern Africa and has been associated with relatively high mortality rates due to antimicrobial resistance and inadequate diagnosis and case management. Prolonged asymptomatic carriage is uncommon; unless there is underlying malnutrition, the organisms are generally cleared in a few weeks.

PATHOGENESIS AND PATHOLOGY

Shigellae are orally ingested and, because they survive low pH more easily than other enteric pathogens (a genetically regulated property), seem to have little difficulty in passing the gastric acid barrier. An essential step in pathogenesis is invasion of colonic epithelial cells and cell-to-cell spread of infection. This step involves initial attachment of the organism to colonic cells, entry by an endocytic mechanism in which organisms are initially encased in and then escape from plasma membrane-enclosed vesicles, and a jet propulsion-like movement to the cell membrane, from which the organism can invade the adjacent cell. This sequence of events not only provides the organism with a means to evade host defenses but also allows its effective local spread. Although invasion is initially innocuous, subsequent intracellular multiplication causes cell damage and death, ultimately resulting in characteristic mucosal ulcerations.

These events are extremely complicated and require the functions of multiple genes and

regulatory elements encoded on both the chromosome and a large 120- to 140-MDa plasmid present in all virulent shigellae as well as enteroinvasive *E. coli* (EIEC), which can cause a *Shigella*-like disease. The number of structural and regulatory genes known to be involved in pathogenesis continues to increase as the process continues to be dissected. Some of these gene products induce the phagocytosis-like uptake of the organism by causing rearrangements of the host cell's cytoskeleton. Once a single *Shigella* organism has invaded a single host cell, the entire process of bacterial escape from the phagocytic vesicle into the host cell's cytoplasm, multiplication, and cell-to-cell spread can take place without exposure of the bacterium to the extracellular milieu and to the host's defenses.

It was originally thought that shigellae invade the host across the intestinal epithelial cells; however, studies using cell culture or a rabbit-ileum in vivo model have suggested that the initial invasion may occur via the antigen-sampling M cell. The resulting limited penetration by organisms initiates an inflammatory response with neutrophil infiltration of the lamina propria, which alters the functional integrity of tight junctions between epithelial cells. These changes allow more organisms to breach the mucosal barrier at intercellular junctions and are essential for the development of illness. If neutrophil migration is directly inhibited by the treatment of animals with antibody to CD18, the escalating invasion by microorganisms does not take place.

Escape from the phagocytic vesicle is necessary for the virulence of shigellae and permits multiplication of the organisms in the cytoplasm. The multiplying organisms spread within the cytoplasm to the plasma membrane of the host cell and then from cell to cell. This spread is achieved by the polymerization of actin at the back end of the dividing bacteria (defined relative to the subsequent direction of motion). Binding and cross-linking by the host protein plastin result in a sphincter-like contraction that provides a forward propulsive force. This so-called actin motor is energized by ATP generated by a microbial-encoded ATPase called *IcsA*, which is, at the same time, phosphorylated and regulated by cyclic nucleotide-dependent protein kinases of the host. Phosphorylation may serve as a molecular host-defense mechanism to modulate virulence, limiting microbial spread.

Another important host protein involved in pathogenesis of shigellosis is the cadherin L-CAM, which is essential in the cell-to-cell spread of infection. Mutations in L-CAM alter the long finger-like protrusions induced by shigellae when they reach the plasma membrane and impair their subsequent fusion with the plasma membrane of the adjacent cell, thus inhibiting the transfer of the bacterium from one cell to another. Ultimately, the invaded host cell dies, possibly as a result of apoptosis induced by or during the process of microbial invasion.

Another property of apparent importance in virulence for *S. dysenteriae* type 1 is the ability to produce Shiga toxin, which is encoded by the iron-regulated chromosomal gene *stx*. Shiga toxin is composed of two distinct peptide subunits, each with highly conserved active regions. The first, located on the larger A subunit, is an *N*-glycosidase that hydrolyzes adenine from specific sites of ribosomal RNA of the mammalian 60S ribosomal subunit, irreversibly inhibiting protein synthesis. The second common region is a binding site on the B subunit that recognizes glycolipids of target cell membranes that terminate in a galactosea1 ® 4-galactose disaccharide. The glycolipid Gb3,

containing a gal-gal-glu trisaccharide, is a specific receptor present on toxin-sensitive rabbit intestinal villus cells but not crypt cells, and toxin action is specific for the former.

Wild-type toxigenic *S. dysenteriae* causes more severe illness in primates than does an isogenic toxin-negative mutant. The toxin of this organism, the prototype of a family of related toxin proteins produced by enterohemorrhagic *E. coli* (EHEC), appears to play a role in the pathogenesis of microangiopathic complications, hemolytic-uremic syndrome (HUS), and thrombotic thrombocytopenic purpura: only toxin-producing shigellae and *E. coli* are associated with these systemic illnesses. Two new *Shigella* enterotoxins, ShET-1 and -2, have been described; the former is restricted almost exclusively to *S. flexneri* 2a, whereas the latter is distributed more widely (e.g., in the physiologically similarEIEC). The two enterotoxins are encoded by chromosomal and plasmid genes, respectively. Both toxins alter electrolyte transport by segments of gut in vitro and cause net fluid secretion in vivo in ligated rabbit ileal loops. Moreover, both toxins induce antibody in infected humans. However, their role (if any) in the pathogenesis of the watery diarrhea phase of shigellosis remains uncertain.

In shigellosis, the epithelial surface of the human colon shows extensive ulcerations, with an exudate consisting of desquamated colonic cells, polymorphonuclear leukocytes, and erythrocytes; the ulcerations may resemble a pseudomembrane in severely affected areas. Marked mucus depletion and increased mitotic activity are evident in the crypt regions and presumably reflect a response to the loss of surface colonic cells. The lamina propria is edematous and hemorrhagic and is infiltrated by neutrophils and plasma cells. There is also swelling of capillary and venular endothelial cells, with margination of neutrophils. At the ultrastructural level, bacteria can be seen within vesicles as well as free in the cytoplasm. Histologic examination of colon from dysenteric humans shows an alteration of mucosal endothelial cells similar to that induced by endotoxin [lipopolysaccharide (LPS)]. Shiga toxin (protein) targets endothelial cells as well, especially when toxin receptor expression is upregulated by exposure to LPS or proinflammatory cytokines. Levels of circulating LPS are high in *S. dysenteriae* type 1 infection and somewhat lower in *S. flexneri* infection, even without bacteremia. The frequency of endotoxemia in shigellosis suggests a broader role for LPS in the pathogenesis of the disease. One likely mechanism is related to the ability of LPS to induce cytokine gene transcription and the strong association of cytokine secretion and inflammation. However, bacterial invasion of the mucosa itself activates the transcription factor NF-kB, which is involved in regulation of cytokine synthesis. Cytokine-producing cells are present in the mucosa of patients infected with *S. dysenteriae* or *S. flexneri* and in their stools as well. In fact, the number of cells producing interleukin 1, interleukin 6, interferon a, and transforming growth factorb is directly related to the severity of the inflammation. Inflammatory changes in *Shigella* infection thus appear to be components of the pathogenesis of dysentery as much as they are a consequence of the bacterial invasive process.

Epidemiologic evidence indicates that immunity develops and is serotype-specific. The precise nature of this immunity is not known. Common surface outer-membrane proteins involved in invasion elicit serum antibodies; although these are cross-reactive among *Shigella* species and serotypes, they do not seem to be protective. The serotype-specific determinants are likely to be somatic antigens, as serum antibody toLPSpredicts resistance to infection, and there is evidence of IgA-mediated mucosal

responses to LPS during convalescence from shigellosis.

CLINICAL MANIFESTATIONS

Shigellosis in the United States, due primarily to *S. sonnei*, is typically an ambulatory disease, presenting as a self-limited nonbloody watery diarrhea chock full of neutrophils. The spectrum of clinical shigellosis was shown in a study in which adult volunteers ingested 10,000 organisms of *S. flexneri* type 2a. While approximately one-quarter of the volunteers never became ill, over the first 24 to 48 h ~25% developed transient fever, another 25% had fever and self-limited watery diarrhea, and the remaining 25% had fever and watery diarrhea that progressed to bloody diarrhea and dysentery. In young children in particular, the temperature can rise rapidly to 40° to 41°C and sometimes results in generalized seizures. These seizures rarely recur or result in serious sequelae. Dysentery is characterized by frequent passage (usually 10 to 30 times per day) of small-volume stools consisting of blood, mucus, and pus; this diarrhea is accompanied by abdominal cramps and tenesmus -- the painful straining with stooling that may lead to rectal prolapse, especially in young children. Severe dysentery is most likely in infection due to *S. dysenteriae* type 1, occurs less commonly with *S. flexneri*, and is least likely in *S. sonnei* infection. Patients with mild disease generally recover without specific therapy in a few days to a week. Severe shigellosis can progress to toxic dilatation and colonic perforation, which may be fatal.

Endoscopy shows the mucosa to be hemorrhagic, with mucous discharge and focal ulcerations and sometimes with overlying exudate. The majority of lesions are in the distal colon and progressively diminish in the more proximal segments of large bowel. Mild dehydration is common among patients with watery diarrhea; severe dehydration is very rare. With extensive colonic involvement, protein-losing enteropathy can occur and can have important adverse nutritional consequences, especially for already poorly nourished children.

A variety of *extraintestinal complications* of shigellosis have been described. The majority arise in patients in developing countries and are related both to the prevalence of infections due to *S. dysenteriae* type 1 and *S. flexneri* and to the poor nutritional state of the host. For example, bacteremia, thought to be relatively infrequent in the United States, develops in up to 8% of patients hospitalized for shigellosis in Dacca, Bangladesh. The causative *Shigella* species is isolated from half the patients; other Enterobacteriaceae are found in the remainder. Bacteremia is associated with higher-than-usual mortality and is more common among infants<1 year of age and among persons with protein-energy malnutrition. Persistent and clinically severe *Shigella* bacteremia has been encountered in the United States in patients with AIDS (Chap. 309).

HUSmay occur with *S. dysenteriae* type 1 infection. In the United States, the more likely cause of HUS is one of the hemorrhagic colitis-causing strains of *E. coli* (such as *E. coli* O157:H7) that produce high levels of Shiga-family toxins. HUS usually develops toward the end of the first week of shigellosis, when dysentery is already resolving. Oliguria and a marked drop in hematocrit (by as much as 10% within 24 h) are the first signs and may progress to anuria with renal failure and to severe anemia with congestive heart failure, respectively. Even with advanced therapy, 5 to 10% of patients with HUS die of

the acute illness. In addition, renal damage progresses slowly over several decades in survivors, an estimated 50% of whom develop significant renal failure and most of whom require long-term dialysis or renal transplantation. Leukemoid reactions, with leukocyte counts of >50,000/uL, may occur along with HUS; thrombocytopenia (with 30,000 to 100,000 platelets/uL) is common. Profound hyponatremia and severe hypoglycemia may be documented. Central nervous system abnormalities include encephalopathic symptoms, seizures, altered consciousness, and bizarre posturing.

Less common extraintestinal manifestations include seizures in some patients and reactive arthritis in others; both of these manifestations are usually due to infection with *S. flexneri* strains. In patients expressing histocompatibility antigen HLA-B27, the full triad of Reiter's syndrome sometimes develops (Chap. 315). Pneumonia, meningitis, vaginitis (in prepubertal girls), keratoconjunctivitis, and "rose spot" rashes are rare events.

DIAGNOSIS AND LABORATORY FINDINGS

Shigellosis is the principal bacterial cause of dysentery and should be considered whenever a patient presents with bloody diarrhea. However, in the United States, because *S. sonnei* is the most common species, most patients present with fever and nonbloody watery diarrhea indistinguishable from signs caused by other bacterial or viral agents of mild to moderate diarrhea, while many patients with bloody diarrhea haveEHEC as the cause. The specific diagnosis is based on culture of *Shigella* from the stool; however, diagnosis by the polymerase chain reaction is possible, and a commercial enzyme immunoassay to detect Shiga-family toxins in stool can identify most patients infected with *S. dysenteriae* type 1 or EHEC within 3 h. The yield of *Shigella* is increased if the organism is sought by stool culture when the patient has fecal leukocytes or bloody diarrhea. The organism is very labile and must be transferred quickly to plates or holding media (such as buffered glycerol saline) if it is to survive. Stool samples are preferable to swabs; when the latter are used, a rectal sample should be obtained. More than one selective medium should be used for culture -- i.e., MacConkey and one other, such as Hektoen enteric or xylose-lysine-deoxycholate. Stool cultures to diagnose nonbloody watery diarrhea have a very low yield of positives and are not cost-effective.

Serologic tests can be performed, since antibodies to somatic antigens develop early in the acute phase of disease. However, the resources for such tests are not generally available, and serologic assessments usually are used only for epidemiologic studies.

The differential diagnosis includes inflammatory colitis due to other microbial agents:EHEC,EIEC, *Campylobacter jejuni*, *Salmonella enteritidis*, *Yersinia enterocolitica*, *Clostridium difficile*, and the protozoan *Entamoeba histolytica*. Ulcerative colitis and Crohn's colitis are among the "noninfectious" conditions that should be considered (Chap. 287). All these infections except that due to *E. histolytica* are associated with the presence of large numbers of fecal leukocytes. Amebiasis can be diagnosed by the detection of erythrophagocytic trophozoites in the stool (Chap. 213).

Other laboratory studies are nonspecific and may disclose neutrophilic leukocytosis, anemia due to blood loss with hemorrhagic diarrhea, prerenal azotemia, or (if watery

diarrhea has been pronounced) hyperchloremic acidosis. Laboratory findings in shigellosis complicated byHUS are discussed above.

TREATMENT

The mild to moderate dehydration in shigellosis is readily corrected with oral rehydration solutions (Chap. 159). The role of antibiotic therapy is variable and depends on the organism and the severity of disease. Since *S. sonnei* infection is usually self-limited, culture results generally do not become available until the patient is better and there is little clinical need for further therapy. The use of antibiotics in severe cases with bloody diarrhea or dysentery reduces the duration of illness and can shorten the carriage state. Resistance to sulfonamides, streptomycin, chloramphenicol, and tetracyclines is almost universal, and many shigellae are now resistant to ampicillin and trimethoprim-sulfamethoxazole as well. Knowledge of the pattern of resistance in a given population, which can change with time, is useful. In the United States, multiresistant strains are most likely to be acquired during travel abroad; either ampicillin (50 to 100 mg/kg per day in children or 2 g/d in adults, in divided doses) or trimethoprim-sulfamethoxazole (8/40 mg/kg per day in children or 2 regular-strength tablets twice a day in adults, given for 5 days) is generally recommended for domestically acquired infection. Short courses of treatment (1 or 3 days) or even single doses of drugs like tetracycline and ciprofloxacin have been employed with success and may soon become the standard. Amoxicillin should *not* be substituted for ampicillin because it is not effective against shigellosis. In developing countries, where resistance to both of these drugs is commonplace, the drug of choice for the treatment of multiresistant *S. dysenteriae* type 1 infections has been nalidixic acid (55 mg/kg per day for 5 days); however, resistance to the latter agent is increasing in prevalence. The 4-fluoroquinolones (e.g., ciprofloxacin) are highly effective against all strains (Chap. 137) but are currently too costly in the developing world and are not yet approved for use in children under 17 in the United States; these drugs have caused cartilage damage in young rodents during toxicity tests, although there is no evidence for a similar effect of therapeutic doses in humans. Alternative drugs shown to be effective include oral pivamdinocillin (amdinocillin, pivoxil, pivmecillinam; still not available in the United States), azithromycin, and intravenous ceftriaxone (50 mg/kg per day for 5 days). In small-scale clinical trials, cephalexin has had no effect in limiting symptoms; single doses of ceftriaxone may be effective, but more information is needed. No antibiotic treatment is recommended for the convalescent carrier state, which usually lasts no more than several weeks. Patients with AIDS may develop chronic carriage of *Shigella* and may be subject to relapsing infection with bacteremia (Chap. 309). This cycle may be interrupted by prolonged (several weeks') treatment with a quinolone.

The role of antimotility agents such as atropine sulfate and diphenoxylate (Lomotil) and loperamide (Imodium) in the early phases of shigellosis is controversial. Loperamide, in particular, may reduce diarrhea and in one study was highly effective in combination with antimicrobials. However, these antimotility drugs are suspected of enhancing the severity of disease by delaying excretion of organisms and thus facilitating further invasion of the mucosa and complicating toxic megacolon. Therefore, they are contraindicated in infants and young children. In adults, these agents are contraindicated for use in the dysenteric phase of disease.

Treatment of complications of shigellosis often differs in developed and developing countries. For example, antibiotic-unresponsive toxic megacolon, with or without perforation, is often managed by colectomy in the United States. Surgery is less often employed in developing countries because of a lack of availability or difficulties in ileostomy management.HUSoften requires dialysis. In developing countries, dialysis may be needed relatively infrequently because azotemia is slow to develop and the risk of significant hyperkalemia is often diminished by a preexisting deficiency in total-body potassium, with malnutrition and wasting of lean body mass. The management of hyponatremia, usually caused by inappropriate secretion of antidiuretic hormone (vasopressin), is governed by the severity of the condition and the symptomatic state of the patient, as outlined inChap. 49. Infusion of glucose can reverse clinical manifestations caused by hypoglycemia, and responses can be monitored by finger-stick blood glucose tests if no biochemistry laboratory is available. Optimal nutritional management is needed to correct deficiencies due to underlying malnutrition as well as the superimposed catabolic stress and protein-losing enteropathy of shigellosis. Nutritional support should begin during the acute illness and may be required for months thereafter (Chap. 76).

PREVENTION

Direct-contact transmission of shigellosis can be prevented by appropriate environmental and personal hygiene. Hand washing with soap and water, decontamination of water supplies, use of sanitary latrines or toilets, and precautions in the preparation and storage of food can all reduce the primary and secondary transmission of *Shigella* infection. In highly endemic developing countries, infants are protected during the period of exclusive breast feeding, which should be encouraged. Any measures that reduce the burden of malnutrition will also reduce the burden of shigellosis in the population. Stool precautions should be instituted for hospitalized infected patients to ensure safe disposal of infected excreta and linens, and hospital personnel must wash their hands and medical instruments (such as stethoscopes) after each contact with an infected patient. Cohorting of asymptomatic infected children, use of antibiotics to reduce infectiousness, and scrupulous attention to hygiene are usually successful in nosocomial outbreaks. Children in day care must be kept at home while clinically ill and ideally should have a negative stool culture before returning to the day-care facility. Likewise, food handlers who develop shigellosis should be culture-negative before returning to work. Antibiotic treatment is not indicated for the asymptomatic carrier state. No effective vaccine is available, although promising initial results have been reported with an *S. sonnei*LPS-protein conjugate vaccine.

158. INFECTIONS DUE TO *CAMPYLOBACTER* AND RELATED SPECIES - *Martin J. Blaser*

DEFINITION

Bacteria of the genus *Campylobacter* and of the related genera *Arcobacter* and *Helicobacter* (Chap. 154) cause a variety of pyogenic infections. Although acute diarrheal illnesses are most common, these organisms may cause infections in virtually all parts of the body, especially in compromised hosts, and these infections may have late nonsuppurative sequelae. The designation *Campylobacter* comes from the Greek for "curved rod" and refers to the organism's vibrio-like morphology.

ETIOLOGY

Campylobacters are motile, non-spore-forming, curved gram-negative rods. Originally known as *Vibrio fetus*, these bacilli were reclassified as a new genus in 1973, after it was recognized that they were quite dissimilar to other vibrios. Since then, more than 15 species have been identified. These species are currently divided into three genera: *Campylobacter*, *Arcobacter*, and *Helicobacter*. Not all of the species are pathogens of humans. The human pathogens can be divided into two major groups: those that primarily cause diarrheal disease and those that cause extraintestinal infection. The principal diarrheal pathogen is *C. jejuni*, which accounts for 80 to 90% of all cases of recognized illness due to campylobacters. Other organisms that cause diarrheal disease include *C. coli*, *C. upsaliensis*, *C. lari*, and *C. fetus*. The major species causing extraintestinal illnesses is *C. fetus*; however, any of the diarrheal agents may cause systemic or localized infection as well. Neither aerobes nor strict anaerobes, these microaerophilic organisms are adapted for survival in the gastrointestinal mucous layer. This chapter will focus on *C. jejuni* and *C. fetus* as the major pathogens and prototypes for their groups; the key features of infection are listed by species (excluding *C. jejuni*, described in detail in the text below) in Table 158-1.

EPIDEMIOLOGY

Campylobacters are found in the gastrointestinal tract of many animals used for food (including poultry, cattle, sheep, and swine) and of many household pets (including birds, dogs, and cats). These microorganisms usually do not cause illness in their animal hosts. In most cases, campylobacters are transmitted to humans in raw or undercooked food products or through direct contact with infected animals. In the United States and other developed countries, ingestion of contaminated poultry that has not been sufficiently cooked is the most common means of acquiring infection (50 to 70% of cases). Other modes of transmission include ingestion of raw (unpasteurized) milk or untreated water, contact with infected household pets, travel to developing countries (campylobacters being among the causes of traveler's diarrhea; Chap. 131), and (occasionally) contact with an index case who is incontinent of stool.

Campylobacter infections are not rare. Several studies indicate that, in the United States, diarrheal disease due to campylobacters is more common than that due to *Salmonella* and *Shigella* combined. Infections occur throughout the year, but their incidence peaks during summer and early autumn. Persons of all ages are affected;

however, attack rates for *C. jejuni* are highest among young children and young adults, while those for *C. fetus* are highest at the extremes of age. Systemic infections due to *C. fetus* (and to other *Campylobacter* and related species) are most common in compromised hosts. Persons at increased risk include those with AIDS, hypogammaglobulinemia, neoplasia, liver disease, diabetes mellitus, and generalized atherosclerosis as well as pregnant women. However, apparently healthy nonpregnant persons occasionally develop transient *Campylobacter* bacteremia as part of a gastrointestinal illness.

In developing countries, *C. jejuni* infections are hyperendemic, with the highest rates among children <2 years old. Infection rates fall with age, as does the illness-to-infection ratio; these observations suggest that frequent exposure to *C. jejuni* leads to the acquisition of immunity.

PATHOLOGY AND PATHOGENESIS

Many *C. jejuni* infections are subclinical, especially in partially immune hosts. Most illnesses occur within 2 to 4 days (range, 1 to 7 days) of exposure to the organism in food or water. The sites of tissue injury include the jejunum, ileum, and colon. Biopsies show an acute nonspecific inflammatory reaction, with neutrophils, monocytes, and eosinophils in the lamina propria, as well as damage to the epithelium, including loss of mucus, glandular degeneration, and crypt abscesses. Biopsy findings may be consistent with Crohn's disease or ulcerative colitis, but these "idiopathic" chronic inflammatory diseases should not be diagnosed unless infectious colitis, *specifically including* that due to infection with *Campylobacter*, has been ruled out.

The high frequency of *C. jejuni* infections and their severity and recurrence among hypogammaglobulinemic patients suggest that antibodies are important in protective immunity. The pathogenesis of infection is uncertain. Both the motility of the strain and its capacity to adhere to host tissues appear to favor disease, but classic enterotoxins and cytotoxins (although described) appear not to play any substantial role in tissue injury or disease production. The organisms have been visualized in the epithelium, albeit in low numbers. The documentation of a significant tissue response and occasionally of *C. jejuni* bacteremia further suggests that tissue invasion is clinically significant.

The pathogenesis of *C. fetus* infections is better defined. Virtually all clinical isolates of *C. fetus* possess a proteinaceous capsule-like structure (an S-layer) that renders the organism resistant to complement-mediated killing and opsonization. As a result, *C. fetus* can cause bacteremia and can seed sites beyond the intestinal tract. The ability of the organism to switch the S-layer proteins expressed, a phenomenon that results in antigenic variability, may contribute to the chronicity and high rate of recurrence of these infections in compromised hosts.

CLINICAL MANIFESTATIONS OF *C. JEJUNI* AND *C. FETUS* INFECTIONS

The clinical features of infections due to all of the *Campylobacter* and related species causing enteric disease appear to be highly similar. There is often a prodrome, with fever, headache, myalgia, and/or malaise, 12 to 48 h before the onset of diarrheal

symptoms. The most common symptoms of the intestinal phase are diarrhea, abdominal pain, and fever. The degree of diarrhea varies from several loose stools to grossly bloody stools; most patients presenting for medical attention have 10 or more bowel movements on the worst day of illness. Abdominal pain usually consists of cramping and may be the most prominent symptom. Pain usually is generalized but may become localized; *C. jejuni* infection may cause pseudoappendicitis. Fever may be the only initial manifestation of *C. jejuni* infection, a situation mimicking the early stages of typhoid fever. Febrile young children may develop convulsions. *Campylobacter* enteritis generally is self-limited; however, symptoms persist for longer than 1 week in 10 to 20% of patients seeking medical attention, and relapses occur in 5 to 10% of untreated patients.

C. fetus may cause a diarrheal illness similar to that due to *C. jejuni*, especially in normal hosts, or may cause either intermittent diarrhea or nonspecific abdominal pain without localizing signs. Sequelae are uncommon, and outcome is benign. *C. fetus* also may cause a prolonged relapsing systemic illness (with fever, chills, and myalgias) that has no obvious primary source; this manifestation is especially common in compromised hosts. Secondary seeding of an organ (e.g., meninges, brain, bone, urinary tract, or soft tissue) complicates the course, which may be fulminant. *C. fetus* infections have a tropism for vascular sites: endocarditis, mycotic aneurysm, and septic thrombophlebitis all may occur. Infection during pregnancy often leads to fetal death. *H. cinaedi* causes recurrent cellulitis with fever and bacteremia in immunocompromised hosts.

COMPLICATIONS

Except in the case of infection with *C. fetus*, bacteremia is uncommon, developing most often in immunocompromised hosts and at the extremes of age. Three patterns of extraintestinal infection have been noted: (1) transient bacteremia in a normal host with enteritis (benign course, no specific treatment needed); (2) sustained bacteremia or focal infection in a normal host (bacteremia originating from enteritis, with patients responding well to antimicrobial therapy); and (3) sustained bacteremia or focal infection in a compromised host. Enteritis may not be clinically apparent. Antimicrobial therapy, possibly prolonged, is necessary for suppression or cure of the infection.

Campylobacter infections in patients with AIDS or hypogamma-globulinemia may be severe, persistent, and extraintestinal; relapse after cessation of therapy is common. Hypogammaglobulinemic patients also may develop osteomyelitis and an erysipelas-like rash.

Local suppurative complications of infection include cholecystitis, pancreatitis, and cystitis; distant complications include meningitis, endocarditis, arthritis, peritonitis, cellulitis, and septic abortion. All are rare. Hepatitis, interstitial nephritis, and the hemolytic-uremic syndrome occasionally complicate acute infection. Reactive arthritis and other rheumatologic complaints may develop several weeks after infection, especially in persons with the HLA-B27 phenotype. Guillain-Barre syndrome follows *Campylobacter* infections uncommonly (i.e., in 1 of every 1000 to 2000 cases). For certain *C. jejuni* serotypes, such as O19, Guillain-Barre syndrome may follow 1 in every 100 to 200 cases. Because of their high incidence, it is now estimated that

Campylobacter infections may trigger 20 to 40% of all cases of Guillain-Barre syndrome.

LABORATORY FINDINGS

In patients with *Campylobacter* enteritis, peripheral leukocyte counts reflect the severity of the inflammatory process. However, stools from nearly all *Campylobacter*-infected patients presenting for medical attention in the United States contain leukocytes or erythrocytes. Fecal smears should be treated with Gram's or Wright's stain and examined in all suspected cases. When the diagnosis of *Campylobacter* enteritis is suspected on the basis of findings indicating inflammatory diarrhea (fever, fecal leukocytes), clinicians can ask the laboratory to attempt the visualization of organisms with characteristic vibrioid morphology by direct microscopic examination of stools with Gram's staining or to use phase-contrast or dark-field microscopy to identify the organisms' characteristic "darting" motility. Confirmation of the diagnosis of *Campylobacter* infection is based on identification of an isolate from cultures of stool, blood, or another site. *Campylobacter*-specific media should be used to culture stools from all patients with inflammatory or bloody diarrhea. Since all *Campylobacter* species are fastidious, they will not be isolated unless selective media or other selective techniques are used. Not all media are equally useful for isolation of the broad array of campylobacters; therefore, failure to isolate campylobacters from stool does not entirely rule out their presence. The detection of the organisms in stool almost always implies infection; there is a brief period of postconvalescent fecal carriage and no commensalism in humans. In contrast, *C. sputorum* and related organisms found in the oral cavity are commensals with rare pathogenic significance.

DIFFERENTIAL DIAGNOSIS

The symptoms of *Campylobacter* enteritis are not sufficiently unusual to distinguish this illness from that due to *Salmonella*, *Shigella*, or *Yersinia*, among other pathogens. The combination of fever and fecal leukocytes or erythrocytes is indicative of inflammatory diarrhea, and definitive diagnosis is based on culture or demonstration of the characteristic organisms on stained fecal smears. Similarly, extraintestinal *Campylobacter* illness is diagnosed by culture. Infection due to *Campylobacter* should be suspected in the setting of septic abortion and that due to *C. fetus* specifically in the setting of septic thrombophlebitis. It is important to reiterate that the presentation of *Campylobacter* enteritis may mimic that of ulcerative colitis or Crohn's disease, that *Campylobacter* enteritis is much more common than either of the latter (especially among young adults), and that biopsy may not distinguish among these entities. Thus a diagnosis of inflammatory bowel disease should not be made until *Campylobacter* infection has been ruled out, especially in persons with a history of foreign travel, significant animal contact, immunodeficiency, or practices incurring a high risk of transmission.

TREATMENT

Fluid and electrolyte replacement is central to the treatment of diarrheal illnesses (Chap. 131). Even among patients presenting for medical attention with *Campylobacter* enteritis, fewer than half will clearly benefit from specific antimicrobial therapy.

Indications for such therapy include high fever, bloody diarrhea, severe diarrhea, persistence for more than 1 week, and worsening of symptoms. A 5- to 7-day course of erythromycin (250 mg orally four times daily or -- for children -- 30 to 50 mg/kg per day, in divided doses) is the regimen of choice. Although no relevant clinical trials have been conducted, the in vitro susceptibility of *Campylobacter* species to macrolides such as clarithromycin and azithromycin suggests that these antibiotics also would be useful therapeutic agents. An alternative regimen for adults is ciprofloxacin (500 mg orally twice daily) or another fluoroquinolone for 5 to 7 days, but resistance to this class of agents is increasing. Other alternatives include tetracycline and furazolidone. Use of antimotility agents, which may prolong the duration of symptoms and has been associated with toxic megacolon and with death, is not recommended.

For systemic infections, treatment with gentamicin (1.7 mg/kg intravenously every 8 h after a loading dose of 2 mg/kg), imipenem (500 mg intravenously every 6 h), or chloramphenicol (50 mg/kg intravenously each day in three or four divided doses) should be started empirically, but susceptibility testing should then be performed. Ciprofloxacin and amoxicillin/clavulanate are alternative agents for susceptible strains. In the absence of immunocompromise or endovascular infections, therapy should be administered for 14 days. For immunocompromised patients with systemic infections due to *C. fetus* and for patients with endovascular infections, prolonged therapy (for up to 4 weeks) is usually necessary.

PROGNOSIS

Nearly all patients recover fully from *Campylobacter* enteritis, either spontaneously or after antimicrobial therapy. Volume depletion likely contributes to the few deaths that are reported. As stated above, occasional patients develop reactive arthritis or Guillain-Barre syndrome. Systemic infection with *C. fetus* is much more often fatal than that due to related species; this higher mortality reflects in part the population affected. Prognosis is dependent on the rapidity with which appropriate therapy is begun. Otherwise healthy hosts usually survive *C. fetus* infections without sequelae. Compromised hosts often have recurrent infections.

159. CHOLERA AND OTHER VIBRIOSES - *Gerald T. Keusch*, *Robert L. Deresiewicz*, *Matthew K. Waldor*

Members of the genus *Vibrio* cause a number of important infectious syndromes. Classic among them is cholera, a devastating diarrheal disease caused by *V. cholerae* that has been responsible for seven global pandemics and much suffering over the past two centuries. Epidemic cholera remains a major public health concern and is dealt with at length in this chapter. Other vibrioses have also been described, including syndromes of diarrhea, soft tissue infection, or primary sepsis caused by additional named species in the genus *Vibrio*. These, too, are considered below.

All members of the genus are highly motile, facultatively anaerobic, curved gram-negative rods with one or more polar flagella. Except for *V. cholerae* and *V. mimicus*, all require salt for growth ("halophilic vibrios"). In nature, vibrios most commonly reside in tidal rivers and bays under conditions of moderate salinity. They proliferate in the summer months when water temperatures exceed 20°C. As might be expected, the illnesses they cause also increase in frequency during the warm months.

CHOLERA

DEFINITION

Cholera is an acute diarrheal disease that can, in a matter of hours, result in profound, rapidly progressive dehydration and death. Accordingly, cholera gravis (the severe form of cholera) is a much-feared disease, particularly in its epidemic presentation. Fortunately, prompt aggressive fluid repletion and supportive care can obviate the high mortality that it has historically wrought. While the term *cholera* has occasionally been applied to any severely dehydrating secretory diarrheal illness, whether infectious in etiology or not, it has generally referred to disease caused by *V. cholerae* serogroup O1. In 1992, however, a new epidemic serogroup (O139) that causes epidemic cholera emerged on the Indian subcontinent and has since killed many thousands of people.

ETIOLOGY AND EPIDEMIOLOGY

The species *V. cholerae* comprises a host of organisms classified on the basis of the carbohydrate determinants of their lipopolysaccharide (LPS) O antigens. Some 155 serogroups have now been recognized. They are divided into those that agglutinate in antisera to the O1 group antigen (*V. cholerae* O1) and those that do not (non-O1 *V. cholerae*). Although some non-O1 *V. cholerae* serogroups have occasionally caused sporadic outbreaks of diarrhea, serogroup O1 was, until the emergence of serogroup O139, the exclusive cause of epidemic cholera. *V. cholerae* O139 (also called *V. cholerae* Bengal) is discussed in greater detail below.

V. cholerae O1 exists in two biotypes, *classical* and *El Tor*, that are distinguished on the basis of a number of characteristics, including phage susceptibility and hemolysin production. Each biotype is further subdivided into two serotypes, termed *Inaba* and *Ogawa*. Serotyping is a useful tool in field epidemiologic studies. Newer molecular epidemiologic techniques, such as ribotyping and other gene-based methods, now make it possible to trace the source and origin of cholera strains from around the world.

The natural habitat of *V. cholerae* is coastal salt water and brackish estuaries, where the organism lives in close relation to plankton and where it may survive in a viable but nonculturable form. Humans become infected incidentally but, once infected, can act as vehicles for spread. Ingestion of water contaminated by human feces is the most common means of acquisition of *V. cholerae*. Consumption of contaminated food in the home, in restaurants, or from street vendors can also contribute to spread. There is no known animal reservoir. While the infectious dose is relatively high, it is markedly reduced in hypochlorhydric persons, in those using antacids, and when gastric acidity is buffered by a meal. Cholera is predominantly a pediatric disease in endemic areas, but it affects adults and children equally when newly introduced into a population. In endemic areas, the disease is more common in the summer and fall months. While this seasonality has not been explained fully, it may be due to environmental conditions that affect the multiplication of vibrios or to seasonal alterations in human behavior that affect contact with water. Asymptomatic infections are frequent and more common with the El Tor than the classical biotype. In endemic areas, children<2 years of age are less likely to develop severe cholera than are older children, perhaps because of passive immunity acquired from breast milk. For unexplained reasons, susceptibility to cholera is significantly influenced by ABO blood group status; those with type O blood are at greatest risk, while those with type AB are at least risk.

Cholera is native to the Ganges delta in the Indian subcontinent. Since 1817, seven global pandemics have occurred. The current (seventh) pandemic -- the first due to the El Tor biotype -- began in Indonesia in 1961 and spread throughout Asia as *V. cholerae* El Tor displaced the endemic classical strain in many areas. It briefly invaded Europe, but effective public health measures and the high level of sanitation combined to limit its impact. In the early 1970s, El Tor cholera exploded in Africa, causing major epidemics before becoming a persistent endemic problem. Its recent history in Africa has been punctuated by severe outbreaks, often fed by the chaos of war and genocide. Such was the case in the camps for Rwandan refugees set up in 1994 around Goma, Zaire. Tens of thousands of cases occurred and mortality was high. In 1995, the occurrence of hundreds of cases in Romania and the Black Sea states of the former Soviet Union demonstrated the potential of this organism to cause epidemics whenever public health measures break down.

Since 1973, sporadic endemic infections due to vibrios related to the seventh-pandemic strain have been recognized along the U.S. Gulf Coast of Louisiana and Texas. These infections are typically associated with the consumption of contaminated, locally harvested shellfish. Occasionally, cases in U.S. locations remote from the Gulf Coast have been linked to shipped-in Gulf Coast seafood.

Although the event was long expected, it was not until 1991 that the current cholera pandemic reached Latin America. Beginning along the Peruvian coast in January 1991, the disease was carried by fishermen to Ecuador and Colombia. It then spread in an explosive epidemic to virtually all of South and Central America and to Mexico (Fig. 159-1). About 400,000 cases were reported in the first year of the outbreak, and >1 million had been reported by the end of 1994. While the cumulative mortality rate has been<1%, the mortality rate approached 30% in the communities first affected, where a lack of familiarity with the disease led initially to the deployment of wholly ineffective

treatment. Intensive education of health care providers and of the community at large has enhanced awareness of the disease and its appropriate management and has greatly diminished mortality. As it did in Africa two decades earlier, the epidemic El Tor strain proved capable of establishing itself in inland waters rather than in its classic niche of coastal salt waters; the organism has already become endemic in many of the Latin American countries into which it was recently introduced.

Cases linked to the Latin American epidemic have occurred in the United States. For example, 11 people in New York and New Jersey were infected in two separate outbreaks in 1991 after eating boiled crabmeat illegally transported by travelers from Ecuador. Although secondary spread of this strain has not taken place in the United States, these events underscore the need for vigilance among health care professionals, even in locations remote from an epidemic.

In October 1992, a large-scale outbreak of clinical cholera occurred in the port city of Madras and surrounding towns in southern India. The etiologic agent proved to be a novel strain of *V. cholerae* belonging neither to the O1 serogroup that typically causes epidemic cholera nor to any of the 137 other serogroups known at the time. This strain spread rapidly up and down the coast of the Bay of Bengal, reaching Bangladesh in December 1992. There alone, it caused more than 100,000 cases of cholera in the first 3 months of 1993. It subsequently spread across the Indian subcontinent and to neighboring countries, affecting Pakistan, Nepal, western China, Thailand, and Malaysia by the end of 1994 (Fig. 159-2). The organism has since been designated *V. cholerae* O139 Bengal in recognition of its novel O antigen and its geographic origin.

The clinical manifestations and epidemiologic features of the disease caused by *V. cholerae* O139 Bengal are indistinguishable from those of O1 cholera. Immunity to the latter, however, is not protective against the former. Thus, although O139 Bengal cholera has been restricted almost exclusively to O1-endemic areas, it has affected patients of all ages, with most cases in adults. Moreover, populations into which *V. cholerae* O139 Bengal has been introduced have responded as virgin populations with respect to severe, lethal cholera. Because naturally acquired immunity to *V. cholerae* O1 does not cross-protect against *V. cholerae* O139 Bengal, vaccines being developed against the former are unlikely to be effective against the latter.

Like the O1 epidemics in cholera-naive areas before it, the O139 epidemic was initially devastating. Some authorities believed that the emergence of *V. cholerae* O139 signaled the beginning of the eighth global cholera pandemic. Indeed, just as O1 El Tor replaced the classical biotype that preceded it, O139 Bengal in 1993 rapidly replaced O1 El Tor as the most common environmental isolate and the predominant cause of clinical cholera in the areas in which it had appeared (Fig. 159-3). However, by the beginning of 1994, O1 El Tor had unexpectedly resumed its dominance in Bangladesh, relegating O139 Bengal cholera to the status of a background endemic infection. In some locales O1 *V. cholerae* remains dominant; in others O139 periodically reemerges. Nevertheless, the potential for global spread of O139 Bengal was underscored by an intercontinental food-borne outbreak that occurred in early 1994 among American and British passengers on a cruise ship in Southeast Asia. Six of the 630 travelers became ill, their symptoms beginning only after they returned home.

PATHOGENESIS

In the final analysis, cholera is a toxin-mediated disease. Its characteristic watery diarrhea is due to the action of cholera toxin (CTX), a potent protein enterotoxin elaborated by the organism following its colonization of the small intestine. The bacterial properties that facilitate intestinal colonization are incompletely understood. For *V. cholerae* to colonize the small intestine and produce CTX, it must first recognize, contend with, and traverse several hostile environments. The first of these is the acidic milieu of the stomach. To elude the bactericidal effects of gastric acidity, *V. cholerae* relies, at least in part, on a relatively large inoculum size (compared to that needed for colonization by *Shigella*, for instance). The organism must next traverse the mucous layer lining the small bowel. *V. cholerae* chemotaxis and motility and a variety of proteases may allow the organism to traverse this gel covering the intestinal epithelium. Adherence to the intestinal epithelium is believed to be mediated by the toxin-coregulated pilus (TCP), so named because its synthesis is regulated in parallel with that of CTX. Studies of volunteers have established that TCP is essential for *V. cholerae* intestinal colonization. Other *V. cholerae* gene products known to be important in intestinal colonization of experimental animals include accessory colonization factors ABCD, a cell-associated hemagglutinin, iron and magnesium transport proteins, and purine and biotin biosynthesis enzymes.

CTX,TCP, and several other virulence factors, including accessory colonization factors and various outer-membrane proteins, are coordinately regulated by the *toxR* gene product. ToxR protein is a "master switch" that modulates the expression of virulence genes in response to signals that it senses within the environment of the host via a cascade of regulatory proteins. Coordinate regulation of virulence factor expression presumably enables the organism to tailor its repertoire of proteins to suit its needs as it passes from one microenvironment to another. Coordinate regulation of virulence gene expression by a central sensor-effect protein like ToxR has become a paradigm for similar systems that have been discovered in a wide range of pathogenic bacteria.

Once established in the human small bowel, the organism producesCTX, which consists of a monomeric enzymatic moiety (the A subunit) and a pentameric binding moiety (the B subunit). The B pentamer binds to G_{M1}ganglioside, a glycolipid on the surface of jejunal epithelial cells that serves as the toxin receptor and makes possible the delivery of the A subunit to its cytosolic target. The activated A subunit (A_1) irreversibly transfers ADP-ribose from nicotinamide adenine dinucleotide to its specific target protein, the GTP-binding regulatory component of adenylate cyclase in intestinal epithelial cells. In this configuration, this G protein permanently upregulates the cyclase catalytic subunit; the result is the intracellular accumulation of high levels of cyclic AMP. In intestinal epithelial cells, cyclic AMP inhibits the absorptive sodium transport system in villus cells and activates the excretory chloride transport system in crypt cells, and these events lead to the accumulation of sodium chloride in the intestinal lumen. Since water moves passively to maintain osmolality, isotonic fluid accumulates in the lumen. When the volume of that fluid exceeds the capacity of the rest of the gut to resorb it, watery diarrhea results. Unless the wasted fluid and electrolytes are adequately replaced, shock (due to profound dehydration) and acidosis (due to loss of bicarbonate) follow.

Although perturbation of the adenylate cyclase pathway is the primary mechanism by

whichCTXcauses excess fluid secretion, it is not the only one. Increasing evidence indicates that CTX also enhances intestinal secretion via prostaglandins and/or neural histamine receptors. It is possible that the redundancy of secretory mechanisms activated by CTX accounts for the profound diarrhea and dehydration characteristic of severe cholera.

The genes encodingCTX(*ctxAB*) are part of the genome of a bacteriophage designated CTXF. The receptor for this phage on the *V. cholerae* surface is the essential *V. cholerae* intestinal colonization factorTCP. Following infection of TCP+ *ctxAB*- *V. cholerae* cells, the CTXF genome stably integrates at a specific site on the *V. cholerae* chromosome. Since *ctxAB* is part of a mobile genetic element (CTXF), horizontal transfer of this bacteriophage may account for the emergence of new toxigenic *V. cholerae* serogroups. In addition, since the CTXF receptor TCP is a *V. cholerae* host colonization factor, it is possible that CTXFinfection of TCP+ *ctxAB*- *V. cholerae* strains occurs primarily within the human intestine. Many of the other genes important for *V. cholerae* pathogenicity, including the genes encoding the biosynthesis of TCP, those encoding accessory colonization factors, and those regulating virulence gene expression, are clustered together on one of the two *V. cholerae* chromosomes. This cluster of virulence genes is referred to as the *V. cholerae pathogenicity island*. Similar clustering of virulence genes is found in other bacterial pathogens. It is believed that these pathogenicity islands have been acquired by horizontal gene transfer.

Molecular analysis of *V. cholerae* O139 Bengal has suggested the basis of its origin and the reasons it was able to cause an explosive epidemic of cholera. Both phenotypically and genotypically, O139 Bengal is closely related to the O1 El Tor strains of the seventh pandemic, and it seems to have arisen from them by horizontal gene transfer. It shares the virulence attributes and general pathogenic mechanisms of O1 vibrios, including possession of the sameCTXprophage and the sameTCP. *V. cholerae* O139 Bengal is in fact virtually identical to the seventh-pandemic strains of *V. cholerae* O1 El Tor except for two important differences: production of the novel O139LPS and of an immunologically related O-antigen polysaccharide capsule. Both of these molecules are putative virulence factors, independently enhancing colonization in a murine infection model. The ability to produce the O139 LPS is due to a replacement of a 22-kb DNA segment encoding O1 antigen biosynthesis with a 35-kb segment containing the genes encoding O139 LPS and capsule biosynthesis. Encapsulation is not a feature of O1 strains and may explain the resistance of O139 strains to human serum in vitro as well as the occasional development of O139 bacteremia.

CLINICAL MANIFESTATIONS

After a 24- to 48-h incubation period, cholera begins with the sudden onset of painless watery diarrhea that may quickly become voluminous and is often followed shortly by vomiting. In severe cases, stool volume can exceed 250 mL/kg in the first 24 h. If fluids and electrolytes are not replaced, hypovolemic shock and death ensue. Fever is usually absent. Muscle cramps due to electrolyte disturbances are common. The stool has a characteristic appearance: a nonbilious, gray, slightly cloudy fluid with flecks of mucus, no blood, and a somewhat sweet, inoffensive odor. It has been called "rice-water" stool because of its resemblance to the water in which rice has been washed. Clinical symptoms parallel volume contraction: At losses of 3 to 5% of normal body weight, thirst

develops; at 5 to 8%, postural hypotension, weakness, tachycardia, and decreased skin turgor are documented; and at >10%, oliguria, weak or absent pulses, sunken eyes (and, in infants, sunken fontanelles), wrinkled ("washerwoman") skin, somnolence, and coma are characteristic. Complications derive exclusively from the effects of volume and electrolyte depletion and include renal failure due to acute tubular necrosis. Thus, if the patient is adequately treated with fluid and salt, complications are averted and the process is self-limited, resolving in a few days.

Laboratory data usually reveal an elevated hematocrit (due to hemoconcentration) in nonanemic patients; mild neutrophilic leukocytosis; elevated levels of blood urea nitrogen and creatinine consistent with prerenal azotemia; normal sodium, potassium, and chloride levels; a markedly reduced bicarbonate level (<15 mmol/L); and an elevated anion gap (due to increases in serum lactate, protein, and phosphate). Arterial pH is usually low (about 7.2).

DIAGNOSIS

The clinical suspicion of cholera can be confirmed by the identification of *V. cholerae* in stool; however, the organism must be specifically sought. In experienced hands, it can be detected directly by dark-field microscopy on a wet mount of fresh stool, and its serotype can be discerned by immobilization with Inaba- or Ogawa-specific antiserum. Laboratory isolation of the organism requires the use of a selective medium. The best of these is thiosulfate-citrate-bile salts-sucrose (TCBS) agar, on which the organism grows as a flat yellow colony. If a delay in sample processing is expected, Carey-Blair transport medium and/or alkaline-peptone water-enrichment medium should be inoculated as well. In endemic areas there is little need for biochemical confirmation and characterization, although these tasks may be worthwhile in places where *V. cholerae* is an uncommon isolate. Standard microbiologic biochemical testing for Enterobacteriaceae will suffice for identification of *V. cholerae*. All vibrios are oxidase-positive. *V. cholerae* can be distinguished from the otherwise similar *V. mimicus* by its ability to ferment sucrose.

The yield of stool cultures for the diagnosis of *V. cholerae* infection declines late in the course of the illness or when effective antibacterial therapy is initiated. Although not generally evaluable in clinical laboratories, serum vibriocidal antibody titers can be used to confirm the diagnosis in non-cholera-endemic regions of the world. Monoclonal antibody-based diagnostic kits and methods based on the polymerase chain reaction and on DNA probes have been developed for *V. cholerae* O1 and O139 but are unlikely to become available in U.S. clinical laboratories.

TREATMENT

Cholera is simple to treat; only the rapid and adequate replacement of fluids, electrolytes, and base is required. The mortality rate for appropriately treated disease is usually <1%. However, analysis of a large outbreak of cholera among airline travelers from an endemic country to the United States revealed frequent misdiagnoses by U.S. health professionals and poor appreciation on their part of the principles of management. Compounding these problems was the general unavailability of appropriate oral fluids. Even intravenous fluid therapy typically was not optimal.

It has been proved conclusively that fluid may be given orally. This approach takes advantage of the hexose-Na^+cotransport mechanism to move Na^+across the gut mucosa together with an actively transported molecule such as glucose. Since Na^+losses in the stool are high, a fluid containing Na^+ at 90 mmol/L has been recommended by the World Health Organization (WHO) (Table 159-1). This amount of Na^+ is higher than that needed to treat diarrhea due to most other causes. The solution is safe, even for infants, if its intake is alternated with the consumption of sodium-free fluids such as breast milk or water. For the sake of simplicity, WHO advises routine use of this single solution for diarrheal disease rather than attempts to choose among multiple formulations according to etiology.

Cereal-based formulations are receiving increased attention as alternative oral rehydration solutions. Because of their lower osmolarity, they may reduce stool output. A mixture with a lower sugar and salt content has also been evaluated in cholera patients, with favorable results. However, concerns have been raised over the safety of its use -- in particular, whether it could cause significant hyponatremia in patients with moderate or severe diarrhea. Because commercial oral rehydration solutions also contain concentrations of glucose and sodium lower than those of theWHOformulation, they should not yet be used routinely to treat cholera.

For initial management of severely dehydrated patients, intravenous fluid replacement is preferable, if available. Because profound acidosis (pH < 7.2) is common in this group, Ringer's lactate is the best choice among commercial products (Table 159-2). It must be used with additional potassium supplements, preferably given by mouth. The total fluid deficit in severely dehydrated patients (³10% of body weight) can be replaced safely within the first 4 h of therapy, half within the first hour. Thereafter, oral therapy can usually be initiated, with the goal of maintaining fluid intake equal to fluid output. However, patients with continued large-volume diarrhea may require prolonged intravenous treatment to keep up with gastrointestinal fluid losses. Severe hypokalemia can develop but will respond to potassium given either intravenously or orally. In the absence of adequate staff to monitor the patient's progress, the oral route of rehydration and potassium replacement is safer than the intravenous route and is physiologically regulated by thirst and urine output.

Although not necessary for cure, the use of an antibiotic to which the organism is susceptible will diminish the duration and volume of fluid loss and will hasten clearance of the organism from the stool. Single-dose tetracycline (2 g) or doxycycline (300 mg) is effective in adults but is not recommended for children under 8 years of age because of possible deposition in bone and developing teeth. Emerging drug resistance is an ever-present concern. For adults with cholera in areas where tetracycline resistance is prevalent, ciprofloxacin -- either in a single dose (30 mg/kg, not to exceed a total dose of 1 g) or in a short course (15 mg/kg bid for 3 days, not to exceed a total daily dose of 1 g) -- or erythromycin (a total of 40 mg/kg daily in three divided doses for 3 days) is a clinically effective substitute. Both drugs are highly effective in reducing total stool output, and each is significantly better than trimethoprim-sulfamethoxazole. Because of the high cost of quinolones,WHOrecommends erythromycin as the first alternative to tetracycline. For children, furazolidone has been the recommended agent and trimethoprim-sulfamethoxazole the second choice. It is of note that *V. cholerae* O139 is

often resistant to both of these drugs but is susceptible to quinolones, erythromycin, tetracycline, and ampicillin (among others). Because of cost and/or toxicity issues related to the other drugs, erythromycin is a good choice for pediatric cholera, especially where O139 Bengal is present. The efficacy of single-dose erythromycin therapy for cholera has not been demonstrated.

CONTROL

In outbreaks, efforts should first be made to identify case contacts and to treat incubating carriers. Next, epidemiologic studies should be undertaken to establish the modes of transmission to define the best strategy to interrupt them. Both the establishment of rehydration centers and instruction in rehydration techniques are essential to the reduction of mortality. Immunization in these circumstances is not an effective means of control.

PREVENTION

Provision of safe water and facilities for sanitary disposal of feces, improved nutrition, and attention to food preparation and storage in the household could significantly reduce the incidence of cholera. Much effort has been devoted to the development of an effective cholera vaccine over the past two decades, with a particular focus on oral vaccine strains. Traditional killed cholera vaccine given intramuscularly provides little protection to nonimmune subjects and predictably causes adverse effects, including pain at the injection site, malaise, and fever. The vaccine's limited efficacy is at least partially due to its failure to induce a local immune response at the intestinal mucosal surface.

Two types of oral cholera vaccines are under development. The first is a killed whole-cell (WC) vaccine. Two formulations of the killed WC vaccine have been prepared: one that also contains the nontoxic B subunit of CTX (WC/BS) and one composed solely of killed bacteria. In field trials in Bangladesh, both of the killed vaccines were compared with placebo and conferred ~50% protection over a 3-year evaluation period. The protective efficacy of WC/BS was superior to that of WC during the initial 8 months of follow-up (69 versus 41%) but equivalent or inferior thereafter. Immunity was relatively sustained in persons vaccinated at an age of>5 years but was not well sustained in younger vaccinees.

The second approach is that of a live attenuated vaccine strain developed, for example, by the isolation or creation of mutants lacking activeCTX. Three criteria must be met in live vaccine design: The vaccine strain must induce protective immunity, it must be safe to administer, and it must be minimally reactogenic. *Safety criteria* include the vaccine strain's potential to regain virulence, either spontaneously or via horizontal gene transfer from environmental strains, as well as its potential to donate virulence genes to other strains. *Reactogenicity* refers to its potential to cause symptoms such as fever or diarrhea in vaccinees.

Strain CVD 103-HgR, an oral live cholera vaccine licensed for immunization of travelers in Europe, is derived from a classical biotype strain of *V. cholerae* by the deletion of theCTX A subunit gene and the insertion in the hemolysin gene of a mercury resistance

marker. This strain has been extensively tested in volunteers; although it is poorly excreted in the stool of human vaccinees, a single dose produces a significant increase in the titer of vibriocidal antibody in ~75% of recipients, including children between the ages of 2 and 4 years, with almost no reactogenicity. Studies in volunteers demonstrate that this vaccine is more effective against classical than against El Tor cholera. Unfortunately, in a large field trial in Indonesian children, this vaccine failed to induce protection against clinical cholera.

Other live attenuated vaccine candidate strains have been prepared from El Tor and O139 *V. cholerae*. In studies in volunteers, these vaccine strains have often exhibited significant reactogenicity whose cause (given the absence of activeCTX) is unclear. Reactogenicity may result from the production of another toxic moiety (e.g., the hemagglutinin/protease or the RTX toxin) by the live attenuated strain. Alternatively, intestinal colonization itself may result in reactogenicity. These El Tor- and O139-derived live vaccine strains are therefore at least several years away from potential licensing. Because of the minimal efficacy of existing parenteral vaccines, cholera immunization is recommended for U.S. travelers only if it is mandated by the countries they plan to visit.

OTHER *VIBRIO* SPECIES

In recent years, the taxonomic, epidemiologic, pathophysiologic, and clinical features of vibrios that do not cause clinical cholera have become increasingly well understood. Ten human pathogens are currently recognized in the genus *Vibrio*. Included are species associated primarily with gastrointestinal illness (*V. parahaemolyticus*, non-O1 *V. cholerae*, *V. mimicus*, *V. fluvialis*, *V. hollisae*, and *V. furnissii*) and species associated primarily with soft tissue infections (*V. vulnificus*, *V. alginolyticus*, and *V. damsela*). In addition, *V. vulnificus* has emerged as a cause of primary sepsis in certain compromised hosts. Vibrios are abundant in coastal waters the world over and tend to concentrate in the tissues of filter-feeding mollusks. Under optimal conditions, some can double in number in as little as 9 min. Consequently, seawater and raw or undercooked shellfish are important sources of human infection (Table 159-3). Vibrios grow best at temperatures of 28°C to 44°C but not at all below 4°C or above 60°C. Most can be cultured on blood or MacConkey agar, each of which contains enough salt to support the growth of the halophilic organisms (³0.5%). As with *V. cholerae*,TCBS is the best selective medium. The species can be differentiated in the laboratory by standard biochemical tests. The most important members of the group are *V. parahaemolyticus* and *V. vulnificus*. These and selected other species are considered below in greater detail.

SPECIES ASSOCIATED PRIMARILY WITH GASTROINTESTINAL ILLNESS

V. parahaemolyticus First implicated as a cause of enteritis by Japanese workers in 1953, *V. parahaemolyticus* is now recognized as an important intestinal pathogen in many parts of the world. In one study from Japan, 24% of reported cases of food poisoning were attributed to this organism, presumably owing to the widespread consumption of raw seafood there. In the United States, *V. parahaemolyticus* has been responsible for several well-documented common-source outbreaks of diarrhea, typically linked to ingestion of undercooked or improperly handled seafood or of other

foods that have been contaminated by seawater. Most reports have come from the Atlantic Coast, the Gulf of Mexico, and Hawaii. The organism is ubiquitous in marine environments and is able to grow in saline concentrations as high as 8 to 10%. The ability to cause hemolysis on Wagatsuma agar (known as the *Kanagawa phenomenon*) is closely linked to enteropathogenicity. In one study, 96.5% of isolates from patients with diarrhea were hemolytic versus only ~1% of isolates from seawater. Hemolysis is attributed to a 42-kDa heat-stable protein, the exact pathophysiologic role of which is uncertain. The mechanism by which *V. parahaemolyticus* causes diarrhea is not clear.

V. parahaemolyticus has been associated with two distinct gastrointestinal presentations. The more common is a syndrome of watery diarrhea, accompanied in most cases by abdominal cramps, nausea, and vomiting and in about one-quarter of cases by fever and chills. The incubation period ranges from 4 h to 4 days, and the symptomatic period lasts for a median of 3 days. The vast majority of North American cases have been of this type. The less common syndrome is one of dysentery, described in India and Bangladesh and characterized by severe abdominal cramps, nausea, vomiting, and bloody or mucoid stools. Most cases of either type are self-limited and require neither antimicrobial treatment nor hospitalization. Severe infections are associated with underlying diseases, including diabetes, preexisting liver disease, iron-overload states, or immunosuppression. The occasional severe case should be treated with fluid replacement and antibiotics, as described above for cholera. Death is very rare. There are no reliable differential diagnostic features. *V. parahaemolyticus* should be considered as a possible cause in all cases of diarrhea that can be epidemiologically linked to seafood consumption or to the sea itself.

In addition to gastrointestinal disease, *V. parahaemolyticus* is a rare cause of extraintestinal infections, including wound infections, otitis, and -- very rarely -- sepsis.

Non-O1 *V. cholerae* The heterogeneous non-O1 *V. cholerae* organisms are biochemically indistinguishable from *V. cholerae* O1 on routine testing but fail to agglutinate in O1 antiserum. While technically a non-O1 vibrio, *V. cholerae* O139 Bengal is not grouped with these pathogens because of its potential to cause epidemic cholera, as detailed above. Non-O1 *V. cholerae* strains have been responsible for several well-described food-borne outbreaks of gastroenteritis as well as for sporadic cases of otitis media, wound infection, and bacteremia. About half of all U.S. isolates are obtained from stool specimens. Like other vibrios, non-O1 *V. cholerae* organisms are widely distributed in marine environments; unlike most other vibrios, however, they require only trace amounts of NaCl to survive (i.e., they are nonhalophilic). Recognized U.S. cases invariably have been associated either with the consumption of raw oysters or with recent travel, typically to Mexico. The clinical spectrum of diarrheal disease caused by non-O1 *V. cholerae* is broad and likely reflects the heterogeneous virulence attributes of the group. Occasional isolates make a protein enterotoxin very similar toCTX. Others produce cytotoxins, hemolysins, or invasins.

Gastroenteritis due to non-O1 *V. cholerae* typically has an incubation period of<2 days. Stools may be copious and watery. On occasion, diarrhea may leave the patient severely dehydrated, as in cholera. Alternatively, the stools may be partly formed, less voluminous, and bloody or mucoid. Abdominal cramps, nausea, vomiting, and fever are often reported. In one series, 11% of patients were hospitalized; in another, the figure

was 50%. The duration of illness ranges from about 2 to 7 days. As in cholera, patients with significant dehydration should be treated with oral or intravenous fluids. The role of antibiotics is uncertain.

Wound infection and otitis media each account for ~10% of non-O1 *V. cholerae* isolates. Bacteremia accounts for another 20%. Patients with extraintestinal infection often have a history of occupational or recreational exposure to seawater. Bacteremia is more likely to develop in the presence of liver disease. Extraintestinal infections should be treated with antibiotics. There is a paucity of information to guide the choice of a specific agent and schedule. Most strains are sensitive in vitro to tetracycline, chloramphenicol, and other agents.

SPECIES ASSOCIATED PRIMARILY WITH SOFT TISSUE INFECTION OR BACTEREMIA

V. vulnificus Though it represents only a small minority of the *Vibrio* species found in nature (4% of Atlantic Coast isolates in one study), *V. vulnificus* is perhaps the most important cause of severe *Vibrio* infections in the United States (0.8 cases per 100,000 population in one study from Louisiana). Formerly included in the species *V. parahaemolyticus*, *V. vulnificus* was distinguished in the 1970s by its ability to ferment lactose and to cause distinct clinical syndromes. Like most vibrios, it proliferates in the warm summer months. It requires a saline environment for growth but prefers concentrations lower than those preferred by *V. parahaemolyticus* and *V. alginolyticus* (range, up to ~8%; optimal, ~1%). Infections in humans typically occur in coastal states between May and October and most often involve men over age 40. *V. vulnificus* has been linked unequivocally to two distinct syndromes: primary sepsis, typically in patients with antecedent liver disease, and primary wound infections, usually in people without underlying disease. Some authors have suggested that this organism causes gastroenteritis, but the evidence for this association is tenuous.

V. vulnificus is remarkably invasive in animal models. It is endowed with a number of virulence attributes, including an antiphagocytic capsule, serum resistance, a cytotoxin/hemolysin (the organism is Kanagawa-positive), collagenase, elastolytic protease, phospholipase, and siderophores. Its virulence, as measured by the 50% lethal dose in mice, is markedly enhanced under conditions of iron overload, a fact consonant with its propensity to infect patients with hemochromatosis.

Primary sepsis occurs most commonly in patients with cirrhosis or hemochromatosis but has also developed in patients with hematopoietic disorders or chronic renal insufficiency, in persons using immunosuppressive medications or alcohol, and (rarely) in individuals without apparent underlying disease. Most of those affected have ingested raw oysters within 2 days of onset (median incubation period, 16 h). The process begins precipitously with malaise, chills, fever (mean temperature, 39.8°C), and prostration. Hypotension develops in one-third of cases, often by the time of admission. Cutaneous manifestations, which develop in three-quarters of cases (usually by 36 h after onset), typically involve the extremities -- lower more often than upper (Fig. 159-CD1). A common sequence is the evolution of erythematous patches followed by ecchymoses, vesicles, and bullae. (Indeed, the presence of sepsis and bullous skin lesions suggests the diagnosis in an appropriate setting.) Necrosis and sloughing may occur. Laboratory

study reveals leukopenia more often than leukocytosis, thrombocytopenia, and (occasionally) elevated levels of fibrin split products. *V. vulnificus* can be cultured from blood or cutaneous lesions.

Mortality approaches 50%, with most deaths due to uncontrolled sepsis. Accordingly, prompt treatment is critical and should include empirical antibiotic administration, aggressive debridement, and general supportive care. *V. vulnificus* is sensitive to a number of antimicrobials in vitro, including tetracycline, gentamicin, and third-generation cephalosporins. No compelling clinical data from studies of humans support the preferential use of any one of these agents. Tetracycline is demonstrably superior in a murine model and on that basis is considered the drug of choice (0.5 to 1 g intravenously every 12 h), either alone or in combination with gentamicin. The duration of therapy is guided by the clinical response.

Wound infections with *V. vulnificus* can develop in patients with or without underlying disease and invariably follow contact of seawater with either a prior or a fresh wound. The incubation period is brief (4 h to 4 days; mean, 12 h). The disease begins with swelling, erythema, and -- in many cases -- intense pain around the wound. Rapidly spreading cellulitis follows, with vesicular, bullous, or necrotic lesions developing in some instances. Metastatic events do not generally occur. Fever (median temperature, 38.9°C) and leukocytosis are demonstrable in most cases. The organism can be cultured from skin lesions and occasionally from blood. Prompt antibiotic therapy and debridement are usually curative.

V. alginolyticus This species was first recognized as a human pathogen in 1973 and is now known to cause occasional wound, ear, and eye infections. It is the most salt-tolerant of the vibrios, able to grow in concentrations >10%. Most clinical isolates come from superinfected wounds, which presumably became contaminated at the beach. Infection varies in severity but is generally not serious and responds well to antibiotic therapy and drainage. A few reports have described otitis externa, otitis media, or conjunctivitis. Therapy with tetracycline is usually curative. *V. alginolyticus* is a rare cause of bacteremia in immunocompromised hosts.

160. BRUCELLOSIS - *M. Monir Madkour*, *Dennis L. Kasper*

DEFINITION

Brucellosis is a zoonosis transmitted to humans from infected animals. Its clinical features are not disease specific. *Brucellosis* has many synonyms derived from the geographical regions in which the disease occurs (e.g., Mediterranean fever, Malta fever, Gibraltar fever, Cyprus fever); from the remittent character of its fever (e.g., undulant fever); or from its resemblance to malaria and typhoid (e.g., typhomalarial fever, intermittent typhoid).

ETIOLOGY

Human brucellosis can be caused by any of four species: *Brucella melitensis* (the most common and most virulent cause of brucellosis worldwide) is acquired primarily from goats, sheep, and camels; *B. abortus* from cattle; *B. suis* from hogs; and *B. canis* from dogs. These small aerobic gram-negative bacilli are unencapsulated, nonmotile, non-spore-forming, facultative intracellular parasites that cause lifelong infection in animals. Brucellae are killed by boiling or pasteurization of milk and milk products. They survive for up to 8 weeks in unpasteurized, white, soft cheese made from goat's milk and are not killed by freezing. The organisms remain viable for up to 40 days in dried soil contaminated with infected-animal urine, stool, vaginal discharge, and products of conception and for longer periods in damp soil.

EPIDEMIOLOGY

The global incidence of human brucellosis is not known because of the variable quality of disease reporting and notification systems in many countries. Worldwide, the only countries believed to be free of brucellosis are Norway, Sweden, Finland, Denmark, Iceland, Switzerland, the Czech and Slovak republics, Romania, the United Kingdom (including the Channel Islands), the Netherlands, Japan, Luxembourg, Cyprus, and Bulgaria; the U.S. Virgin Islands are also free of the disease. Reports indicate that, even in developed nations, the true incidence of brucellosis may be up to 26 times higher than official figures suggest. In the United States, about 200 new cases are reported every year; however, it is estimated that only 4 to 10% of cases are recognized and reported. Consumption of imported cheese, travel abroad, and occupation-related exposures are the most frequently identified sources of infection. In communities where brucellosis is endemic, the disease occurs in children and the family members of infected persons are at risk. Even in countries where animal brucellosis is controlled, the disease occasionally develops among farmers, meat-processing workers, veterinarians, and laboratory workers.

The *Brucella* organism is transmitted most commonly through the ingestion of untreated milk or milk products; raw meat (i.e., blood) and bone marrow have also been implicated. However, the organism can be contracted via inhalation during contact with animals, especially by children and by slaughterhouse, farm, and laboratory workers. Other routes of infection for at-risk workers include skin abrasion, autoinoculation, and conjunctival splashing. The organism has occasionally been transmitted from person to person through the placenta, during breast-feeding, and during sexual activity.

Aerosolized *B. melitensis* is a classic agent of biological warfare.

PATHOGENESIS AND IMMUNITY

Serum opsonizes *Brucella* organisms for ingestion by polymorphonuclear leukocytes and activated macrophages. Brucellae resist intracellular phagocytic killing by mechanisms such as the suppression of the myeloperoxide-hydrogen peroxide-halide system and the production of superoxide dismutase. The pathogen-phagocyte interaction plays a key role in determining the severity and outcome of brucellosis. The organisms surviving within and escaping from the phagocytes multiply and reach the bloodstream via the lymphatics, subsequently localizing in the liver, spleen, bones, kidneys, lymph nodes, heart valves, nervous system, and testes. In these organs, the bacteria are ingested by macrophages and survive by inhibition of phagosome-lysosome fusion. In infected tissues, inflammatory responses or noncaseating granulomas typically develop, and caseating granulomas and abscesses have been described.

Cytokines, including interleukin (IL) 1, IL-12, and tumor necrosis factor, appear to be important in host defense against *Brucella* infection. The smooth lipopolysaccharide (LPS) of *Brucella* is the major known virulence factor. Strains with rough LPS are more likely than those with smooth LPS to be lysed by nonimmune serum. In virulent strains, the foremost target for specific antibodies is the LPS. Serum IgM antibodies to LPS appear within 1 week after infection and are followed later by IgG and IgA. Titers of both IgM and IgG antibody fall after treatment, and failure of these titers to decline should prompt an evaluation for relapse or persistent infection.

CLASSIFICATION

Brucellosis is classified according to whether or not the disease is active (i.e., symptoms or progressive tissue damage and significantly raised *Brucella* agglutinin levels with or without positive cultures) and whether or not there is localized infection. The state of activity and the site of localization have a significant impact on recommended treatment. Classification of brucellosis as acute, subacute, serologic, bacteremic, or of mixed types serves no purpose in diagnosis and management.

CLINICAL MANIFESTATIONS AND COMPLICATIONS

Brucellosis is a systemic disease with protean manifestations. Its features may mimic those of other febrile illnesses. The incubation period lasts for about 1 to 3 weeks but may be as long as several months, depending on the virulence of the organisms, their route of entry, the infecting dose, and the host's preexisting health status. The onset of symptoms may be either abrupt (over 1 to 2 days) or gradual (³1 week). The most common symptoms are fever, chills, diaphoresis, headaches, myalgia, fatigue, anorexia, joint and low-back pain, weight loss, constipation, sore throat, and dry cough. Physical examination often reveals no abnormalities, and patients can look deceptively well. Some patients, in contrast, are acutely ill, with pallor, lymphadenopathy, hepatosplenomegaly, arthritis, spinal tenderness, epididymoorchitis, rash, meningitis, cardiac murmurs, or pneumonia. The fever of brucellosis has no distinctive pattern but may exhibit diurnal variation, with normal temperatures in the morning and high

temperatures in the afternoon and evening. Localization to an organ or a system may be evident at the onset of the disease.Table 160-1 lists the frequencies of key historic features, symptoms, and signs among 500 patients with brucellosis due to *B. melitensis*.

Bones and Joints Although monarticular septic arthritis occurs, 30 to 40% of patients have reactive asymmetric polyarthritis involving the knees, hips, shoulders, and sacroiliac and sternoclavicular joints. The total white cell count in synovial fluid ranges from 4000 to 40,000/mL, typically with about 60% polymorphonuclear leukocytes. The synovial fluid glucose concentration may be reduced and the protein concentration elevated; cultures of synovial fluid are positive in about 50% of cases.

Infection with *Brucella* organisms commonly causes osteomyelitis of the lumbar vertebrae, starting at the superior end plate (an area with a rich blood supply) and occasionally progressing to involve the entire vertebra, disk space, and adjacent vertebrae. Extraspinal *Brucella* osteomyelitis is rare. In *Brucella* septic arthritis and osteomyelitis, the peripheral white cell count is typically normal, while the erythrocyte sedimentation rate may be either normal or elevated.

Heart Cardiovascular complications of brucellosis include endocarditis, myocarditis, pericarditis, aortic root abscess, mycotic aneurysms, thrombophlebitis with pulmonary aneurysm, and pulmonary embolism. *Brucella* endocarditis may develop on valves previously damaged by rheumatic fever or congenital malformation but also occurs on previously normal valves. The clinical features are indistinguishable from those of endocarditis caused by other organisms (Chap. 126). Endocarditis is the leading cause of death in brucellosis, although the outcome of *Brucella* endocarditis has been more favorable in recent years because of advances in early diagnosis, antibiotic treatment, and cardiac surgery. Physicians who suspect brucellae as a cause of culture-negative endocarditis in patients with possible environmental exposure should notify the bacteriology laboratory performing the blood culture so that extended incubation, specific media, and biohazard precautions can be employed.

Respiratory Tract Brucellae can produce respiratory symptoms. A flulike illness with sore throat, tonsillitis, and dry cough is common and usually mild. Hilar and paratracheal lymphadenopathy, pneumonia, solitary or multiple pulmonary nodules, lung abscess, and empyema have been reported.

Gastrointestinal Tract and Hepatobiliary System Gastrointestinal manifestations of *Brucella* infection are generally mild and may include nausea, vomiting, constipation, acute abdominal pain, and/or diarrhea. Pathologic examination of the liver may reveal any of several changes, including noncaseating granulomas (Fig. 160-CD1), suppurative abscesses, mononuclear cell infiltration, or hyperemia of the intestinal mucosa. Acute ileitis with inflammation of Peyer's patches and colitis have been reported. Hepatic and splenic enlargement may be documented in 15 to 20% of cases, and abscesses may develop in the liver and spleen. Infected ascites, pancreatitis, and cholecystitis have been reported. Mild jaundice may be evident, with elevated levels of bilirubin and hepatic enzymes.

Genitourinary Tract The various genitourinary infections attributed to brucellae include unilateral or bilateral epididymoorchitis, which is rarely associated with testicular

abscess. Prostatitis, seminal vesiculitis, dysmenorrhea, amenorrhea, tuboovarian abscess, salpingitis, cervicitis, acute pyelonephritis, glomerulonephritis, and massive proteinuria have also been documented. *Brucella* organisms have been cultured from the urine in up to 50% of cases of genitourinary tract infection.

Central Nervous System Neurobrucellosis is uncommon but serious and includes meningitis, meningoencephalitis, multiple cerebral or cerebellar abscesses, ruptured mycotic aneurysms, myelitis, Guillain-Barre syndrome, cranial nerve lesions, hemiplegia, sciatica, myositis, and rhabdomyolysis. Papillitis, papilledema, retrobulbar neuritis, optic atrophy, and ophthalmoplegia due to lesions in cranial nerves III, IV, and VI may occur in *Brucella* meningoencephalitis. Cerebrospinal fluid (CSF) pressure is usually elevated; the fluid may appear clear, turbid, or hemorrhagic; the protein concentration and cell count (predominantly lymphocytes) are elevated; and the glucose concentration may be either reduced or normal. In *Brucella* meningitis, which can occur at any time during the course of the disease, the organism may be cultured from the CSF.

Other Manifestations Conjunctival splashing with live attenuated *B. abortus* vaccine (S19) during animal vaccination may cause conjunctivitis, keratitis, and corneal ulcers, with progression to systemic disease in some cases. Uveitis, optic neuritis, retinopathy, retinal detachment, and endophthalmitis may result from hematogenous spread.

Skin manifestations of brucellosis are uncommon. They include maculopapular eruptions, purpura and petechiae, chronic ulcerations, multiple cutaneous and subcutaneous abscesses, discharging sinuses, superficial thrombophlebitis, erythema nodosum, and pemphigus.

Brucellosis during human pregnancy can cause abortion or intrauterine fetal death. Brucellae have been isolated from the human placenta, fetus, and newborn.

The bone marrow of *Brucella*-infected patients frequently contains noncaseating granulomas. Among the hematologic complications of brucellosis are anemia, leukopenia, and thrombocytopenia.

Endocrinologic findings reported in brucellosis include thyroiditis with abscess formation, adrenal insufficiency, and the syndrome of inappropriate secretion of antidiuretic hormone.

DIAGNOSIS

The combination of potential exposure, consistent clinical features, and significantly raised levels of *Brucella* agglutinin (with or without positive cultures of blood, body fluid, or tissues) confirms the diagnosis of active brucellosis. The organism's identity is confirmed by phage typing, DNA characterization, or metabolic profiling. Use of a CO_2detection system (such as BACTEC; Becton Dickinson, Sparks, MD) for blood culture provides a more sensitive and rapid culture result than standard methods, with positivity usually apparent after only 2 to 5 days of incubation. Serum antibodies to *Brucella* can be detected by several methods, including standard tube agglutinins (STA), the 2-mercaptoethanol agglutination test, Coombs' test, enzyme-linked immunosorbent

assay, and polymerase chain reaction (PCR). *B. abortus* antigens, which are commonly used for serologic tests, cross-react with *B. melitensis* and *B. suis* but not with *B. canis*. The specific antigen required for assay of antibodies to *B. canis* is not commercially available. *B. canis* antibody titers can be determined in the United States at the Centers for Disease Control and Prevention in Atlanta. A false-negative result in the STA may be obtained because of the prozone phenomenon, which can be avoided by testing of sera at both low and high dilutions.

In endemic areas a *Brucella* antibody titer of 1:320 or 1:640 is significant, while in nonendemic areas an antibody titer of 1:160 is considered significant. Detection of elevated levels of antibody to *Brucella* organisms in the absence of symptoms during the screening of potential blood donors is common in endemic areas. To establish a diagnosis in these regions, clinical and serologic evaluation should be repeated after 2 to 4 weeks and a further rise in titer sought. A high titer of specific IgM suggests recent exposure, while a high titer of specific IgG suggests active disease. Lower titers of IgG may indicate past exposure or treated infection.

Cooperation and consultation with a clinical microbiology laboratory are important when brucellosis is suspected. It may be necessary to observe culture bottles for up to 6 weeks before organisms become detectable. Subcultures should be prepared on duplicate blood agar plates (with and without an atmosphere of 10% CO_2) and special media (such as a blood- or serum-enriched peptone-based medium) or with a rapid CO_2detection system. Patients whose blood or bone marrow is cultured are positive at one site or the other in 50 to 70% of cases. The peripheral white cell count is usually normal but may be low, with relative lymphocytosis. Thrombocytopenia and disseminated intravascular coagulation may be documented. Levels of hepatic enzymes and serum bilirubin may be raised.

Radiologic investigations aimed at detecting skeletal involvement include plain radiography, bone scintigraphy, computed tomography (CT), and magnetic resonance imaging (MRI). Bone scintigraphy is more sensitive than conventional radiography in detecting areas of spinal and extraspinal involvement, particularly in the early stage of infection. CT is useful for further evaluation of spinal lesions and of the extension of infection into the spinal canal. MRI is the modality of choice for the assessment of *Brucella* spondylitis and is more sensitive than scintigraphy or CT for demonstration of the extent of disease.

Plain lateral radiography of the spine may reveal bone sclerosis, with destruction and erosion of the superior end plate anteriorly. As the disease progresses, healing with osteophyte formation and reduction of disk space may take place. In *Brucella* septic monarthritis, plain radiography may show effusion and soft tissue swelling without bone or joint destruction. Scintigraphy may document increased uptake in sacroiliac joints or lumbar vertebrae, even when plain radiography gives normal results.MRIshows diffuse high-signal intensity of the affected vertebrae and may reveal narrowing of the spinal canal as well as loss of definition of the posterior aspect of the vertebrae.

TREATMENT

Single-agent therapy for brucellosis has now been abandoned because of the high rates

of failure and relapse and the potential development of antibiotic resistance. Relatively short courses (<8 weeks) of treatment with antibiotic combinations have similarly been associated with high rates of relapse. The combination of doxycycline and an aminoglycoside (gentamicin, streptomycin, or netilmicin) for 4 weeks followed by the combination of doxycycline and rifampin for 4 to 8 weeks is the most effective regimen. Doxycycline (which is preferred over tetracycline) is given orally in a dose of 100 mg twice daily. Gentamicin is given intramuscularly or as a slow intravenous infusion (3 to 5 mg/kg per day in divided doses every 8 h). Netilmicin (which is preferred to streptomycin) is given (intramuscularly to outpatients, intravenously to inpatients) in a dose of 2 mg/kg every 12 h; trough levels in plasma should be monitored regularly and maintained at£2 ug/mL. Streptomycin is given intramuscularly in a dose of 1 g once daily to patients under 45 years of age and in a dose of 0.5 to 0.75 g/d to older patients. Tetracycline is given orally in a dose of 250 mg every 6 h and rifampin as a single daily dose of 600 to 900 mg. An alternative regimen consists of the doxycycline/rifampin combination given for 8 to 12 weeks. The doxycycline/aminoglycoside combination is more effective than the doxycycline/rifampin combination in that rifampin reduces levels of doxycycline in plasma.

Patients with serious complications of brucellosis require urgent surgical and medical treatment. These complications include endocarditis, aortic root abscesses, mycotic aortic aneurysms, meningitis, cerebral or cerebellar abscesses, spinal or extraspinal osteomyelitis, and liver or splenic abscess. These patients should be hospitalized and given first a three-drug regimen -- i.e., oral doxycycline with intravenous aminoglycoside and rifampin -- for 4 weeks and then a two-drug regimen -- i.e., doxycycline and rifampin -- for 8 to 12 weeks. In instances of renal failure, doxycycline (at adjusted doses) can be used safely. In contrast, the use of aminoglycosides requires facilities for the monitoring of plasma levels; if such facilities are not available, then the doxycycline/rifampin combination should be administered for 8 to 12 weeks.

When used alone, fluoroquinolones (which exhibit good intracellular penetration and efficacy against *Brucella* organisms in vitro) have been associated with the development of quinolone resistance and with high rates of failure and relapse. At present, clinical data are inadequate for the formulation of recommendations regarding the combination of fluoroquinolones with doxycycline, rifampin, or streptomycin.

Third-generation cephalosporins (e.g., ceftriaxone), although active in vitro against brucellae when used alone, have also been associated with a high incidence of clinical failure and relapse. These agents may be useful in combination with other drugs for the treatment of *Brucella* meningitis.

In pregnancy, trimethoprim-sulfamethoxazole (TMP-SMZ) can be given in combination with rifampin for 8 to 12 weeks. The TMP-SMZ dosage appropriate for pregnant women is two or three tablets every 12 h (each tablet contains 80 mg of TMP and 400 mg of SMZ). Children below the age of 8 years can also be treated with rifampin and TMP-SMZ for 8 to 12 weeks, while older children should receive the same antibiotics as adults in the following doses: doxycycline, 100 mg/d orally; an aminoglycoside (gentamicin, 2 mg/kg per day in divided doses every 8 h); and rifampin, 15 mg/kg per day orally or by slow intravenous infusion. TMP-SMZ is given orally every 12 h in a dose that depends on the patient's age (birth to 6 months, 120 mg; 6 months to 6 years, 240

mg).

Within 4 to 14 days after the initiation of therapy, patients become afebrile and constitutional symptoms disappear. The enlarged liver and spleen return to their normal size within 2 to 4 weeks. An acute, intense flare-up of symptoms may follow the start of treatment, especially that with tetracyclines. This reaction is transient and does not necessitate the discontinuation of therapy. In endemic areas the coexistence of brucellosis and tuberculous spondylitis may result in a failure to respond to appropriate treatment. Treated patients whose infections are apparently cured should be followed clinically and serologically, with repeat blood cultures, every 3 to 6 months for 2 years.

PREVENTION

Efforts at prevention should be aimed at the source of infection. Immunization of animals and boiling or pasteurization of milk and milk products are important. Workers in the meat and dairy industries in the former Soviet Union, China, and France have been vaccinated; the vaccine (two injections given 2 weeks apart, each containing 1 mg of an insoluble fraction of phenol-extracted bacteria) markedly reduces the rate of infection. However, the vaccine induces fever in 6% of recipients and severe pain at the injection site in 16%. Moreover, immunity is short-lived, and vaccination should be repeated every 2 years. This vaccine is not used in the United States.

PROGNOSIS

Deaths attributable to brucellosis should be avoidable. Even before the discovery of antibiotics, the mortality rate was <2% and endocarditis was most frequently the cause of death. Morbidity due to brucellosis remains significant; its severity depends on the infecting *Brucella* species and is greatest with *B. melitensis*. Spinal damage, paraplegia, and other neurologic deficits may occur. Nerve deafness due to meningitis or secondary to treatment with streptomycin has been documented.

161. TULAREMIA - *Richard F. Jacobs*

DEFINITION

Tularemia is a zoonosis caused by *Francisella tularensis*, so named in 1974 in recognition of the contributions of Edward Francis. Humans of any age, sex, or race are universally susceptible to this systemic infection. Tularemia is primarily a disease of wild animals and persists in contaminated environments, ectoparasites, and animal carriers. Human infection is incidental and usually results from interaction with biting or blood-sucking insects, wild or domestic animals, or the environment. Tularemia is common in Arkansas, Oklahoma, and Missouri, where more than 50% of the cases in the United States occur. An increasing number of cases of tularemia have been reported from the Scandinavian countries, eastern Europe, and Siberia. The illness is characterized by various clinical syndromes, the most common of which consists of an ulcerative lesion at the site of inoculation, with regional lymphadenopathy and lymphadenitis. Systemic manifestations, including pneumonia, typhoidal tularemia, and fever without localizing findings, pose a greater diagnostic challenge.

ETIOLOGY AND EPIDEMIOLOGY

F. tularensis is the etiologic agent of tularemia, which, with rare exceptions, is the only disease produced by this genus. The organism is a small, gram-negative, pleomorphic, nonmotile, non-spore-forming bacillus measuring 0.2 um by 0.2 to 0.7 um. Bipolar staining results in a coccoid appearance. The organism is a thinly encapsulated, nonpiliated strict aerobe that invades host cells.

In nature, *F. tularensis* is a hardy organism that persists for weeks or months in mud, water, and decaying animal carcasses. Dozens of biting and blood-sucking insects, especially ticks and tabanid flies, serve as vectors. Ticks and wild rabbits are the source for most of the human cases in the endemic areas of the southeastern United States and the Rocky Mountain states. In Utah, Nevada, and California, tabanid flies are the most common vectors. Animal reservoirs include wild rabbits, squirrels, birds, sheep, beavers, muskrats, and domestic dogs and cats.

The two main biovars of *F. tularensis* -- *tularensis* (type A) and *palearctica* (type B) -- are both found in the United States. Type A produces more serious disease in humans; without treatment, the associated fatality rate is approximately 5%. Type B produces a milder, often subclinical infection that is usually contracted from water or marine mammals. Although all strains appear serologically identical, individual strains may possess varying degrees of virulence. *F. tularensis* does not produce an exotoxin, but an endotoxin similar to that of other gram-negative bacilli has been identified. The progression of illness depends upon the organism's virulence, the inoculum size, the portal of entry, and the host's immune status.

Ticks pass the organism to their offspring via a transovarian route. The organism is found in tick feces but not in large quantities in tick salivary glands. In the United States, the disease can be carried by *Dermacentor andersoni* (Rocky Mountain wood tick), *D. variabilis* (American dog tick), *D. occidentalis* (Pacific coast dog tick), and *Amblyomma americanum* (Lone Star tick). *F. tularensis* is transmitted frequently during blood meals

taken by embedded ticks following hours of attachment. It is the taking of a blood meal through a fecally contaminated field that transmits the organism. Tularemia is more common among men than among women. Person-to-person transmission is rare or nonexistent. Transmission of the organism by ticks and tabanid flies takes place mainly in the spring and summer. However, continued transmission in the winter months by trapped or hunted animals has been documented. The organism is extremely infectious. Biosafety level 2 is recommended for clinical laboratory work with material whose contamination is suspected, and biosafety level 3 is required for culture of the organism in large quantities.

PATHOGENESIS AND PATHOLOGY

The most common portal of entry for human infection is through skin or mucous membranes, either directly -- through the bite of ticks, other arthropods, or other animals -- or via inapparent abrasions. Inhalation or ingestion of *F. tularensis* can also result in infection. Although more than 10^8 organisms are usually required to produce infection via the oral route (oropharyngeal or gastrointestinal tularemia), fewer than 50 organisms will result in infection when injected into the skin (ulceroglandular/glandular tularemia) or inhaled (pneumonia). After inoculation into the skin, the organism multiplies locally; within 2 to 5 days (range, 1 to 10 days), it produces an erythematous, tender, or pruritic papule. The papule rapidly enlarges and forms an ulcer with a black base (chancriform lesion). The bacteria spread to regional lymph nodes, producing lymphadenopathy (buboes), and, with bacteremia, may spread to distant organs.

Tularemia is characterized by mononuclear cell infiltration with pyogranulomatous pathology. The histopathologic findings can be quite similar to those in tuberculosis, although tularemia develops more rapidly. As a facultatively intracellular bacterium, *F. tularensis* can parasitize both phagocytic and nonphagocytic host cells and survive intracellularly for prolonged periods. In the acute phase of infection, the primary organs affected (skin, lymph nodes, liver, and spleen) include areas of focal necrosis, initially surrounded by polymorphonuclear leukocytes (PMNs). Subsequently, granulomas form, with epithelioid cells, lymphocytes, and multinucleated giant cells surrounded by areas of necrosis. These areas may resemble caseation necrosis but later coalesce to form abscesses.

Conjunctival inoculation can result in infection of the eye, with regional lymph node enlargement (preauricular lymphadenopathy, Parinaud's complex). Aerosolization and inhalation or hematogenous spread of organisms can result in pneumonia. In the lung, an inflammatory reaction -- including foci of alveolar necrosis and cell infiltration (initially polymorphonuclear and later mononuclear) with granulomas -- develops. Chest roentgenograms usually reveal bilateral patchy infiltrates rather than large areas of consolidation. Pleural effusions are common and may contain blood. Lymphadenopathy occurs in regions draining infected organs. Therefore, in pulmonary infection, mediastinal adenopathy may be evident, while patients with oropharyngeal tularemia develop cervical lymphadenopathy. In gastrointestinal or typhoidal tularemia, mesenteric lymphadenopathy may follow the ingestion of large numbers of organisms. The term *typhoidal tularemia* may be used to describe severe bacteremic disease, irrespective of the mode of transmission or portal of entry. Meningitis has been reported as a primary or secondary manifestation of bacteremia. Patients may also present with fever and no

localizing signs.

IMMUNOLOGY

Infection with *F. tularensis* stimulates the host to produce antibodies. However, this antibody response probably plays only a minor role in the containment of infection. In contrast, cell-mediated immunity, which develops over 2 to 4 weeks, plays a major role in containment and eradication of the infection. Macrophages, once activated, are capable of killing *F. tularensis*.

Immunospecific protection against tularemia can be afforded either by natural infection or by vaccination with live attenuated strains of *F. tularensis*. Killed vaccines, on the other hand, induce no protection against virulent *F. tularensis*. After natural infection or vaccination, serum antibodies to surface-exposed carbohydrate antigens predominate, whereas T cell determinants are located on membrane proteins beneath the bacterial capsule. T cell responses are thought to be due to priming by the organism. The anamnestic T cell response to *F. tularensis* seems to involve a multitude of microbial proteins, each with a distinct set of T cell determinants. A predominant role for CD4+ T cells is supported by the results of experiments in mice, which indicated that resistance to infection was restricted at the level of the MHC class II determinants. Humans primed to *F. tularensis* (like those primed to *Mycobacterium tuberculosis*) show a T_H1-like response. T cell proliferation is associated with the production of interleukin (IL) 2 and interferon g but with little or no production of IL-4.

Investigations of neutrophils in cases of tularemia have suggested thatPMNs are needed for defense against primary infection. PMNs may restrict the growth of *F. tularensis* before the organism becomes intracellular.

CLINICAL MANIFESTATIONS

Tularemia often starts with a sudden onset of fever, chills, headache, and generalized myalgias and arthralgias (Table 161-1). This onset takes place when the organism penetrates the skin, is ingested, or is inhaled. An incubation period of 2 to 10 days is followed by the formation of an ulcer at the site of penetration (Fig. 161-CD1), with local inflammation. The ulcer may persist for several months as organisms are transported via the lymphatics to the regional lymph nodes. These nodes enlarge (Fig. 161-CD1) and may become necrotic and suppurative. If the organism enters the bloodstream, widespread dissemination as well as signs and symptoms of endotoxemia may result.

In the United States, most patients with tularemia (75 to 85%) acquire the infection by inoculation of the skin. In adults, the most common localized form is inguinal/femoral lymphadenopathy; in children, it is cervical lymphadenopathy. About 20% of patients develop a generalized maculopapular rash, which occasionally becomes pustular. Erythema nodosum occurs infrequently. The clinical manifestations of tularemia have been divided into various syndromes, which are listed inTable 161-2.

Ulceroglandular/Glandular Tularemia These two forms of tularemia account for approximately 75 to 85% of cases. The predominant form in children involves cervical or posterior auricular lymphadenopathy and is usually related to tick bites on the head and

neck. In adults, the most common form is inguinal/femoral lymphadenopathy resulting from insect and tick exposures on the lower limbs. In cases related to wild game, the usual portal of entry for *F. tularensis* is either an injury sustained while skinning or cleaning an animal carcass or a bite (usually on the hand). Epitrochlear lymphadenopathy/lymphadenitis is common in patients with bite-related injuries.

In ulceroglandular tularemia, the ulcer is erythematous, indurated, and nonhealing, with a punched-out appearance that lasts from 1 to 3 weeks. The papule may begin as an erythematous lesion that is tender or pruritic; it evolves over several days into an ulcer with sharply demarcated edges and a yellow exudate. The ulcer gradually develops a black base, and simultaneously the regional lymph nodes become tender and severely enlarged (Fig. 161-1). The affected lymph nodes may become fluctuant and drain spontaneously, but usually the condition resolves with effective treatment. Late suppuration of lymph nodes has been described in up to 25% of patients with ulceroglandular/glandular tularemia. Examination of material taken from these late fluctuant nodes after successful antimicrobial treatment has revealed sterile necrotic tissue. In 5 to 10% of patients, the skin lesion may be inapparent, with lymphadenopathy plus systemic signs and symptoms the only physical findings. This clinical syndrome is designated *glandular tularemia*. Conversely, a tick or deerfly bite on the trunk may result in an ulcer without evident lymphadenopathy.

Oculoglandular Tularemia In about 1% of patients, the portal of entry for *F. tularensis* is the conjunctiva. Usually, the organism reaches the conjunctiva through contact with contaminated fingers. The inflamed conjunctiva is painful, with numerous yellowish nodules and pinpoint ulcers. Purulent conjunctivitis with regional lymphadenopathy (preauricular, submandibular, or cervical) is evident. Because of debilitating pain, the patient may seek medical attention before regional lymphadenopathy develops. Painful preauricular lymphadenopathy is unique to tularemia and distinguishes it from cat-scratch disease, tuberculosis, sporotrichosis, and syphilis. Corneal perforation may occur.

Oropharyngeal and Gastrointestinal Tularemia Rarely, tularemia follows the ingestion of contaminated undercooked meat, the oral inoculation of *F. tularensis* from the hands in association with the skinning and cleaning of animal carcasses, or the consumption of contaminated food or water. Oral inoculation may result in acute, exudative, or membranous pharyngitis associated with cervical lymphadenopathy or in ulcerative intestinal lesions associated with mesenteric lymphadenopathy, diarrhea, abdominal pain, nausea, vomiting, and gastrointestinal bleeding. Infected tonsils become enlarged and develop a yellowish-white pseudomembrane, which can be confused with that of diphtheria. The clinical severity of gastrointestinal tularemia varies from mild, unexplained, persistent diarrhea with no other symptoms to a rapidly fulminant, fatal disease. In fatal cases, the extensive intestinal ulceration found at autopsy suggests an enormous inoculum.

Pulmonary Tularemia Tularemia pneumonia presents as variable parenchymal infiltrates that are unresponsive to treatment with b-lactam antibiotics. Tularemia must be considered in the differential diagnosis of atypical pneumonia in a patient with a history of travel to an endemic area. The disease can result from either inhalation of an infectious aerosol or spread to the lungs and pleura after bloodstream dissemination.

Inhalation-related pneumonia has been described in laboratory workers after exposure to contaminated materials and is associated with a relatively high mortality rate. Exposure to *F. tularensis* in aerosols from live domestic animals or dead wildlife (including birds) has been reported to cause pneumonia. Hematogenous dissemination to the lungs occurs in 10 to 15% of cases of ulceroglandular tularemia and in about half of cases of typhoidal tularemia. Previously, tularemia pneumonia was thought to be a disease of older patients, but as many as 10 to 15% of children with clinical manifestations of tularemia have parenchymal infiltrates detected by chest roentgenography. Patients with pneumonia usually have a nonproductive cough and may have dyspnea or pleuritic chest pain. Roentgenograms of the chest usually reveal bilateral patchy infiltrates (described as ovoid or lobar densities), lobar parenchymal infiltrates, and cavitary lesions. Pleural effusions may have a predominance of mononuclear leukocytes orPMNs and sometimes red blood cells. Empyema may develop. Patients with tularemia pneumonia can have blood cultures positive for *F. tularensis*.

Typhoidal Tularemia Once thought to represent up to 10% of all cases of tularemia, the typhoidal presentation is now considered rare in the United States. In this presentation, fever develops without apparent skin lesions or lymphadenopathy. In the absence of a history of possible contact with a vector, diagnosis can be extremely difficult. Blood cultures may be positive and patients may present with classic sepsis or septic shock in this acute systemic form of the infection. Typhoidal tularemia is usually associated with a huge inoculum or with a preexisting compromising condition. High continuous fevers, signs of endotoxemia, and severe headache are common findings. The patient may be delirious and may develop prostration and shock. If presumptive antibiotic therapy in culture-negative cases does not include an aminoglycoside, the mortality rate can approach 30%.

Other Manifestations *F. tularensis* infection has been associated with meningitis, pericarditis, hepatitis, peritonitis, endocarditis, osteomyelitis, and sepsis and septic shock with rhabdomyolysis and acute renal failure. In the rare cases of tularemia meningitis, a predominantly lymphocytic response is demonstrated in cerebrospinal fluid.

DIFFERENTIAL DIAGNOSIS

When patients in endemic areas present with fever, chronic ulcerative skin lesions, and large tender lymph nodes, a diagnosis of tularemia should be made presumptively, and confirmatory diagnostic testing and appropriate therapy should be undertaken. When the possibility of tularemia is considered in a patient with this presentation in a nonendemic area, an attempt should be made to determine whether the individual has come into contact with a potential animal vector. The level of suspicion of tularemia should be especially high in hunters, trappers, game wardens, veterinarians, laboratory workers, and individuals with a history of exposure to an insect or another animal vector. However, up to 40%of patients with tularemia have no known history of epidemiologic contact with an animal vector.

The characteristic presentation of ulceroglandular tularemia does not pose a diagnostic problem, but a less classic progression of regional lymphadenopathy or glandular

tularemia must be differentiated from other diseases. The skin lesion may resemble those seen in sporotrichosis; skin infection with *Staphylococcus aureus*, *Streptococcus pyogenes*, or *Mycobacterium marinum*; syphilis; anthrax; rat-bite fever (due to *Spirillum minus*); or rickettsiosis (scrub typhus). In the latter infections, regional lymphadenopathy is usually not as impressive as in tularemia. The lymphadenopathy of tularemia (especially glandular tularemia) must be differentiated from that of plague, lymphogranuloma venereum, and cat-scratch disease. In children, the differentiation from cat-scratch disease is made more difficult by the chronic papulovesicular lesion associated with *Bartonella henselae* infection (Chap. 163).

Oropharyngeal tularemia can resemble and must be differentiated from pharyngitis due to group A b-hemolytic streptococci, *Arcanobacterium haemolyticum*, or *Corynebacterium diphtheriae* as well as from infectious mononucleosis. Tularemia pneumonia may resemble any of the atypical pneumonias, including those due to various viruses, *Mycoplasma pneumoniae*, *Chlamydia pneumoniae*, *C. psittaci*, *Legionella pneumophila*, *Coxiella burnetii*, and (occasionally) *Histoplasma capsulatum.* Typhoidal tularemia may resemble typhoid fever, other *Salmonella* bacteremias, rickettsial infections (Rocky Mountain spotted fever, ehrlichiosis), brucellosis, infectious mononucleosis, acquired toxoplasmosis, miliary tuberculosis, sarcoidosis, and hematologic or reticuloendothelial malignancies.

LABORATORY DIAGNOSIS

Direct microscopic examination of polychromatically stained tissue smears or clinical specimens reveals *F. tularensis* organisms, singly and in groups, both intra- and extracellularly. Gram's staining of clinical or biopsy material is of little value, as the small, weakly staining organisms cannot be readily distinguished from the background. An indirect fluorescent antibody test with commercially available antisera can be useful, although false-positive results due to *Legionella* spp. have been reported.

The diagnosis of tularemia is most frequently confirmed by serologic testing. In the standard tube agglutination test, a single titer of ³1:160 is interpreted as a presumptive positive result. A fourfold increase in titer between paired serum samples collected 2 to 3 weeks apart is considered diagnostic. False-negative serologic responses are obtained early in infection; up to 30% of patients infected for 3 weeks have sera that test negative. Late in infection, titers into the thousands are common, and titers of 1:20 to 1:80 may persist for years. A microagglutination test that may be as much as 100-fold more sensitive than the standard tube agglutination test has been described and is currently being used in many clinical microbiology laboratories. Enzyme-linked immunosorbent assays have proven useful for the detection of both antibodies and antigens. Analysis of urine for *F. tularensis* antigen has yielded promising results in clinical trials, but facilities for this type of analysis are not widely available. A skin test for delayed hypersensitivity to *F. tularensis* turns positive during the first week of illness and remains positive for years. The skin-test antigen, which is not commercially available, can boost titers of agglutinating antibody.

Culture and isolation of *F. tularensis* are difficult. In one study the organism was isolated in only 10% of more than 1000 human cases, 84% of which were confirmed by serology. The medium of choice is cysteine-glucose-blood agar. *F. tularensis* can be

isolated directly from infected ulcer scrapings, lymph-node biopsy specimens, gastric washings, sputum, and blood cultures. Colonies are blue-gray, round, smooth, and slightly mucoid. On media containing blood, a small zone ofa hemolysis usually surrounds the colony. Slide agglutination tests or direct fluorescent antibody tests with commercially available antisera can be applied directly to culture suspensions for identification.

The polymerase chain reaction (PCR) has been used to detect *F. tularensis* DNA. During a recent outbreak, a multiplex PCR was used to target 16S rRNA and to diagnose ulceroglandular tularemia with DNA extracted from wound swabs; the PCR result was positive in 29 (73%) of 40 serologically confirmed cases. However, this test has not been shown to be more sensitive than direct culture and at present remains a research tool.

TREATMENT

F. tularensis cannot be subjected to standardized antimicrobial susceptibility testing because the organism will not grow on the media used. A wide variety of antibiotics, including all b-lactam antibiotics and the newer cephalosporins, are ineffective for the treatment of this infection. Several studies indicated that third-generation cephalosporins were active against *F. tularensis* in vitro, but clinical case reports suggested a nearly universal failure rate of ceftriaxone in pediatric patients with tularemia. Although in vitro data indicate that imipenem may be active, therapy with imipenem, sulfanilamides, and macrolides is not presently recommended because of the lack of relevant clinical data. Fluoroquinolones have shown promise in terms of their relatively low toxicity and their potential for oral administration. Chloramphenicol and tetracycline have been used successfully for treatment of the acute stages of tularemia but have been associated with higher relapse rates (up to 20%) than conventionally used agents.

Streptomycin, given intramuscularly at a dose of 7.5 to 10 mg/kg every 12 h, is considered the drug of choice for adults. In severe cases, 15 mg/kg every 12 h may be used for the first 48 to 72 h. Streptomycin is also considered the drug of choice for children; the appropriate dose is 30 to 40 mg/kg daily in two divided doses administered intramuscularly. In children, after a clinical response is demonstrated at 3 to 5 days, the dose can be reduced to 10 to 15 mg/kg daily in two divided doses. Therapy is typically continued for 7 to 10 days; however, in mild to moderate cases of tularemia in which the patient becomes afebrile within the first 48 to 72 h of streptomycin treatment, a 5- to 7-day course has been successful.

Gentamicin, at a dose of 1.7 mg/kg given intravenously or intramuscularly every 8 h, is also effective. The published experience in adults consists of two reports describing, respectively, nine and eight patients who were treated effectively with gentamicin. The eight patients in one of the reports all had fever before treatment, and all eight became afebrile within 24 to 72 h. In a recent pediatric study, other symptoms, such as tender lymphadenitis and pharyngitis, also responded within 24 to 72 h of the start of gentamicin therapy.

Virtually all strains of *F. tularensis* are susceptible to streptomycin and gentamicin. In

successfully treated patients, defervescence usually occurs within 2 days, but skin lesions and lymph nodes may take 1 to 2 weeks to heal. When therapy is not initiated within the first several days of illness, defervescence may be delayed. Relapses are uncommon with streptomycin or gentamicin therapy. Late lymph-node suppuration, however, occurs in approximately 40% of children, regardless of the treatment received. These nodes have typically been found to contain sterile necrotic tissue without evidence of active infection. Patients with fluctuant nodes should receive several days of antibiotic therapy before drainage to minimize the risk to hospital personnel. Unlike streptomycin and gentamicin, tobramycin is ineffective in the treatment of tularemia and should not be used.

PROGNOSIS

If tularemia goes untreated, symptoms usually last 1 to 4 weeks but may continue for months. The mortality rate from severe untreated infection (including all cases of untreated tularemia pneumonia and typhoidal tularemia) can be as high as 30%. However, the overall mortality rate for untreated tularemia is<8%. Mortality is<1% with appropriate treatment. Poor outcomes are often associated with long delays in diagnosis and treatment. Lifelong immunity usually follows tularemia.

PREVENTION

The prevention of tularemia is based on avoidance of exposure to biting and blood-sucking insects, especially ticks and deerflies. An intradermal vaccine made from live attenuated *F. tularensis* is available from the Centers for Disease Control and Prevention. This vaccine is effective in reducing the frequency and severity of infection. Vaccination of high-risk individuals working with large quantities of cultured organisms is recommended. Others who come into contact with the organisms, such as veterinarians, hunters, or game wardens, should consider vaccination, particularly if they live in endemic areas. The avoidance of skinning wild animals, especially rabbits, and the wearing of gloves while handling animal carcasses decrease the risk of transmission. Use of insect repellents and preparations that prevent tick attachment as well as prompt removal of ticks can be helpful. Prophylaxis of tularemia has not proved effective in patients with embedded ticks or insect bites. However, in patients who are known to have been exposed to large quantities of organisms (e.g., in the laboratory) and who have incubating infection with *F. tularensis*, early treatment can prevent the development of significant clinical disease.

162. PLAGUE AND OTHER *YERSINIA* INFECTIONS - *Grant L. Campbell, David T. Dennis*

PLAGUE

DEFINITION

Plague is an acute, febrile, zoonotic disease caused by infection with *Yersinia pestis*. Although human cases are infrequent and are curable with antibiotics, plague is one of the most virulent and potentially lethal bacterial diseases known. The plague bacterium occurs in widely scattered foci in Asia, Africa, and the Americas, where its usual hosts are wild and peridomestic rodents. It is transmitted to humans typically by flea bite and less commonly by direct contact with infected animal tissues or by airborne droplet. The principal clinical forms of plague are bubonic, septicemic, and pneumonic. Although most cases are now sporadic, occurring singly or in small clusters, the potential for epidemic spread remains.

ETIOLOGIC AGENT

Y. pestis is a gram-negative coccobacillus in the family Enterobacteriaceae. It is microaerophilic, nonmotile, nonsporulating, oxidase and urease negative, and biochemically unreactive. The organism is nonfastidious and infective for laboratory rodents. It grows well, if slowly, on routinely used microbiologic media (e.g., sheep blood agar, brain-heart infusion broth, and MacConkey agar). *Y. pestis* can multiply within a wide range of temperatures (-2°C to 45°C) and pH values (5.0 to 9.6), but optimal growth occurs at 28°C and at pH ~7.4. When incubated on agar plates at 37°C, colonies are pinpoint in size at 24 h and 1 to 2 mm in diameter at 48 h. The colonies are gray-white with irregular surfaces, described as having a "hammered-metal" appearance when viewed microscopically. In broth culture, *Y. pestis* grows without turbidity in clumps clinging to the sides of tubes. When stained with a polychromatic stain (e.g., Wayson or Giemsa), *Y. pestis* isolated from clinical specimens exhibits a characteristic bipolar appearance, often resembling closed safety pins. The bacterium is nonencapsulated but when grown at ³30°C produces a plasmid-expressed immunogenic envelope glycoprotein, fraction 1 (F1).

HISTORIC BACKGROUND

Plague's deadly epidemic potential is notorious and well documented. The Justinian pandemic (542 to 767 A.D.) spread from central Africa to the Mediterranean littoral and thence to Asia Minor, causing an estimated 40 million deaths. The second pandemic began in central Asia, was carried to Sicily by ship from Constantinople in 1347, and swept through Europe and the British Isles in successive waves over the next four centuries. At its height, it killed as many as a quarter of the affected population and became known as the Black Death. In the third (modern) pandemic, plague appeared in Yunnan, China, in the latter half of the nineteenth century; established itself in Hong Kong in 1894; and spread by ship to Bombay in 1896 and subsequently to major port cities throughout the world, including San Francisco and several other West Coast and Gulf Coast ports in the United States. The plague bacillus was first cultured by Alexandre Yersin in Hong Kong in 1894. In 1898, Paul-Louis Simond, a French scientist

sent to investigate epidemic bubonic plague in Bombay, identified the bacillus in the tissues of dead rats and proposed transmission by rat fleas. Waldemar Haffkine, also in Bombay at that time, developed a crude vaccine.

By 1910, plague had circled the globe and established itself in rodent populations on all inhabited continents other than Australia. After 1920, however, the spread of plague was largely halted by international regulations that mandated control of rats in harbors and inspection and rat-proofing of ships. Before the third pandemic subsided, it resulted in an estimated 26 million plague cases and more than 12 million deaths, the vast majority in India. By 1950, plague outbreaks around the world had become isolated, sporadic, and manageable with modern techniques of surveillance, flea and rat control, and antimicrobial treatment of patients. Plague has nearly disappeared from cities and now occurs mostly in rural and semirural areas, where it is maintained in various rodents and their fleas. In the United States, the last outbreak of urban plague occurred in Los Angeles in 1924 and 1925, and human cases since then have resulted from animal plague exposures in rural areas of western states.

Because of its pandemic history, plague remains one of three quarantinable diseases subject to international health regulations (the other two being cholera and yellow fever). The alarm that plague is still able to evoke was highlighted by the public panic over an exaggerated international response to purported outbreaks of bubonic and pneumonic plague in India in 1994. The plague bacillus is considered to have a high potential for use in biologic terrorism; the agent is available around the world, has been "weaponized" for airborne delivery, and would be expected to cause a high primary fatality rate as well as secondary spread among an affected population.

EPIDEMIOLOGY

Y. pestis is maintained in enzootic cycles involving relatively resistant wild rodents and their fleas in mostly remote, lightly populated areas of Asia, Africa, and the Americas and in limited rural foci in extreme southeastern Europe near the Caspian Sea. Humans and other nonrodent mammals are incidental hosts. Enzootic transmission places humans at low risk, and cases are typically infrequent and sporadic. Epizootic transmission involving susceptible rodents and efficient flea vectors (both are amplifying hosts) results in local or even widespread depopulation of susceptible rodents and poses a more serious threat to humans than does enzootic transmission. In the United States, the principal epizootic hosts are various ground squirrels, prairie dogs, and chipmunks; a variety of burrowing rodents act as epizootic hosts in rural areas elsewhere in the world. *Y. pestis* occasionally spills over from wild rodents to rat species that inhabit cultivated fields and adjacent homes, villages, and towns. The organism can then be transported from towns to cities by these highly adaptable rats and their fleas. Urban plague is currently reported sporadically from a few countries such as Vietnam, Myanmar, and Madagascar.

Plague in populated areas is most likely to develop when sanitation is poor and rats are numerous -- especially the common black or roof rat (*Rattus rattus*), its close relatives, and the larger brown sewer or Norway rat (*R. norvegicus*). A high mortality rate from plague in these susceptible rat populations forces their fleas to seek alternative hosts, including humans. The cosmopolitan oriental rat flea *Xenopsylla cheopis* and (in

southern Africa and Brazil) the related species *X. brasiliensis* are efficient vectors of the plague bacillus among rats and are also efficient vectors to humans. *Y. pestis* can multiply to enormous numbers in the foregut (proventriculus) of these fleas, resulting in a bolus of organisms and clotted blood that blocks the passage of subsequent blood meals. This situation occurs only at temperatures of£28°C and depends on a single protease expressed by the plasminogen activator (*pla*) gene of a 9.5-kb plasmid of *Y. pestis*. Regurgitation by a "blocked" flea while it feeds facilitates transmission of the plague bacillus to the new host.

Except for large outbreaks of pneumonic plague in Manchuria in the early part of the twentieth century, person-to-person respiratory transmission of plague during and since the third pandemic has occurred only sporadically and has been limited to clusters of close contacts of pneumonic plague patients, such as household members and caregivers. The 1994 outbreak of pneumonic plague in the city of Surat, India, although reported to be extensive, most likely involved fewer than 100 cases and 50 deaths; in 1998, a small outbreak of pneumonic plague occurred in the Ecuadoran Andes.

International health regulations require that national health authorities immediately report plague cases to the World Health Organization. From 1982 through 1996, 23,904 human plague cases and 2105 deaths (mortality, 9%) were reported by 24 countries. In the same 15-year period, the United States reported 212 plague cases (mean, 14 cases per year) and 27 deaths (mortality, 13%). Cases reported by the United States are confirmed by the plague laboratory of the Centers for Disease Control and Prevention (CDC). Animal plague occurs in 17 contiguous western states, extending from the Great Plains states and eastern Texas to the Pacific Coast; around 80% of human cases in this country now occur in New Mexico, Arizona, and Colorado and around 10% in California. Although plague in the United States is a rural disease, more than 50% of cases are thought to be caused by peridomestic exposures, especially in the southwestern states, where homes are often situated in natural surroundings that provide a favorable habitat for plague-susceptible animals (such as rock squirrels and wood rats) and their fleas. In the Sierra Nevadas of California and Nevada, epizootic plague in chipmunks and ground squirrels poses a risk to visitors in public parks. Hikers, campers, and hunters in natural areas throughout the western states are at a small but finite risk of exposure to plague, especially in the summer months.

Plague can be transmitted during the skinning and handling of carcasses of wild animals such as rabbits and hares, prairie dogs, wildcats, and coyotes. Such direct inoculation of mammal-adapted organisms is associated with primary septicemia and high mortality. Oropharyngeal plague can result from the ingestion of undercooked contaminated meat and perhaps from the manual transfer of infected fluids to the mouth during the handling of infected animal tissues.

Carnivores, including dogs and cats, can become infected with *Y. pestis* by eating infected rodents and perhaps by being bitten by fleas from infected rodents. Although clinical plague commonly develops in infected cats, it rarely does so in infected dogs, which thus do not directly expose humans to infection. However, both dogs and cats may transport infected fleas from rodent-infested areas to the home environment.

From 1950 through 1996, 387 plague cases were reported in the United States. Of the

376 evaluable cases, 322 cases (86%) presented as primary lymphadenitic (bubonic) plague, almost all of them thought to be associated with flea bites; 46 cases (12%) presented as primary septicemic plague, many of them following direct animal exposures; and 8 cases (2%) presented as primary pneumonic plague, 6 resulting from the inhalation of respiratory droplets released by infected cats and 2 from unknown sources. The last case of human-to-human plague transmission in the United States occurred in the Los Angeles outbreak of 1924/1925.

PATHOGENESIS AND PATHOLOGY

Y. pestis is highly invasive and pathogenic. The mechanisms by which the organism causes disease are incompletely understood, but both chromosome- and plasmid-encoded gene products as well as altered cell-mediated immune responses are probably involved. Three plasmids encode for a variety of known or presumed virulence factors, including the F1 envelope antigen, which confers bacterial resistance to phagocytosis by polymorphonuclear leukocytes (PMNs) in vitro; a murine exotoxin; the V antigen, which is essential for virulence, may immunocompromise the host by suppressing the synthesis of interferon g and tumor necrosis factor a, and stimulates protective immunity in laboratory animals; pesticin, a bactericidal protein of unknown function and importance; a protease that can activate plasminogen and degrade serum complement and that is thought to play a role in the dissemination of *Y. pestis* from peripheral sites of infection; a coagulase; and a fibrinolysin. A lipopolysaccharide endotoxin, believed to be chromosomally encoded, is probably important in triggering the systemic inflammatory response syndrome and its complications.

Y. pestis organisms inoculated through the skin or mucous membranes usually invade superficial lymphatic vessels and are carried to regional lymph nodes, although direct bloodstream inoculation may take place. Mononuclear phagocytes, which can phagocytize *Y. pestis* organisms without destroying them, may play a role in dissemination of the infection to distant sites. Plague can involve almost any organ, and untreated plague generally results in widespread and massive tissue destruction. In the early stages, infected lymph nodes (buboes,Fig. 162-1) are characterized by edema and congestion without inflammatory infiltrates or apparent vascular injury. Fully developed buboes contain huge numbers of infectious plague organisms and show distorted or obliterated lymph node architecture with vascular destruction and hemorrhage, serosanguineous effusion, necrosis, and a mild neutrophilic infiltration. At this stage, the effusion often involves perinodal tissues. If several adjacent lymph nodes are involved, a boggy edematous mass can result.

Primary septicemic plague results from the direct inoculation of bacteria from infected fluids or tissues or from an infective flea bite in the apparent absence of a bubo; secondary septicemic plague occurs when lymphatic and other host defenses are breached and the plague bacillus multiplies within the bloodstream. In fatal septicemic plague, multifocal hepatic and splenic necrosis is common. Diffuse interstitial myocarditis with cardiac dilatation is sometimes found. If disseminated intravascular coagulation (DIC) ensues, vascular necrosis may lead to widespread cutaneous, mucosal, and serosal ecchymoses and petechiae. Acral gangrene sometimes develops.

Primary plague pneumonia generally begins as a lobular process and then extends by

confluence, becoming lobar and then multilobar (Fig. 162-2). Plague organisms are typically most numerous in the alveoli. Secondary plague pneumonia begins more diffusely, with organisms usually most numerous in the interstitium. In untreated cases of both primary and secondary plague pneumonia, diffuse pulmonary hemorrhage, necrosis, and neutrophilic infiltration develop.

MANIFESTATIONS

Plague is characterized by a rapid onset of fever and other systemic manifestations of gram-negative bacterial infection. If it is not quickly and correctly treated, plague can follow a toxic course, resulting in shock, multiple-organ failure, and death. In humans, the three principal forms of plague are bubonic, septicemic, and pneumonic. Bubonic plague, the most common form, is almost always caused by the bite of an infected flea but occasionally results from direct inoculation of infectious fluids. Septicemic and pneumonic plague can be either primary or secondary to metastatic spread. Unusual secondary forms include plague meningitis, endophthalmitis, and lymphadenitis at multiple sites. Primary plague pharyngitis has been documented by culture of organisms from throat swabs and can result from respiratory exposure or ingestion of contaminated meat.

Bubonic plague usually has an incubation period of 2 to 6 days, occasionally longer. Typically, the patient experiences chills; fever, with temperatures that rise within hours to³38°C; myalgias; arthralgias; headache; and a feeling of weakness. Soon -- usually within 24 h -- the patient notices tenderness and pain in one or more regional lymph nodes proximal to the site of inoculation of the plague bacillus (Fig. 162-1). Because fleas often bite the legs, femoral and inguinal nodes are most commonly involved; axillary and cervical nodes are next most commonly affected. The enlarging bubo becomes progressively painful and tender, sometimes exquisitely so. The patient usually guards against palpation and limits movement, pressure, and stretch around the bubo. The surrounding tissue often becomes edematous, sometimes markedly so, and the overlying skin may be erythematous, warm, and tense. Inspection of the skin surrounding or distal to the bubo sometimes reveals the site of a flea bite marked by a small papule, pustule, eschar, or ulcer. A list of lymphadenitic conditions that could be confused with a plague bubo would include *Staphylococcus aureus* and group A b-hemolytic streptococcal infections, cat-scratch disease, and tularemia. The bubo of plague is distinguishable from lymphadenitis of most other causes, however, by its rapid onset, its extreme tenderness, the accompanying signs of toxemia, and the absence of cellulitis or obvious ascending lymphangitis.

Treated in the uncomplicated state with an appropriate antibiotic, bubonic plague usually responds quickly, with defervescence and alleviation of other systemic manifestations over 2 to 5 days. Buboes often remain enlarged and tender for a week or more after the initiation of treatment and can become fluctuant. Without effective antimicrobial treatment, patients with typical bubonic plague manifest an increasingly toxic state of fever, tachycardia, lethargy leading to prostration, agitation and confusion, and (occasionally) convulsions and delirium. Secondary plague sepsis may result in an alarmingly rapid and refractory cascade ofDIC, bleeding, shock, and organ failure. Mild forms of bubonic plague, called *pestis minor*, have been described in South America and elsewhere; in these cases, the patients are ambulatory, are only mildly febrile, and

have subacute buboes.

Septicemic plague is a progressive, overwhelming bacterial infection. Primary septicemia develops in the absence of apparent regional lymphadenitis, and the diagnosis of plague is often not suspected until preliminary blood culture results are reported to be positive by the laboratory. *Y. pestis*, however, can also be cultured from the blood of most bubonic plague patients, and bacteremia should be distinguished from septicemia, in which the patient is desperately ill and requires aggressive care. Patients with septicemic plague often present with gastrointestinal symptoms of nausea, vomiting, diarrhea, and abdominal pain, which may further confound the correct diagnosis. If not treated early with appropriate antibiotics, septicemic plague can be fulminant and fatal. In the United States in 1950 through 1996, 66 cases of septicemic plague and 18 deaths were reported, for a case-fatality rate of 27%. Petechiae, ecchymoses, bleeding from puncture wounds and orifices, and gangrene of acral parts are manifestations ofDIC; refractory hypotension, renal shutdown, obtundation, and other signs of shock are preterminal events. Adult respiratory distress syndrome (ARDS), which can occur at any stage of septicemic plague, is sometimes confused with other conditions, such as hantavirus pulmonary syndrome.

Of all forms of the disease, pneumonic plague develops most rapidly and is most frequently fatal. The incubation period for primary pneumonic plague is rarely longer than 1 to 4 days. The onset is most often sudden, with chills, fever, headache, myalgias, weakness, and dizziness. Pulmonary signs, including cough, sputum production, chest pain, tachypnea, and dyspnea, typically arise on the second day of illness and may be accompanied by hemoptysis, increasing respiratory distress, cardiopulmonary insufficiency, and circulatory collapse. In primary plague pneumonia, the sputum is most often watery or mucoid, frothy, and blood-tinged, but it may become frankly bloody. Pulmonary signs in primary pneumonic plague may indicate involvement of a single lobe in the early stage, with rapidly developing segmental consolidation before bronchopneumonic spread to other lobes of the same and opposite lungs. Liquefaction necrosis and cavitation may occur early in areas of consolidation and may or may not leave significant residual scarring.

Secondary plague pneumonia manifests first as diffuse interstitial pneumonitis in which sputum production is scant; since the sputum is more likely to be inspissated and tenacious in character than the sputum found in primary pneumonia, it may be less infectious. In the United States in 1950 through 1996, 39 cases of secondary pneumonic plague and 8 cases of primary pneumonic plague were reported, with no known transmission to contacts and an overall case-fatality rate of 41%. Observers in the early twentieth century remarked on the relative lack of auscultatory findings, the usual presence of toxemia, and the frequency of sudden death in patients with pneumonic plague as compared to patients with other bacterial pneumonias.

Meningitis is an unusual manifestation of plague. In the United States, there were 12 meningitis cases among the 376 evaluable plague cases reported in 1950 through 1996. All cases of meningitis were complications of bubonic plague, and all patients survived. Although meningitis may be a part of the initial presentation of plague, its onset is often delayed and is a manifestation of insufficient treatment. Recent cases in the United States have occurred during the first and second weeks of antibiotic

treatment for bubonic plague. Chronic relapsing meningeal plague over periods of weeks or even months was described in the preantibiotic era. The affected patients typically presented with fever, headache, meningismus, and pleocytosis.

Plague pharyngitis presents as fever, sore throat, cervical lymphadenitis, and headache and is often indistinguishable clinically from pharyngitis of other infectious etiologies. Caregivers working in plague-endemic areas must be alert to the possibility of plague to avoid misdiagnosis leading to delayed and/or inappropriate treatment.

LABORATORY FINDINGS AND DIAGNOSIS

Since plague is a rare disease in the United States, a high index of clinical suspicion as well as the elicitation of a thorough clinical and epidemiologic history and a careful physical examination are required for timely diagnosis and prompt institution of specific therapy. When the diagnosis of plague is delayed or missed altogether, a high case-fatality rate results; infected travelers who seek medical care after they have left endemic areas (peripatetic plague cases) are at especially high risk. Plague must be considered in the differential diagnosis of sepsis in an otherwise-healthy person who has a history of recent travel to or residence in the rural western United States. When the diagnosis of plague is being considered, close communication between clinicians and the diagnostic laboratory and between the diagnostic laboratory and a qualified reference laboratory is essential. Tests for plague are highly reliable when conducted by laboratory personnel experienced with *Y. pestis*, but such expertise is usually limited to selected reference laboratories, including state health department laboratories in some plague-endemic states and theCDCplague laboratory (Fort Collins, Colorado; tel. 970-221-6400).

When plague is suspected, specimens should be collected promptly for laboratory studies, chest roentgenograms should be obtained, and specific antimicrobial therapy should be initiated pending confirmation. Appropriate diagnostic specimens for smear and culture include citrated or heparinized whole blood from all patients with suspected plague, bubo aspirates from those with suspected buboes, sputum samples or tracheal aspirates from those with suspected pneumonic plague, and cerebrospinal fluid (CSF) from those with suspected plague meningitis. Since early buboes are often exquisitely tender and are seldom fluctuant or necrotic, these lesions usually require aspiration under local anesthesia following the injection of 1 to 2 mL of normal saline (sterile but nonbacteriostatic) into the bubo with a 20- to 22-gauge needle. A variety of appropriate culture media (including brain-heart infusion broth, sheep blood agar, and MacConkey agar) should be inoculated with a portion of each specimen. Moreover, for each specimen, at least one smear should be examined immediately with Wayson or Giemsa stain and at least one with Gram's stain; a smear should also be submitted for direct fluorescent antibody testing. An acute-phase serum specimen should be tested for antibody to *Y. pestis*; whenever possible, a convalescent-phase serum specimen collected 3 to 4 weeks later should also be tested. When a patient dies and plague is suspected, appropriate autopsy tissues for culture, direct fluorescent antibody testing, and immunohistochemical staining include buboes, all solid organs (especially liver, spleen, and lung), and bone marrow. If culture of such specimens is to be attempted, they should be sent to the laboratory either fresh or frozen on dry ice, not in preservatives or fixatives. If necessary, Cary-Blair or a similar medium can be used to

transport *Y. pestis*-infected tissues.

Laboratory confirmation of plague depends on the isolation of *Y. pestis* from cultures of body fluids or tissues. Cultures of three blood samples taken over a 45-min period before treatment will usually result in isolation of the bacterium. *Y. pestis* strains are readily distinguished from those of the closely related species *Y. pseudotuberculosis* by differences in biochemical profile, temperature-dependent susceptibility to lysis by a *Y. pestis*-specific bacteriophage, and motility. Automated bacteriologic test systems can be used to assist in the identification of isolates as *Y. pestis*, but *Y. pestis* can be misidentified (e.g., as *Y. pseudotuberculosis*) or overlooked if these systems are improperly programmed.

In the absence of *Y. pestis* isolation, plague cases can be confirmed either by the demonstration of seroconversion (a fourfold or greater titer rise) to *Y. pestis* F1 antigen in passive hemagglutination tests of acute- and convalescent-phase serum specimens or by detection of an antibody titer of>128 in a single serum sample from a patient with a plague-compatible illness who has not received plague vaccine. The specificity of a positive passive-hemagglutination test requires confirmation with the F1 antigen hemagglutination-inhibition test. A few plague patients seroconvert to F1 antigen as early as 5 days after the onset of illness. Most seroconvert between 1 and 2 weeks after onset; a few seroconvert 3 weeks or more after onset; and a few (<5%) fail to seroconvert at all. Early, specific antibiotic treatment may delay seroconversion by several weeks. After seroconversion, positive serologic titers diminish gradually over months to years. Enzyme-linked immunosorbent assays (ELISAs) for IgM and IgG antibodies to *Y. pestis* are replacing hemagglutination tests in some laboratories. Other new test methods include IgM antibody capture and competitive blocking for detection of antibody to F1.

Detection of F1 antigen in tissues or fluids by direct fluorescent antibody testing or by antigen capture is presumptive evidence of plague, as is an F1 antibody titer of>10 in a single serum sample from a patient with a plague-compatible illness who has not received plague vaccine. Visualization of characteristic bipolar bacilli in a Giemsa- or Wayson-stained smear constitutes supportive evidence of plague. Tularemia, especially the glandular, typhoidal, and pneumonic forms, can sometimes be confused clinically and epidemiologically with plague, but the results of microbiologic and serologic tests should readily distinguish these two diseases.

Patients with plague typically have white blood cell (WBC) counts of 15,000 to 25,000/uL, with a predominance ofPMNs and a left shift. Leukemoid reactions with WBC counts as high as 100,000/uL can occur. Modest thrombocytopenia is usually documented, and fibrin-fibrinogen split products are often detected even in patients without frankDIC. Serum levels of aminotransferases and bilirubin may be elevated. Chest roentgenograms of patients with pneumonic plague usually show patchy bronchopneumonic infiltrates as well as lobar or segmental consolidation with or without confluence (Fig. 162-2); they occasionally show cavitation. Stained sputum samples usually contain PMNs and characteristic bipolar-staining bacilli. In *Y. pestis* septicemia, visualization of the characteristic bacilli in a routine blood smear or a buffy-coat smear is an uncommon but grave prognostic sign (Fig. 162-3). In patients with plague meningitis, pleocytosis with a predominance of PMNs is the rule, and the characteristic bacilli are

usually visible in stainedCSFsmears.

TREATMENT

Left untreated, plague is fatal in more than 50% of cases of bubonic disease and in nearly all cases of septicemic and pneumonic disease. The overall mortality rate for plague cases in the United States since 1950 has been ~16%; deaths are almost always due to delays in seeking treatment, misdiagnosis, delays in the institution of treatment, or incorrect treatment. Rapid diagnosis and appropriate antimicrobial therapy are essential.

Guidelines for the treatment of plague are given in Table 162-1. Although streptomycin is the drug of choice, gentamicin is increasingly used for the treatment of plague in the United States because of its ready availability; it is probably as effective as streptomycin, although results of controlled studies in humans have not been published. Alternative antibiotics include the tetracyclines and chloramphenicol; these agents are usually given orally with initial loading doses but may be given intravenously to critically ill patients and to patients unable to tolerate oral medication. Penicillins, cephalosporins, and macrolides are suboptimal and should not be used. Doxycycline may be as effective as other tetracyclines or even more so, but comparative evaluations have not been made. Trimethoprim-sulfamethoxazole has been used successfully to treat bubonic plague but is not considered a first-line choice. Chloramphenicol is indicated for the treatment of plague meningitis, pleuritis, endophthalmitis, and myocarditis because of its superior tissue penetration; it is used alone or in combination with streptomycin. In general, antimicrobial treatment should be continued for 10 days or for at least 3 days after the patient has become afebrile and has made a clinical recovery. Patients initially given intravenous antibiotics may be switched to oral regimens upon clinical improvement. Such improvement is usually evident 2 or 3 days after the start of treatment, even though fever may continue for several days.

Consequences of delayed treatment of plague includeDIC,ARDS, and other complications of gram-negative sepsis. Patients with these disorders require intensive monitoring and close physiologic support, as outlined elsewhere (Chaps. 117 and265). Buboes may require surgical drainage. Abscessed nodes can cause recurrent fever in patients who have apparently recovered; this relation may be occult if intrathoracic or intraabdominal nodes are involved. Although *Y. pestis* is considered to be genetically stable, a multidrug-resistant strain was isolated from a plague patient in Madagascar. This strain exhibited resistance (mediated by a transferable plasmid) to all first-line antibiotics used for treatment of plague and to the principal alternatives used for treatment and prophylaxis.

PREVENTION AND CONTROL

Persons at greatest risk for plague in the United States are those who live, work, and participate in outdoor recreational activities in areas of those western states in which plague is enzootic. Surveillance, education, and environmental management are the cornerstones of prevention and control. A network of biologists and public health specialists coordinates these activities through local and state health departments and theCDC. Personal protective measures include the avoidance of areas with known

epizootic plague (which may be posted) and of sick or dead animals; the use of repellents, insecticides, and protective clothing when at risk of exposure to rodents' fleas; and the wearing of gloves when handling animal carcasses. Short-term antibiotic prophylaxis (Table 162-2) is recommended for persons known to have had direct contact with a patient with suspected or confirmed pneumonic plague and occasionally for persons who are unable to avoid an area where a plague outbreak is in progress or who may be caring for patients with plague. Patients in whom plague is suspected should be managed under isolation precautions for respiratory droplet transmission until pneumonia has been ruled out or until 48 h of specific antimicrobial therapy has been administered, after which universal precautions are adequate.

Rodent food (garbage, pet food) and habitats (brush piles, junk heaps, woodpiles) should be eliminated in domestic, peridomestic, and working environments; buildings and food stores should be rodent-proofed. The control of fleas with insecticides is a key public health measure in situations where epizootic plague activity places humans at high risk; this effort includes dusting and spraying of rodent burrows, rodent runs, and other sites where rodents and their fleas are found. In plague-endemic areas of the western United States, persons should keep their dogs and cats free of fleas and restrained. The decision to control plague by killing rodents should be left to public health authorities, and such a program should be carried out only in conjunction with effective flea control. Killing of rodents has no lasting benefit without environmental sanitation.

The previously used killed, whole-cell plague vaccine is no longer manufactured in the United States. Efforts are being made to develop improved vaccines in which the production of specific immunoprotective antibodies to *Y. pestis* is induced by recombinant antigens. In the United States, the indications for use of these newer vaccines would probably be similar to those for the previously available killed vaccine, which was mostly limited to protecting laboratory personnel who routinely worked with *Y. pestis* and some persons whose vocations brought them into regular contact with wild rodents and their fleas in areas with enzootic or epizootic plague. In addition, a vaccine might be useful in protecting selected military personnel and in responding to the possible use of *Y. pestis* as a weapon of bioterrorism.

OTHER *YERSINIA* INFECTIONS

DEFINITION

Yersiniosis is an uncommon bacterial zoonosis caused by infection with either of the two enteropathogenic *Yersinia* species: *Y. enterocolitica* or *Y. pseudotuberculosis*. Reservoir hosts of these bacteria include swine and other wild and domestic animals. These yersiniae are transmitted to humans predominantly via the oral route. Both sporadic cases and common-source outbreaks occur. The most frequent acute clinical manifestations are (1) enteritis or enterocolitis with self-limited diarrhea (especially with *Y. enterocolitica*), and (2) mesenteric adenitis and terminal ileitis (especially with *Y. pseudotuberculosis*), which can be difficult to distinguish from acute appendicitis. Septicemia and metastatic focal infections are less common. Some cases of yersiniosis are complicated by nonsuppurative, extraintestinal, inflammatory sequelae -- e.g., reactive arthritis (Chap. 315) and erythema nodosum (Chap. 18).

ETIOLOGIC AGENTS

Y. enterocolitica and *Y. pseudotuberculosis* are pleomorphic gram-negative bacilli in the family Enterobacteriaceae. They are aerobic or facultatively anaerobic, motile at 25°C, nonmotile at 37°C, oxidase negative, urease positive, able to ferment glucose, unable to ferment lactose, and usually able to reduce nitrates. They grow well, if slowly, on nonselective media (e.g., blood agar) and on most of the routine media used to select for enteric bacteria (e.g., MacConkey agar). They can multiply within a wide temperature range (-1°C to 45°C). The most clinically and epidemiologically useful methods for identifying pathogenic *Y. enterocolitica* isolates are biotyping based on biochemical profiles and serotyping according to somatic O and H antigens. Six biotypes and more than 60 serotypes of *Y. enterocolitica* are recognized. A separate serotyping system for *Y. pseudotuberculosis* (also based on somatic antigens) has distinguished six major serotypes (I through VI) and their subtypes.

EPIDEMIOLOGY

Y. enterocolitica is distributed worldwide and has been isolated from soil, fresh water, contaminated foodstuffs (e.g., meat, milk, and vegetables), and a wide variety of wild and domestic animals, including mammals, birds, amphibians, fish, and shellfish. Many serotypes isolated from environmental sources, however, evidently are not human pathogens. Most human infections have been caused by *Y. enterocolitica* serotypes O:3, O:5, O:8, and O:9, which are primarily associated with wild and domestic mammals. The incidence of these infections and their sequelae is highest in Scandinavia and some other northern European countries, but this observation may be in part an artifact of underrecognition in other countries. Because many individuals with enteric *Y. enterocolitica* infection are asymptomatic or minimally symptomatic and do not seek medical attention, reliable population-based estimates of incidence are unavailable. However, in many clinical microbiology laboratories in recent decades, *Y. enterocolitica* has been the fourth most common bacterial pathogen isolated from patients' fecal specimens, trailing *Salmonella* (the most frequently isolated), *Campylobacter*, and *Shigella* species.

All age groups are susceptible to *Y. enterocolitica* infections, but the majority of cases of enterocolitis are in children aged 1 to 4. Moreover, these infections show a modest predilection for males. Mesenteric adenitis and terminal ileitis are most common among older children and young adults. Risk factors for *Y. enterocolitica* septicemia and metastatic focal infections include chronic liver disease, malignancy, diabetes mellitus, immunosuppressive therapy, alcoholism, malnutrition, advanced age, iron overload (see below), and hemolytic anemias (including the thalassemias). The nonsuppurative sequelae of yersiniosis are most common among adults. HLA-B27 is expressed in 70 to 80% of patients who develop reactive arthritis associated with yersiniosis. HLA-B27 is not a risk factor for *Yersinia*-induced erythema nodosum; females with this condition outnumber males by 2 to 1. In Europe, *Y. enterocolitica* infections are more common in the cooler months than in warmer weather. In North America, no consistent seasonal pattern has been documented.

For several decades, serotypes O:3 and O:9 have predominated among *Y.*

enterocolitica isolates from patients in Europe. Serotype O:3 has also predominated in Canada and Japan. In the United States, serotype O:3 emerged in the 1980s to surpass serotype O:8 in frequency of isolation from patients. The incidence of *Yersinia*-induced nonsuppurative sequelae reportedly is 10 to 30% in Scandinavia and much lower in most other countries, including the United States. No convincing explanation for this observation has been confirmed, but reasonable possibilities include population genetic factors and geographic strain variation.

Common-source outbreaks of *Y. enterocolitica* enteritis have been traced to such vehicles as raw milk, contaminated pasteurized milk, and foods prepared with contaminated fresh water. In Belgium, the ingestion of ground raw pork (a regional custom) is a significant risk factor for sporadic infection with *Y. enterocolitica* serotypes O:3 and O:9. These serotypes commonly colonize the oral cavity and intestines of European swine, and *Y. enterocolitica* infection is an occupational risk of swine butchers in Europe. In the United States, sporadic cases and one outbreak of *Y. enterocolitica* O:3 infection have been associated with the preparation or ingestion of raw pork intestines (chitterlings). In some cases of yersiniosis, circumstantial evidence suggests transmission via contact with dogs and cats or their feces. Several nosocomial outbreaks of *Y. enterocolitica* infection have been described; fecal-oral transmission from person to person was suspected. Fecal-oral transmission among family members may also explain occasional secondary cases in households. In a prospective study of 50 children with *Y. enterocolitica* enteritis, fecal excretion of the organism persisted for an average of 27 days (range, 4 to 79 days) after the cessation of symptoms. A chronic carrier state, however, has not been demonstrated. *Y. enterocolitica* is a rare but often lethal cause of transfusion-associated septicemia. The explanation is that blood donors occasionally have transient, occult *Y. enterocolitica* bacteremia and that this organism can slowly multiply to high concentrations in blood refrigerated for at least 10 to 20 days.

The ecology of *Y. pseudotuberculosis* seems to parallel that of *Y. enterocolitica* closely. *Y. pseudotuberculosis* is also widespread in wild and domestic animals and is isolated from many environmental sources. Human infections with *Y. pseudotuberculosis*, however, appear to be rare. In North America and Europe, most such infections have been with serotype I, but outbreaks involving other serotypes have occurred in Japan and Scandinavia. Swine appear to be an important reservoir for pathogenic strains of *Y. pseudotuberculosis*.

PATHOGENESIS AND PATHOLOGY

Except in rare instances of transmission via contaminated blood products or direct cutaneous inoculation, the enteropathogenic yersiniae are thought to enter the host via the oral route. The 50% infectious dose in humans is uncertain but may be $^{3}10^{9}$. The incubation period averages 5 days (range, 1 to 11 days). Studies of animals have shown that the organisms initially invade the ileal epithelium, then are translocated via M cells into the lamina propria, and finally enter Peyer's patches, where they are able to replicate. They subsequently drain into the mesenteric lymph nodes, which undergo hyperplasia and from which the bacteria can be distributed systemically. The mesenteric lymph nodes can become intensely swollen and matted and are occasionally detected on physical examination as a tender right lower quadrant mass. Intestinal inflammation (most commonly of the distal ileum and less commonly of the ascending colon)

develops and may be accompanied by mucosal ulcerations and by the shedding ofPMNs and red blood cells into the intestinal lumen. In relatively severe cases, thrombosis of mesenteric blood vessels, intestinal hemorrhage, and necrosis can occur. In patients with enteropathogenic yersinial infections who undergo exploratory laparotomy, the appendix usually is histologically normal or shows only lymphoid hyperplasia, but frank suppuration is sometimes evident.

A plasmid of ~70 kb is essential for virulence of the enteropathogenic yersiniae because it encodes at least six *Yersinia* outer-membrane proteins, some of which confer to bacterial strains such properties as cytotoxicity; resistance to phagocytosis byPMNs; and the abilities to cause monocyte apoptosis (programmed cell death), to suppress the host's expression of tumor necrosis factora, to interfere with platelet aggregation and host complement activation, and to dephosphorylate host proteins. A chromosomal gene (*inv*) encodes for the surface protein invasin, which is necessary for yersinial invasion of nonphagocytic host cells (e.g., epithelial cells) in vitro and which facilitates the translocation of bacteria across the intestinal epithelium. Both *Y. enterocolitica* and *Y. pseudotuberculosis* can express at least one protein superantigen that selectively stimulates the proliferation of T cells. Many strains of *Y. enterocolitica* produce a heat-stable enterotoxin that is similar to *Escherichia coli* enterotoxin. The cell walls of *Y. enterocolitica* and *Y. pseudotuberculosis* contain a lipopolysaccharide (endotoxin). The roles of superantigens, enterotoxin, and endotoxin in the pathogenesis of yersiniosis are unclear. Some *Yersinia* strains are unable to synthesize bacterial iron chelators called *siderophores*. However, they can exploit host-chelated iron stores and the drug deferoxamine (a siderophore produced by *Streptomyces pilosus*). Therefore, iron overload (e.g., caused by hemodialysis or multiple transfusions) and deferoxamine therapy appear to be independent risk factors for *Y. enterocolitica* bacteremia (especially that involving serotypes O:3 and O:9) and to a lesser degree for *Y. pseudotuberculosis* bacteremia.

Immunogenetic factors and cell-mediated immune responses are clearly involved in the pathogenesis of reactive arthritis following infection with the enteropathogenic yersiniae. As noted above, most patients with *Yersinia*-induced reactive arthritis express HLA-B27. In addition, *Y. pseudotuberculosis* shares at least one cross-reactive epitope with HLA-B27, and *Y. enterocolitica* infection alters the expression of serologic HLA-B27 epitopes on lymphocytes and monocytes. In patients with reactive arthritis following *Y. enterocolitica* infection, yersinial antigens are commonly detectable in synovial fluid cells in the apparent absence of whole organisms. Thus, it is unknown whether the arthritis results from occult bacterial persistence through self-tolerance of HLA-B27 with a failure of cross-reactive immune responses to yersiniae, from an immune response to common antigenic determinants shared by the bacteria and host HLA-B27 (i.e., molecular mimicry), or from other mechanisms. The pathogenesis of *Yersinia*-induced erythema nodosum is obscure.

In some assays, patients with Graves' disease have an increased prevalence of serum antibodies to *Y. enterocolitica*, and the immunoglobulins of patients recovering from *Y. enterocolitica* infections react with the human thyroid-stimulating hormone receptor. However, a link between *Y. enterocolitica* infection and the subsequent development of autoimmune thyroiditis has not been convincingly demonstrated.

MANIFESTATIONS

The principal clinical manifestations of *Y. enterocolitica* infection are enteritis, enterocolitis, mesenteric adenitis, and terminal ileitis. Less common manifestations include exudative pharyngitis, septicemia, metastatic focal infections, reactive polyarthritis, and erythema nodosum. When age groups are combined, the most common presentation of *Y. enterocolitica* infection is acute diarrhea from enteritis or enterocolitis. Low-grade fever and cramping abdominal pain occur in most cases, nausea and vomiting in 15 to 40%, hematochezia in up to 30%, and a generalized maculopapular skin rash in a few cases. Diarrhea persists for an average of 2 weeks (range, 1 day to many months), during which the frequency of bowel movements diminishes. Uncommonly, enteritis or enterocolitis can be complicated by severe abdominal pain and high fever. Rare (and sometimes fatal) complications include diffuse inflammation, ulceration, hemorrhage, and necrosis of the small bowel and colon; intestinal perforation; peritonitis; ascending cholangitis; mesenteric vein thrombosis; diverticulitis; toxic megacolon; and ileocecal intussusception.

The syndrome of mesenteric adenitis and terminal ileitis without diarrhea is easily confused with appendicitis. Low-grade fever and right lower quadrant pain, tenderness, guarding, and rebound tenderness are common. During six recognized common-source outbreaks in the United States, 10% of 444 patients with symptomatic undiagnosed *Y. enterocolitica* infections underwent laparotomy for suspected appendicitis; surgical incisions became infected with *Y. enterocolitica* in a few of these cases.

Acute pharyngitis and pharyngotonsillitis, with or without cervical adenitis or intestinal illness, are less common but potentially lethal manifestations of *Y. enterocolitica* infection, particularly in adults. *Y. enterocolitica* septicemia generally presents as a severe illness with fever and leukocytosis, often with abdominal pain and jaundice and without localized signs of infection. Metastatic focal *Y. enterocolitica* infections can occur with or without clinically apparent bacteremia and can affect almost any organ system. Examples include abscess formation (e.g., in liver, spleen, kidney, lung, skeletal muscle, lymph node, or cutaneous tissue), osteomyelitis, meningitis, peritonitis, urinary tract infection, pneumonia, empyema, endocarditis, pericarditis, mycotic aneurysm, septic arthritis, suppurative conjunctivitis, panophthalmitis, Parinaud's oculoglandular syndrome, and cutaneous pustules or bullae.

In Scandinavia, the incidence of reactive arthritis following *Y. enterocolitica* infection among adults is estimated to be at least 10%. About 80% of these patients have preceding symptoms such as fever, diarrhea, or abdominal pain. Typically, these symptoms precede the arthritis by 1 week and are of short duration. The most commonly affected joints are the knees and ankles, but other joints can be involved. Typically, multiple (two to eight) joints become involved sequentially and asymmetrically over a period of a few days to 2 weeks, after which no additional joints are affected. Monoarticular arthritis occurs less commonly. In two-thirds of cases, the acute arthritis remits spontaneously within 1 to 3 months. Chronic joint disease is documented in a minority of cases. A few HLA-B27-positive patients with *Y. enterocolitica*-induced arthritis have subsequent ankylosing spondylitis, but this development is best explained by the fact that HLA-B27 is a major risk factor for each of these diseases. Mild, self-limited myocarditis accompanies about 10% of cases of *Yersinia*-induced arthritis

and can occur independently. Typical manifestations include cardiac murmurs and transient electrocardiographic abnormalities, such as prolongation of the PR interval and nonspecific ST-segment and T-wave changes. The syndrome of *Yersinia*-induced arthritis and carditis can be confused with acute rheumatic fever. In Scandinavia, erythema nodosum occurs in 15 to 20% of patients with yersiniosis, usually within a few days to 3 weeks after the onset of intestinal illness. Lesions typically are located on the lower extremities and resolve within 1 month. Less commonly reported nonsuppurative sequelae of *Y. enterocolitica* infections include reactive uveitis, iritis, conjunctivitis, urethritis, and glomerulonephritis. The complete triad of Reiter's syndrome (arthritis, conjunctivitis, and urethritis) is seen in 5 to 10% of patients with *Yersinia*-induced arthritis.

The most common clinical presentation of *Y. pseudotuberculosis* infection is fever and abdominal pain caused by mesenteric adenitis; diarrheal illness is less common than in *Y. enterocolitica* infection. Systemic manifestations, including septicemia, focal infections, reactive arthritis, and erythema nodosum, are generally similar to those associated with *Y. enterocolitica* infection. In addition, *Y. pseudotuberculosis* has been associated with a scarlet fever-like syndrome, acute interstitial nephritis, and hemolytic-uremic syndrome.

LABORATORY FINDINGS AND DIAGNOSIS

Results of routine laboratory tests in most patients with yersiniosis are nonspecific. Leukocyte counts are usually normal or slightly elevated, often with a modest left shift. Standard microbiologic methods are sufficient to isolate *Y. enterocolitica* and *Y. pseudotuberculosis* from otherwise-sterile sites, such as blood,CSF, lymph node tissue, and peritoneal fluid, and from abscesses. Isolation of these organisms from feces is impeded by their slow growth and the overgrowth of normal fecal flora on culture media routinely used to select for enteric bacteria. When routine enteric media are used, the yield of yersinial isolates from feces is increased by incubation at 22 to 25°C for 48 h. The yield from feces and other grossly contaminated specimens can be further increased by the use of *Yersinia*-selective cefsulodin-Irgasan-novobiocin (CIN) agar and by cold enrichment (i.e., inoculation of feces into buffered saline and incubation at 4°C for 2 to 4 weeks, with periodic plating onto enteric media). Because bacteriologic procedures designed to isolate yersiniae from feces are not considered cost-effective, many laboratories undertake them by special request only.

The results of serologic tests can be used to support a diagnosis of yersiniosis. Agglutination tests orELISAsare used most commonly; immunoblotting has also been used. The existence of multiple serotypes makes routine serologic tests laborious; thus these tests are generally conducted only in research laboratories or large commercial laboratories. Since these tests are experimental and are neither standardized nor well validated, and since some strains of *Yersinia* cross-react with other bacteria (e.g., *Brucella*, *Salmonella*, and *Vibrio*) and with serum from some patients with thyroiditis, results should be interpreted with caution. In typical uncomplicated cases of yersiniosis, agglutinin titers begin to rise within the first week of illness, peak in the second week, and then gradually diminish and return to normal within 3 to 6 months, although agglutinating antibody may remain detectable for several years in some cases. Because an initial serum specimen is often collected a week or more after the onset of illness,

when agglutinin titers are already high, it is usually impossible to document a fourfold or greater rise in titer between paired specimens (although a fourfold or greater fall in titer may be found). Immunohistologic techniques and polymerase chain reaction tests to detect yersinial antigens and DNA, respectively, in clinical specimens are experimental at this time.

In patients with *Yersinia*-induced reactive arthritis, synovial fluid is sterile and the leukocyte count ranges from a few hundred to 60,000/uL, with a majority ofPMNs. The erythrocyte sedimentation rate is often >100 mm/h. Rheumatoid factor and antinuclear antibodies are usually absent. The diagnosis of *Yersinia*-induced reactive arthritis or other nonsuppurative inflammatory sequelae can be difficult, especially when triggering infections are asymptomatic or clinically mild or occur several weeks before the diagnosis is attempted. Because the isolation of a pathogenic *Yersinia* strain from feces is the most specific diagnostic test in such cases, it should be attempted. Since culture is of limited sensitivity in this clinical setting, a high index of suspicion and positive results of serologic tests for *Y. enterocolitica* or *Y. pseudotuberculosis* are usually required for diagnosis.

TREATMENT

The effectiveness of antimicrobial agents in the treatment of yersinial enteritis, enterocolitis, mesenteric adenitis, or terminal ileitis has not been established. These conditions are usually self-limited, and their treatment is symptom-based and supportive. In uncomplicated cases, diarrhea should be treated with fluid and electrolyte replacement, with the route of delivery dependent on clinical severity. Enteric precautions are advisable for patients hospitalized with yersinial diarrhea. In general, antimicrobial treatment should be reserved for patients with septicemia, metastatic focal infections, or immunosuppression and enterocolitis. Controlled clinical comparisons of antimicrobial agents in the treatment of severe cases of yersiniosis have not yet been conducted. In such cases, drug selection should ultimately be guided by clinical response and bacterial sensitivity patterns. Clinical isolates of *Y. enterocolitica* and *Y. pseudotuberculosis* are usually susceptible in vitro to aminoglycosides, third-generation cephalosporins, chloramphenicol, quinolones, tetracyclines, and trimethoprim-sulfamethoxazole. In laboratory animals infected with enteropathogenic yersiniae, the fluoroquinolones have exerted the strongest bactericidal effects in vivo; clinical experience with these drugs against these pathogens in humans is promising but limited. Because they produceb-lactamases, isolates typically are resistant to penicillin, ampicillin, carbenicillin, and first-generation and most second-generation cephalosporins. Optimal dosages and durations of therapy have not been established. Mortality from *Y. enterocolitica* septicemia currently is ~10% despite treatment. Focal extraintestinal infections may require at least 3 weeks of therapy. No role for antimicrobial agents in the management of the nonsuppurative inflammatory manifestations of yersiniosis has been established. Patients with reactive arthritis may benefit from treatment with nonsteroidal anti-inflammatory drugs, intraarticular steroid injections, and physical therapy.

PREVENTION AND CONTROL

The importance of safe food-handling and food-preparation practices in the prevention

of yersiniosis cannot be overemphasized. Caution is particularly warranted in the case of pork and other animal products. The consumption of raw or undercooked meats, especially pork, should be avoided. Increased efforts to prevent the spread of enteric pathogens in household, pet-care, day-care, and hospital settings and in the food industry would be likely to decrease the incidence of yersiniosis. Current regulations of the U.S. Food and Drug Administration require visual inspection of packed red cell units before transfusion, with the discarding of units in which bacterial contamination is suspected on the basis of darkening (reflecting decreased oxygen saturation and hemolysis). Since the risk is minimal, more specific measures to further decrease the likelihood of transfusion of *Y. enterocolitica*-contaminated blood products (e.g., limiting the period for which red cells can be stored before transfusion) are not considered cost-effective.

Yersiniosis is not routinely reportable to public health authorities in most jurisdictions. However, clinicians who suspect a common-source outbreak (e.g., because they have documented a familial case cluster or have diagnosed the disease in several apparently unrelated patients over a short period) or some other public health threat (e.g., because they have found occult *Y. enterocolitica* bacteremia in a recent blood donor) should consult promptly with local public health officials.

163. *BARTONELLA* INFECTIONS, INCLUDING CAT-SCRATCH DISEASE - *Lucy Stuart Tompkins*

Bartonella spp., including *B. bacilliformis*, *B. henselae*, *B. quintana*, and *B. clarridgeiae*, are tiny gram-negative bacilli that can adhere to and invade mammalian cells, including endothelial cells and erythrocytes. Previously classified as *Rochalimaea* spp. within the rickettsia group, *Bartonella* spp. have now been removed from the order Rickettsiales on the grounds that they are not obligate intracellular parasites. These agents cause a wide spectrum of clinical illnesses, including trench fever, cat-scratch disease (CSD), bacillary angiomatosis, endocarditis, Oroya fever, and verruga peruana (Fig. 163-CD1). The pathologic manifestations of *Bartonella* disease vary with the immune status of the host.

OROYA FEVER AND VERRUGA PERUANA

DEFINITION AND ETIOLOGY

Oroya fever and verruga peruana are caused by *B. bacilliformis*. Oroya fever is characterized by fever, profound anemia, and -- unless antibiotic treatment is given -- high mortality. The lesions referred to as verruga peruana may develop during the convalescent phase of Oroya fever or during chronic infection with *B. bacilliformis*. In 1885 Daniel Carrion, a Peruvian medical student, inoculated himself with blood from a patient with verruga peruana and subsequently died of Oroya fever, thus proving that both diseases are caused by a single agent.

EPIDEMIOLOGY

Infection with *B. bacilliformis* follows the bite of the sandfly vector *Phlebotomus*, an insect found in the river valleys of the Andes Mountains at altitudes of 600 to 2500 m. Oroya fever develops in nonimmune individuals who are not residents of the endemic region, whereas verruga peruana occurs in persons who apparently have been exposed in the past, including those who have recently had Oroya fever. The infection has not been acquired in the United States.

PATHOLOGY

During initial infection in the nonimmune host, *B. bacilliformis* cells adhere to erythrocytes and produce indentations in the cell membrane; the bacteria subsequently enter the erythrocytes and cause persistent deformation of the cytoskeleton. The parasitized erythrocytes are ultimately phagocytosed and destroyed. Although the life span of infected erythrocytes is markedly shortened, not all of this change can be attributed to the mechanical fragility induced by the internalization of bacteria. Decreased bone marrow erythropoiesis also contributes to anemia.

CLINICAL MANIFESTATIONS

The onset of symptoms in Oroya fever may be either insidious or abrupt, after an incubation period of approximately 3 weeks. The subacute presentation may include low-grade fever, malaise, headache, and anorexia. Sudden-onset disease commences

with high fever, chills, diaphoresis, headaches, and changes in mental status. These manifestations are followed by the sudden development of profound anemia, which is due to a marked decrease in erythrocyte numbers and is associated with macrocytic changes, poikilocytosis, Howell-Jolly bodies, nucleated erythrocytes, and immature myeloid cells. The leukocyte differential usually shifts to the left, although the total leukocyte count may be normal. The erythrocyte count may fall to extremely low levels. In eosin/thiazine-stained peripheral-blood smears, numerous microorganisms can be seen adhering to most erythrocytes.

During the acute phase, muscle and joint pain and headache may be severe; central nervous system changes include insomnia, delirium, and a decreased level of consciousness. Thrombocytopenic purpura may develop. If the patient survives, a convalescent phase ensues, characterized by the sudden disappearance of bacteria from blood smears, declining fever, and an increase in the erythrocyte count. Although much of the mortality associated with Oroya fever is due to profound anemia and toxicity, secondary bacterial infections (including salmonellosis and other enteric infections, malaria, and tuberculosis) are often an important contributing factor.

After convalescence from acute Oroya fever, verrugas may develop. These red or purple cutaneous lesions may be either tiny and sessile or large, pedunculated, and nodular. They bear a marked resemblance to the lesions of bacillary angiomatosis and to Kaposi's sarcoma.

DIAGNOSIS

During acute infection, bacteria can be cultured from the blood on agar containing rabbit blood, with incubation at 28°C. The hallmark of verruga peruana is the formation of new blood vessels (angiogenesis) at the sites of bacterial replication.

TREATMENT

Oroya fever responds to a variety of antimicrobial agents, including chloramphenicol, tetracyclines, penicillin, and streptomycin. Chloramphenicol is used most often because of its efficacy against most *Salmonella* infections (as salmonellosis may develop intercurrently). Verruga peruana may respond similarly; however, failure to respond to therapy and relapse are common and require the reinstitution of prolonged therapy.

BACILLARY ANGIOMATOSIS

DEFINITION AND ETIOLOGY

Bacillary angiomatosis was initially described as a condition occurring primarily in patients with AIDS and characterized by vascular cutaneous lesions resembling Kaposi's sarcoma. The disease can disseminate to involve virtually any organ system. Immunocompromised individuals, especially those infected with HIV, are at particularly high risk for bacillary angiomatosis, although in rare instances the patient is not obviously immunosuppressed. Both *B. henselae* and *B. quintana* (the infectious agent initially associated with trench fever) produce bacillary angiomatosis in persons with immunodeficiency.

EPIDEMIOLOGY

Acquisition of *B. henselae* has been significantly associated with exposure to young cats infested with fleas (*Ctenocephalides felis)*. Because a high percentage of cats are seropositive, it has been suggested that patients with HIV infection avoid exposure to these animals. The finding that a large proportion of cats with fleas have persistent asymptomatic *B. henselae* bacteremia suggests that the domestic cat is the animal reservoir of this microorganism. The flea may serve as a transmitting vector in the cross-infection of cats, but its role in human infection is not clear. Tick-associated cases of *B. henselae* bacteremia have been reported in healthy immunocompetent individuals.

Person-to-person transmission of *B. quintana* by the human body louse (*Pediculus humanis corporis*) was documented during World War I under conditions of poor personal hygiene and sanitation. Although lice are suspected of transmission, the reservoir of *B. quintana* has not been identified.

A case-control study revealed that *B. henselae* and *B. quintana* differ significantly in terms of epidemiologic risk factors. All cases of *B. henselae* infection were associated with exposure to cats and their fleas and occurred sporadically, whereas the cases of *B. quintana* infection occurred in clusters and were associated with low socioeconomic status, homelessness, and exposure to body lice. Direct transmission of *B. henselae* from cats to their owners, presumably through cutaneous trauma, was supported by the matching DNA fingerprint patterns of isolates from the two sources.

MICROBIOLOGY

B. henselae can be demonstrated in tissue by Warthin-Starry staining. Clumps and clusters of pleomorphic bacilli appear as purple deposits in tissue stained with hematoxylin and eosin. Although the bacteria may be difficult to cultivate in the laboratory, they can eventually be isolated from cultures of blood and of material from other sites. Colonies develop after prolonged incubation (1 to 4 weeks) on blood-containing media and pit the agar; bacterial cells are gram-negative. *B. quintana* grows as a smooth, nonpitting colony on solid agar after prolonged incubation.

Classification of *B. henselae* was first accomplished when molecular techniques were used to analyze bacterial ribosomal genes extracted from tissue samples. Definitive identification of *Bartonella* spp. is based on sequence analysis of 16S ribosomal DNA.

PATHOGENESIS AND PATHOLOGY

Bacillary angiomatosis is characterized by a lobular proliferation of new blood vessels (angiogenesis) and a neutrophilic inflammatory response to myriad bacilli located within collagen-rich microscopic and macroscopic nodules. The endothelial cells lining the vascular spaces have a typical epithelioid appearance, and the lesions may resemble Kaposi's sarcoma histopathologically, although the characteristic spindle cell of the latter disease is usually absent. The bacterial and eukaryotic host factors that elicit the pathologic response are unknown.

CLINICAL MANIFESTATIONS

The skin lesions of bacillary angiomatosis (also called *epithelioid angiomatosis*) are vascular nodules, papules, or tumors (Fig. 163-CD2) that range from tiny lesions resembling cherry angiomas or pyogenic granulomas to large, pedunculated, exophytic masses (Fig. 163-1). Characteristically, the lesions are red or purple, resembling Kaposi's sarcoma; they may be surrounded by an epithelial collarette, may be located anywhere on the skin, and may involve mucous membranes. The overlying epidermis may be focally ulcerated, and the underlying bone may be invaded and destroyed.

Dissemination of *B. henselae* infection occurs primarily in patients with cellular immune defects. Clinical manifestations accompanying dissemination are often nonspecific and include persistent fever, abdominal pain, weight loss, and malaise. Although the liver, spleen, bone marrow, and lymph nodes are primarily affected, HIV-infected patients may also develop central nervous system abnormalities (including psychiatric disorders and brain lesions), which are responsive to antibiotic therapy. Skin lesions usually are not evident in disseminated infection. Involvement of the liver or spleen may produce bacillary peliosis hepatis. Patients with the latter condition may report localized pain on palpation of the abdomen. Nodular lesions of variable size can be demonstrated by computed tomography or magnetic resonance imaging, with or without contrast agents.

In a case-control study of bacillary angiomatosis (see "Epidemiology" above), only *B. henselae* was associated with hepatosplenic disease (peliosis hepatis) and displayed a predilection for the lymph nodes. *B. quintana*, in contrast, was associated with osseous and subcutaneous infection.

DIAGNOSIS

The diagnosis of bacillary angiomatosis is based primarily on the typical histopathologic findings of angiomas in association with clumps of tiny bacilli revealed by Warthin-Starry silver stain. Infection due to *B. henselae* can also be established by culture or by identification of specific DNA sequences. *B. henselae* is most easily isolated from blood through a lysis-centrifugation system. Colonies may be detected on blood-containing agar (rabbit blood is preferred) incubated with 5 to 10% CO_2 at 37°C for 2 to 4 weeks. *B. quintana* may be isolated from BACTEC (Becton Dickinson, Sparks, MD) aerobic bottles containing resin. Isolation from skin lesions and other tissues is more difficult but should be attempted when feasible. Initial reports suggested that cocultivation with endothelial cell monolayers was necessary; however, isolation by direct plating onto freshly prepared agar media has also been successful. Bacilli picked from new colonies but not subcultured may not stain, even with acridine orange; they stain weakly with safranin. Identification of *B. henselae* and *B. quintana* is based primarily on cellular fatty-acid analysis and polymerase chain reaction (PCR)-based restriction fragment length polymorphism analysis. Definitive identification of *Bartonella* spp. depends on DNA sequence analysis of 16S ribosomal RNA genes. The diagnosis ofCSD (see next section) can be made by specific serologic testing that detects *B. henselae*-specific antibodies, but the sensitivity and specificity of this method in patients with cutaneous and disseminated bacillary angiomatosis have not been determined.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of cutaneous bacillary angiomatosis includes Kaposi's sarcoma, angiomas, and pyogenic granulomas. These conditions can be distinguished by histopathologic examination of biopsied material.

Cutaneous bacillary angiomatosis caused by *B. henselae* or *B. quintana* resembles verruga peruana, which is not seen outside of South America. In patients with AIDS, Kaposi's sarcoma lesions and bacillary angiomatosis may coexist.

TREATMENT

Cutaneous lesions have been treated with a wide variety of antimicrobial drugs, including macrolides, tetracyclines, and antituberculous agents; *B. henselae* is susceptible to most antibiotics in vitro. Erythromycin (2 g/d), given orally for 3 weeks, is usually effective, as are newer macrolides; however, relapse may require prolonged therapy (3 weeks to 2 months) with an antibiotic that reaches an intracellular compartment, such as a macrolide or doxycycline (200 mg/d). Patients with peliosis hepatis should be treated with intravenous antibiotics, and those with disseminated disease or bacteremia should be treated with a prolonged course (3 weeks to 2 months) of systemic antibiotic, such as a macrolide (e.g., erythromycin, 2 g/d). In a case-control study of bacillary angiomatosis, treatment with a macrolide was associated with a therapeutic response and sterile tissue samples and may have been protective, whereas treatment with trimethoprim-sulfamethoxazole, ciprofloxacin, penicillins, or cephalosporins had no protective effect. Cutaneous lesions may or may not regress spontaneously, perhaps depending on the status of the host's immunity. The safety of ciprofloxacin in pregnant or lactating women has not been established. No antimicrobial has been studied prospectively, and information on efficacy comes only from case reports.

CAT-SCRATCH DISEASE

DEFINITION AND ETIOLOGY

TypicalCSD is manifested by painful regional lymphadenopathy persisting for several weeks or months after a cat scratch. Occasionally, infection may disseminate and produce more generalized lymphadenopathy and systemic manifestations, which may be confused with the manifestations of lymphoma. *B. henselae* is the causative agent of CSD. There is no evidence that *B. quintana* causes CSD, and this microbe is not carried by cats. The role of *Afipia felis* (originally proposed as the agent of CSD) is unclear inasmuch as only a few cases are associated with its isolation. *B. henselae* remains the predominant species causing typical CSD. Several reports suggest that *B. clarridgeiae* may also cause feline lymphadenopathy.

EPIDEMIOLOGY

Approximately 60% of cases ofCSD in the United States occur in children. Exposure to bacteremic young cats that either are flea-infested or have been in contact with another cat carrying fleas poses a significant risk of infection. Most infections are caused by a scratch and only rare cases by a bite or by licking. Most cases occur in the warmer

months, when fleas are active. Regions of the United States where fleas are endemic have higher rates of infection. The flea may serve to transmit infection between cats; it is not known whether humans can be infected through the bite of an infected flea.

CLINICAL MANIFESTATIONS

A localized papule, progressing to a pustule that often crusts over, develops 3 to 5 days after a cat scratch (Fig. 163-CD3). Tender regional lymphadenopathy develops within 1 to 2 weeks after inoculation; by this time, the papule may have healed spontaneously. Scratches are most often sustained on the hands or face, producing epitrochlear, axillary, pectoral, and cervical lymph node involvement. The involved nodes occasionally become suppurative; bacterial superinfection with staphylococci or other cutaneous pathogens may develop. Although most patients do not have fever, systemic symptoms are frequent and include malaise, anorexia, and weight loss. Without treatment, lymphadenopathy persists for weeks or even months and may be confused with lymphatic malignancy. Other manifestations in apparently immunocompetent patients include encephalitis, seizures and coma (especially in children), meningitis, transverse myelitis, granulomatous hepatitis and splenitis, osteomyelitis, and disseminated infection. Conjunctival inoculation may cause Parinaud's oculoglandular syndrome, with conjunctivitis and preauricular lymphadenopathy.

PATHOLOGY

The histopathologic hallmark ofCSD is granulomatous inflammation with stellate necrosis but no evidence of angiogenesis. Thus, infection by *B. henselae* can produce two entirely different pathologic reactions, depending on the immune status of the host: CSD or bacillary angiomatosis.

DIAGNOSIS

CSDshould be suspected if the patient has a history of exposure to cats and develops lymphadenopathy and a skin lesion. The diagnosis can be confirmed by pathologic examination of the involved nodes. Tiny bacilli in clusters can sometimes be seen in biopsy samples stained with Warthin-Starry silver. The CSD skin test, in which lymph node material obtained from patients with CSD serves as an antigen, is no longer used for diagnosis because of concerns about the transmission of viral agents. A specific serologic test has been developed and may produce a positive result in 70 to 90% of patients with intact immunity. The identification of *B. henselae* 16S ribosomal RNA genes in biopsy material by PCR amplification with specific oligonucleotide primers can also be diagnostically useful; however, these methods are not yet commercially available. Cultures of lymph nodes, cerebrospinal fluid, or other tissues are rarely positive.

TREATMENT

AlthoughCSD is generally self-limited, tender regional lymphadenopathy and systemic symptoms may be debilitating. Patients with encephalitis or other serious manifestations should be treated with antibiotics. A randomized, double-blind, placebo-controlled trial demonstrated significant clinical benefit of treatment with oral azithromycin for 5 days in

cases of typical CSD (regimen for adults weighing >100 lb: one dose of 500 mg on day 1, 250 mg on days 2 through 5). Several reports suggest that aminoglycoside treatment (e.g., intravenous gentamicin at standard doses calculated to result in therapeutic levels) is effective in patients with encephalitis and other systemic infections. The oral agents that appear to be useful are those that also are most effective for the treatment of bacillary angiomatosis; they include ciprofloxacin, doxycycline, and azithromycin. Unlike bacillary angiomatosis, CSD responds to treatment with ciprofloxacin. The necessary duration of therapy is variable.

TRENCH FEVER

DEFINITION AND ETIOLOGY

Trench fever was first described as a debilitating febrile illness associated with prolonged *B. quintana* bacteremia in soldiers fighting in Europe during World War I. Although not usually fatal, the illness accounted for substantial morbidity. In recent years, trench fever has reemerged in the United States and has been caused by either *B. henselae* -- the agent ofCSD and bacillary angiomatosis -- or *B. quintana*.

EPIDEMIOLOGY

Although trench fever was thought to have disappeared from the United States, recent cases have been diagnosed in homeless persons (*B. quintana*) and in persons bitten by ticks (*B. henselae*). During World War I, trench fever was transmitted from person to person by the human body louse. Transmission by ectoparasites is suspected in the recent cases of *B. quintana* infection but has not been firmly documented. Patients with trench fever have apparently normal immune defenses.

CLINICAL MANIFESTATIONS

Trench fever is characterized by the sudden onset of headache, aseptic meningitis, persistent fever (which can be high-grade and is commonly paroxysmal), malaise, weight loss, and other nonspecific symptoms. Severe musculoskeletal pain is more common among immunocompetent than among immunocompromised patients. Bacteremia can persist for days or weeks, and relapses have followed short courses of antibiotic therapy. Localized findings are uncommon.

DIAGNOSIS

Trench fever is diagnosed by the finding of sustained bacteremia. *B. henselae* and *B. quintana* grow slowly. Colonies develop on rabbit blood agar after 1 to 4 weeks of incubation under conditions of increased CO_2. Serologic tests for this disease have not yet been standardized.

TREATMENT

A prolonged course (4 weeks) of antimicrobial therapy may be required. Agents that can cross the mammalian cell membrane are most effective, including erythromycin (2 g/d) or azithromycin (500 mg/d). Data on the efficacy of these agents come from a limited

number of case reports.

OTHER *BARTONELLA* INFECTIONS, INCLUDING CULTURE-NEGATIVE ENDOCARDITIS

The application of molecular methods to the detection of microorganisms that are difficult to cultivate in the laboratory has revealed new *Bartonella* spp. and has established *Bartonella* spp. as a cause of endocarditis cases previously classified as being of unknown etiology. *B. quintana* is the most frequently isolated *Bartonella* species in these cases. Two new species, *B. elizabethae* and *B. clarridgeiae*, as well as *B. henselae* have also been identified as agents of subacute and chronic endocarditis.

The diagnosis of *Bartonella* endocarditis is confirmed by blood cultures. Specific antibodies are produced; however, *B. quintana* infection may produce antibodies that cross-react with *Chlamydia pneumoniae*.

(Bibliography omitted in Palm version)

Back to Table of Contents

164. DONOVANOSIS - *Gavin Hart*

Donovanosis is a chronic, progressively destructive bacterial infection of the genital region that is generally regarded as sexually transmitted. The disease has been known by many other names, the most common of which are granuloma inguinale and granuloma venereum.

ETIOLOGY

Donovanosis is caused by *Calymmatobacterium granulomatis*, an intracellular, gram-negative, pleomorphic, encapsulated (when mature) bacterium measuring 1.5 by 0.7 um. *C. granulomatis* shares many morphologic and serologic characteristics and >99% homology at the nucleotide level with *Klebsiella* species that are pathogenic to humans. Polymerase chain reaction amplification of the *phoE* gene shows it to be closely related to that in *Klebsiella pneumoniae*, *K. rhinoscleromatis*, and *K. ozaenae*. Electron microscopy shows typical gram-negative morphology and a large capsule but no flagella. Filiform or vesicular protrusions occur on a corrugated cell wall.

EPIDEMIOLOGY

Donovanosis is endemic among Aborigines in central Australia as well as in Papua New Guinea, southeastern India, southern Africa, and the Caribbean and adjacent areas of South America. In the first half of the twentieth century, the disease was endemic in parts of the United States (with an estimated 5000 to 10,000 cases in 1947); small epidemics still occur in this country and in other developed countries. Over 70% of cases involve persons 20 to 40 years of age. The infection is predominantly sexually transmitted, but extragenital skin lesions can follow transmission from concurrent genital lesions via the fingers or through other nonsexual contact, and autoinoculation may produce new lesions from contact with adjacent skin ("kissing" lesions). Infants born to infected mothers have acquired infection at birth.

The classification of donovanosis as a sexually transmitted disease (STD) has been disputed because of cases in young children and occasionally in sexually inactive individuals, transmission by direct body contact and via inanimate intermediaries, and the low and variable prevalence of donovanosis among sexual partners (0.4 to 52%). The dominance of sexual transmission is suggested by the combined factors of lesions predominantly affecting the genitalia, the highest prevalence among persons in age and socioeconomic groups that are most often affected by STDs, and the predictable occurrence of disease in visitors to areas of endemicity following sexual exposure.

CLINICAL MANIFESTATIONS

The incubation period is usually 1 to 4 weeks but may extend to 1 year. Skin lesions have been detected in infants 6 weeks to 6 months after birth. The disease begins as one or more subcutaneous nodules that erode through the skin to produce clean, granulomatous, sharply defined, usually painless lesions (Fig. 164-1). These lesions, which bleed readily on contact, slowly enlarge. The genitalia are involved in 90% of cases, the inguinal region in 10%, and the anal region in 5 to 10%. Genital swelling, particularly of the labia, is a common feature and occasionally progresses to

pseudoelephantiasis. Phimosis and paraphimosis are common local complications, and progressive erosion of affected tissues may completely destroy the penis or other organs. Less common clinical variants include a hypertrophic form (cauliflower- or wartlike lesions), a necrotic form (destructive lesions with foul-smelling exudate, often resembling amebiasis), and a sclerotic or cicatricial form, which has a dry base with extensive scar tissue (Fig. 132-CD3).

Extragenital lesions occur in at least 6% of cases. Oral donovanosis, the most common extragenital manifestation, presents as pain or bleeding in the mouth, lesions on the lips, or extensive swelling of the gums and palate. Donovanosis may affect most bones, and sometimes many bones are affected at the same time; the tibia is involved in over 50% of such cases. Bony lesions are associated with constitutional symptoms (weight loss, fever, night sweats, and malaise) and are usually found in women. More than 50% of women have primary lesions on the cervix. Prompt pelvic examinations and early diagnosis are likely to substantially decrease the morbidity and mortality (a likely outcome in misdiagnosed spinal lesions) associated with extragenital donovanosis in women.

DIAGNOSIS

Laboratory Diagnosis The preferred method involves demonstration of typical intracellular Donovan bodies within large mononuclear cells visualized in smears prepared from lesions or biopsy specimens. With typical beefy lesions, a small piece of tissue is removed with forceps and scalpel, and a crush impression of the deep surface is made on a glass slide. The smear is air-dried, heat-fixed, and stained with Giemsa, Leishman's, or Wright's stain. For dry, flat, or necrotic lesions, a punch-biopsy specimen should be obtained from the advancing edge. This specimen can be used to prepare a smear or embedded for histologic examination (with a silver stain). Histologic examination shows epithelial proliferation, often simulating neoplasia, with a heavy inflammatory infiltrate of plasma cells, some neutrophils, and few if any lymphocytes. The large mononuclear cells are 25 to 90 um in diameter, with a vesicular or pyknotic nucleus. Up to 20 intracytoplasmic vacuoles contain pleomorphic Donovan bodies in either young uncapsulated forms (which often resemble closed safety pins) or mature capsulated forms. *C. granulomatis* has never been grown on artificial solid media but has been cultured in chicken embryonic yolk sacs, on human monocytes, and on human epithelial (HEp-2) cells. A sensitive and specific serologic test, based on indirect immunofluorescence, has been developed.

Differential Diagnosis Condylomata lata of secondary syphilis may be confused with donovanosis; however, these lesions usually appear as white or pale moist plaques in the anogenital area, whereas the lesions of donovanosis are usually bright red. Syphilis and donovanosis frequently coexist because syphilis is usually highly prevalent in areas where donovanosis is endemic; thus positive syphilis serology does not exclude a diagnosis of donovanosis. Condylomata lata subside within 1 week of treatment with benzathine penicillin (2.4 million units), whereas donovanosis lesions remain unchanged.

The necrotic form of donovanosis may resemble squamous cell carcinoma; likewise, cervical and vulvar lesions may closely resemble carcinoma. Penile amebiasis may

resemble necrotic donovanosis but usually follows anal intercourse and is much less common than donovanosis in areas where the latter is endemic. Atypical clinical variants of chancroid, referred to as *pseudogranuloma inguinale*, have been described in patients seen at clinics in Atlanta. Disseminated donovanosis lesions of bones, particularly in the spine, can mimic tuberculosis. Lesions that produce draining sinuses near the jaw may simulate actinomycosis. The histologic findings of donovanosis must be distinguished from those of rhinoscleroma, leishmaniasis, and histoplasmosis. Genital ulcers are a risk factor for HIV acquisition in developing countries, and patients with donovanosis should be tested for HIV infection.

TREATMENT

Table 164-1 shows the most effective regimens for treating donovanosis. Doxycycline is the first choice for therapy in developed countries. Erythromycin provides an effective option for pregnant patients, and azithromycin is an effective alternative that is more convenient to administer. Extensive lesions have been cured with oral azithromycin at a dosage of 500 mg/d, but the more convenient dose of 1 g weekly is also effective. Although chloramphenicol is the drug of choice in some developing countries, it is unlikely to be acceptable in developed countries because of bone marrow toxicity. Penicillin is not effective for treating donovanosis. Patients should be examined weekly, and therapy should be continued until lesions have healed (3 to 5 weeks, except in severe cases). If antibiotic therapy is stopped earlier, lesions often continue to heal, but the relapse rate is higher. If the lesions are unchanged after 2 weeks of treatment, an alternative antibiotic regimen should be used.

The treatment regimens just described are usually adequate in HIV-infected patients without immunosuppression, but an increasing failure rate has been reported in immunosuppressed patients, for whom daily administration of azithromycin is recommended if other regimens fail to elicit a response.

SECTION 7 -MISCELLANEOUS BACTERIAL INFECTIONS

165. NOCARDIOSIS - *Gregory A. Filice*

The term *nocardiosis* refers to invasive disease associated with members of the genus *Nocardia*. Of the several distinctive syndromes, pneumonia and disseminated disease are most common. Others include cellulitis, lymphocutaneous syndrome, actinomycetoma, and keratitis.

MICROBIOLOGY

Nocardiae are saprophytic aerobic actinomycetes that are common worldwide in soil, where they contribute to decay of organic matter. Nocardial taxonomy is complex and incompletely understood. Seven species have been associated with human disease: *N. asteroides*, *N. brasiliensis*, *N. otitidis-caviarum* (formerly *N. caviae*), *N. farcinica*, *N. nova*, *N. transvalensis*, and *N. pseudobrasiliensis*. *N. asteroides* is the species most commonly associated with invasive disease. *N. farcinica* is less common but tends to be virulent and prone to dissemination. The new species *N. pseudobrasiliensis* accounts for most cases of invasive disease previously attributed to *N. brasiliensis*. True *N. brasiliensis* isolates are usually associated with disease limited to the skin. *N. transvalensis* is generally associated with mycetoma or, in immunosuppressed persons, with pulmonary or systemic disease.

EPIDEMIOLOGY

Approximately 1000 cases of nocardial infection are diagnosed annually in the United States, 85% of them pulmonary and/or systemic. The disease is more common among adults and males. Outbreaks, which are rare, have been associated with contamination of the hospital environment, solutions, or drug injection equipment. Person-to-person spread is not well documented. There is no known seasonality.

The risk of pulmonary or disseminated disease is greater than usual among people with deficient cell-mediated immunity, especially that associated with lymphoma, transplantation, or AIDS. In persons with AIDS, nocardiosis usually presents at a $CD4_+$lymphocyte concentration of <250/uL. Prophylaxis with sulfamethoxazole and trimethoprim appears to reduce the risk of nocardiosis in persons with AIDS or transplanted organs. Nocardiosis has also been associated with pulmonary alveolar proteinosis, tuberculosis and other mycobacterial diseases, and chronic granulomatous disease.

N. brasiliensis, *N. asteroides*, *N. otitidis-caviarum*, and *N. transvalensis* are associated with actinomycetoma. Cases occur mainly in tropical and subtropical regions, especially those of Mexico, Central and South America, Africa, and India. The most important risk factor is frequent contact with soil or vegetable matter.

PATHOLOGY AND PATHOGENESIS

Pneumonia and disseminated disease are both thought to follow inhalation of fragmented bacterial mycelia. The characteristic histologic feature of nocardiosis is an

abscess with extensive infiltration by neutrophils and prominent necrosis. Granulation tissue usually surrounds the lesions, but extensive fibrosis or encapsulation is uncommon. Actinomycetoma is characterized by suppurative inflammation with sinus tract formation. Granules -- microcolonies composed of dense masses of bacterial filaments extending radially from a central core -- are occasionally observed in histologic preparations. They are frequently found in discharges from lesions of actinomycetoma but almost never from lesions in other forms of nocardiosis.

Nocardiae have evolved a number of properties that enable them to survive within phagocytes, including neutralization of oxidants, prevention of phagosome-lysosome fusion, and prevention of phagosome acidification. Neutrophils phagocytose the organisms and limit their growth but do not kill them efficiently. Cell-mediated immunity is important for definitive control and elimination of nocardiae.

CLINICAL MANIFESTATIONS

Respiratory Tract Disease Pneumonia is by far the most common respiratory tract nocardial disease. Nocardial pneumonia is typically subacute; symptoms have usually been present for days or weeks at presentation. The onset may be more acute in immunosuppressed patients. Cough is prominent and produces small amounts of thick, purulent sputum that is not malodorous. Fever, anorexia, weight loss, and malaise are common; dyspnea, pleuritic pain, and hemoptysis are less common. Remissions and exacerbations over several weeks are frequent.

Roentgenographic patterns are variable (Fig. 165-CD1), but some characteristics are highly suggestive. Infiltrates vary in size and are typically of at least moderate density. Single or multiple nodules are common, sometimes suggesting metastatic tumors. Infiltrates and nodules tend to cavitate. Empyema is present in one-third of cases.

Nocardiosis may spread directly from the lungs to adjacent tissues. Pericarditis, mediastinitis, and the superior vena cava syndrome have all been reported. Spread through the chest wall is rare.

Nocardial laryngitis, tracheitis, and bronchitis are much less common than pneumonia. In the major airways, disease often presents as a nodular or granulomatous mass. A few cases of sinusitis have been reported.

Nocardiae are sometimes isolated from respiratory secretions of patients without apparent nocardial disease. Most of these patients have chronic pulmonary disease with abnormal airways or parenchyma.

Extrapulmonary Dissemination In half of all cases of pulmonary nocardiosis, disease appears outside the lungs. In one-fifth of cases of disseminated disease, lung disease is not apparent. The most common site of dissemination is the brain. Other common sites include the skin and supporting structures, kidneys, bone, and muscle, but almost any organ can be involved. Peritonitis and endocarditis have been reported. The typical manifestation of extrapulmonary dissemination is a subacute abscess. A minority of abscesses outside the lungs or central nervous system (CNS) form fistulae and discharge small amounts of pus. Nocardiae have been recovered from blood in a few

cases of pneumonia or disseminated disease.

InCNSinfections, brain abscesses are usually supratentorial, are often multiloculated, and may be single or multiple (Fig. 165-1, 165-CD2). Brain abscesses tend to burrow into the ventricles or extend out into the subarachnoid space. The symptoms and signs are somewhat more indolent than those of other types of bacterial brain abscess. Meningitis is uncommon and is usually due to spread from a nearby brain abscess. Nocardiae are not easily recovered from cerebrospinal fluid (CSF).

Disease Following Transcutaneous Inoculation Disease following transcutaneous nocardial inoculation usually takes one of three forms: cellulitis, lymphocutaneous syndrome, or actinomycetoma. Cellulitis generally begins 1 to 3 weeks after a recognized breach of the skin, often with soil contamination. Subacute cellulitis with pain, swelling, erythema, and warmth develops over days to weeks. The lesions are usually firm and nonfluctuant. Disease may progress to involve underlying muscle, tendon, bones, or joints. Dissemination is rare. *N. asteroides* is common in colder climates, while *N. brasiliensis* predominates in warmer climates.

In the lymphocutaneous syndrome, there is typically a pyodermatous lesion at the site of inoculation, with central ulceration and purulent or honey-colored drainage. Subcutaneous nodules often appear along lymphatics that drain the primary lesion. The lymphangitic form closely resembles lymphocutaneous sporotrichosis (Chap. 208). Most cases of the lymphocutaneous syndrome are associated with *N. brasiliensis*.

Actinomycetoma usually begins with a nodular swelling, sometimes at a site of local trauma. Lesions typically develop on the feet or hands but may involve the posterior part of the neck, the upper back, the head, and other sites. The nodule eventually breaks down and a fistula appears. This fistula is soon accompanied by others. The fistulas tend to come and go, with new ones forming as old ones disappear. The discharge is serous or purulent, may be bloody, and often contains 0.1- to 2-mm white granules consisting of masses of mycelia. The lesions spread slowly along fascial planes to involve adjacent areas of skin, subcutaneous tissue, and bone. Over months or years, there may be extensive deformation of the affected part. Lesions involving soft tissues are only mildly painful; those affecting bones or joints are more so. Systemic symptoms are absent or minimal. Infection rarely disseminates from actinomycetoma, and lesions on the hands and feet usually cause only local disability. Lesions on the head, neck, and trunk can invade locally to involve deep organs and result in severe disability or death.

Keratitis *Nocardia* spp., usually *N. asteroides*, are uncommon causes of subacute keratitis. The infection usually follows eye trauma. Nocardial infection of lacrimal glands has been reported. Disease involving deeper eye structures is usually a manifestation of dissemination.

DIAGNOSIS

The first step in diagnosis is examination of sputum or pus for crooked, branching, beaded, gram-positive filaments 1 um wide and up to 50 um long. Most nocardiae are acid-fast in direct smears if a weak acid is used for decolorization (e.g., in the modified Kinyoun, Ziehl-Neelsen, and Fite-Faraco methods) (Fig. 165-CD3). The organisms often

take up silver stains. Nocardiae grow relatively slowly; colonies may take up to 2 weeks to appear and may not develop their characteristic appearance for up to 4 weeks. Several blood culture systems support nocardial growth. Yield is enhanced when blood cultures are incubated aerobically for up to 4 weeks and when blind subcultures are performed. Nocardial growth is so different from that of more common pathogens that the laboratory should be alerted when nocardiosis is suspected to maximize the likelihood of isolation. Since nocardiae are among the few aerobic microorganisms that use paraffin as a carbon source, paraffin baiting can be useful in isolating the organisms from mixed cultures.

In cases of pneumonia, sputum smears are often negative. Unless the diagnosis can be made in these cases by sampling lesions in other, more accessible sites, bronchoscopy or lung aspiration is usually necessary. Transtracheal aspiration should be avoided, as it frequently leads to nocardial cellulitis in tissues around the puncture wound.

In patients with nocardial pneumonia, a careful history should be obtained and a thorough physical examination performed to evaluate the possibility of dissemination. Suggestive symptoms or signs should be pursued with further diagnostic tests. Computed tomography or magnetic resonance imaging of the head, with and without contrast material, should be undertaken if signs or symptoms suggest brain involvement. Many authorities recommend brain imaging in all cases of pulmonary or disseminated disease.

When clinically indicated,CSF or urine should be concentrated and then cultured. In actinomycetoma cases, granules should be sought in the discharge. Suspect particles should be washed in saline, examined microscopically, and cultured.

Isolation of nocardiae from sputum or blood occasionally represents colonization, transient infection, or contamination. In typical cases of respiratory tract colonization, Gram-stained specimens are negative and cultures are only intermittently positive. A positive sputum culture in an immunosuppressed patient usually reflects disease. When nocardiae are isolated from an immunocompetent patient without apparent nocardial disease, the patient should be observed carefully without treatment. A patient with a host-defense defect that increases the risk of nocardiosis should usually receive antimicrobial treatment.

Nocardia spp. are difficult to differentiate from one another with standard biochemical tests, and isolates from patients with systemic or severe disease should be sent to a reference laboratory for definitive identification and antimicrobial susceptibility testing. Susceptibility results, which help differentiate species, are of less certain clinical value but sometimes guide therapy in difficult cases.

In vitro, strains of *N. farcinica* differ from most in that they are usually resistant to cephalosporins and in one-fifth of cases are resistant to imipenem. *N. pseudobrasiliensis* strains often exhibit resistance to minocycline or amoxicillin/clavulanic acid and susceptibility to ciprofloxacin or clarithromycin. *N. transvalensis* displays increased resistance to many antimicrobial agents, including amikacin, tobramycin, cefotaxime, ceftriaxone, and amoxicillin/clavulanic acid. *N. nova* isolates appear to be susceptible to ampicillin and erythromycin in vitro but also produce

b-lactamase constitutively or in the presence of ab-lactam.

Several presumptive diagnostic tests for nocardial infection have been studied, including tests for antibodies, nocardial metabolites, and nocardial DNA. None is ready for clinical use at this time.

TREATMENT

Sulfonamides are the drugs of choice for nocardiosis (Table 165-1). Initially, 6 to 8 g of sulfadiazine or sulfisoxazole per day in four divided doses should be used. After disease is controlled, 4 g/d can be used to complete therapy. In difficult cases, sulfonamide levels should be measured and dosages adjusted to keep serum levels between 100 and 150 ug/mL. The combination of sulfamethoxazole (SMZ) and trimethoprim (TMP) is probably equivalent to sulfonamides; some authorities believe that the combination may in fact be more effective, but it also poses a modestly greater risk of hematologic toxicity. At the outset, 10 to 20 mg of TMP per kg and 50 to 100 mg of SMZ per kg should be given each day in two divided doses. Later, the daily doses can be decreased to as little as 5 mg/kg and 25 mg/kg, respectively. In persons with sulfonamide allergies, desensitization usually allows continuation of therapy with these effective and inexpensive drugs.

Minocycline is the best-established alternative oral drug and should be given in doses of 100 to 200 mg twice a day. Other tetracyclines are usually ineffective. *N. nova* infections can be treated with erythromycin (500 to 750 mg four times a day) and/or ampicillin (1 g four times a day), but other *Nocardia* spp. are often resistant to both drugs. Amoxicillin (500 mg) combined with clavulanic acid (125 mg), given three times a day, has been effective in a few cases but should be avoided in cases due to *N. nova*, in which clavulanate inducesb-lactamase production. Ofloxacin (400 mg twice a day) and clarithromycin (500 mg twice a day) have each been successful in a few cases.

Amikacin, the best-established parenteral drug, is given in doses of 5 to 7.5 mg/kg every 12 h. Serum levels should be monitored with prolonged therapy in patients with diminished renal function and in the elderly. Newer b-lactam antibiotics, including cefotaxime, ceftizoxime, ceftriaxone, and imipenem, are usually effective. They may be less effective in some cases caused by *N. farcinica*.

In patients receiving immunosuppressive therapy, the regimen should be continued if necessary for treatment of an underlying disease or prevention of transplant rejection. In many cases, two or more antimicrobial agents have been used to treat nocardiosis, often in combinations including a sulfonamide or minocycline. Whether such therapy is better than monotherapy is not known, and combination therapy increases the risk of toxicity.

Surgical management of nocardial disease is similar to that of other bacterial diseases. Brain abscesses should be aspirated, drained, or excised if the diagnosis is unclear, if an abscess is large and accessible, or if an abscess fails to respond to chemotherapy. Abscesses that are small or inaccessible should be treated medically; in these cases, clinical improvement should be noticeable within 1 to 2 weeks. Brain imaging should be repeated to document the resolution of lesions, although abatement on images often

lags behind clinical improvement.

Antimicrobial therapy usually suffices for nocardial actinomycetoma. In deep or extensive cases, drainage or excision of heavily involved tissue may facilitate healing, but structure and function should be preserved whenever possible.

Nocardial infections tend to relapse (particularly in patients with chronic granulomatous disease), and long courses of antimicrobial therapy are necessary. If disease is unusually extensive, if the patient is immunosuppressed, or if the response to therapy is slow, the recommendations in Table 165-1 should be exceeded.

The mortality rate for pulmonary or disseminated nocardiosis outside theCNSshould be <5%. CNS disease carries a higher mortality rate. Patients should be followed carefully for at least 6 months after therapy has ended. Any child with nocardiosis and no known cause of immunosuppression should undergo tests to determine the adequacy of the phagocytic respiratory burst.

166. ACTINOMYCOSIS - *Thomas A. Russo*

Actinomycosis is an indolent, slowly progressive infection caused by anaerobic or microaerophilic bacteria, primarily of the genus *Actinomyces*, that colonize the mouth, colon, and vagina. Mucosal disruption may lead to infection at virtually any site in the body. The clinical presentations of actinomycosis are myriad; however, classic features include purulent foci surrounded by dense fibrosis that, over time, cross natural anatomic boundaries into contiguous structures, with the formation of fistulae and sinus tracts in some cases. In vivo growth of actinomycetes usually results in the formation of clumps called *grains* or *sulfur granules*. This infection is commonly confused with a neoplasm. Common in the preantibiotic era, actinomycosis has diminished in incidence, as has its timely recognition. Actinomycosis has been called "the most misdiagnosed disease," and it has been said that "no disease is so often missed by experienced clinicians." Thus this entity remains a diagnostic challenge. An awareness of the full spectrum of the disease will expedite its diagnosis and treatment and will minimize the unnecessary surgical interventions, morbidity, and mortality that are reported all too often.

ETIOLOGIC AGENTS

Actinomycosis is most commonly caused by *A. israelii*. *A. naeslundii*, *A. odontolyticus*, *A. viscosus*, *A. meyeri*, *A. gerencseriae*, and *Propionibacterium propionicum* are established but less common causes of the disease. Most if not all actinomycotic infections are polymicrobial. *Actinobacillus actinomycetemcomitans*, *Eikenella corrodens*, Enterobacteriaceae, and species of *Fusobacterium*, *Bacteroides*, *Capnocytophaga*, *Staphylococcus*, and *Streptococcus* are commonly isolated with actinomycetes in various combinations, depending on the site of infection. The contribution of these other species to the pathogenesis of actinomycosis is uncertain.

An increasing number of bacterial species isolated from human clinical specimens have recently been classified as *Actinomyces*. Although their role in disease has not always been defined, *A. europaeus*, *A. neuii* subspecies *neuii*, *A. neuii* subspecies *anitratus*, *A. radingae*, *A. graevenitzii*, and *A. turicensis* appear to be infrequent and often opportunistic human pathogens. The nature of the infections described to date does not clearly establish these agents as causes of the typical syndrome of actinomycosis.

EPIDEMIOLOGY

The agents of actinomycosis are members of the normal oral flora and are often cultured from the bronchi, the gastrointestinal tract, and the female genital tract. Infection occurs throughout life, with a peak incidence in the middle decades. Males have a threefold higher incidence of infection, possibly because of poorer dental hygiene and/or more frequent trauma. Likely contributing factors to the decrease in the incidence of actinomycosis since the preantibiotic era include improved dental hygiene and the initiation of antimicrobial treatment early on -- before the full development of the disease. Individuals who do not seek or have access to health care are undoubtedly at higher risk.

PATHOGENESIS AND PATHOLOGY

A vital step in the development of actinomycosis is disruption of the mucosal barrier, which allows the actinomycetes to invade beyond their endogenous habitat in the mouth, lower gastrointestinal tract, and female genitourinary tract. Local infection, subsequent extension, and (in rare instances) distant hematogenous seeding may ensue. Initial acute inflammation is followed by the characteristic chronic, indolent phase. Lesions usually appear as single or multiple indurations. Central fluctuance, with pus containing neutrophils and sulfur granules, is virtually diagnostic of this disease (Fig. 166-1). The fibrous walls of the mass are typically described as "woody." The responsible bacterial and/or host factors have not yet been identified. Once established, actinomycosis spreads contiguously in a slow progressive manner, ignoring tissue planes. Given time, sinus tracts, which can spontaneously close and reopen, will form and extend to skin, adjacent organs, or bone. These unique features of actinomycosis mimic malignancy, with which it is often confused.

Foreign bodies appear to facilitate infection. This association most frequently involves intrauterine contraceptive devices (IUCDs). In addition, an increasing number of reports have described an association of actinomycosis with HIV infection, transplantation, and chemotherapy. Ulcerative mucosal infections (e.g., by herpes simplex virus or cytomegalovirus) and abnormalities in host defenses may facilitate the development of actinomycosis in the latter settings.

CLINICAL MANIFESTATIONS

Oral-Cervicofacial Disease Actinomycosis occurs most frequently at an oral, cervical, or facial site, usually as a soft tissue swelling, abscess, or mass lesion that is often mistaken for a neoplasm. The angle of the jaw is generally involved, but a diagnosis of actinomycosis should be considered with any mass lesion or relapsing infection in the head and neck. Otitis, sinusitis, and canaliculitis can also develop. Pain, fever, and leukocytosis are variably reported. Contiguous extension to the cranium, cervical spine, or thorax is a potential sequela.

Thoracic Disease Thoracic actinomycosis usually follows an indolent progressive course, with involvement of the pulmonary parenchyma and/or the pleural space. Chest pain, fever, and weight loss are common. A cough, when present, is variably productive. The usual radiographic appearance is either a mass lesion or pneumonitis. Cavitary disease or hilar adenopathy may develop. More than 50% of cases include pleural thickening, effusion, or empyema. Rarely, pulmonary nodules or endobronchial lesions occur. Pulmonary lesions suggestive of actinomycosis may cross fissures or pleura; may involve the mediastinum, contiguous bone, or chest wall; or may be associated with a sinus tract. In the absence of these findings, thoracic actinomycosis is usually mistaken for a neoplasm or for pneumonitis due to more usual causes.

Mediastinal infection is uncommon, usually arising from thoracic extension but rarely resulting from perforation of the esophagus, from trauma, or from head and neck or abdominal disease. The structures within the mediastinum and the heart can be involved in various combinations; consequently, the possible presentations are diverse. Isolated disease of the breast has been described.

Abdominal Disease Abdominal actinomycosis poses a great diagnostic challenge. Months or years usually pass from the inciting event (e.g., appendicitis, diverticulitis, peptic ulcer disease, foreign-body perforation, bowel surgery, or ascension fromIUCD-associated pelvic disease) to clinical recognition. Because of the flow of peritoneal fluid and/or the direct extension of primary disease, virtually any abdominal organ, region, or space can be involved. The disease usually presents as an abscess or a mass lesion that is often fixed to underlying tissue and mistaken for a tumor. Infiltrative disease with irregular contrast enhancement may be seen on computed tomography (CT). Sinus tracts to the abdominal wall or perianal region may develop. Recurrent disease or a wound or fistula that fails to heal (in the absence of inflammatory bowel disease) suggests actinomycosis.

Hepatic infection usually presents as single or multiple abscesses or masses. Isolated disease presumably develops via hematogenous seeding from cryptic foci. Presently available imaging and percutaneous techniques have resulted in improved diagnosis and treatment.

All levels of the urogenital tract can be infected. Renal disease usually presents as pyelonephritis and/or renal and perinephric abscess. Bladder involvement, usually due to extension of pelvic disease, may result in ureteral obstruction or fistulas to bowel, skin, or uterus.

Pelvic Disease Actinomycotic involvement of the pelvis occurs most commonly in association with anIUCD. Pelvic symptoms when an IUCD is in place or has recently been removed should prompt consideration of actinomycosis. Although the risk has not yet been quantified, it appears to be small. The disease rarely develops when the IUCD has been in place for <1 year, but the risk increases with time. Actinomycosis can also present months after the removal of the device. Symptoms are typically indolent; fever, weight loss, abdominal pain, and abnormal vaginal bleeding or discharge are the most common. The earliest stage of disease -- often endometritis -- commonly progresses to pelvic masses or a tuboovarian abscess (Fig. 166-2). Unfortunately, because the diagnosis is often delayed, a "frozen pelvis" mimicking malignancy or endometriosis can develop by the time of recognition.

An unresolved issue is whether the isolation of *Actinomyces*-like organisms (ALOs) from cultures of cervical or endometrial specimens or the detection of ALOs by immunofluorescence is correlated withIUCD-associated disease. A Papanicolaou smear may fail to detect ALOs even in the presence of active actinomycosis. Although the risk appears to be small, the consequences of infection are significant. Therefore, until more quantitative data become available, detection of ALOs or immunofluorescence-positive organisms in conjunction with symptoms that cannot be accounted for appears to warrant removal of the IUCD and -- if advanced disease is excluded -- initiation of a 14-day course of empirical treatment for possible early pelvic actinomycosis. The detection of ALOs or immunofluorescence-positive organisms in the absence of symptoms warrants education of the patient and close follow-up but not removal of the IUCD.

Central Nervous System Disease Actinomycosis of the central nervous system is rare. Single or multiple brain abscesses are most common. An abscess usually appears

onCT as a ring-enhancing lesion with a thick wall that may be irregular or nodular. Meningitis, epidural or subdural space infection, and cavernous sinus syndrome have also been described.

Musculoskeletal Infection Actinomycotic infection of the bone is usually due to adjacent soft tissue infection but may be associated with trauma (e.g., fracture of the mandible) or hematogenous spread. Because of slow disease progression, new bone formation and bone destruction are seen concomitantly. Infection of an extremity is uncommon and is usually a result of trauma. Skin, subcutaneous tissue, muscle, and bone (with periostitis or acute or chronic osteomyelitis) are involved alone or in various combinations. Cutaneous sinus tracts frequently develop.

Disseminated Disease Hematogenous dissemination of disease from any location rarely results in multiple organ involvement. The lungs and liver are most commonly affected, with the presentation of multiple nodules mimicking disseminated malignancy. The clinical presentation may be surprisingly indolent given the extent of disease.

DIAGNOSIS

The diagnosis of actinomycosis, particularly when it mimics malignancy, is rarely considered. All too often, the first mention of actinomycosis is by the pathologist after extensive surgery has been performed. Since medical therapy alone is often sufficient for cure, the challenge for the clinician is to consider the possibility of actinomycosis in time to diagnose it in the least invasive fashion and to avoid unnecessary surgery. Both fine-needle aspiration and biopsy are being used successfully to obtain clinical material for diagnosis, as areCT- and ultrasound-guided aspirations or biopsies. The diagnosis is most commonly made by microscopic identification of sulfur granules (Fig. 166-CD1); occasionally these granules, if sought, can be grossly identified from draining sinus tracts or other purulent material. Although sulfur granules are a defining characteristic of actinomycosis, granules are also found in mycetoma and botryomycosis; however, these entities can easily be differentiated from actinomycosis with appropriate histopathologic and microbiologic studies. Microbiologic identification of actinomycetes is possible in only a minority of cases and is often precluded by prior antimicrobial therapy. Therefore, for optimal yield, the avoidance of even a single dose of antibiotics is mandatory. Primary isolation usually requires 5 to 7 days but may take as long as 2 to 4 weeks. Immunofluorescence testing for *A. israelii*, *A. naeslundii*, and *P. propionicum* (available through the Centers for Disease Control and Prevention in Atlanta) has become a useful diagnostic alternative. Because these organisms are components of the normal oral and genital-tract flora, their identification in sputum, bronchial washings, and cervicovaginal secretions is of little significance in the absence of sulfur granules. *Actinomyces* can be detected in urine by means of appropriate staining and culture.

TREATMENT

Actinomycosis must be treated with high doses of antimicrobials for a prolonged period. Although therapy needs to be individualized, the intravenous administration of 18 to 24 million units of penicillin for 2 to 6 weeks, followed by oral therapy with penicillin or amoxicillin for 6 to 12 months, is a reasonable guideline for serious infections. Less extensive disease, particularly that involving the oral-cervicofacial region, may require

less intensive therapy. If therapy is extended beyond the point of resolution of measurable disease, the risk of relapse -- a clinical hallmark of this infection -- will be minimized. A similar approach is reasonable for immunocompromised patients, although refractory disease has been described in HIV-infected individuals. Antimicrobial agents whose use is supported by extensive clinical experience are listed inTable 166-1. Although the role played by "companion" microbes in actinomycosis is unclear, many isolates are pathogens in their own right, and a regimen covering these organisms during the initial treatment course is reasonable. Agents whose success has been reported anecdotally are ceftriaxone, ceftizoxime, imipenem, and ciprofloxacin. Drugs that should be avoided are metronidazole, aminoglycosides, oxacillin, dicloxacillin, and cephalexin.

Combined medical-surgical therapy is still advocated by some authorities. However, an increasing body of literature now supports an initial attempt at cure with medical therapy alone, even in extensive disease.CT and magnetic resonance imaging should be used to monitor the response to therapy. Percutaneous drainage is an additional option. When a critical location is involved (e.g., the epidural space, the central nervous system) or when suitable medical therapy fails, surgical intervention may be appropriate.

167. INFECTIONS DUE TO MIXED ANAEROBIC ORGANISMS - *Dennis L. Kasper*

DEFINITIONS

Anaerobic bacteria are organisms that require reduced oxygen tension for growth, failing to grow on the surface of solid media in 10% CO_2 in air. (In contrast, *microaerophilic* bacteria can grow in 10% CO_2 in air or under anaerobic or aerobic conditions, although they grow best in the presence of only a small amount of atmospheric oxygen, and *facultative* bacteria can grow in the presence or absence of air.) This chapter describes infections caused by nonsporulating anaerobic bacteria. In general, anaerobes associated with human infections are relatively aerotolerant. They can survive for as long as 72 h in the presence of oxygen, although generally they will not multiply in this environment. A far smaller number of pathogenic anaerobic bacteria (which are also part of the normal flora) die after brief contact with oxygen, even in low concentrations.

The nonsporulating anaerobic bacteria exist as components of the normal flora on the mucosal surfaces of humans and animals. The major reservoirs of these bacteria are the mouth, lower gastrointestinal tract, skin, and female genital tract. Among the constituents of the oral flora, anaerobes are the predominant commensal organisms, ranging in concentration from 10^9/mL in saliva to 10^{12}/mL in gingival scrapings. In the oral cavity, the ratio of anaerobic to aerobic bacteria ranges from 1:1 on the surface of a tooth to 1000:1 in the gingival crevice. Anaerobic bacteria are not found in appreciable numbers in the normal upper intestine until the distal ileum. In the colon, the proportion of anaerobes increases significantly, as does the overall bacterial count. For example, in the colon there are 10^{11} to 10^{12}organisms per gram of stool, with a ratio of anaerobes to aerobes of approximately 1000:1. In the female genital tract, there are approximately 10^9organisms per milliliter of secretions, with a ratio of anaerobes to aerobes of approximately 10:1.

Hundreds of species of anaerobic bacteria have been identified as part of the normal flora of humans. Identification of as many as 500 different anaerobic species in fecal specimens reflects the diversity of the anaerobic flora. Despite the complex array of bacteria in the normal flora, relatively few species are isolated commonly from human infection.

Anaerobic infections occur when the harmonious relationship between the host and the bacteria is disrupted. Any site in the body is susceptible to infection with these indigenous organisms when a mucosal barrier or the skin is compromised by surgery, trauma, tumor, or ischemia or necrosis, which reduce local tissue redox potentials. Because the sites that are colonized by anaerobes contain many species of bacteria, disruption of anatomic barriers allows penetration of many organisms, resulting in mixed infections involving multiple species of anaerobes combined with facultative or microaerophilic organisms. Such mixed infections are seen in the head and neck (chronic sinusitis, chronic otitis media, Ludwig's angina, and periodontal abscesses). Brain abscesses and subdural empyema are the most frequent anaerobic infections of the central nervous system. Anaerobes are responsible for pleuropulmonary diseases such as aspiration pneumonia, necrotizing pneumonia, lung abscess, and empyema. These organisms also play an important role in various intraabdominal infections, such

as peritonitis and intraabdominal and liver abscesses (Chap. 130). They are isolated frequently in female genital tract infections, such as salpingitis, pelvic peritonitis, tuboovarian abscess, vulvovaginal abscess, septic abortion, and endometritis (Chaps. 132 and133). Anaerobic bacteria also are frequently found in infections of the skin, soft tissues, and bones and in bacteremia.

ETIOLOGY

The major anaerobic gram-positive cocci that produce disease are *Peptostreptococcus* spp. The major species involved in infections are *Peptostreptococcus intermedius*, *P. micros*, *P. magnus*, *P. asaccharolyticus*, *P. anaerobius*, and *P. prevotii*. Clostridia are gram-positive rods that are isolated from wounds, abscesses, sites of abdominal infection, and blood; they are discussed inChap. 145. The principal anaerobic gram-negative bacilli found in human infections are the members of the *Bacteroides* "family," which includes the *Bacteroides fragilis* group as well as *Fusobacterium*, *Prevotella*, and *Porphyromonas* spp. Another gram-negative rod, *Bilophila wadsworthia*, has been isolated from infected sites. Gram-positive anaerobic non-spore-forming bacilli are uncommon as etiologic agents of human infections. *Propionibacterium acnes*, a rare cause of foreign body infections, is one of the few non-clostridial gram-positive rods associated with infections.

The *B. fragilis* group contains the anaerobic pathogens most frequently isolated from clinical infections. Members of this group are part of the normal bowel flora; they include several distinct species, such as *B. fragilis*, *B. thetaiotaomicron*, *B. distasonis*, *B. vulgatus*, *B. uniformis*, and *B. ovatus*. (Ribosomal RNA analysis has shown that *B. distasonis* is more closely related to the genus *Porphyromonas* than it is to other *Bacteroides*.) Of this group, *B. fragilis* is the most important clinical isolate. However, *B. fragilis* is isolated from the normal fecal flora in lower numbers than other *Bacteroides* spp.

A second major group of phenotypically similar organisms is part of the indigenous oral flora. Thus these organisms are found at infected sites that can be seeded with oral microflora. Many of these species are pigment-producing bacteria previously classified as *Bacteroides melaninogenicus*. The nomenclature of this group has changed so that two distinct genera, *Prevotella* and *Porphyromonas*, are now recognized; these genera comprise several pathogenic species, including *Porphyromonas gingivalis*, *Porphyromonas asaccharolytica*, and *Prevotella oralis*. *Porphyromonas* and *Prevotella* spp. cause localized infections that can spread contiguously.

In female genital tract infections, organisms normally colonizing the vagina, such as *Prevotella bivia* and *Prevotella disiens*, are the most frequent isolates, although *B. fragilis* is not uncommon. The *Fusobacterium* species *Fusobacterium necrophorum*, *F. nucleatum*, and *F. varium*, which reside primarily in the oral cavity and the gastrointestinal tract, are also isolated from clinical infections, including necrotizing pneumonia and abscesses. *Bilophila wadsworthia* has been reported to cause serious infections, including bacteremia, necrotizing fasciitis, and abscesses; this organism is frequently resistant to several antimicrobials, including imipenem, cefoxitin, and other b-lactam agents.

Infections caused by anaerobic bacteria most frequently are due to more than one organism. These polymicrobial infections may be caused by one or several anaerobic species or by a combination of anaerobic organisms and microaerophilic or facultative bacteria acting synergistically.

Approach to the Patient

The physician must consider several points when approaching the patient with presumptive infection due to anaerobic bacteria.

1. Most of the organisms colonizing mucosal sites are harmless commensals; very few cause disease.

2. For anaerobes to cause tissue infection, they must spread beyond the normal mucosal barriers.

3. Conditions favoring the propagation of these bacteria, particularly a lowered oxidation-reduction potential, are necessary. These conditions exist at sites of trauma, tissue destruction, compromised vascular supply, and complications of preexisting infection, which produce necrosis.

4. There is a complex array of infecting flora. For example, as many as 12 different types of organisms can be isolated from a suppurative site.

5. Anaerobic organisms tend to be found in abscess cavities or in necrotic tissue. The failure of an abscess to yield organisms on routine culture is a clue that the abscess is likely to contain anaerobic bacteria. Often smears of this "sterile pus" are found to be teeming with bacteria when Gram's stain is applied. Malodorous pus suggests anaerobic infection. Although some facultative organisms, such as *Staphylococcus aureus*, are also capable of causing abscesses, abscesses in organs or deeper body tissues should call to mind anaerobic infection.

6. Gas is found in many anaerobic infections of deep tissues.

7. Some species (the best example being the *B. fragilis* group) require specific therapy. However, many synergistic infections can be cured with antibiotics directed at some but not all of the organisms involved. Antibiotic therapy, combined with debridement and drainage, disrupts the interdependent relationship among the bacteria, and some species that are resistant to the antibiotic do not survive without the coinfecting organisms.

8. Manifestations of disseminated intravascular coagulation are unusual in patients with purely anaerobic infection.

EPIDEMIOLOGY

Difficulties in the performance of appropriate cultures, contamination of cultures by aerobic bacteria or components of the normal flora, and the lack of readily available, reliable culture techniques have made it impossible to obtain accurate incidence or

prevalence data. However, anaerobic infections are encountered frequently in hospitals with active surgical, trauma, and obstetric and gynecologic services. In some centers, anaerobic bacteria, particularly *B. fragilis*, account for approximately 4% of positive blood cultures.

PATHOGENESIS

Anaerobic bacterial infections usually occur when an anatomic barrier becomes disrupted and constituents of the local flora enter a site that was previously sterile. Because of the specific growth requirements of anaerobic organisms and their presence as commensals on mucosal surfaces, conditions must arise that allow these organisms to penetrate mucosal barriers and enter tissue with a lowered oxidation-reduction potential. Therefore, tissue ischemia, trauma, surgery, perforated viscus, shock, and aspiration provide environments conducive to the proliferation of anaerobes. In the case of a perforated viscus, hundreds of species of anaerobic bacteria are spilled into the peritoneal cavity, but many of these organisms are unable to survive because the highly vascularized tissue provides a sufficiently high redox potential. The entry of oxygen into the environment results in the selection of the more aerotolerant anaerobic organisms.

The ability of an organism to adhere to host tissues is important to the establishment of infection. Some oral species adhere to crevicular epithelium in the oral cavity. *Prevotella melaninogenica* actually attaches to other microorganisms; *P. gingivalis* is a common isolate in periodontal disease. These organisms have fimbriae that facilitate attachment. Some unencapsulated *Bacteroides* strains appear to be piliated, a characteristic that may account for their ability to adhere.

The most extensively studied virulence factor of the nonsporulating anaerobes is the polysaccharide capsule of *B. fragilis*. This polysaccharide possesses distinct biologic properties, such as the ability (owing to a unique zwitterionic motif of charged sugars) to promote abscess formation. Intraabdominal abscess induction is related to the capacity of the polysaccharide to stimulate the release of cytokines, in particular interleukin 8 (IL-8) and tumor necrosis factora (TNF-a), from resident peritoneal cells. IL-8 results in the chemotaxis of polymorphonuclear neutrophils (PMNs) into the peritoneum, where they adhere to mesothelial cells induced by TNF-a to upregulate their expression of intercellular adhesion molecule 1 (ICAM-1). PMNs adherent to ICAM-1-expressing cells probably represent the nidus for an abscess. Prophylactic or therapeutic administration of the polysaccharide or a zwitterionic mimetic to experimental animals confers protection against abscess induction following challenge with intestinal microorganisms capable of inducing abscesses. This protection is mediated by T cells controlling cytokine release, which blocks the tissue response of abscess formation. Although abscesses constitute a host response that localizes and contains infecting bacteria, abscess formation in patients with sepsis often results in severe and chronic illness that requires surgical drainage in combination with antimicrobial therapy.

Anaerobic bacteria produce a number of exoproteins that are capable of enhancing the organisms' virulence. The collagenase produced by *P. gingivalis* may enhance tissue destruction. An enterotoxin has been identified in *B. fragilis* strains associated with diarrheal disease in animals and young children. This 20-kDa zinc-dependent metalloprotease reversibly alters the morphology of the tight junctional complexes of

intestinal epithelial cells. Both *B. fragilis* and *P. melaninogenica* possess lipopolysaccharides (endotoxins) that are less biologically potent than endotoxins associated with aerobic gram-negative bacteria. This relative biologic inactivity may account for the lower frequency of disseminated intravascular coagulation and purpura in *Bacteroides* bacteremia than in facultative and aerobic gram-negative bacillary bacteremia.

CLINICAL MANIFESTATIONS

Anaerobic Infections of the Mouth, Head, and Neck (See alsoChap. 30) Infections of the mouth can arise from either the supragingival or the subgingival dental plaque. Supragingival plaque formation begins with the adherence of gram-positive bacteria to the tooth surface. This form of plaque is influenced by salivary and dietary components, oral hygiene, and local host factors. Once the supragingival plaque is established, the acquisition of pathogenic bacteria and an increase in the amount of plaque are responsible for the ultimate development of gingivitis. Early bacteriologic changes in the supragingival plaque initiate an inflammatory response in the gingiva, including edema, swelling, and increased gingival fluid, and cause the development of caries and endodontic (pulp) infections. In addition, these changes contribute to the subsequent pathogenic alteration in the subgingival plaque that arises from poor or inadequate oral hygiene.

Subgingival plaque is associated with periodontal disease and disseminated infection arising from the oral cavity. Bacteria that colonize the subgingival area are primarily anaerobic. The black-pigmented gram-negative anaerobic bacilli, principally *P. gingivalis* and *P. melaninogenica*, are the most important. Infections in this area are frequently mixed and involve both anaerobic and aerobic bacteria. After establishment of local infection either in root canals or in the periodontal area, infection may extend into the mandible, causing osteomyelitis to the maxillary sinuses; or to local tissues in the submandibular or submental spaces, depending on which teeth are involved. Periodontitis also may result in spreading infection that can involve adjacent bone or soft tissues.

Gingivitis Gingivitis may become a necrotizing infection (trench mouth, Vincent's stomatitis). The onset of disease is usually sudden and is associated with tender bleeding gums, foul breath, and a bad taste. The gingival mucosa, especially the papillae between the teeth, becomes ulcerated and may be covered by a gray exudate, which is removable with gentle pressure. Patients may become systemically ill, developing fever, cervical lymphadenopathy, and leukocytosis. Occasionally, ulcerative gingivitis can spread to the buccal mucosa, the teeth, and the mandible or maxilla, resulting in widespread destruction of bone and soft tissue. This infection is termed *acute necrotizing ulcerative mucositis* (cancrum oris, noma). It destroys tissue rapidly, causing the teeth to fall out and large areas of bone -- or even the whole mandible -- to be sloughed. A strong putrid odor is frequently detected, although the lesions are not painful. The gangrenous lesions eventually heal, leaving large disfiguring defects. This infection is seen most commonly following a debilitating illness or in severely malnourished children. It has been known to complicate leukemia or to develop in individuals with a genetic deficiency of catalase.

Acute Necrotizing Infections of the Pharynx These infections usually occur in association with ulcerative gingivitis. Symptoms include an extremely sore throat, foul breath, and a bad taste accompanied by fever and a sensation of choking. Examination of the pharynx demonstrates that the tonsillar pillars are swollen, red, ulcerated, and covered with a grayish membrane that peels easily. Lymphadenopathy and leukocytosis are common. The disease may last for only a few days or, if not treated, may persist for weeks. Lesions begin unilaterally but may spread to the other side of the pharynx or the larynx. Aspiration of the infected material by the patient can result in lung abscesses. Soft tissue infection of the oral-facial area may or may not be odontogenic. *Ludwig's angina*, a periodontal infection usually arising from the tissues surrounding the third molar, may produce submandibular cellulitis that results in marked local swelling of tissues, with pain, trismus, and superior and posterior displacement of the tongue. Submandibular swelling of the neck can impair swallowing and cause respiratory obstruction. In some cases, tracheotomy may be life-saving.

Fascial Infections These infections arise from the spread of organisms originating in the upper airways to potential spaces formed by the fascial planes of the head and neck. Perimandibular space infection most commonly involves the submandibular, peritonsillar, and parapharyngeal spaces. Peritonsillar abscesses occur in association with pharyngitis. Complicated dental infections spread to the submandibular and buccal spaces. Entry of organisms by either portal can result in parapharyngeal space infections. Although there are few well-documented reports on the microbiology of these syndromes, anaerobes from the oral flora have been implicated in many cases. Fascial infections associated with *S. aureus* or *Streptococcus pyogenes* may arise from boils or impetigo, whereas anaerobes are associated with space infections either occurring spontaneously or arising from diseases of the mucous membranes or from dental manipulations.

Sinusitis and Otitis The role of anaerobic bacteria in acute sinusitis may be underestimated because of improper collection of specimens. In a study of chronic sinusitis, anaerobic bacteria were found in 52% of specimens collected during external frontoethmoidotomy or radical antrotomy. Anaerobic bacteria are much more easily implicated in chronic suppurative otitis media than in acute otitis media. Purulent exudate from chronically draining ears has been found to contain anaerobes, particularly *Bacteroides* spp., in up to 50% of cases. *B. fragilis* has been isolated from up to 28% of patients with chronic otitis media.

Complications of Anaerobic Head and Neck Infections Contiguous craniad spread of these infections may result in osteomyelitis of the skull or mandible or in intracranial infections such as brain abscess and subdural empyema. Caudad spread can produce mediastinitis or pleuropulmonary infection. Hematogenous complications may also result from anaerobic infections of the head and neck. Bacteremia, which occasionally is polymicrobial, can lead to endocarditis or other distant infections. When infections spread to produce suppurative thrombophlebitis of the internal jugular vein, a destructive syndrome (*Lemierre's*) -- with prolonged fever, bacteremia, septic emboli to both the lung and the brain, and multiple metastatic foci of suppurative infection -- may develop. This syndrome has been reported with fusobacterial septicemia following exudative pharyngitis but has been uncommon in the antimicrobial era.

Central Nervous System Infections Brain abscesses are frequently associated with anaerobic bacteria (Chap. 372). If optimal bacteriologic techniques are employed, as many as 85% of brain abscesses yield anaerobic bacteria -- most often anaerobic gram-positive cocci (especially peptostreptococci), which are followed in frequency by *Fusobacterium* and *Bacteroides* spp. Facultative or microaerophilic streptococci and coliforms often are part of a mixed infecting flora in brain abscesses.

Pleuropulmonary Infections Anaerobic pleuropulmonary infections result from the aspiration of oropharyngeal contents, often in the context of an altered state of consciousness or an absent gag reflex. Four clinical syndromes are associated with anaerobic pleuropulmonary infection produced by aspiration: simple aspiration pneumonia, necrotizing pneumonia, lung abscess, and empyema.

Aspiration Pneumonitis Aspiration pneumonitis must be distinguished from two other clinical syndromes associated with aspiration that are not of bacterial etiology. One syndrome results from aspiration of solids, usually food. Obstruction of major airways typically results in atelectasis and moderate nonspecific inflammation. Therapy consists of removal of the foreign body.

The second aspiration syndrome is more easily confused with bacterial aspiration. *Mendelson's* syndrome results from regurgitation of stomach contents and aspiration of chemical material, usually gastric juices. Pulmonary inflammation -- including the destruction of the alveolar lining, with transudation of fluid into the alveolar space -- occurs with remarkable rapidity. Typically this syndrome develops within hours, often following anesthesia when the gag reflex is depressed. The patient becomes tachypneic, hypoxic, and febrile. The leukocyte count may rise, and the chest x-ray may evolve suddenly from normal to a complete bilateral "whiteout" within 8 to 24 h. Sputum production is minimal. The pulmonary signs and symptoms can resolve quickly with symptom-based therapy or can culminate in respiratory failure, with the subsequent development of bacterial superinfection over a period of days. Antibiotic therapy is not indicated unless bacterial infection supervenes. The signs of bacterial infection include sputum production, persistent fever, leukocytosis, and clinical evidence of sepsis.

In contrast to these syndromes, bacterial aspiration pneumonia develops more slowly. It is seen in patients who are hospitalized and have a depressed gag reflex, impaired swallowing, or a tracheal or nasogastric tube; elderly patients; or those with transiently impaired consciousness in the wake of seizures, cerebrovascular accidents, or alcoholic blackouts. Patients who enter the hospital with this syndrome typically have been ill for several days and generally report low-grade fever, malaise, and sputum production. Usually the history reveals factors predisposing to aspiration, such as alcohol overdose or residence in a nursing home. Sputum characteristically is not malodorous unless the process has been under way for at least a week. A mixed bacterial flora with many PMNs is evident on Gram's staining; cultures are reliable only if contamination with the normal oral flora is avoided -- that is, if specimens are obtained by transtracheal aspiration. In general, this procedure is not indicated in the evaluation of these patients. The most commonly encountered anaerobes in these infections are pigmented and nonpigmented *Prevotella* spp., *F. nucleatum*, *Peptostreptococcus* spp., and *Bacteroides* spp. Chest x-rays show consolidation in dependent pulmonary segments: in the basilar segments of the lower lobes if the patient has aspirated while upright and in either the

posterior segment of the upper lobe (usually on the right side) or the superior segment of the lower lobe if the patient has aspirated while supine. The organisms isolated reflect the pharyngeal flora; *P. melaninogenica*, *Fusobacterium* spp., and anaerobic cocci are the most frequent isolates. The patient who aspirates in the hospital also may have a mixed infection involving enteric gram-negative rods.

Necrotizing Pneumonitis This form of anaerobic pneumonitis is characterized by numerous small abscesses that spread to involve several pulmonary segments. The process can be indolent or fulminating. This syndrome is less common than either aspiration pneumonia or lung abscess and includes features of both types of infection.

Anaerobic Lung Abscesses (Fig. 167-CD1) These abscesses result from subacute anaerobic pulmonary infection. The clinical syndrome typically involves a history of constitutional symptoms, including malaise, weight loss, fever, chills, and foul-smelling sputum, perhaps over a period of weeks (Chap. 255). Patients who develop lung abscesses characteristically have dental infection and periodontitis, but lung abscesses in edentulous patients have been reported. Abscess cavities may be single or multiple and generally occur in dependent pulmonary segments. Anaerobic abscesses must be distinguished from those associated with tuberculosis, neoplasia, and other conditions. Oral anaerobes predominate, although *B. fragilis* is isolated in up to 10% of cases. *S. aureus* may be found as well.

Empyema Empyema is a manifestation of long-standing anaerobic pulmonary infection. The clinical presentation, which includes the presence of foul-smelling sputum, resembles that of other anaerobic pulmonary infections. Patients may report pleuritic chest pain and marked chest-wall tenderness.

Empyema may be masked by overlying pneumonitis and should be considered especially in cases of persistent fever despite antibiotic therapy. Diligent physical examination and the use of ultrasound to localize a loculated empyema are important diagnostic tools. The collection of a foul-smelling exudate by thoracentesis is typical. Cultures of infected pleural fluid yield an average of 3.5 anaerobes and 0.6 facultative or aerobic bacterial species. Drainage is required. Defervescence, a return to a feeling of well-being, and resolution of the process may require several months.

Extension from a subdiaphragmatic infection also may result in anaerobic empyema. Septic pulmonary emboli may originate from intraabdominal or female genital tract infections and can produce anaerobic pneumonia.

Intraabdominal Infections Enterotoxigenic *B. fragilis* has been associated with watery diarrhea in a small number of young children and adults. In case-control studies of children with undiagnosed diarrheal disease, enterotoxigenic *B. fragilis* was isolated from significantly more children with diarrhea than children in the control group. This organism may play a role in a small proportion of childhood diarrhea cases. Neutropenic enterocolitis (typhlitis) has been associated with anaerobic infection of the cecum but -- in the setting of neutropenia (Chap. 85) -- may involve the entire bowel. Patients usually present with fever; abdominal pain, tenderness, and distension; and watery diarrhea. The bowel wall is edematous with hemorrhage and necrosis. The primary pathogen is thought by some authorities to be *C. septicum*, but other clostridia and mixed anaerobic

infections have also been implicated. More than 50% of patients developing early clinical signs can benefit from antibiotic therapy and bowel rest. Surgery is sometimes required to remove gangrenous bowel.*See Chap. 130 for a complete discussion of intraabdominal infections.*

Pelvic Infections The vagina of a healthy woman is one of the major reservoirs of anaerobic and aerobic bacteria. In the normal flora of the female genital tract, anaerobes outnumber aerobes by a ratio of approximately 10:1 and include anaerobic gram-positive cocci and *Bacteroides* spp. Anaerobes are isolated from most patients with genital tract infections not caused by a sexually transmitted pathogen. The major anaerobic pathogens are *B. fragilis*, *P. bivia*, *P. disiens*, *P. melaninogenica*, anaerobic cocci, and *Clostridium* spp. Anaerobes frequently are encountered in tuboovarian abscess, septic abortion, pelvic abscess, endometritis, and postoperative wound infection, particularly following hysterectomy. Although these infections are frequently mixed, involving both anaerobes and coliforms, pure anaerobic infections without coliform or other facultative bacterial species occur more often in pelvic than in intraabdominal sites and are characterized by drainage of foul-smelling pus or blood from the uterus, generalized uterine or local pelvic tenderness, and continued fever and chills. Suppurative thrombophlebitis of the pelvic veins may complicate the infections and lead to repeated episodes of septic pulmonary emboli.

Anaerobic bacteria have been thought to be contributing factors in the etiology of *bacterial vaginosis*. This syndrome of unknown etiology is characterized by a profuse malodorous discharge and an increase in the number of bacteria in the vagina, including *Gardnerella vaginalis*, *Prevotella* spp., *Mobiluncus* spp., peptostreptococci, and genital mycoplasmas. Anaerobic bacteria are thought to play a role in the etiology of pelvic inflammatory disease (Chap. 133), and several investigations have shown an association between bacterial vaginosis and the development of pelvic inflammatory disease.

Pelvic infections due to *Actinomyces* spp. have been associated with use of intrauterine devices (Chap. 166).

Skin and Soft Tissue Infections Injury to skin, bone, or soft tissue by trauma, ischemia, or surgery creates a suitable environment for anaerobic infections. These infections are most frequently found in sites prone to contamination with feces or with upper airway secretions -- for example, wounds associated with intestinal surgery, decubitus ulcers, or human bites. Anaerobic bacteria can be isolated in cases of crepitant cellulitis, synergistic cellulitis, or gangrene and necrotizing fasciitis (Chaps. 128 and145). Moreover, these organisms have been isolated from cutaneous abscesses, rectal abscesses, and axillary sweat gland infections (hydradenitis suppurativa). Anaerobes are frequently cultured from foot ulcers in diabetic patients.

These soft tissue or skin infections are usually polymicrobial. A mean of 4.8 bacterial species are isolated, with a roughly 3:2 ratio of anaerobes to aerobes. The most frequently isolated organisms include *Bacteroides* spp., *Peptostreptococcus* spp., enterococci, *Clostridium* spp., and *Proteus* spp. The involvement of anaerobes in these types of infections is associated with a higher frequency of fever, foul-smelling lesions, gas in the tissues, or visible foot ulcer.

Anaerobic bacterial *synergistic gangrene* (*Meleney's gangrene*) is characterized by exquisite pain, redness, and swelling followed by induration. Erythema surrounds a central zone of necrosis. A granulating ulcer forms at the original center as necrosis and erythema extend outward. Symptoms are limited to pain; fever is not typical. These infections usually involve a combination of *Peptostreptococcus* spp. and *S. aureus*; the usual site of infection is an abdominal surgical wound or the area surrounding an ulcer on an extremity. Treatment includes surgical removal of necrotic tissue and antimicrobial administration.

Necrotizing fasciitis, a rapidly spreading destructive disease of the fascia, is usually attributed to group A streptococci but can also be caused by anaerobic bacteria, including *Peptostreptococcus* and *Bacteroides* spp. Gas may be found in the tissues. Similarly, myonecrosis can be associated with mixed anaerobic infection. *Fournier's gangrene* consists of cellulitis involving the scrotum, perineum, and anterior abdominal wall, with mixed anaerobic organisms spreading along deep external fascial planes and causing extensive loss of skin.

Bone and Joint Infections Although *actinomycosis* (Chap. 166) accounts on a worldwide basis for most anaerobic infections in bone, organisms including *Peptostreptococcus* spp. or microaerophilic cocci, *Bacteroides* spp., *Fusobacterium* spp., and *Clostridium* spp. can also be found. These infections frequently arise adjacent to soft tissue infections. Hematogenous seeding of bone is uncommon. *Prevotella* and *Porphyromonas* spp. are detected in infections involving the maxilla and mandible, whereas *Clostridium* spp. have been reported as anaerobic pathogens in cases of osteomyelitis of the long bones following fracture or trauma. Fusobacteria have been isolated in pure culture from sites of osteomyelitis adjacent to the perinasal sinuses. *Peptostreptococcus* spp. and microaerophilic cocci have been reported as significant pathogens in infections involving the skull, mastoid, and prosthetic implants placed in bone. In patients with osteomyelitis (Chap. 129), the most reliable culture specimen is a bone biopsy sample free of normal uninfected skin and subcutaneous tissue. In patients with anaerobic osteomyelitis, a mixed flora is frequently isolated from a bone biopsy specimen.

In cases of anaerobic septic arthritis, the most common isolates are *Fusobacterium* spp. Most of the patients involved have uncontrolled peritonsillar infections progressing to septic cervical venous thrombophlebitis and resulting in hematogenous dissemination with a predilection for the joints. Unlike anaerobic osteomyelitis, anaerobic pyoarthritis in most cases is not polymicrobial and may be acquired hematogenously. Anaerobes are important pathogens in infections involving prosthetic joints; in these infections, the causative organisms (such as *Peptostreptococcus* spp. and *P. acnes*) are part of the normal skin flora.

Bacteremia Transient bacteremia is a well-known event in healthy people whose anatomic mucosal barriers have been injured (e.g., during dental extractions or dental scaling). These bacteremic episodes, which are often due to anaerobes, have no pathologic consequences. However, anaerobic bacteria are found in cultures of blood from clinically ill patients when proper culture techniques are used. *B. fragilis* is the single most common anaerobic isolate from the bloodstream.

In recent years, the rate of isolation of anaerobic bacteria from blood cultures has been decreasing. Studies from the 1970s and early 1980s found that 10 to 15% of positive blood cultures yielded anaerobes, while more recent surveys have found rates as low as 4%. The cause of this change is unknown but may be related to the administration of antibiotic prophylaxis before intestinal surgery, the earlier recognition of localized infections, and the empirical use of broad-spectrum antibiotics for presumed infection.

Once the organism has been identified, both the portal of bloodstream entry and the underlying problem that probably led to seeding of the bloodstream can often be deduced from an understanding of the organism's normal site of residence. For example, mixed anaerobic bacteremia including *B. fragilis* usually implies colonic pathology with mucosal disruption from neoplasia, diverticulitis, or some other inflammatory lesion. The initial manifestations are determined by the portal of entry and reflect the localized condition. When bloodstream invasion occurs, patients can become extremely ill, with rigors and hectic fevers ranging up to 40.6°C (105°F). The clinical picture may be quite similar to that seen in sepsis involving aerobic gram-negative bacilli. Although other complications of anaerobic bacteremia, such as septic thrombophlebitis and septic shock, have been reported, the incidence of these complications in association with anaerobic bacteremia is low. Anaerobic bacteremia is potentially fatal and requires rapid diagnosis and appropriate therapy. Mortality appears to increase with the age of the patient (with reported rates of more than 66% among patients over 60 years old), with the isolation of multiple species from the bloodstream, and with the failure to surgically remove a focus of infection.

Endocarditis and Pericarditis (See also Chap. 126) Endocarditis due to anaerobes is uncommon. However, anaerobic streptococci, which are often classified incorrectly, are responsible for this disease more frequently than is generally appreciated. Gram-negative anaerobes are unusual causes of endocarditis. Anaerobes, particularly *B. fragilis* and *Peptostreptococcus* spp., are uncommonly found in infected pericardial fluids. Anaerobic pericarditis is associated with a mortality rate of>50%.

DIAGNOSIS

Because of the time and difficulty involved in the isolation of anaerobic bacteria, diagnosis of anaerobic infections must frequently be based on presumptive evidence. Certain sites (such as avascular necrotic tissues) with lowered oxidation-reduction potential favor the diagnosis of an anaerobic infection. When infections occur in proximity to mucosal surfaces normally harboring an anaerobic flora, such as the gastrointestinal tract, female genital tract, or oropharynx, anaerobes should be considered as potential etiologic agents. A foul odor is often indicative of anaerobes, which produce certain organic acids as they proliferate in necrotic tissue. Although these odors are nearly pathognomonic for anaerobic infection, the absence of odor does not exclude an anaerobic etiology. Because anaerobes often coexist with other bacteria to cause mixed or synergistic infection, Gram's staining of exudate frequently reveals numerous pleomorphic cocci and bacilli suggestive of anaerobes. Sometimes these organisms have morphologic characteristics associated with specific species.

The presence of gas in tissues is highly suggestive, but not diagnostic, of anaerobic

infection. When cultures of obviously infected sites yield no growth, streptococci only, or a single aerobic species (such as *Escherichia coli*) and Gram's staining reveals a mixed flora, the implication is that the anaerobic microorganisms failed to grow because of inadequate transport and/or culture techniques. Failure of a patient to respond to antibiotics that are not active against anaerobes -- for example, aminoglycosides and in some circumstances penicillin, cephalosporins, or tetracyclines -- suggests anaerobic infection.

There are three critical steps in the diagnosis of anaerobic infection: (1) proper specimen collection; (2) rapid transport of the specimens to the microbiology laboratory, preferably in anaerobic transport media; and (3) proper handling of the specimens by the laboratory. Specimens must be collected by meticulous sampling of infected sites, with avoidance of contamination by the normal flora. When such contamination is likely, the specimen is unacceptable. Examples of specimens unacceptable for anaerobic culture include sputum collected by expectoration or nasal tracheal suction, bronchoscopy specimens, samples collected directly through the vaginal vault, urine collected by voiding, and feces. Specimens that can be cultured for anaerobes include blood, pleural fluid, transtracheal aspirates, pus obtained by direct aspiration from an abscess cavity, fluid obtained by culdocentesis, suprapubic bladder aspirates, cerebrospinal fluid, and lung puncture specimens.

Because even brief exposure to oxygen may kill some anaerobic organisms and result in failure to isolate them in the laboratory, air must be expelled from the syringe used to aspirate the abscess cavity, and the needle must be capped with a sterile rubber stopper. Proper precautions should be used in the handling of contaminated needles. Specimens can be injected into transport bottles containing a reduced medium or taken immediately in syringes to the laboratory for direct culture on anaerobic media. In general, swabs should not be used. If a swab must be used, it should be placed in a reduced semisolid carrying medium before transport to the laboratory. Delays in transport may lead to a failure to isolate anaerobes due to exposure to oxygen or overgrowth of facultative organisms, which may eliminate or obscure any anaerobes that are present. All clinical specimens from suspected anaerobic infections should be Gram-stained and examined for organisms with characteristic morphology (Fig. 167-CD2). It is not unusual for organisms to be observed on Gram's staining but not isolated in culture. If purulent materials are found to be sterile or organisms are seen on Gram's staining but do not grow in the culture, the involvement of anaerobes should be suspected.

TREATMENT

Successful therapy for anaerobic infections requires the administration of a combination of appropriate antibiotics, surgical resection, debridement of devitalized tissues, and drainage. Perforations must be closed promptly, closed spaces drained, tissue compartments decompressed, and an adequate blood supply established. Abscess cavities should be drained as soon as fluctuation or localization occurs. Surgery was formerly required to establish drainage; however, computed tomography (CT), magnetic resonance imaging (MRI), and ultrasound now allow diagnostic radiologists to drain many abscess sites percutaneously.

Antibiotic Therapy and Resistance Decisions about the treatment of anaerobic infections with antibiotics are usually based on known resistance patterns in certain species, on the likelihood of encountering a given species in the case at hand, and on Gram's stain findings. Antibiotics active against *Bacteroides* spp., penicillin-resistant *Prevotella* and *Porphyromonas* spp., and *Fusobacterium* spp. can be grouped into four categories on the basis of their predicted activity against anaerobes (Table 167-1). (Nearly all the drugs listed have toxic side effects, which are described in detail inChap. 137.) In many infections, anaerobes are mixed with coliforms and other facultative organisms. The best therapeutic regimens, therefore, are usually those active against both aerobic and anaerobic bacteria. The choice of empirical antibiotics for the anaerobes in mixed infections can nearly always be made reliably, since patterns of antimicrobial susceptibility are usually predictable (Chap. 137 andTable 167-1).

Antibiotic susceptibility testing of anaerobic bacteria has been difficult and controversial. Owing to the slow growth rate of many anaerobes, the lack of standardized testing methods and of clinically relevant standards for resistance, and the generally good results obtained with empirical therapy, susceptibility testing has been recommended only for the study of local or regional resistance patterns, for the prediction of the efficacy of new antibiotics, and for the management of selected patients.

Anaerobic gram-negative rods that are frequently resistant to penicillin are listed inTable 167-2. Clinically important *Bacteroides* spp. are essentially all resistant to penicillin. Failures of therapy are common when documented *Bacteroides* (especially *B. fragilis*) infection is treated with penicillin or first-generation cephalosporins. The number of antimicrobial agents effective against *Bacteroides* spp. has expanded, and there are currently several useful choices (Table 167-1). In general, cure rates of>80% can be attained in patients with *Bacteroides* infection by means of appropriate antimicrobial therapy and drainage.

Resistance to metronidazole has been reported only rarely in *Bacteroides* spp. This well-tolerated drug, which reaches significant levels in serum and also can be found at high concentrations in abscess cavities, should be considered first-line therapy against *Bacteroides* infection. However, if metronidazole is used to treat mixed anaerobic and aerobic infections, it is imperative that other appropriate antibiotics be used in conjunction. Metronidazole is inactive against aerobic and facultative bacteria, *Actinomyces* spp., and *Propionibacterium* spp. The sensitivity of peptostreptococci to metronidazole is unpredictable, and penicillin remains the drug of choice.

If a patient fails to respond to one of the group 1 or group 2 drugs (Table 167-1), consideration should be given to alternative therapy and to determination of the resistance patterns among *Bacteroides* isolates. Although in vitro resistance of *Bacteroides* spp. to chloramphenicol has not been reported, this drug may not be as effective as other group 1 drugs. Ampicillin/sulbactam, ticarcillin/clavulanic acid, piperacillin/tazobactam, imipenem, and meropenem have been effective in the treatment of *B. fragilis* infection. Some newer fluoroquinolones, such as clinafloxacin, appear to be highly active against most anaerobes, including *B. fragilis*; however, ciprofloxacin and other earlier-generation quinolones should not be used as primary agents.

Treatment of Infections at Specific Sites In clinical situations, specific regimens must be tailored to the initial site of infection. The duration of therapy also depends on the infection site; the reader is referred to specific chapters on sites of infection for recommendations.

b-Lactamase production has been reported in anaerobic strains that are usually isolated from infections originating above the diaphragm. Up to 60% of clinical isolates classified as *Prevotella* or *Porphyromonas* spp., non-*B. fragilis* species of *Bacteroides*, or *Fusobacterium* spp. reportedly produceb-lactamase (Table 167-2). The clinical significance of resistance in these organisms has been suggested by studies showing clindamycin to be superior to penicillin (which for many years was considered the therapeutic gold standard) for the treatment of lung abscesses. Presumably, the success of clindamycin is attributable to a broader spectrum of activity against oral anaerobes; thus, a combination of penicillin and metronidazole or another antibiotic combination that is active against both oral anaerobes and aerobes is likely to be as effective as clindamycin. Bronchoscopy in lung abscess is indicated only to rule out airway obstruction and does not enhance drainage; in any event, it should be delayed until the antimicrobial regimen has begun to affect the disease process so that the procedure does not spread the infection. Surgery is almost never indicated because of the danger of spilling the abscess contents into the lungs.

Although most oral anaerobic infections and most cases of anaerobic pneumonia still respond to penicillin therapy, some infections due to oral organisms fail to respond to this drug, and in these cases the use of a drug that is effective against penicillin-resistant anaerobes is recommended (Table 167-1). Life-threatening infections involving the anaerobic flora of the mouth, such as space infections of the head and neck, should be treated empirically as if penicillin-resistant anaerobes are involved. Less serious infections involving the oral microflora can be treated with penicillin alone; metronidazole can be added (or clindamycin can be substituted) if the patient responds poorly to penicillin therapy. Combinations of antibiotics used to treat mixed infections of oral origin must include drugs active against the gram-positive aerobic flora of the mouth.

Chloramphenicol has been used successfully against anaerobic central nervous system infections at doses of 30 to 60 mg/kg per day, with the exact dose depending on the severity of illness. However, penicillin G and metronidazole also cross the blood-brain barrier and are bactericidal for many anaerobic organisms (Chap. 372).

Anaerobic infections arising below the diaphragm (e.g., colonic and intraabdominal infections) must be treated specifically with agents active against *Bacteroides* spp. (see Table 167-1). In intraabdominal sepsis (Chap. 130), the use of antibiotics effective against penicillin-resistant anaerobes has clearly reduced the incidence of postoperative infections and serious infectious complications. Specifically, a drug from group 1 (Table 167-1) must be included for broad-spectrum coverage. Recommended doses for commonly used group 1 drugs are given inTable 167-3. Therapy for intraabdominal sepsis also must include drugs active against the gram-negative aerobic flora of the bowel. If the involvement of gram-positive bacteria such as enterococci is suspected, either ampicillin or vancomycin should be added.

Cases of anaerobic osteomyelitis in which a mixed flora is isolated from a bone biopsy specimen should be treated with a regimen that covers all the isolates. When an anaerobic organism is recognized as a major or sole pathogen infecting a joint, the duration of treatment should be similar to that used for arthritis caused by aerobic bacteria (Chap. 323). Therapy includes the management of underlying disease states, the administration of appropriate antimicrobial agents, temporary joint immobilization, percutaneous drainage of effusions, and usually the removal of infected prostheses or internal fixation devices. Surgical drainage and debridement procedures such as sequestrectomy are essential for the removal of necrotic tissue that can sustain anaerobic infections.

The outcome of anaerobic bacteremia has been shown to be significantly better in patients either initially given or switched to appropriate therapy based on known antibiotic susceptibilities.

Failure of Therapy Anaerobic infections that fail to respond to treatment or that relapse should be reassessed. Consideration should be given to additional surgical drainage or debridement. Superinfections with resistant gram-negative facultative or aerobic bacteria should be ruled out. The possibility of drug resistance must be entertained; if resistance is involved, repeated cultures may yield the pathogenic organism.

Supportive Measures Other supportive measures in the management of anaerobic infections include careful attention to fluid and electrolyte balance (since extensive local edema may lead to hypoalbuminemia); hemodynamic support for septic shock; immobilization of infected extremities; maintenance of adequate nutrition during chronic infections by parenteral hyperalimentation; relief of pain; and anticoagulation with heparin for thrombophlebitis. For patients with severe anaerobic infections of soft tissues, hyperbaric oxygen therapy is advocated by some experts, but its value has not been proven in controlled trials.

SECTION 8 -MYCOBACTERIAL DISEASES

168. ANTIMYCOBACTERIAL AGENTS - *Paul W. Wright*, *Richard J. Wallace, Jr.*

The physician is greatly challenged to provide optimal therapy for mycobacterial illnesses because of the advent of AIDS, the increase in both drug-susceptible and multidrug-resistant tuberculosis, and the plethora of new antibiotics with antimycobacterial potential. This chapter reviews the agents used for the treatment of tuberculosis, leprosy (Hansen's disease), and diseases caused by pathogenic nontuberculous mycobacteria, including *Mycobacterium avium-intracellulare*, *M. kansasii*, the rapidly growing mycobacteria, and *M. marinum*. The use of antimycobacterial agents in patients with renal or hepatic disease and in pregnant women is summarized inTable 168-1. The effects of major antimycobacterial agents on the levels, activity, and toxicity of other commonly used drugs are summarized in Table 168-2.

TUBERCULOSIS

Drugs used to treat tuberculosis are classified as first-line and second-line agents. *First-line essential* antituberculous agents are the most effective and are a necessary component of any short-course therapeutic regimen. The three drugs in this category are rifampin, isoniazid, and pyrazinamide. The *first-line supplemental* agents, which are highly effective and infrequently toxic, include ethambutol and streptomycin. *Second-line* antituberculous drugs are clinically much less effective than first-line agents and much more frequently elicit severe reactions. These drugs are rarely used in therapy and then only by caregivers experienced with their use. They include para-aminosalicylic acid (PAS), ethionamide, cycloserine, kanamycin, amikacin, capreomycin, viomycin, and thiacetazone. *Newer* antituberculous drugs, which have not yet been placed in the above categories, include rifapentine, rifabutin, and the quinolones, especially ciprofloxacin, ofloxacin, and sparfloxacin.

FIRST-LINE ESSENTIAL DRUGS

Rifampin Rifampin, a semisynthetic derivative of *Streptomyces mediterranei*, is considered the most important and potent antituberculous agent. It is also active against a wide spectrum of other organisms, including some gram-positive and gram-negative bacteria, *Legionella* spp., *M. kansasii*, and *M. marinum*.

Pharmacology Rifampin is a fat-soluble complex macrocyclic antibiotic that is absorbed readily after either oral or intravenous administration. Serum levels of 10 to 20 ug/mL follow a standard oral dose of 600 mg. Rifampin distributes well throughout most body tissues, including inflamed meninges. The fact that rifampin turns body fluids (urine, saliva, sputum, tears) to a red-orange color makes it simple and inexpensive to check on a patient's compliance with therapy. Rifampin is excreted primarily through the bile and the enterohepatic circulation, while 30 to 40% of a dose is excreted via the kidneys. The drug is administered either twice weekly or daily at a dose of 600 mg for adults (10 mg/kg) and 10 to 20 mg/kg for children.

Mechanism of action Rifampin has both intracellular and extracellular bactericidal

activity. It blocks RNA synthesis by specifically binding and inhibiting DNA-dependent RNA polymerase. Susceptible strains of *M. tuberculosis* as well as *M. kansasii* and *M. marinum* are inhibited by£1 ug/mL.

Adverse effects (Table 168-3) Rifampin is generally well tolerated; the most common adverse event is gastrointestinal upset. Patients with chronic liver disease, especially those with alcoholism and the elderly, appear to be at unusually high risk for the most serious adverse reaction: hepatitis. Other adverse effects of rifampin include rash (0.8%), hemolytic anemia (<1%), thrombocytopenia, and immunosuppression of unknown clinical importance. Rifampin is a potent inducer of the hepatic microsomal enzymes and thereby decreases the half-life of a number of drugs, including digoxin, warfarin, prednisone, cyclosporine, methadone, oral contraceptives, clarithromycin, the HIV protease inhibitors, and quinidine (Table 168-2).

Resistance Resistance to rifampin results from spontaneous point mutations that alter theb subunit of the RNA polymerase (*rpoB*) gene. Studies have shown that 96% of rifampin-resistant strains have a missense mutation within a 91-bp central core region of the gene. Rifampin-resistant strains of *M. leprae* have similar mutations that alter a single serine residue (Ser-425) in the same core region of the *rpoB* gene.

Isoniazid Now considered the best antituberculous drug available after rifampin, isoniazid should be included in all tuberculosis treatment regimens unless the organism is resistant. Isoniazid is inexpensive, readily synthesized, available worldwide, highly selective for mycobacteria, and well tolerated, with only 5% of patients exhibiting adverse effects.

Mechanism of Action Isoniazid is the hydrazide of isonicotinic acid, a small water-soluble molecule that easily penetrates the cell. Its mechanism of action involves inhibition of mycolic acid cell-wall synthesis via oxygen-dependent pathways such as the catalase-peroxidase reaction. Isoniazid is bacteriostatic against resting bacilli and bactericidal against rapidly multiplying organisms, both extracellularly and intracellularly. The minimal inhibitory concentrations (MICs) of isoniazid for wild-type (untreated) strains of *M. tuberculosis* are <0.1 ug/mL, while those for *M. kansasii* are usually 0.5 to 2.0 ug/mL. The MICs of this drug for other mycobacteria are much higher.

Pharmacology Both oral and intramuscular preparations of isoniazid are readily absorbed. A 300-mg oral dose generally produces peak serum levels of 3 to 5 ug/mL. Isoniazid diffuses well throughout the body and reaches therapeutic concentrations in serum, cerebrospinal fluid (CSF), and infected tissue, including caseous granulomas. Isoniazid is metabolized in the liver via acetylation and hydrolysis; its metabolites are excreted into the urine. The rate of acetylation is genetically controlled. The recommended daily dose for the treatment of tuberculosis in the United States is 5 mg/kg for adults and 10 to 20 mg/kg for children, with a maximal daily dose of 300 mg for both groups. (Tuberculosis organizations outside the United States have recommended 5 mg/kg daily for both groups.) For intermittent therapy (usually directly observed), a maximal dose of 900 mg twice or thrice weekly is used. Even in moderate or severe renal failure, the adult dose rarely needs to be reduced below 200 mg/d.

Adverse Effects (Table 168-3) The two most important adverse effects of isoniazid

therapy are hepatotoxicity and peripheral neuropathy. Other adverse reactions are either rare or less significant and include rash (2%), fever (1.2%), anemia, acne, arthritic symptoms, a systemic lupus erythematosus-like syndrome, optic atrophy, seizures, and psychiatric symptoms. Isoniazid-associated hepatitis is idiosyncratic and increases in incidence with age. It occurs in 0.3% of treated persons under 35 years of age, 1.2% of those under 49 years of age, and 2.3% of those over 50 years of age. The risk of isoniazid-associated hepatitis is increased by daily alcohol consumption, concomitant rifampin administration, and slow isoniazid acetylation. Mortality rates from isoniazid-induced hepatitis have been reported to be 6 to 12%, but the real risk is certainly much lower: the reported rates were documented in high-risk patients who continued to take the drug despite progressive symptoms of hepatitis and without monitoring of liver enzyme levels. Liver enzymes are monitored in most settings among high-risk patients, and administration of the drug is discontinued at the onset of hepatitis. The American Thoracic Society (ATS) recommends that serum concentrations of aspartate aminotransferase (AST) or alanine aminotransferase (ALT) be determined at baseline in patients over 35 years of age who are receiving isoniazid for chemoprophylaxis, with monthly determinations thereafter. The benefit of such routine monitoring remains controversial, however. Measurement of the ALT or AST level is certainly mandatory whenever a patient notices the onset of symptoms suggestive of isoniazid-associated hepatitis (e.g., fever, anorexia, nausea, vomiting, and/or a flulike syndrome including fever and myalgias), and treatment should be discontinued until the relationship between therapy and symptoms is ascertained. Several studies have demonstrated that many patients with isoniazid intolerance can be desensitized. The ATS also recommends that discontinuation of isoniazid be strongly considered whenever an asymptomatic AST or ALT level exceeds 150 to 200 IU (three to five times the upper limit of normal) in high-risk patients whose baseline values were normal. In one study, only 11 (0.1%) of 11,141 patients had hepatotoxic reactions to isoniazid during preventive treatment.

Peripheral neuritis associated with isoniazid develops at a dose-dependent rate of 2 to 20% and probably relates to interference with pyridoxine (vitamin B_6) metabolism. This rate can be reduced to 0.2% with the prophylactic administration of 10 to 50 mg of pyridoxine daily.

Resistance Isoniazid-resistant mutants of *M. tuberculosis* occur spontaneously at a rate of 1 in 10^5 to 10^6organisms. The molecular sites of isoniazid resistance have been detailed. Almost all isoniazid-resistant strains have amino acid changes in the catalase-peroxidase gene (*katG*) or a two-gene locus known as *inhA*. Missense mutations or deletion of *katG* is also associated with reduced catalase and peroxidase activity. Primary isoniazid resistance is detected in 7% of untreated patients in native U.S. populations, but the percentage is much higher in many immigrant populations.

Pyrazinamide A derivative of nicotinic acid, pyrazinamide is an important bactericidal drug used in short-course therapy for tuberculosis.

Pharmacology Pyrazinamide is well absorbed after oral administration, with a plasma concentration range of 20 to 60 ug/mL 1 to 2 h after oral ingestion of 15 to 30 mg/kg, and is well distributed throughout the body. Levels in CSF are excellent, reaching 50 to 100% of levels in serum. The serum half-life of the drug is 9 to 11 h. Pyrazinamide is

metabolized by at least two major pathways and one minor pathway in the liver; its several metabolites include pyrazinoic acid, 5-hydroxypyrazinamide, and 5-hydroxypyrazinoic acid.

Mechanism of Action Pyrazinamide is similar to isoniazid in its narrow spectrum of antibacterial activity, which essentially includes only *M. tuberculosis*. The drug is bactericidal to slowly metabolizing organisms located within the acidic environment of the phagocyte or caseous granuloma; it is active only at a pH of<6.0. Pyrazinamide is considered a prodrug and is converted by the tubercle bacillus to the active form pyrazinoic acid. The target for this compound, however, remains unknown. Susceptible strains of *M. tuberculosis* are inhibited by 20 ug/mL.

Adverse Effects (Table 168-3) At the high dosages used in the past, hepatotoxicity was a prominent complication of pyrazinamide therapy. However, at the currently recommended daily dosage of 15 to 30 mg/kg, with a maximum of 2 g (which can be given in one dose), the frequency of hepatotoxicity is no higher than that for concomitant isoniazid and rifampin therapy. Although pyrazinamide is recommended by international tuberculosis organizations for routine use in pregnancy, it is not recommended in the United States because of inadequate teratogenicity data. Hyperuricemia is a common adverse effect of pyrazinamide therapy whose incidence is probably reduced by concurrent rifampin therapy. Clinical gout is seen only rarely. Polyarthralgias are encountered fairly commonly but are not related to hyperuricemia.

Resistance Resistance to pyrazinamide is associated with loss of pyrazinamidase activity such that pyrazinamide is no longer converted to pyrazinoic acid. More than 90% of isolates withMICs of>100 ug/mL have mutations in the *pncA* gene, which encodes for pyrazinamidase. All strains of *M. bovis* are naturally resistant to pyrazinamide and have a point mutation within the *pncA* gene.

FIRST-LINE SUPPLEMENTAL DRUGS

Ethambutol A derivative of ethylenediamine, ethambutol is a water-soluble compound that is active only against mycobacteria. Susceptible species include *M. tuberculosis*, *M. marinum*, *M. kansasii*, and *M. avium-intracellulare* (MAI). Among first-line drugs, ethambutol is the least potent against *M. tuberculosis*. It is used most often with rifampin for the treatment of tuberculosis in patients who cannot tolerate isoniazid or who are thought or known to be infected with isoniazid-resistant organisms.

Mechanism of Action Ethambutol is bacteriostatic against rapidly growing mycobacteria. Its primary mechanism of action appears to be inhibition of arabinosyltransferases that mediate the polymerization of arabinose into arabinogalactan within the cell wall.

Pharmacology After oral administration, 75 to 80% of a dose of ethambutol is absorbed from the gastrointestinal tract. Serum levels peak at 2 to 4 ug/mL 2 to 4 h after a dose of 15 mg/kg. The drug's distribution throughout the body is adequate except in the CSF, where it reaches only low levels. However, ethambutol can reach CSF levels up to 50% as high as peak plasma levels when administered at a daily dose of 25 mg/kg to a patient with inflamed meninges. Almost all of the dose is excreted by the kidneys within 24 h of ingestion, either unchanged or as metabolites. The usual daily adult dosage of

ethambutol is 25 mg/kg (which may be given in one dose) for the first 2 months, with a subsequent reduction to 15 mg/kg. In cases where pretreatment is necessary, the higher dose may be given for the duration. For intermittent therapy, the dosage is 50 mg/kg twice weekly or 30 mg/kg three times weekly. The dosage must be lowered for patients with renal insufficiency (a creatinine clearance rate of <25 mL/min) to prevent drug accumulation and toxicity.

Adverse Effects (Table 168-3) Ethambutol is usually well tolerated. Retrobulbar optic neuritis is the most serious adverse effect; axial or central neuritis -- the only form reported in patients taking daily doses of <30 mg/kg -- involves the papillomacular bundle of fibers and results in reduced visual acuity, central scotoma, and loss of the ability to see green. Symptoms of ocular toxicity typically develop several months after the initiation of therapy, but rapid-onset optic neuritis has been reported. The risk of optic neuritis depends on the dose and duration of therapy: this reaction develops in 5% of patients receiving a daily dose of 25 mg/kg but in fewer than 1% of patients given a daily dose of 15 mg/kg. Patients taking the lower dose should be tested at baseline and whenever there is a subjective visual change for visual acuity and red-green color discrimination. Patients taking the higher dose should be tested at baseline, monthly thereafter, and whenever there is a subjective visual change. Optic neuritis with associated visual loss is usually reversible, but recovery may take 6 months or longer.

Other adverse effects of ethambutol are infrequent. Hyperuricemia occurs but is usually asymptomatic. Optic neuritis is rare at the low dose in children; however, the use of ethambutol in very young children is problematic because visual complications are difficult to monitor.

Resistance Resistance in *M. tuberculosis* relates to missense mutations in the *embB* gene that encodes for arabinosyltransferase. Such mutations have been found in 70% of resistant strains and involve amino acid residue 306 in approximately 90% of cases. Species of nontuberculous mycobacteria that are intrinsically resistant to ethambutol have variant amino acids in this region of the gene, while susceptible species have the same amino acid sequences as *M. tuberculosis*.

Streptomycin An aminoglycoside isolated from *Streptomyces griseus*, streptomycin is available for intramuscular and intravenous administration only. In the United States, it is the least-used first-line supplemental drug for tuberculosis because of its toxicity, the difficulty in obtaining adequateCSFlevels, and the inconvenience of its parenteral administration. In developing countries, however, streptomycin is frequently used because of its low cost. The drug is active against untreated strains of *M. tuberculosis*, *M. kansasii*, and *M. marinum* and against some strains ofMAI at readily achievable serum levels.

Pharmacology Serum levels of streptomycin peak at 25 to 40 ug/mL after a 1.0-g dose. Streptomycin is bactericidal for rapidly dividing extracellular mycobacteria but is ineffective in the acidic environment within the macrophage. It diffuses poorly into the meninges and, in patients with meningitis, reachesCSFlevels that are only 20% of serum levels.

The usual adult dose of streptomycin is 0.5 to 1.0 g (10 to 15 mg/kg) daily or five times

per week; the pediatric dose is 20 to 40 mg/kg daily, with a maximum of 1 g/d. Because streptomycin is eliminated almost exclusively by the kidneys, the dosage must be lowered and the frequency of administration reduced (to only two or three times per week) in most patients over 50 years of age and in any patient with renal impairment.

Mechanism of Action Streptomycin inhibits protein synthesis by disruption of ribosomal function.

Adverse Effects (Table 168-3) Adverse reactions to streptomycin therapy occur in 10 to 20% of patients. Ototoxicity and renal toxicity are the most common and the most serious. Renal toxicity, usually manifested as nonoliguric renal failure, is less common with streptomycin than with other frequently used aminoglycosides, such as gentamicin. Ototoxicity involves both hearing loss and vestibular dysfunction. The latter is more common and includes loss of balance, vertigo, and tinnitus. Patients receiving streptomycin must be monitored carefully for these adverse effects. Less serious reactions include perioral paresthesia, eosinophilia, rash, and drug fever.

Resistance Spontaneous resistance to streptomycin occurs in 1 in 10^5 to 10^7 organisms. In two-thirds of streptomycin-resistant strains of *M. tuberculosis*, mutations have been identified in one of two targets: a 16S rRNA gene (*rrs*) and the gene encoding ribosomal protein S12 (*rpsL*). Both targets are believed to be involved in streptomycin ribosomal binding. No mutational change has been identified in the other one-third of resistant isolates. Strains of *M. tuberculosis* that are resistant to streptomycin are not cross-resistant to capreomycin or amikacin.

SECOND-LINE DRUGS

Second-line and/or newer antituberculous agents are used either when tuberculosis is drug resistant or when first-line supplemental drugs are not available. The most important second-line drugs are discussed below in the general (descending) order of usefulness.

Capreomycin Capreomycin, a complex cyclic polypeptide antibiotic derived from *Streptomyces capreolus*, is similar to streptomycin in terms of dosing, mechanism of action, pharmacology, and toxicity. It is administered only by the intramuscular route in doses of 10 to 15 mg/kg daily or five times per week (maximal daily dose, 1 g), with peak blood levels of 20 to 40 ug/mL. After 2 to 4 months, the dosage should be reduced to 1 g two or three times a week. Cross-resistance to kanamycin and amikacin -- but not to streptomycin -- is common. After streptomycin, capreomycin is the injectable drug of choice for tuberculosis.

Amikacin and Kanamycin These well-known aminoglycosides are bactericidal to extracellular organisms. Kanamycin is rarely used because of its toxicity. Amikacin is active against *M. tuberculosis* and several of the nontuberculous species, including the rapidly growing mycobacteria, *M. scrofulaceum*, *M. leprae*, and *MAI*. The usual adult dosage is 10 to 15 mg/kg intramuscularly or intravenously three to five times per week. Resistance to both drugs relates to a single-base-pair change at position 1408 in the 16S ribosomal RNA gene.

Para-Aminosalicylic Acid PAS, a calcium or sodium salt that inhibits the growth of *M. tuberculosis* by impairing folate synthesis, is rarely indicated for the treatment of tuberculosis because of its low level of antituberculous activity and its high level of gastrointestinal toxicity (manifesting as nausea, vomiting, and diarrhea). Enteric-coated PAS granules (4 g every 8 h) may be better tolerated than other formulations and produce higher therapeutic blood levels. PAS is well absorbed after oral administration but reaches only low concentrations in theCSF. The drug has a short half-life (1 h), and 80% of the dose is excreted in the urine.

Thiacetazone Also called amithiozone, thiacetazone is not available in the United States but -- because it is inexpensive and readily available -- is widely used in the developing world as a single-tablet combination with isoniazid to treat tuberculosis. The usual daily dosage is 150 mg. Thiacetazone is structurally related to isoniazid but is bacteriostatic and more toxic. The World Health Organization advises against the use of thiacetazone by HIV-infected patients because of an unacceptably high rate of severe adverse (gastrointestinal) and fatal (skin) reactions.

Viomycin A complex basic polypeptide antibiotic, viomycin has properties similar to those of capreomycin, amikacin, and kanamycin and must be administered by intramuscular injection. Ninety percent of strains of multidrug-resistant *M. tuberculosis* are inhibited by viomycin levels of 1 to 10 ug/mL. Toxic effects are more common and severe than with other polypeptide antibiotics. This drug is not available in the United States.

Ethionamide Like isoniazid and pyrazinamide, ethionamide is a derivative of isonicotinic acid. This agent is bacteriostatic against metabolizing *M. tuberculosis* and some nontuberculous mycobacteria. It is most useful in therapy for multidrug-resistant tuberculosis. However, its use is severely limited by its toxicity and frequent side effects, which include intense gastrointestinal intolerance (anorexia, vomiting, and dysgeusia), serious neurologic reactions, reversible hepatitis (5% of cases), hypersensitivity reactions, and hypothyroidism. Ethionamide is well absorbed orally and is widely distributed throughout the body at sites including theCSF.

Cycloserine Cycloserine (D-4-amino-3-isoxazolidinone) is produced by *Streptomyces orchidaceus* and is active against a broad spectrum of bacteria, including *M. tuberculosis*. Cycloserine is well absorbed after oral administration and is widely distributed throughout the body fluids, including theCSF. Serious side effects limit the use of this drug and include psychosis (with suicide in some cases), seizures, peripheral neuropathy, headaches, somnolence, and allergic reactions. Cycloserine should not be given to patients with epilepsy, active alcohol abuse, severe renal insufficiency, or a history of depression or psychosis.

Newer Antituberculous Drugs A number of other drugs are being evaluated for their antituberculous activity. This group includes rifabutin, rifapentine, the newer fluorinated quinolones, amoxicillin/clavulanic acid, clofazimine, clarithromycin, and rifamycins not yet approved by the U.S. Food and Drug Administration (FDA), such as KRM-1648 (benzoxazinorifamycin).

Rifabutin Rifabutin, a semisynthetic rifamycin spiropiperidyl derivative, shares many

characteristics with rifampin, including activity against *M. tuberculosis*. Rifabutin is also active against some strains of rifampin-resistant *M. tuberculosis* and is more active than rifampin againstMAI and other nontuberculous mycobacteria. To date, rifabutin has been most useful in the prophylaxis of disseminated MAI infection and in the treatment of drug-resistant tuberculosis. Because it seems to exhibit more antituberculous activity than rifampin in vitro and in animals, its possible clinical advantages over rifampin are being evaluated. In a multinational trial in which either rifampin (600 mg/d) or rifabutin (150 mg/d) was administered in combination with isoniazid plus a 2-month regimen of pyrazinamide and ethambutol, the two rifamycins were equally effective and well tolerated in the treatment of newly diagnosed pulmonary tuberculosis. Rifabutin is recommended in place of rifampin for the treatment of HIV-positive individuals who are also taking a protease inhibitor.

PHARMACOLOGY The pharmacology of rifabutin is dramatically different from that of rifampin. Rifabutin is readily absorbed after a single oral dose of 300 mg and reaches peak serum levels (0.35 ug/mL) in 2 to 4 h. This lipophilic drug distributes best to tissues: tissue levels are 5 to 10 times higher than plasma levels.CSFconcentrations are 30 to 70% of plasma levels in HIV-infected patients who have meningitis. The drug's slow clearance via hepatic metabolism and renal excretion results in a mean serum half-life of 45 h, which is much longer than the 3- to 5-h half-life of rifampin. Clarithromycin (but not azithromycin) and fluconazole appear to block the hepatic metabolism of rifabutin, with consequent increases in serum levels. When rifabutin is administered orally with food, its rate of absorption is slowed, but the extent of its absorption is unchanged. Adjustment of dosage is usually unnecessary in elderly patients and in patients with reduced hepatic or renal function.

MECHANISM OF ACTION In *Escherichia coli* and *Bacillus subtilis*, rifabutin inhibits DNA-dependent RNA polymerase in the same manner as rifampin. Its mode of action against mycobacteria is believed to be the same.

ADVERSE EFFECTS Most adverse effects of rifabutin are dose related and occur most frequently in patients receiving >300 mg/d. Discontinuation of therapy because of adverse drug reactions is reported in 16% of patients receiving rifabutin as opposed to 8% of those receiving a placebo. The most common symptoms are gastrointestinal; other reactions include rash, headache, asthenia, chest pain, myalgia, and insomnia. Like those taking rifampin, most patients taking rifabutin have discolored (orange to tan) urine and other body fluids. Less common adverse reactions include fever, chills, a flulike syndrome, hepatitis, *Clostridium difficile*-associated diarrhea, and a yellow skin discoloration ("pseudojaundice"). After a rifabutin dose of 450 to 600 mg in combination with clarithromycin, anterior uveitis is reported in up to 40% of patients; also common at these high doses are hyperpigmentation and the polymyalgia/arthralgia syndrome. All of these conditions are reversible when treatment is discontinued. Laboratory abnormalities include neutropenia, leukopenia, thrombocytopenia, and increased levels of liver enzymes.

Rifabutin induces the hepatic cytochrome P450 enzymes but does so much less strongly than rifampin. Drugs whose metabolism is enhanced by rifabutin include anticoagulants, quinidine, oral contraceptives, sulfonylureas, analgesics, dapsone, narcotics, glucocorticoids, clarithromycin, zidovudine, and cardiac glycosides.

RESISTANCE Resistance to rifabutin is attributable to the same mechanism as that to rifampin -- i.e., mutations involving the *rpoB* gene. However, of the 14 mutant *rpoB* alleles that confer resistance to rifampin, only nine confer high-level resistance to rifabutin, while the remaining five result in only small changes in rifabutinMICs, which remain £0.5 ug/mL. The MIC of rifabutin for susceptible strains of *M. tuberculosis* is low (<0.06 ug/mL), and the drug is considered clinically active against partially resistant strains that are inhibited by plasma levels of £0.5 ug/mL. Thus rifabutin inhibits about one-quarter of rifampin-resistant strains of *M. tuberculosis*.

Rifapentine A semisynthetic cyclopentyl rifamycin antibiotic, rifapentine has received accelerated approval from theFDA for the treatment of tuberculosis. It is the first new drug approved for tuberculosis in 25 years in the United States. While similar to rifampin, rifapentine is lipophilic and longer acting -- characteristics that enhance patient compliance; the drug can be administered at a dose of 600 mg once or twice weekly. It has antibacterial activity against *M. tuberculosis* but has undergone only minimal testing against nontuberculous mycobacteria. Rifapentine has not yet been approved for the treatment of patients with HIV disease because rifapentine/rifampin monoresistance frequently develops in HIV-positive patients receiving isoniazid plus rifapentine. Like rifampin, rifapentine is active against many nonmycobacterial organisms, including *Haemophilus influenzae*, *Bordetella pertussis*, *B. parapertussis*, *Brucella* spp., *Legionella* spp., *Neisseria* spp., streptococci, and staphylococci.

In a randomized comparative study, 672 Chinese patients received isoniazid plus either rifapentine or rifampin. The isoniazid/rifapentine group had a higher relapse rate (10% versus 5%) than the isoniazid/rifampin group. Nevertheless, this disadvantage was considered acceptable in light of the lower rate of adverse effects and less frequent administration in the isoniazid/rifapentine group.

PHARMACOLOGY Food enhances the oral absorption of rifapentine, while antacids impair its absorption. After oral administration with food, this drug reaches peak serum concentrations in 5 to 6 h and achieves a steady state in 10 days. The half-life of rifapentine and its active metabolite 25-desacetyl rifapentine is approximately 13 h. The drug is highly bound to serum protein (93 to 97%), and most of the administered dose is excreted via the liver (70%). Oral clearance is more rapid in males than in females (2.51 vs 1.69 L/h), but the clinical significance of this difference is unknown.

MECHANISM OF ACTION Rifapentine exerts its bactericidal effect by inhibiting DNA-dependent RNA polymerase in susceptible bacteria. TheMICs of rifapentine for rifampin-susceptible strains of *M. tuberculosis* range from 0.03 to 0.12 ug/mL.

ADVERSE EFFECTS Rifapentine demonstrates an adverse-event pattern similar to that of rifampin. Both drugs are frequently associated with hyperuricemia when administered with pyrazinamide and with elevated hepatocellular enzyme levels in 3 to 4% of patients when administered with other antituberculous agents. Liver enzyme levels should be monitored in patients receiving rifapentine who already have elevated liver enzyme concentrations or known liver disease. Like rifampin, rifapentine causes an orange-red discoloration of body fluids, including urine, saliva, and tears, and stains contact lenses.

Rifapentine induces the hepatic cytochrome P450 enzymes CYP3A4 and 2C8/9. Current induction studies suggest that its potential for drug-drug interaction may be less than that of rifampin but greater than that of rifabutin. Other drugs potentially affected by concomitant administration of rifapentine are listed inTable 168-2.

Rifapentine is in category C for use in pregnancy (Table 168-1) because of its teratogenesis in rats and rabbits. There are insufficient data concerning use of this drug in pregnant and breast-feeding patients.

RESISTANCE Strains of *M. tuberculosis* resistant to rifapentine, rifampin, and rifabutin all involve spontaneous point mutations in the *rpoB* gene. All strains resistant to rifampin are also resistant to rifapentine.

Quinolones A surprisingly large number of fluorinated quinolones are being developed and studied as inhibitors of mycobacteria. Their mode of action presumably is the prevention of DNA synthesis through the inhibition of DNA gyrase. Ofloxacin, ciprofloxacin, sparfloxacin, and pefloxacin are active against many mycobacteria, including *M. tuberculosis*, *M. leprae*, *M. marinum*, *M. kansasii*, and *M. fortuitum*. These drugs are well absorbed orally, reach high serum levels, and distribute well to body tissues and fluids. While not approved for antituberculous therapy in the United States, ofloxacin -- used in combination with isoniazid and rifampin for the treatment of pulmonary tuberculosis -- has been as active and safe as ethambutol in initial trials. Adverse effects are relatively uncommon, occurring in 0.5 to 10% of cases and consisting mostly of benign reactions such as gastrointestinal intolerance, rashes, dizziness, and headache. However, more serious adverse effects are being reported and include confusion, seizures, interstitial nephritis, skin vasculitis, and acute renal failure.

Mycobacterial resistance to the fluoroquinolones develops rapidly. Its molecular basis is complex; only some strains exhibit missense mutations in the A subunit (*gyrA* gene) of DNA gyrase. Fluoroquinolone-resistant tuberculosis is a source of growing concern: 22 such cases were reported recently from New York City. Antituberculous therapy with quinolones should be reserved for patients with multidrug resistance or those who cannot tolerate first-line drugs.

LEPROSY (HANSEN'S DISEASE)

Therapy for leprosy remains difficult, especially in developing countries, because of the long course required, the high cost and low availability of most drugs, the frequency of adverse reactions to drugs, the acquisition of drug resistance, the difficulty of determining a disease end point or cure, and (given that *M. leprae* still cannot be grown in vitro) the difficulty of conducting susceptibility testing. While many drugs are active against *M. leprae*, efficacy in the treatment of leprosy has been established only for dapsone, rifampin, clofazimine, and ethionamide.

Rifampin Rifampin is considered the most active agent for the treatment of leprosy. Its worldwide use is limited only by its cost. This drug is markedly bactericidal against *M. leprae* and reduces the number of viable bacilli in the patient's tissues faster than any other available agent. Rifampin must be combined with other antileprosy drugs to

forestall resistance. For cost reasons, the drug is given at a dose of 600 mg once a month (supervised) outside the United States, but it is given daily in the United States. For details on pharmacology, adverse events, and resistance, see relevant sections under "Tuberculosis."

Dapsone Dapsone (4,4¢-diaminodiphenylsulfone) inhibits bacterial folic acid synthesis. It is now considered the second drug of choice (after rifampin) in most cases of Hansen's disease because of its ready availability, low cost, and low toxicity and the susceptibility of untreated strains of *M. leprae* to very low concentrations.

Pharmacology Dapsone is well absorbed orally and distributes well throughout the body. The usual daily dosage is 100 mg for adults and 0.9 to 1.4 mg/kg for children. Plasma concentrations peak within 1 to 3 h. The median elimination half-life is 22 h. Dapsone is cleared by acetylation in the liver, with genetic variation similar to that documented for the acetylation of isoniazid. The drug is 70% bound to plasma protein. Usual daily doses produce serum concentrations of 10 to 15 ug/mL, which far exceed theMIC for *M. leprae* (0.01 to 0.001 ug/mL).

Adverse Effects Hemolysis and methemoglobinemia are common untoward reactions to dapsone. Patients should be screened for glucose-6-phosphate dehydrogenase deficiency to prevent drug-induced hemolysis. However, most patients tolerate dapsone therapy well with adequate clinical and laboratory supervision. Other side effects include gastrointestinal intolerance, headache, pruritus, peripheral neuropathies, nephritic syndrome, fever, and rash. In lepromatous and borderline lepromatous leprosy, erythema nodosum leprosum (ENL) may occur. This reaction may be difficult to distinguish from reactions of leprosy, including drug reactions and the infectious mononucleosis-like dapsone syndrome.

Clofazimine A phenazine iminoquinone dye, clofazimine is weakly bactericidal against *M. leprae*. It is useful in treating dapsone-resistant leprosy and may lessen the severity of ENL. Clofazimine's mode of action is not well understood, but the drug may inhibit DNA binding. It is absorbed orally and distributed to the fatty tissues and the reticuloendothelial system. Its serum half-life is about 60 to 70 days; only a small proportion of the dose is excreted daily into the urine or bile. Bactericidal activity is very slow and is evident for about 50 days after administration. The usual adult dosage is 50 to 100 mg/d, 100 mg three times a week, or (for treatment of ENL) 300 mg/d. Untoward effects include skin discoloration and, less commonly, gastrointestinal intolerance. Clofazimine was reported to be responsible for a case of cardiotoxicity induced via ventricular arrhythmia. Even though clofazimine-resistant disease has been reported only rarely when this agent is used alone, it should be used with other effective antibiotics. Clofazimine is active in vitro against some nontuberculous mycobacterial species, includingMAI, *M. kansasii*, *M. simiae*, and *M. abscessus*.

Ethionamide While ethionamide (250 mg/d) has not been approved by theFDA for the treatment of leprosy, it is sometimes used in the United States in combination with rifampin (600 mg/d) to treat dapsone-resistant leprosy in patients who cannot accept the skin-depigmentation effect of clofazimine. Because resistance to ethionamide develops quickly when the drug is used alone, it must be used with other effective agents. Patients should be monitored closely for hepatotoxicity when taking ethionamide

(especially in combination with rifampin), and treatment should be discontinued if the patient'sALTlevels exceed 2.5 times the normal value. Prothionamide, a congener of ethionamide that is not available in the United States, has pharmacologic properties similar to those of ethionamide and is widely used throughout the world.

Other Agents A number of other drugs exhibit significant activity against *M. leprae*, but clinical experience with these agents is lacking. Thalidomide is now approved by theFDA for treatment ofENL. Although this drug may be useful in suppressing ENL, it acts as a tranquilizer, is extremely teratogenic, and should *never* be taken by anyone who is or may become pregnant. Physicians wishing to prescribe thalidomide must register with the System for Thalidomide Education and Prescription Safety (S.T.E.P.S.) at 1-888-423-5436 (Celgese Corporation).

The newer macrolide antibiotics (particularly clarithromycin), minocycline (a long-acting tetracycline), and a number of fluoroquinolones (including ofloxacin, sparfloxacin, and pefloxacin) have shown promising bactericidal activity against *M. leprae*. Ofloxacin and minocycline are being investigated with rifampin in short-course regimens for lepromatous disease. All of these newer leprosy drugs have low toxicity profiles, modes of action different from those of the established agents, and powerful bactericidal activity against *M. leprae*. However, their levels of bactericidal activity are lower than that of rifampin.

NONTUBERCULOUS MYCOBACTERIA

Although less pathogenic than *M. tuberculosis*, the nontuberculous mycobacteria can cause pulmonary, skin, bone and joint, lymph node, and soft tissue infection as well as disseminated disease in immunocompromised hosts, including patients with AIDS.MAI and *M. kansasii* are the two most common causes of nontuberculous mycobacterial pulmonary infection. Up to 40% of AIDS patients develop disseminated disease due to MAI.

Clarithromycin Clarithromycin (6-*O*-methylerythromycin) is a new macrolide that is similar to erythromycin in its mechanism of action. However, unlike erythromycin, it is well absorbed with or without meals and elicits little gastrointestinal intolerance at low doses. Clarithromycin distributes well into body tissues and fluids and is highly concentrated in macrophages. The drug is metabolized in the liver, and approximately 30% of a given dose is excreted in the urine. The dosage should be reduced if the creatinine clearance rate is£30 mL/min. Like erythromycin, clarithromycin binds with plasma proteins (65 to 70%) and can raise the levels of drugs such as theophylline and carbamazepine. As noted earlier, serum levels of clarithromycin are reduced by the concomitant administration of rifampin and to a lesser degree by that of rifabutin; clarithromycin treatment increases serum levels of rifabutin and some antihistamines (e.g., terfenadine), thus increasing their toxicity. Clarithromycin and (probably) azithromycin are the most active agents for the treatment ofMAIinfections; one of these drugs is considered an essential component of any regimens for this purpose. However, because of mutational drug resistance, clarithromycin should be given in combination with other agents, such as ethambutol and rifampin or rifabutin. The drug is also highly active against almost all other nontuberculous mycobacteria, including *M. marinum*, *M. kansasii*, *M. haemophilum*, *M. genavense*, *M. xenopi*, *M. abscessus*, *M. chelonae*, and

most isolates of *M. fortuitum*. Standard antimycobacterial doses have been 500 mg twice daily; doses of 1000 mg twice daily have been associated with increased mortality among patients with AIDS and disseminated MAI disease. The more common side effects of high doses include nausea, vomiting, a bitter taste, and (occasionally) abnormal liver-function tests. Most side effects can be minimized by reducing the dose, usually by 50%. Clarithromycin is teratogenic in laboratory animals and is in category C for use in pregnancy (Table 168-1). Mutational resistance occurs in one in 10^8 to 10^9organisms and develops rapidly with monotherapy, especially that for disseminated MAI disease. Resistance results from point mutations involving adenine at positions 2058 or 2059 in the 23S ribosomal binding site.

Azithromycin Azithromycin is a macrolide that belongs to the family of azalides. It reaches much lower serum levels than clarithromycin (usually £0.5 ug/mL) but attains high tissue and macrophage concentrations and has a longer half-life, which suggests the feasibility of intermittent therapy. It is involved in few drug interactions since it does not affect the cytochrome P450 system. The usual dose is 250 to 500 mg/d. No alteration in dose is required in renal failure. The most common side effects are gastrointestinal symptoms and reversible hearing loss. Azithromycin appears to be less active than clarithromycin for both pulmonary and disseminatedMAIdisease. Resistance to azithromycin develops by the same mechanism as that to clarithromycin, with cross-resistance between the two macrolides.

THERAPY FOR SPECIFIC NONTUBERCULOUS MYCOBACTERIA

MAI First-line antituberculous drugs are much less active against MAI than against *M. tuberculosis*. Therapy for MAI is controversial because of the lack of controlled clinical trials. In 1990 theATSrecommended the following four-drug regimen for MAI lung disease in HIV-negative patients: 18 to 24 months of isoniazid (300 mg), rifampin (600 mg), and ethambutol (25 mg/kg, then 15 mg/kg beginning in the third month), with intermittent streptomycin. However, two subsequent events -- the demonstration of the dramatic activity of clarithromycin against both pulmonary and disseminated MAI infection and the introduction of rifabutin -- have altered the therapeutic approach to MAI infection. In the 1997 ATS recommendations for MAI lung disease, clarithromycin (500 mg twice daily) now replaces isoniazid, and rifabutin (300 mg/d) is often used in place of rifampin. Therapy for pulmonary disease is generally given until cultures have been negative for 12 months.

For disseminated disease in AIDS, one of the newer macrolides (clarithromycin or azithromycin) and ethambutol (15 mg/kg) are considered essential components of any treatment regimen, with rifabutin (300 mg) a commonly used third drug in patients not taking a protease inhibitor for their HIV infection. Other alternative drugs include ciprofloxacin, streptomycin, and amikacin. Clofazimine appears to increase mortality and should be avoided. For the prophylaxis of disseminatedMAIdisease, rifabutin (300 mg/d), clarithromycin (500 mg twice daily), and azithromycin (1200 mg once weekly) have all been demonstrated to be effective in controlled or comparative clinical trials.

Mycobacterium kansasii *M. kansasii* is usually susceptible to most antituberculous drugs except for pyrazinamide. CurrentATSrecommendations for the treatment of *M. kansasii* pulmonary disease are 18 to 24 months of daily isoniazid (300 mg), rifampin

(600 mg), and ethambutol (15 mg/kg). In patients taking protease inhibitors, rifabutin (150 mg) or clarithromycin (500 mg) twice daily should be substituted for rifampin. The potential advantages of the highly active rifabutin and the newer macrolides in immunocompetent patients have not been studied.

Rapidly Growing Mycobacteria *M. fortuitum*, *M. abscessus*, and *M. chelonae* account for more than 80% of cases of clinical disease due to rapidly growing mycobacteria. These organisms are resistant to antituberculous agents other than amikacin but are variably susceptible to several other antibiotics. Clarithromycin has dramatically changed the approach to therapy for infection with these organisms, as it inhibits all rapidly growing mycobacteria -- except for 20% of *M. fortuitum* strains and most *M. smegmatis* strains -- at concentrations of£4 ug/mL. Other drugs with good activity include amikacin (which inhibits 80 to 100% of strains), cefoxitin (80% of *M. abscessus* and *M. fortuitum* strains), doxycycline (50% of *M. fortuitum* strains), imipenem (100% of *M. fortuitum* strains, 70% of *M. chelonae* strains, and 70% of *M. abscessus* strains), the fluorinated quinolones ciprofloxacin and ofloxacin (100% of *M. fortuitum* strains), and sulfonamides (90% of *M. fortuitum* strains).

Mycobacterium marinum *M. marinum*, a photochromogen, is typically susceptible to minocycline, rifampin, ethambutol, clarithromycin, and trimethoprim-sulfamethoxazole and is resistant to isoniazid.

Mycobacterium haemophilum Infection due to *M. haemophilum* occurs most commonly as disseminated disease in immunocompromised patients with or without AIDS. This organism can cause bone and joint infection and skin infection. Isolates typically show in vitro resistance to most drugs but may be susceptible to rifampin, rifabutin, quinolones, and clarithromycin.

Mycobacterium xenopi In the United States, *M. xenopi* most often causes nosocomial infections; these infections most commonly occur in the environment of the hospital's hot-water system. In one study from Brooklyn, NY, *M. xenopi* was the second most common pathogenic nontuberculous mycobacterial species; of the 86 hospitalized patients from whom it was isolated, 41% were HIV-positive. Drug therapy for *M. xenopi* infection is difficult because in vitro drug sensitivity tests do not reliably predict clinical results. *M. xenopi* is often resistant to first-line antituberculous agents but susceptible to the newer macrolides, quinolones, streptomycin, and ethionamide.

Mycobacterium genavense *M. genavense* is a newly recognized organism that grows only in liquid media, such as Bactec 12B or 13A. This organism almost exclusively infects AIDS patients, causing disseminated disease and being isolated from blood, bone marrow, liver, lymph node, spleen, and intestinal cultures. The in vitro susceptibility profile of *M. genavense* has not been well established. Some isolates are susceptible to amikacin, clarithromycin, ofloxacin, rifampin, and rifabutin.

169. TUBERCULOSIS - *Mario C. Raviglione*, *Richard J. O'Brien*

DEFINITION

Tuberculosis, one of the oldest diseases known to affect humans, is caused by bacteria belonging to the *Mycobacterium tuberculosis* complex. The disease usually affects the lungs, although in up to one-third of cases other organs are involved. If properly treated, tuberculosis caused by drug-susceptible strains is curable in virtually all cases. If untreated, the disease may be fatal within 5 years in more than half of cases. Transmission usually takes place through the airborne spread of droplet nuclei produced by patients with infectious pulmonary tuberculosis.

ETIOLOGIC AGENT

Mycobacteria belong to the family Mycobacteriaceae and the order Actinomycetales. Of the pathogenic species belonging to the *M. tuberculosis* complex, the most frequent and important agent of human disease is *M. tuberculosis* itself. The complex includes *M. bovis* (the bovine tubercle bacillus, once an important cause of tuberculosis transmitted by unpasteurized milk and currently the cause of a small percentage of cases in developing countries), *M. africanum* (isolated in a small proportion of cases in West and Central Africa), and *M. microti* (the "vole" bacillus, a closely related but rarely encountered organism).

M. tuberculosis is a rod-shaped, non-spore-forming, thin aerobic bacterium measuring about 0.5 um by 3 um. Mycobacteria, including *M. tuberculosis*, do not stain readily and are often neutral on Gram's staining. However, once stained, the bacilli cannot be decolorized by acid alcohol, a characteristic justifying their classification as acid-fast bacilli (AFB). Acid fastness is due mainly to the organisms' high content of mycolic acids, long-chain cross-linked fatty acids, and other cell-wall lipids. Microorganisms other than mycobacteria that display some acid fastness include species of *Nocardia* and *Rhodococcus*, *Legionella micdadei*, and the protozoa *Isospora* and *Cryptosporidium*. In the mycobacterial cell wall, lipids (e.g., mycolic acids) are linked to underlying arabinogalactan and peptidoglycan. This structure is responsible for the very low permeability of the cell wall and thus for the ineffectiveness of most antibiotics against the organism. Another molecule in the mycobacterial cell wall, lipoarabinomannan, is involved in the pathogen-host interaction and facilitates the survival of *M. tuberculosis* within macrophages. The several proteins characteristic of *M. tuberculosis* include those in purified protein derivative (PPD) tuberculin, a precipitate of non-species-specific molecules obtained from filtrates of heat-sterilized, concentrated broth cultures. The complete genome sequence of *M. tuberculosis* comprises about 4000 genes and has a high guanine-plus-cytosine content. A large proportion of the genes are devoted to the production of enzymes involved in lipogenesis and lipolysis and of glycine-rich proteins that are probably responsible for antigenic variations.

EPIDEMIOLOGY

Between 3.5 and 4 million new cases of tuberculosis -- all forms (pulmonary and extrapulmonary), 90% of them from developing countries -- were reported annually to the World Health Organization (WHO) in the late 1990s. However, because of a low

level of case detection and incomplete notifications in many national programs, reported cases represent only a fraction of the total. It is estimated that 8 million new cases of tuberculosis occurred worldwide in 1997, 95% of them in developing countries of Asia (5 million), Africa (1.6 million), the Middle East (0.6 million), and Latin America (0.4 million). It is also estimated that nearly 2 million deaths from tuberculosis occurred in 1997, 98% of them in developing countries.

Beginning in the mid-1980s in many industrialized countries, the number of tuberculosis case notifications, which had been falling steadily, stabilized or even began to increase. This phenomenon was first noted in the United States but was soon observed in many European countries as well. A number of factors were implicated in the resurgence of tuberculosis in the United States in 1986 through 1992 -- most notably, immigration from countries with a high prevalence of tuberculosis; infection with HIV; emergence of multidrug-resistant (MDR) tuberculosis due to strains resistant at least to isoniazid and rifampin; and social problems such as poverty, homelessness, and drug abuse. In some areas (e.g., New York City), deterioration in the public health system and dismantling of tuberculosis management services also contributed to the worsening situation.With the implementation of stronger control programs, cases began to decrease in 1993. In 1998, 18,361 cases of tuberculosis (6.8 per 100,000 population) were reported to the U.S. Centers for Disease Control and Prevention (CDC) -- a 31% decrease from the 1992 peak.

In the United States, tuberculosis is uncommon among young adults of European descent, who have only rarely been exposed to *M. tuberculosis* infection during recent decades. In contrast, because of a high risk in the past, the prevalence of *M. tuberculosis* infection is relatively high among elderly Caucasians, who remain at increased risk of developing active tuberculosis. Tuberculosis in the United States is also a disease of young adult members of the HIV-infected, immigrant, and disadvantaged/marginalized populations. Similarly, in Europe, tuberculosis has reemerged as an important public health problem, mainly as a result of cases among immigrants from high-prevalence countries.

In developing countries of Africa and Asia, tuberculosis trends over the past several decades are not entirely clear. However, in sub-Saharan African countries with reliable reporting systems, the recent spread of the HIV epidemic has been accompanied by doubling or tripling of the number of reported cases of tuberculosis during a period as short as 10 years. The growing number of young adults with *M. tuberculosis* infection has fueled the rates of active tuberculosis in many developing countries. Without greater control efforts, the annual incident cases of tuberculosis globally may increase by 40% between now and 2020.

From Exposure to Infection *M. tuberculosis* is most commonly transmitted from a patient with infectious pulmonary tuberculosis to other persons by droplet nuclei, which are aerosolized by coughing, sneezing, or speaking. The tiny droplets dry rapidly; the smallest (<5 to 10 um in diameter) may remain suspended in the air for several hours and may gain direct access to the terminal air passages when inhaled. There may be as many as 3000 infectious nuclei per cough. In the past, a frequent source of infection was raw milk containing *M. bovis* from tuberculous cows. Other routes of transmission of tubercle bacilli, such as through the skin or the placenta, are uncommon and of no

epidemiologic significance.

The probability of contact with a case of tuberculosis, the intimacy and duration of that contact, the degree of infectiousness of the case, and the shared environment of the contact are all important determinants of transmission. Several studies of close contacts have clearly demonstrated that tuberculosis patients whose sputum containsAFBvisible by microscopy play the greatest role in the spread of infection. These patients often have cavitary pulmonary disease or tuberculosis of the respiratory tract (endobronchial or laryngeal tuberculosis) and produce sputa containing as many as 10^5AFB/mL. Patients with sputum smear-negative/culture-positive tuberculosis are less infectious, and those with culture-negative pulmonary disease and extrapulmonary tuberculosis are essentially noninfectious. Crowding in poorly ventilated rooms is one of the most important factors in the transmission of tubercle bacilli, since it increases the intensity of contact with a case.

In short, the risk of acquiring *M. tuberculosis* infection is determined mainly by exogenous factors. Because of delays in seeking care and in diagnosis, it is estimated that up to 20 contacts will usually be infected by eachAFB-positive case before detection in high-prevalence countries.

From Infection to Disease Unlike the risk of acquiring infection with *M. tuberculosis*, the risk of developing disease after being infected depends largely on endogenous factors, such as the individual's innate susceptibility to disease and level of function of cell-mediated immunity. Clinical illness directly following infection is classified as *primary tuberculosis* and is common among children up to 4 years of age. Although this form may be severe and disseminated, it is usually not transmissible. When infection is acquired later in life, the chance is greater that the immune system will contain it, at least temporarily. The majority of infected individuals who ultimately develop tuberculosis do so within the first year or two after infection. Dormant bacilli, however, may persist for years before being reactivated to produce *secondary* (or *postprimary*) *tuberculosis*, which is often infectious. Overall, it is estimated that about 10% of infected persons will eventually develop active tuberculosis. *Reinfection* of a previously infected individual, which is probably common in areas with high rates of tuberculosis transmission, may also favor the development of disease. Molecular typing and comparison of strains of *M. tuberculosis* have suggested that up to one-third of cases of active tuberculosis in U.S. inner-city communities are due to recent transmission rather than to reactivation of latent infection.

Age is an important determinant of the risk of disease after infection. Among infected persons, the incidence of tuberculosis is highest during late adolescence and early adulthood; the reasons are unclear. The incidence among women peaks at 25 to 34 years of age. In this age group rates among women are usually higher than those among men, while at older ages the opposite is true. The risk may increase in the elderly, possibly because of waning immunity and comorbidity.

A variety of diseases favor the development of active tuberculosis. The most potent risk factor for tuberculosis among infected individuals is clearly HIV co-infection, which suppresses cellular immunity. The risk that latent *M. tuberculosis* infection will proceed to active disease is directly related to the patient's degree of immunosuppression. In a

study of HIV-infected, PPD-positive persons, this risk varied from 2.6 to 13.3 cases per 100 person-years and depended upon the CD4+ cell count. The risk of developing tuberculosis is significantly greater among HIV-infected than among HIV-uninfected hosts. Other conditions known to increase the risk of active tuberculosis among persons infected with tubercle bacilli include silicosis; lymphoma, leukemia, and other malignant neoplasms; hemophilia; chronic renal failure and hemodialysis; insulin-dependent diabetes mellitus; immunosuppressive treatment, including that administered for solid-organ transplantation; and conditions associated with malnutrition, such as gastrectomy and jejunoileal bypass surgery. Finally, the presence of old, self-healed, fibrotic tuberculous lesions constitutes a serious risk of active disease.

NATURAL HISTORY OF DISEASE

Studies conducted in various countries before the advent of chemotherapy clearly showed that untreated tuberculosis is often fatal. About one-third of patients died within 1 year after diagnosis, and one-half within 5 years. Five-year mortality among sputum smear-positive cases was 65%. Of the survivors at 5 years, about 60% had undergone spontaneous remission, while the remainder were still excreting tubercle bacilli.

The introduction of effective chemotherapy has markedly affected the natural history of tuberculosis. With proper treatment, patients have a high chance of being cured. However, improper use of antituberculosis drugs, while reducing mortality, may also result in large numbers of chronic infectious cases, often with drug-resistant bacilli.

PATHOGENESIS AND IMMUNITY

The interaction of *M. tuberculosis* with the human host begins when droplet nuclei containing microorganisms from infectious patients are inhaled. While the majority of inhaled bacilli are trapped in the upper airways and expelled by ciliated mucosal cells, a fraction (usually fewer than 10%) reach the alveoli. There, nonspecifically activated alveolar macrophages ingest the bacilli. Invasion of macrophages by mycobacteria may result in part from association of C2a with the bacterial cell wall followed by C3b opsonization of the bacteria and recognition by the macrophages. The balance between the bactericidal activity of the macrophage and the virulence of the bacillus (the latter being partially linked to the bacterium's lipid-rich cell wall and to its glycolipid capsule, both of which confer resistance to complement and free radicals of the phagocyte) determines the events following phagocytosis. The number of invading bacilli is also important.

Several genes thought to confer virulence to *M. tuberculosis* have been identified. *katG* encodes for catalase, an enzyme protective against oxidative stress; *rpoV* is the main sigma factor initiating transcription of several genes. Defects in these two genes result in loss of virulence. The *erp* gene, encoding a protein required for multiplication, also contributes to virulence. The effects of a highly virulent strain are exemplified by an outbreak of tuberculosis in two rural counties in Tennessee and Kentucky in 1994 through 1996. In this outbreak, both epidemiologic evidence of enhanced transmission with high rates of disease and accelerated growth of the strain in mice were documented.

Several observations suggest that genetic factors play a key role in innate nonimmune resistance to infection with *M. tuberculosis*. The existence of this resistance is suggested by the differing degrees of susceptibility to tuberculosis in different populations. In mice, a gene called *Nramp1* (natural resistance-associated macrophage protein 1) has a regulatory role in resistance/susceptibility to mycobacteria. The human homologue NRAMP1, cloned to chromosome 2q, may have a role in determining susceptibility to tuberculosis. In a study among West Africans, subjects heterozygous for two polymorphisms of NRAMP1 (INT4 and 3¢UTR) had an apparently increased risk of tuberculosis, a finding suggesting that the susceptibility allele behaves as dominant.

In the initial stage of host-bacterium interaction, either the host's macrophages contain bacillary multiplication by producing proteolytic enzymes and cytokines or the bacilli begin to multiply. If the bacilli multiply, their growth quickly kills the macrophages, which lyse. Nonactivated monocytes attracted from the bloodstream to the site by various chemotactic factors ingest the bacilli released from the lysed macrophages. These initial stages of infection are usually asymptomatic.

About 2 to 4 weeks after infection, two additional host responses to *M. tuberculosis* develop: a tissue-damaging response and a macrophage-activating response. The *tissue-damaging response* is the result of a delayed-type hypersensitivity (DTH) reaction to various bacillary antigens; it destroys nonactivated macrophages that contain multiplying bacilli. The *macrophage-activating response* is a cell-mediated phenomenon resulting in the activation of macrophages that are capable of killing and digesting tubercle bacilli. Although both of these responses can inhibit mycobacterial growth, it is the balance between the two that determines the form of tuberculosis that will develop subsequently.

With the development of specific immunity and the accumulation of large numbers of activated macrophages at the site of the primary lesion, granulomatous lesions (tubercles) are formed. These lesions consist of lymphocytes and activated macrophages, such as epithelioid cells and giant cells. Initially, the newly developed tissue-damaging response is the only event capable of limiting mycobacterial growth within macrophages. This response, mediated by various bacterial products, not only destroys macrophages but also produces early solid necrosis in the center of the tubercle. Although *M. tuberculosis* can survive, its growth is inhibited within this necrotic environment by low oxygen tension and low pH. At this point, some lesions may heal by fibrosis and calcification, while others undergo further evolution.

Cell-mediated immunity is critical at this early stage. In the majority of infected individuals, local macrophages are activated when bacillary antigens processed by macrophages stimulate T lymphocytes to release a variety of lymphokines. These activated cells aggregate around the lesion's center and effectively neutralize tubercle bacilli without causing further tissue destruction. In the central part of the lesion, the necrotic material resembles soft cheese (*caseous necrosis*). Even when healing takes place, viable bacilli may remain dormant within macrophages or in the necrotic material for years or even throughout the patient's lifetime. These "healed" lesions in the lung parenchyma and hilar lymph nodes may later undergo calcification (*Ranke complex*).

In a minority of cases, the macrophage-activating response is weak, and mycobacterial

growth can be inhibited only by intensifiedDTHreactions, which lead to tissue destruction. The lesion tends to enlarge further, and the surrounding tissue is progressively damaged. At the center of the lesion, the caseous material liquefies. Bronchial walls as well as blood vessels are invaded and destroyed, and cavities are formed. The liquefied caseous material, containing large numbers of bacilli, is drained through bronchi. Within the cavity, tubercle bacilli multiply well and spread into the airways and the environment through expectorated sputum.

In the early stages of infection, bacilli are usually transported by macrophages to regional lymph nodes, from which they disseminate widely to many organs and tissues. The resulting lesions may undergo the same evolution as those in the lungs, although most tend to heal. In young children with poor natural immunity, hematogenous dissemination may result in fatal miliary tuberculosis or tuberculous meningitis.

Cell-mediated immunity confers partial protection against *M. tuberculosis*, while humoral immunity has no defined role in protection. Two types of cells are essential: macrophages, which directly phagocytize tubercle bacilli, and T cells (mainly CD4+ lymphocytes), which induce protection through the production of lymphokines.

After infection with *M. tuberculosis*, alveolar macrophages secrete a number of cytokines: interleukin (IL) 1 contributes to fever; IL-6 contributes to hyperglobulinemia; and tumor necrosis factor a(TNF-a) contributes to the killing of mycobacteria, the formation of granulomas, and a number of systemic effects, such as fever and weight loss. Macrophages are also critical in processing and presenting antigens to T lymphocytes; the result is a proliferation of CD4+ lymphocytes, which are crucial to the host's defense against M*. tuberculosis*. Qualitative and quantitative defects of CD4+ T cells explain the inability of HIV-infected individuals to contain mycobacterial proliferation. Reactive CD4+ lymphocytes produce cytokines of the T_H1 pattern and participate in MHC class II-restricted killing of cells infected with *M. tuberculosis*. T_H1 CD4+ cells produce interferon g(IFN-g) and IL-2 and promote cell-mediated immunity. T_H2 cells produce IL-4, IL-5, and IL-10 and promote humoral immunity. The interplay of these various cytokines and their cross-regulation determine the host's response. The role of cytokines in promoting intracellular killing of mycobacteria has not been entirely elucidated. IFN-gmay induce release of nitric oxide, and TNF-a seems also to be important. Finally, the role of other cells, such as natural killer (NK) cells, "double-negative" CD4-CD8- cells, andg/d T cells, in protective immunity remains unclear.

M. tuberculosis possesses various protein antigens. Some are present in the cytoplasm and cell wall; others are secreted. That the latter are more important in eliciting a T lymphocyte response is suggested by experiments documenting the appearance of protective immunity in animals after immunization with live, protein-secreting mycobacteria. Among the antigens with a potential protective role are the 30-kDa (or 85B) and the ESAT-6 antigens. Protective immunity is probably the result of reactivity to a large number of different mycobacterial antigens.

Coincident with the appearance of immunity,DTH to *M. tuberculosis* develops. This reactivity is the basis of thePPD skin test, currently the only test that reliably detects *M. tuberculosis* infection in persons without symptoms. The cellular mechanisms

responsible for PPD reactivity are related mainly to previously sensitized CD4+ lymphocytes, which are attracted to the skin-test site. There, they proliferate and produce cytokines.

In 1891, Robert Koch discovered components of *M. tuberculosis* in a concentrated liquid culture medium. Subsequently named "old tuberculin" (OT), this material was initially believed to be useful in the treatment of tuberculosis (although this idea was later disproved). It soon became clear that OT was capable of eliciting a skin reaction when injected subcutaneously into patients with tuberculosis. In 1932, Seibert and Munday purified this product by ammonium sulfate precipitation. The result was an active protein fraction known as tuberculinPPD. However, the complexity and diversity of the constituents of PPD rendered its standardization difficult. PPD-S, developed by Seibert and Glenn in 1941, was chosen as the international standard. Later, theWHO and UNICEF sponsored large-scale production of a master batch of PPD, termed RT23, and made it available for general use. The greatest limitation of PPD is its lack of mycobacterial species specificity, a property that is due to the large number of proteins in this product that are highly conserved in the various species of mycobacteria.

WhileDTH is associated with protective immunity (PPD-positive persons being less susceptible to a new *M. tuberculosis* infection than PPD-negative persons), it by no means guarantees protection against reactivation. In fact, severe cases of active tuberculosis are often accompanied by strongly positive skin-test reactions.

CLINICAL MANIFESTATIONS

Tuberculosis is usually classified as pulmonary or extrapulmonary. Before the recognition of HIV infection, more than 80% of all cases of tuberculosis were limited to the lungs. However, up to two-thirds of HIV-infected patients with tuberculosis may have both pulmonary and extrapulmonary disease or extrapulmonary disease alone.

Pulmonary Tuberculosis Pulmonary tuberculosis can be categorized as primary or postprimary (secondary).

Primary Disease Primary pulmonary tuberculosis results from an initial infection with tubercle bacilli. In areas of high tuberculosis prevalence, this form of disease is often seen in children and is frequently localized to the middle and lower lung zones. The lesion forming after infection is usually peripheral and accompanied by hilar or paratracheal lymphadenopathy, which may not be detectable on chest radiography. In the majority of cases, the lesion heals spontaneously and may later be evident as a small calcified nodule (*Ghon lesion*).

In children and in persons with impaired immunity, such as those with malnutrition or HIV infection, primary pulmonary tuberculosis may progress rapidly to clinical illness. The initial lesion increases in size and can evolve in different ways. Pleural effusion, a frequent finding, results from the penetration of bacilli into the pleural space from an adjacent subpleural focus. In severe cases, the primary site rapidly enlarges, its central portion undergoes necrosis, and acute cavitation develops (progressive primary tuberculosis). Tuberculosis in young children is almost invariably accompanied by hilar or mediastinal lymphadenopathy due to the spread of bacilli from the lung parenchyma

through lymphatic vessels. Enlarged lymph nodes may compress bronchi, causing obstruction and subsequent segmental or lobar collapse. Partial obstruction may cause obstructive emphysema, and bronchiectasis may also develop. Hematogenous dissemination, which is common and is often asymptomatic, may result in the most severe manifestations of primary *M. tuberculosis* infection. Bacilli reach the bloodstream from the pulmonary lesion or the lymph nodes and disseminate into various organs, where they may produce granulomatous lesions. Although healing frequently takes place, immunocompromised persons (e.g., patients with HIV infection and those recovering from measles) may develop miliary tuberculosis and/or tuberculous meningitis.

Postprimary Disease Also called adult-type, reactivation, or secondary tuberculosis, postprimary disease results from endogenous reactivation of latent infection and is usually localized to the apical and posterior segments of the upper lobes, where the high oxygen concentration favors mycobacterial growth (Fig. 169-CD1). In addition, the superior segments of the lower lobes are frequently involved. The extent of lung parenchymal involvement varies greatly, from small infiltrates to extensive cavitary disease. With cavity formation, liquefied necrotic contents are ultimately discharged into the airways, resulting in satellite lesions within the lungs that may in turn undergo cavitation. Massive involvement of pulmonary segments or lobes, with coalescence of lesions, produces tuberculous pneumonia. While up to one-third of untreated patients reportedly succumb to severe pulmonary tuberculosis within a few weeks or months after onset, others undergo a process of spontaneous remission or proceed along a chronic, progressively debilitating course ("consumption"). Under these circumstances, some pulmonary lesions become fibrotic and may later calcify, but cavities persist in other parts of the lungs. Individuals with such chronic disease continue to discharge tubercle bacilli into the environment. Most patients respond to treatment, with defervescence, decreasing cough, weight gain, and a general improvement in well-being within several weeks.

Early in the course of disease, symptoms and signs are often nonspecific and insidious, consisting mainly of fever and night sweats, weight loss, anorexia, general malaise, and weakness. However, in the majority of cases, cough eventually develops -- perhaps initially nonproductive and subsequently accompanied by the production of purulent sputum. Blood streaking of the sputum is frequently documented. Massive hemoptysis may ensue as a consequence of the erosion of a fully patent vessel located in the wall of a cavity. Hemoptysis, however, may also result from rupture of a dilated vessel in a cavity (*Rasmussen's aneurysm*) or from aspergilloma formation in an old cavity. Pleuritic chest pain sometimes develops in patients with subpleural parenchymal lesions but can also result from muscle strain due to persistent coughing. Extensive disease may produce dyspnea and (occasionally) adult respiratory distress syndrome (ARDS).

Physical findings are of limited use in pulmonary tuberculosis. Many patients have no abnormalities detectable by chest examination, while others have detectable rales in the involved areas during inspiration, especially after coughing. Occasionally, rhonchi due to partial bronchial obstruction and classic amphoric breath sounds in areas with large cavities may be heard. Systemic features include fever (often low-grade and intermittent) and wasting. In some cases, pallor and finger clubbing develop. The most common hematologic findings are mild anemia and leukocytosis. Hyponatremia due to

the syndrome of inappropriate secretion of antidiuretic hormone (SIADH) has also been reported.

Extrapulmonary Tuberculosis In order of frequency, the extrapulmonary sites most commonly involved in tuberculosis are the lymph nodes, pleura, genitourinary tract, bones and joints, meninges, and peritoneum. However, virtually all organ systems may be affected. As a result of hematogenous dissemination in HIV-infected individuals, extrapulmonary tuberculosis is seen more commonly today than in the past.

Lymph-Node Tuberculosis (Tuberculous Lymphadenitis) The commonest presentation of extrapulmonary tuberculosis (being documented in more than 25% of cases), lymph-node disease is particularly frequent among HIV-infected patients. In the United States, children and women (particularly non-Caucasians) also seem to be especially susceptible. Lymph-node tuberculosis presents as painless swelling of the lymph nodes, most commonly at cervical and supraclavicular sites. Lymph nodes are usually discrete in early disease but may be inflamed and have a fistulous tract draining caseous material (Fig. 169-CD2). Systemic symptoms are usually limited to HIV-infected patients, and concomitant lung disease may or may not be present. The diagnosis is established by fine-needle aspiration or surgical biopsy.AFB are seen in up to 50% of cases, cultures are positive in 70 to 80%, and histologic examination shows granulomatous lesions. Among HIV-infected patients, granulomas are usually not seen. Differential diagnosis includes a variety of infectious conditions as well as neoplastic diseases such as lymphomas or metastatic carcinomas (Chap. 63).

Pleural Tuberculosis Involvement of the pleura is common in primary tuberculosis and results from penetration by a few tubercle bacilli into the pleural space. Depending on the extent of reactivity, the effusion may be small, remain unnoticed, and resolve spontaneously or may be sufficiently large to cause symptoms such as fever, pleuritic chest pain, and dyspnea. Physical findings are those of pleural effusion: dullness to percussion and absence of breath sounds. A chest radiograph reveals the effusion and, in no more than one-third of cases, also shows a parenchymal lesion. Thoracentesis is required to ascertain the nature of the effusion. The fluid is straw colored and at times hemorrhagic; it is an exudate with a protein concentration >50% of that in serum, a normal to low glucose concentration, a pH that is generally<7.2, and detectable white blood cells (usually 500 to 2500/mL). Neutrophils may predominate in the early stage, while mononuclear cells are the typical finding later. Mesothelial cells are generally rare or absent.AFB are very rarely seen on direct smear, but cultures may be positive for *M. tuberculosis* in up to one-third of cases. Needle biopsy of the pleura is often required for diagnosis and reveals granulomas and/or yields a positive culture in up to 70% of cases. This form of pleural tuberculosis responds well to chemotherapy and may resolve spontaneously.

Tuberculous empyema is a less common complication of pulmonary tuberculosis. It is usually the result of the rupture of a cavity, with delivery of a large number of organisms into the pleural space, or of a bronchopleural fistula from a pulmonary lesion. A chest radiograph may show pyopneumothorax with an air-fluid level. The effusion is purulent and thick and contains large numbers of lymphocytes. An acid-fast smear of pleural fluid is often found to be positive when examined by microscopy, as is culture of the pleural fluid. Surgical drainage is usually required as an adjunct to chemotherapy. Tuberculous

empyema may result in severe pleural fibrosis and restrictive lung disease.

Tuberculosis of the Upper Airways Nearly always a complication of advanced cavitary pulmonary tuberculosis (Fig. 169-CD3), tuberculosis of the upper airways may involve the larynx, pharynx, and epiglottis. Symptoms include hoarseness and dysphagia in addition to chronic productive cough. Findings depend on the site of involvement, and ulcerations may be seen on laryngoscopy. Acid-fast smear of the sputum is often positive, but biopsy may be necessary in some cases to establish the diagnosis. Cancer may have similar features but is usually painless.

Genitourinary Tuberculosis Genitourinary tuberculosis accounts for about 15% of all extrapulmonary cases, may involve any portion of the genitourinary tract, and is usually due to hematogenous seeding following primary infection. Local symptoms predominate. Urinary frequency, dysuria, hematuria, and flank pain are common presentations. However, patients may be asymptomatic and the disease discovered only after severe destructive lesions of the kidneys have developed. Urinalysis gives abnormal results in 90% of cases, revealing pyuria and hematuria. The documentation of culture-negative pyuria in acidic urine raises the suspicion of tuberculosis. An intravenous pyelogram helps in diagnosis. Calcifications and ureteral strictures are suggestive findings. Culture of three morning urine specimens yields a definitive diagnosis in nearly 90% of cases. Severe ureteral strictures may lead to hydronephrosis and renal damage.

Genital tuberculosis is diagnosed more commonly in females than in males. In females, it affects the fallopian tubes and the endometrium and may cause infertility, pelvic pain, and menstrual abnormalities. Diagnosis requires biopsy or culture of specimens obtained by dilatation and curettage. In males, tuberculosis preferentially affects the epididymis, producing a slightly tender mass that may drain externally through a fistulous tract; orchitis and prostatitis may also develop. In almost half of cases of genitourinary tuberculosis, urinary tract disease is also present. Genitourinary tuberculosis responds well to chemotherapy.

Skeletal Tuberculosis In the United States, tuberculosis of the bones and joints is responsible for about 10% of extrapulmonary cases. In bone and joint disease, pathogenesis is related to reactivation of hematogenous foci or to spread from adjacent paravertebral lymph nodes. Weight-bearing joints (spine, hips, and knees -- in that order) are affected most commonly. Spinal tuberculosis (Pott's disease or tuberculous spondylitis) often involves two or more adjacent vertebral bodies. While the upper thoracic spine is the most common site of spinal tuberculosis in children, the lower thoracic and upper lumbar vertebrae are usually affected in adults. From the anterior superior or inferior angle of the vertebral body, the lesion reaches the adjacent body, also destroying the intervertebral disk. With advanced disease, collapse of vertebral bodies results in kyphosis (*gibbus*). A paravertebral "cold" abscess may also form. In the upper spine, this abscess may track to the chest wall as a mass; in the lower spine, it may reach the inguinal ligaments or present as a psoas abscess. Computed tomography (CT) or magnetic resonance imaging (MRI) reveals the characteristic lesion and suggests its etiology, although the differential diagnosis includes other infections and tumors. Aspiration of the abscess or bone biopsy confirms the tuberculous etiology, as cultures are usually positive and histologic findings highly typical. A catastrophic

complication of Pott's disease is paraplegia, which is usually due to an abscess or a lesion compressing the spinal cord. Paraparesis due to a large abscess is a medical emergency and requires abscess drainage. Tuberculosis of the hip joints causes pain and limping; tuberculosis of the knee produces pain and swelling and sometimes follows trauma. If the disease goes unrecognized, the joints may be destroyed. Skeletal tuberculosis responds to chemotherapy, but severe cases may require surgery.

Tuberculous Meningitis and Tuberculoma Tuberculosis of the central nervous system accounts for about 5% of extrapulmonary cases. It is seen most often in young children but also develops in adults, especially those who are infected with HIV. Tuberculous meningitis results from the hematogenous spread of primary or postprimary pulmonary disease or from the rupture of a subependymal tubercle into the subarachnoid space. In more than half of cases, evidence of old pulmonary lesions or a miliary pattern is found on chest radiography. The disease may present subtly as headache and mental changes or acutely as confusion, lethargy, altered sensorium, and neck rigidity. Typically, the disease evolves over 1 or 2 weeks, a course longer than that of bacterial meningitis. Paresis of cranial nerves (ocular nerves in particular) is a frequent finding, and the involvement of cerebral arteries may produce focal ischemia. Hydrocephalus is common. Lumbar puncture is the cornerstone of diagnosis. In general, examination of the cerebrospinal fluid (CSF) reveals a high leukocyte count (usually with a predominance of lymphocytes but often with a predominance of neutrophils in the early stage), a protein content of 1 to 8 g/L (100 to 800 mg/dL), and a low glucose concentration; however, any of these three parameters can be within the normal range.AFB are seen on direct smear of CSF sediment in only 20% of cases, but repeated lumbar punctures increase the yield. Culture of CSF is diagnostic in up to 80% of cases. Imaging studies (CT andMRI) may show hydrocephalus and abnormal enhancement of basal cisterns or ependyma. If unrecognized, tuberculous meningitis is uniformly fatal. This disease responds to chemotherapy; however, neurologic sequelae are documented in 25% of treated cases, in most of which the diagnosis has been delayed. Clinical trials have demonstrated that patients treated with adjunctive glucocorticoids experience a significantly faster resolution of CSF abnormalities and elevated CSF pressure. Adjunctive glucocorticoids enhance survival and reduce the frequency of neurologic sequelae.

Tuberculoma, an uncommon manifestation of tuberculosis, presents as one or more space-occupying lesions and usually causes seizures and focal signs.CT orMRIreveals contrast-enhanced ring lesions, but biopsy is necessary to establish the diagnosis.

Gastrointestinal Tuberculosis Any portion of the gastrointestinal tract may be affected by tuberculosis. Various pathogenetic mechanisms are involved: swallowing of sputum with direct seeding, hematogenous spread, or (although rarely today) ingestion of milk from cows affected by bovine tuberculosis. The terminal ileum and the cecum are the sites most commonly involved. Abdominal pain (at times similar to that associated with appendicitis), diarrhea, obstruction, hematochezia, and a palpable mass in the abdomen are common findings at presentation. Fever, weight loss, and night sweats are also frequent. With intestinal-wall involvement, ulcerations and fistulae may simulate Crohn's disease. Anal fistulae should prompt an evaluation for rectal tuberculosis. As surgery is required in most cases, the diagnosis can be established by histologic examination and culture of specimens obtained intraoperatively.

Tuberculous peritonitis follows either the direct spread of tubercle bacilli from ruptured lymph nodes and intraabdominal organs or hematogenous seeding. Nonspecific abdominal pain, fever, and ascites should raise the suspicion of tuberculous peritonitis. The coexistence of cirrhosis (Chap. 298) in patients with tuberculous peritonitis complicates the diagnosis. In tuberculous peritonitis, paracentesis reveals an exudative fluid with a high protein content and leukocytosis that is usually lymphocytic (although neutrophils occasionally predominate). The yield of direct smear and culture is relatively low; culture of a large volume of ascitic fluid can increase the yield, but peritoneal biopsy is often needed to establish the diagnosis.

Pericardial Tuberculosis (Tuberculous Pericarditis) Due to direct progression of a primary focus within the pericardium, to reactivation of a latent focus, or to rupture of an adjacent lymph node, pericardial tuberculosis has often been a disease of the elderly in countries with low tuberculosis prevalence but develops frequently in HIV-infected patients. Case-fatality rates are as high as 40% in some series. The onset may be subacute, although an acute presentation, with fever, dull retrosternal pain, and a friction rub, is possible. An effusion eventually develops in many cases; cardiovascular symptoms and signs of cardiac tamponade may ultimately appear (Chap. 239). In the presence of effusion detected on chest radiography, tuberculosis must be suspected if the patient belongs to a high-risk population (HIV-infected, originating in a high-prevalence country), if there is evidence of previous tuberculosis or disease in other organs, or if echocardiography shows thick strands crossing the pericardial space. Diagnosis can be facilitated by pericardiocentesis under echocardiographic guidance. The pericardial fluid must be submitted for biochemical, cytologic, and microbiologic study. The effusion is exudative in nature, with a high count of leukocytes (predominantly mononuclear cells). Hemorrhagic effusion is frequent. Culture of the fluid reveals *M. tuberculosis* in about 30% of cases, while biopsy has a higher yield. Without treatment, pericardial tuberculosis is usually fatal. Even with treatment, complications may develop, including chronic constrictive pericarditis with thickening of the pericardium, fibrosis, and sometimes calcification, which may be visible on a chest radiograph. A course of glucocorticoid treatment is useful in the management of acute disease, reducing effusion, facilitating hemodynamic recovery, and thus decreasing mortality. Progression to chronic constrictive pericarditis, however, seems unaffected by such therapy.

Miliary or Disseminated Tuberculosis Miliary tuberculosis is due to hematogenous spread of tubercle bacilli. Although in children it is often the consequence of a recent primary infection, in adults it may be due to either recent infection or reactivation of old disseminated foci. Lesions are usually yellowish granulomas 1 to 2 mm in diameter that resemble millet seeds (thus the term *miliary*, coined by nineteenth-century pathologists).

Clinical manifestations are nonspecific and protean, depending on the predominant site of involvement. Fever, night sweats, anorexia, weakness, and weight loss are presenting symptoms in the majority of cases. At times, patients have a cough and other respiratory symptoms due to pulmonary involvement as well as abdominal symptoms. Physical findings include hepatomegaly, splenomegaly, and lymphadenopathy. Eye examination may reveal choroidal tubercles, which are pathognomonic of miliary tuberculosis, in up to 30% of cases. Meningismus occurs in fewer than 10% of cases.

A high index of suspicion is required for the diagnosis of miliary tuberculosis. Frequently, chest radiography (Fig. 169-CD5) reveals a miliary reticulonodular pattern (more easily seen on underpenetrated film), although no radiographic abnormality may be evident early in the course and among HIV-infected patients. Other radiologic findings include large infiltrates, interstitial infiltrates (especially in HIV-infected patients), and pleural effusion. A sputum smear is negative in 80% of cases. Various hematologic abnormalities may be seen, including anemia with leukopenia, neutrophilic leukocytosis and leukemoid reactions, and polycythemia. Disseminated intravascular coagulation has been reported. Elevation of alkaline phosphatase levels and other abnormal values in liver function tests are detected in patients with severe hepatic involvement. The PPDtest may be negative in up to half of cases, but reactivity may be restored during chemotherapy. Bronchoalveolar lavage and transbronchial biopsy are more likely to permit bacteriologic confirmation, and granulomas are evident in liver or bone-marrow biopsy specimens from many patients. If it goes unrecognized, miliary tuberculosis is lethal; with proper treatment, however, it is amenable to cure.

A rare presentation seen in the elderly is *cryptic miliary tuberculosis*, which has a chronic course characterized by mild intermittent fever, anemia, and -- ultimately -- meningeal involvement preceding death. An acute septicemic form, *nonreactive miliary tuberculosis*, occurs very rarely and is due to massive hematogenous dissemination of tubercle bacilli. Pancytopenia is common in this form of disease, which is rapidly fatal. At postmortem examination, multiple necrotic but nongranulomatous ("nonreactive") lesions are detected.

Less Common Extrapulmonary Forms Tuberculosis may cause chorioretinitis, uveitis, panophthalmitis, and painful hypersensitivity-related phlyctenular conjunctivitis. Tuberculous otitis is rare and presents as hearing loss, otorrhea, and tympanic membrane perforation. In the nasopharynx, tuberculosis may simulate Wegener's granulomatosis. Cutaneous manifestations of tuberculosis include primary infection due to direct inoculation, abscesses and chronic ulcers, scrofuloderma (Fig. 169-CD2), lupus vulgaris (Fig. 169-CD4), miliary lesions, and erythema nodosum. Adrenal tuberculosis is a manifestation of advanced disease presenting as signs of adrenal insufficiency. Finally, congenital tuberculosis results from transplacental spread of tubercle bacilli to the fetus or from ingestion of contaminated amniotic fluid. This rare disease affects the liver, spleen, lymph nodes, and various other organs.

HIV-Associated Tuberculosis Tuberculosis is an important opportunistic disease among HIV-infected persons worldwide. In developing countries of Africa, Southeast Asia, and Latin America, an estimated 10 million persons were coinfected as of 1997. In the United States, coinfection with HIV and *M. tuberculosis* is common in certain segments of the population, including drug users and some minorities. A person with skin test-documented *M. tuberculosis* infection who acquires HIV infection has a 3 to 15% annual risk of developing active tuberculosis.

The association between tuberculosis and HIV infection is supported by other epidemiologic observations. First, the rate of HIV seropositivity among patients with tuberculosis is several times higher than that among the general population: in African countries it reaches 60 to 70%. Second, marked increases in numbers of tuberculosis

cases have been reported at locations hard hit by the HIV epidemic, such as large parts of Africa (including Kenya, Tanzania, and Malawi), northern Thailand, and New York City. Globally, the proportion of tuberculosis cases associated with HIV infection reached 8% in 1997.

HIV directly attacks the critical immune mechanisms involved in protection against tuberculosis. Tuberculosis can appear at any stage of HIV infection, but its presentation varies with the stage. When cell-mediated immunity is only partially compromised, pulmonary tuberculosis presents as a typical pattern of upper lobe infiltrates and cavitation, without significant lymphadenopathy or pleural effusion. In late stages of HIV infection, a primary tuberculosis-like pattern, with diffuse interstitial or miliary infiltrates, little or no cavitation, and intrathoracic lymphadenopathy, is more common. Overall, sputum smears may be positive less frequently among tuberculosis patients with HIV infection than among those without; thus the diagnosis of tuberculosis may be unusually difficult, especially in view of the variety of HIV-related pulmonary conditions mimicking tuberculosis.

As has been mentioned, extrapulmonary tuberculosis is common among HIV-infected patients. In various series studied in the United States and many developing countries, extrapulmonary tuberculosis -- alone or in association with pulmonary disease -- has been documented in 40 to 60% of all cases in HIV co-infected individuals. The most common forms are lymphatic, disseminated, pleural, and pericardial. Mycobacteremia and meningitis are also frequent, particularly in advanced HIV disease.

The diagnosis of tuberculosis in HIV-infected patients may be difficult not only because of the increased frequency of sputum-smear negativity (up to 40% in culture-proven pulmonary cases) but also because of atypical radiographic findings, a lack of classic granuloma formation in the late stages, and negative results inPPD skin tests. Delays in treatment may prove fatal. The response to short-course chemotherapy is similar to that in HIV-seronegative patients. However, adverse effects may be more pronounced, including severe or even fatal skin reactions to amithiozone (thiacetazone).

Exacerbations in symptoms, signs, and laboratory or radiographic manifestations of tuberculosis -- termed *paradoxical reactions* -- have been associated with the administration of highly active antiretroviral treatment (HAART) regimens. The presumed pathogenesis of paradoxical reactions is an immune response to antigens released as bacilli are killed by effective chemotherapy. In patients in whom antiretroviral therapy has recently been started, paradoxical reactions may be due to improving immune function. The first priority in the management of a possible paradoxical reaction is to ensure that the clinical syndrome does not represent a failure of tuberculosis treatment or the development of another infection. Mild paradoxical reactions can be managed with symptom-based treatment. More severe manifestations may necessitate discontinuation of antiretroviral therapy. Immunomodulators, such as glucocorticoids, have been used to treat severe paradoxical reactions, although this practice has not been formally evaluated in clinical trials.

Recommendations for the prevention and treatment of tuberculosis in HIV-infected individuals have been published by theCDC.

DIAGNOSIS

The key to the diagnosis of tuberculosis is a high index of suspicion. Diagnosis is not difficult with a high-risk patient -- e.g., a homeless alcoholic who presents with typical symptoms and a classic chest radiograph showing upper lobe infiltrates with cavities. On the other hand, the diagnosis can easily be missed in an elderly nursing-home resident or a teenager with a focal infiltrate.

Often, the diagnosis is first entertained when the chest radiograph of a patient being evaluated for respiratory symptoms is abnormal. If the patient has no complicating medical conditions that favor immunosuppression, the chest radiograph may show the typical picture of upper lobe infiltrates with cavitation. The longer the delay between the onset of symptoms and the diagnosis, the more likely is the finding of cavitary disease. In contrast, immunosuppressed patients, including those with HIV infection, may have "atypical" findings on chest radiography -- e.g., lower zone infiltrates without cavity formation.

AFB Microscopy A presumptive diagnosis is commonly based on the finding of AFB on microscopic examination of a diagnostic specimen such as a smear of expectorated sputum or of tissue (for example, a lymph node biopsy). Most modern laboratories processing large numbers of diagnostic specimens use auramine-rhodamine staining and fluorescence microscopy. The more traditional method -- light microscopy of specimens stained with Kinyoun or Ziehl-Neelsen basic fuchsin dyes -- is satisfactory, although more time-consuming. For patients with suspected pulmonary tuberculosis, three sputum specimens, preferably collected early in the morning, should be submitted to the laboratory for AFB smear and mycobacteriology culture. If tissue is obtained, it is critical that the portion of the specimen intended for culture not be put in formaldehyde. The use of AFB microscopy on urine or gastric lavage fluid is limited by the presence of mycobacterial commensals, which can cause false-positive results.

Mycobacterial Culture Definitive diagnosis depends on the isolation and identification of *M. tuberculosis* from a diagnostic specimen -- in most cases, a sputum specimen obtained from a patient with a productive cough. Specimens may be inoculated onto egg- or agar-based medium (e.g., Lowenstein-Jensen or Middlebrook 7H10) and incubated at 37°C under 5% CO_2. Because most species of mycobacteria, including *M. tuberculosis*, grow slowly, 4 to 8 weeks may be required before growth is detected. Although *M. tuberculosis* may be presumptively identified on the basis of growth time and colony pigmentation and morphology, a variety of biochemical tests have traditionally been used to speciate mycobacterial isolates. In today's laboratories, the use of liquid media with radiometric growth detection (e.g., BACTEC-460) and the identification of isolates by nucleic acid probes or high-pressure liquid chromatography of mycolic acids have replaced the traditional methods of isolation on solid media and identification by biochemical tests. These new methods have decreased the time required for isolation and speciation to 2 to 3 weeks. Other systems for culture on liquid media with nonradiometric detection have become available.

Nucleic Acid Amplification Several test systems based on amplification of mycobacterial nucleic acid are available. These systems permit the diagnosis of tuberculosis in as short a period as several hours. However, their applicability is limited

by low sensitivity (lower than culture) and high cost. At present, these tests are approved by the U.S. Food and Drug Administration only for species identification onAFB-positive sputa. With further improvements in performance, these tests may also be useful for the diagnosis of patients with AFB-negative pulmonary and extrapulmonary tuberculosis.

Radiographic Procedures As noted above, the initial suspicion of pulmonary tuberculosis is often based on abnormal chest radiographic findings in a patient with respiratory symptoms. Although the "classic" picture is that of upper lobe disease with infiltrates and cavities, virtually any radiographic pattern -- from a normal film or a solitary pulmonary nodule to diffuse alveolar infiltrates in a patient withARDS -- may be seen. In the era of AIDS, no radiographic pattern can be considered pathognomonic.

PPDSkin Testing Skin testing with PPD is most widely used in screening for *M. tuberculosis* infection (see below). The test is of limited value in the diagnosis of active tuberculosis because of its low sensitivity and specificity. False-negative reactions are common in immunosuppressed patients and in those with overwhelming tuberculosis. Positive reactions are obtained when patients have been infected with *M. tuberculosis* but do not have active disease and when persons have been sensitized by nontuberculous mycobacteria (Chap. 171) or bacille Calmette-Guerin (BCG) vaccination. Although BCG vaccine is not commonly used in the United States, many immigrants will have received it. In the absence of a history of BCG vaccination, a positive skin test may provide additional support for the diagnosis of tuberculosis in culture-negative cases.

Drug Susceptibility Testing In general, the initial isolate of *M. tuberculosis* should be tested for susceptibility to the primary drugs used for treatment: isoniazid, rifampin, ethambutol, pyrazinamide, and streptomycin. In addition, drug susceptibility tests are mandatory when patients fail to respond to initial therapy or experience a relapse after the completion of treatment (see below). Susceptibility testing may be conducted directly (with the clinical specimen) or indirectly (with mycobacterial cultures) on solid or liquid medium. Results are obtained most rapidly by direct susceptibility testing on liquid medium, with an average reporting time of 3 weeks. With indirect testing on solid media, results may not be available for 8 weeks or longer. Molecular methods for the rapid identification of drug resistance are becoming available. One of the most promising uses polymerase chain reaction (PCR) for the *rpoB* gene to detect resistance to rifampin.

Additional Diagnostic Procedures Other diagnostic tests may be used when pulmonary tuberculosis is suspected. Sputum induction by ultrasonic nebulization of hypertonic saline may be useful for patients unable to produce a sputum specimen spontaneously. Frequently, patients with radiographic abnormalities that are consistent with other diagnoses (e.g., bronchogenic carcinoma) undergo fiberoptic bronchoscopy with bronchial brushings or transbronchial biopsy of the lesion. Bronchoalveolar lavage of a lung segment containing an abnormality may also be performed. In all cases, it is essential that specimens be submitted forAFBsmear and mycobacterial culture. For the diagnosis of primary pulmonary tuberculosis in children, who often do not expectorate sputum, specimens from early-morning gastric lavage may yield positive cultures.

Invasive diagnostic procedures are indicated for patients with suspected extrapulmonary

tuberculosis. In addition to specimens of involved sites (e.g.,CSF for tuberculous meningitis, pleural fluid and biopsy samples for pleural disease), bone marrow and liver biopsy and culture have a good diagnostic yield in disseminated (miliary) tuberculosis, particularly in HIV-infected patients, who also have a high frequency of positive blood cultures.

In some cases, cultures will be negative, but a clinical diagnosis of tuberculosis will be supported by consistent epidemiologic evidence (e.g., a history of close contact with an infectious patient), a positivePPD skin test, and a compatible clinical and radiographic response to treatment. In the United States and other industrialized countries with low rates of tuberculosis, some patients with limited abnormalities on chest radiographs and sputum positive forAFB are infected with organisms of the *M. avium* complex or *M. kansasii* (Chap. 171). Factors favoring the diagnosis of nontuberculous mycobacterial disease over tuberculosis include an absence of risk factors for tuberculosis, a negative PPD skin test, and underlying chronic obstructive pulmonary disease.

Patients with HIV-associated tuberculosis pose several diagnostic problems, as noted above in the description of clinical manifestations. Moreover, HIV-infected patients with sputum culture-positive andAFB-positive tuberculosis may present with a normal chest radiograph. Thus, in a patient with HIV infection, the finding of a normal chest radiograph does not rule out the diagnosis of pulmonary tuberculosis. An additional consideration is that, among relatively severely immunosuppressed AIDS patients in Europe and North America, *M. avium* complex disease is more common than tuberculosis, usually presenting as a disseminated disease without pulmonary parenchymal involvement.

Adjunctive Diagnostic Tests A number of methods have been evaluated as adjuncts to standard laboratory diagnosis. The most thoroughly investigated is serologic diagnosis based on detection of antibody to a variety of mycobacterial antigens. However, tests with most of the target antigens have a low predictive value when used in a population with a presumably low probability of disease. Tests aimed at detection of mycobacterial antigen by serologic methods have generally not been sufficiently sensitive to be useful. Nonspecific tests, such as the measurement of adenine deaminase in pleural fluid, have been evaluated but have not gained acceptance.

TREATMENT

Chemotherapy for tuberculosis became possible with the discovery of streptomycin in the mid-1940s. Randomized clinical trials clearly indicated that the administration of streptomycin to patients with chronic tuberculosis reduced mortality and led to cure in the majority of cases. However, monotherapy with streptomycin was frequently associated with the development of resistance to streptomycin and the attendant failure of treatment. With the discovery of para-aminosalicylic acid (PAS) and isoniazid, it became axiomatic that cure of tuberculosis required the concomitant administration of at least two agents to which the organism was susceptible. Furthermore, early clinical trials demonstrated that a long period of treatment -- i.e., 12 to 24 months -- was required to prevent the recurrence of tuberculosis.

The introduction of rifampin in the early 1970s heralded the era of effective short-course

chemotherapy, with a treatment duration of <12 months. The discovery that pyrazinamide, which was first used in the 1950s, augmented the potency of isoniazid/rifampin regimens led to the use of a 6-month course of this triple-drug regimen as standard therapy.

Drugs Five major drugs are considered the first-line agents for the treatment of tuberculosis: isoniazid, rifampin, pyrazinamide, ethambutol, and streptomycin (Table 169-1). The first four, which are usually given orally, are well absorbed, with peak serum levels at 2 to 4 h and nearly complete elimination within 24 h. These agents are recommended on the basis of their bactericidal activity (ability to rapidly reduce the number of viable organisms), their sterilizing activity (ability to kill all bacilli and thus sterilize the affected organ, measured in terms of the ability to prevent relapses), and their low rate of induction of drug resistance. Rifapentine and rifabutin, two drugs related to rifampin, are also available in the United States.*For a detailed discussion of the drugs used for the treatment of tuberculosis, see Chap. 168.*

Because of a lower degree of efficacy and a higher degree of intolerability and toxicity, a number of second-line drugs are used only for the treatment of patients with tuberculosis resistant to first-line drugs. Included in this group are the injectable drugs kanamycin, amikacin, and capreomycin and the oral agents ethionamide, cycloserine, andPAS. Recently, quinolone antibiotics have become the most commonly used second-line drugs. Of available agents, ofloxacin is the most widely used, but levofloxacin and sparfloxacin are the most active, although the latter drug is associated with high rates of photosensitization. Other second-line drugs include clofazimine, amithiozone (thiacetazone, widely used with isoniazid in less wealthy countries but not marketed in North America or Europe), and amoxicillin/clavulanic acid.

Regimens Short-course regimens are divided into an initial or bactericidal phase and a continuation or sterilizing phase. During the initial phase, the majority of the tubercle bacilli are killed, symptoms resolve, and the patient becomes noninfectious. The continuation phase is required to eliminate semidormant "persisters."

The treatment regimen of choice for virtually all forms of tuberculosis in both adults and children consists of a 2-month initial phase of isoniazid, rifampin, and pyrazinamide followed by a 4-month continuation phase of isoniazid and rifampin (Table 169-2). Except for patients who seem unlikely on epidemiologic grounds to be initially infected with a drug-resistant strain, ethambutol (or streptomycin) should be included in the regimen for the first 2 months or until the results of drug susceptibility testing become available. Treatment may be given daily throughout the course or intermittently (either three times weekly throughout the course or twice weekly following an initial phase of daily therapy). A continuation phase of once-weekly rifapentine and isoniazid appears to be effective for patients who have adhered to the initial-phase treatment and have negative sputum cultures at 2 months. Intermittent treatment is especially useful for patients whose therapy is being directly observed (see below). For patients with sputum culture-negative pulmonary tuberculosis, the duration of treatment may be reduced to a total of 4 months. Pyridoxine (10 to 25 mg/d) should be added to the regimen given to persons at high risk of vitamin deficiency (e.g., alcoholics; malnourished persons; pregnant and lactating women; and patients with conditions such as chronic renal failure, diabetes, and HIV infection or AIDS, which are also associated with neuropathy).

Lack of adherence to treatment regimens is recognized worldwide as the most important impediment to cure. Moreover, the mycobacterial strains infecting patients who do not adhere to the prescribed regimen are especially likely to develop acquired drug resistance. Both patient- and provider-related factors may affect compliance. Patient-related factors include a lack of belief that the illness is significant and/or that treatment will have a beneficial effect; the existence of concomitant medical conditions (notably substance abuse); lack of social support; and poverty, with attendant joblessness and homelessness. Provider-related factors that may promote compliance include the education and encouragement of patients, the offering of convenient clinic hours, and the provision of incentives such as bus tokens.

In addition to specific measures addressing noncompliance, two other strategic approaches are used: direct observation of treatment and provision of drugs in combined formulations. Because it is difficult to predict which patients will adhere to the recommended treatment, all patients should have their therapy directly supervised, especially during the initial phase. In the United States, personnel to supervise therapy are usually available through tuberculosis control programs of local public health departments. Supervision increases the proportion of patients completing treatment and greatly lessens the chances of relapse and acquired drug resistance. Combination products (e.g., isoniazid/rifampin and isoniazid/rifampin/pyrazinamide) are available and are strongly recommended as a means of minimizing the likelihood of prescription error and of the development of drug resistance (as the result of treatment with only one agent). In some formulations of these combination products, the bioavailability of rifampin has been found to be substandard. In North America and Europe, regulatory authorities ensure that combination products are of good quality; however, this type of monitoring cannot be assumed to take place in less affluent countries. Alternative regimens for patients who exhibit drug intolerance or adverse reactions are listed inTable 169-2. However, severe side effects prompting discontinuation of any of the first-line drugs and use of these alternative regimens are uncommon.

Monitoring the Response to Treatment Bacteriologic evaluation is the preferred method of monitoring the response to treatment for tuberculosis. Patients with pulmonary disease should have their sputum examined monthly until cultures become negative. With the recommended 6-month regimen, more than 80% of patients will have negative sputum cultures at the end of the second month of treatment. By the end of the third month, virtually all patients should be culture-negative. In some patients, especially those with extensive cavitary disease and large numbers of organisms,AFBsmear conversion may follow culture conversion. This phenomenon is presumably due to the expectoration and microscopic visualization of dead bacilli. When a patient's sputum cultures remain positive at or beyond 3 months, treatment failure and drug resistance should be suspected (see below). A sputum specimen should be collected at the end of treatment to document cure. If mycobacterial cultures are not practical, then monitoring by AFB smear examination should be undertaken at 2, 5, and 6 months. Smears positive after 5 months are indicative of treatment failure.

Bacteriologic monitoring of patients with extrapulmonary tuberculosis is more difficult and often is not feasible. In these cases, the response to treatment must be assessed clinically.

Monitoring of the response to treatment during chemotherapy by serial chest radiographs is not recommended, as radiographic changes may lag behind bacteriologic response and are not highly sensitive. After the completion of treatment, neither sputum examination nor chest radiography is recommended for follow-up purposes. However, a chest radiograph may be obtained at the end of treatment and used for comparative purposes should the patient develop symptoms of recurrent tuberculosis months or years later. Patients should be instructed to report promptly for medical assessment should they develop any such symptoms.

During treatment, patients should be monitored for drug toxicity (see alsoTable 168-3). The most common adverse reaction of significance is hepatitis. Patients should be carefully educated about the signs and symptoms of drug-induced hepatitis (e.g., dark urine, loss of appetite) and should be instructed to discontinue treatment promptly and see their health care provider should these symptoms occur. Although biochemical monitoring is not routinely recommended, all adult patients should undergo baseline assessment of liver function (e.g., measurement of levels of hepatic aminotransferases and serum bilirubin). Older patients, those with histories of hepatic disease, and those using alcohol daily should be monitored especially closely (i.e., monthly), with repeated measurements of aminotransferases, during the initial phase of treatment. Up to 20% of patients have small increases in aspartate aminotransferase (up to three times the upper limit of normal) that are accompanied by no symptoms and are of no consequence. For patients with symptomatic hepatitis and those with marked (five- to sixfold) elevations in aspartate aminotransferase, treatment should be stopped and drugs reintroduced one at a time after liver function has returned to normal.

Hypersensitivity reactions usually require the discontinuation of all drugs and rechallenge to determine which agent is the culprit. Because of the variety of regimens available, it is usually not necessary -- although it is possible -- to desensitize patients. Hyperuricemia and arthralgia caused by pyrazinamide can usually be managed by the administration of acetylsalicylic acid; however, pyrazinamide treatment should be stopped if the patient develops gouty arthritis. Individuals who develop autoimmune thrombocytopenia secondary to rifampin therapy should not receive the drug thereafter. Similarly, the occurrence of optic neuritis with ethambutol and the development of eighth-nerve damage with streptomycin are indications for permanent discontinuation of these respective drugs. Other common manifestations of drug intolerance, such as pruritus and gastrointestinal upset, can generally be managed without the interruption of therapy.

Treatment Failure and Relapse As stated above, treatment failure should be suspected when a patient's sputum cultures remain positive after 3 months or whenAFBsmears remain positive after 5 months. In the management of such patients, it is imperative that the current isolate be tested for susceptibility to first- and second-line agents. When the results of susceptibility testing are expected to become available within a few weeks, changes in the regimen can be postponed until that time. However, if the patient's clinical condition is deteriorating, an earlier change in regimen may be indicated. A cardinal rule in the latter situation is always to add more than one drug at a time to a failing regimen: at least two and preferably three drugs that have never been used should be added. The patient may continue to take isoniazid and rifampin along

with these new agents pending the results of susceptibility tests.

The mycobacterial strains infecting patients who experience a relapse after apparently successful treatment are less likely to have acquired drug resistance (see below) than are strains from patients in whom treatment has failed. However, if the regimen administered initially does not contain rifampin (and thus is not a short-course regimen), the probability of isoniazid resistance is high. Acquired resistance is uncommon among strains from patients who relapse after completing a short course of therapy. However, it is prudent to begin the treatment of all relapses with all five first-line drugs pending the results of susceptibility testing. In less affluent countries and other settings where facilities for culture and drug susceptibility testing are not available, a standard regimen should be used in all instances of relapse and treatment failure (Table 169-2).

Adjunctive Glucocorticoid Therapy The use of glucocorticoids for adjunctive treatment of tuberculosis is justified by their potent anti-inflammatory activity in a disease where host response plays a major role. There is a sound basis for using glucocorticoids in tuberculous meningitis and pericarditis to hasten clinical improvement (see above). Long-term benefits are limited to reduced mortality in effusive-constrictive pericarditis and decreased neurologic sequelae in meningitis. Studies have indicated that the usefulness of these agents in pleuritis may be less important than previously thought. There is not yet conclusive evidence that glucocorticoids produce benefits in patients with acute life-threatening pulmonary tuberculosis, includingARDS. In general, depending upon the urgency and severity of clinical conditions, prednisone may be administered at a daily dose of 20 to 60 mg for up to 6 weeks. In meningitis, dexamethasone (up to 12 mg/d) is the preferred drug; therapy continues for 4 to 6 weeks, with gradual tapering of the dose after the first 2 weeks. Rifampin interaction with glucocorticoids, resulting in accelerated metabolism and potential adrenal crisis, must be taken into account. Caution should be exercised in the use of glucocorticoids in HIV-infected patients.

Drug-Resistant Tuberculosis Strains of *M. tuberculosis* resistant to individual drugs arise by spontaneous point mutations in the mycobacterial genome, which occur at low but predictable rates. Because there is no cross-resistance among the commonly used drugs, the probability that a strain will be resistant to two drugs is the product of the probabilities of resistance to each drug and thus is low. The development of drug-resistant tuberculosis is invariably the result of monotherapy -- i.e., the failure of the health care provider to prescribe at least two drugs to which tubercle bacilli are susceptible or of the patient to take properly prescribed therapy.

Drug-resistant tuberculosis may be either primary or acquired. *Primary* drug resistance is that in a strain infecting a patient who has not previously been treated. *Acquired* resistance develops during treatment with an inappropriate regimen. In North America and Europe, rates of primary resistance are generally low, and isoniazid resistance is most common. In the United States, while isoniazid resistance was stable at about 8% in 1993 through 1996, rates ofMDRtuberculosis were declining. Resistance rates are higher among foreign-born and HIV-infected patients. Worldwide, MDR tuberculosis is a serious problem in some regions, especially in the former USSR and parts of Asia. As noted above, drug-resistant tuberculosis can be prevented by adherence to the principles of sound therapy: the inclusion of at least two bactericidal drugs to which the

organism is susceptible (in practice, four drugs are commonly given in the initial phase) and the verification that patients complete the prescribed course.

Although the 6-month regimen described in Table 169-2 is highly effective for patients with initial isoniazid-resistant disease, it is prudent to extend treatment to 9 months and to include ethambutol throughout. Alternatively, rifampin, pyrazinamide, and ethambutol may be given for 6 months. For disease with high-level isoniazid resistance, isoniazid probably does not contribute to a successful outcome and can be omitted.MDRtuberculosis is more difficult to manage than is disease caused by a drug-susceptible organism, especially because resistance to other first-line drugs as well as to isoniazid and rifampin is common. For strains resistant to isoniazid and rifampin, combinations of ethambutol, pyrazinamide, and streptomycin (or, for those resistant to streptomycin as well, another injectable agent such as amikacin), given for 12 to 18 months in all and for at least 9 months after sputum culture conversion, may be effective. Many authorities would add a quinolone antibiotic to this regimen. For patients with bacilli resistant to all of the first-line agents, cure may be attained with a combination of four second-line drugs, including one injectable agent (Table 169-2). The optimal duration of treatment in this situation is not known; however, a duration of up to 24 months is recommended. For patients with localized disease and sufficient pulmonary reserve, lobectomy or pneumonectomy may be helpful. Because the management of patients with MDR tuberculosis is complicated by both social and medical factors, care of these patients should be restricted to specialists and tuberculosis control programs.

Special Clinical Situations Although comparative clinical trials of treatment for extrapulmonary tuberculosis are limited, the available evidence indicates that most forms of disease can be treated with the 6-month regimen recommended for patients with pulmonary disease. The American Academy of Pediatrics recommends that children with bone and joint tuberculosis, tuberculous meningitis, or miliary tuberculosis receive a minimum of 12 months of treatment.

Treatment for tuberculosis may be complicated by underlying medical problems that require special consideration (see also Table 168-1). As a rule, patients with chronic renal failure should not receive aminoglycosides and should receive ethambutol only if serum levels can be monitored. Isoniazid, rifampin, and pyrazinamide may be given in the usual doses in cases of mild to moderate renal failure, but the dosages of isoniazid and pyrazinamide should be reduced for all patients with severe renal failure except those undergoing hemodialysis. Patients with hepatic disease pose a special problem because of the hepatotoxicity of isoniazid, rifampin, and pyrazinamide. Patients with severe hepatic disease may be treated with ethambutol and streptomycin and, if required, with isoniazid and rifampin under close supervision. The use of pyrazinamide by patients with liver failure should be avoided. Silicotuberculosis necessitates the extension of therapy by at least 2 months. Patients with HIV infection or AIDS appear to respond well to standard 6-month therapy, although treatment may need to be prolonged if the response is suboptimal. Rifampin, a powerful inducer of hepatic microsomal enzymes, shortens the half-life of HIV protease inhibitors and therefore is contraindicated for patients receiving these drugs; instead, these individuals should be given rifabutin (150 mg/d or 300 mg twice weekly) with either indinavir or nelfinavir. Studies have shown that total systemic drug exposure, especially for rifampin, is

reduced in HIV-infected patients because of decreased bioavailability secondary to malabsorption. The clinical importance of this phenomenon remains unclear.

The regimen of choice for pregnant women (see alsoTable 168-1) is 9 months of treatment with isoniazid and rifampin supplemented by ethambutol for the first 2 months. When required, pyrazinamide may be given, although there are no data concerning its safety in pregnancy. Streptomycin is contraindicated because it is known to cause eighth-cranial-nerve damage in the fetus. Treatment for tuberculosis is not a contraindication to breast feeding; most of the drugs administered will be present in small quantities in breast milk, albeit at concentrations far too low to provide any therapeutic or prophylactic benefit to the child.

PREVENTION

By far the best way to prevent tuberculosis is to diagnose infectious cases rapidly and administer appropriate treatment until cure. Additional strategies includeBCGvaccination and preventive chemotherapy.

BCG Vaccination BCG was derived from an attenuated strain of *M. bovis* and was first administered to humans in 1921. Many BCG vaccines are available worldwide; all are derived from the original strain, but the vaccines vary in efficacy. In fact, estimates of efficacy from randomized, placebo-controlled trials have ranged from 80% to nil. A similar range of efficacy was found in recent observational studies (case-control, historic cohort, and cross-sectional) in areas where infants are vaccinated at birth. These studies also found higher rates of efficacy in the protection of infants and young children from relatively serious forms of tuberculosis, such as tuberculous meningitis and miliary tuberculosis.

BCGvaccine is safe and rarely causes serious complications. The local tissue response begins 2 to 3 weeks after vaccination, with scar formation and healing within 3 months. Side effects -- most commonly, ulceration at the vaccination site and regional lymphadenitis -- occur in 1 to 10% of vaccinated persons. Some vaccine strains have caused osteomyelitis in approximately one case per million doses administered. Disseminated BCG infection and death have occurred in 1 to 10 cases per 10 million doses administered, although this problem is restricted almost exclusively to persons with impaired immunity, such as children with severe combined immunodeficiency syndrome (SCIDS) or adults with HIV infection. BCG vaccination inducesPPDreactivity, which tends to wane with time. The presence or size of PPD skin-test reactions after vaccination does not predict the degree of protection afforded.

BCGvaccine is recommended for routine use at birth in countries with high tuberculosis prevalence. However, because of the low risk of transmission of tuberculosis in the United States and the unreliable protection afforded by BCG, the vaccine has never been recommended for general use in the United States. Currently, vaccination should be considered forPPD-negative infants and children who reside in settings where the likelihood of *M. tuberculosis* transmission and subsequent infection is high, provided no other measures can be implemented (e.g., removing the child from the source of infection). BCG vaccination may also be considered for health care workers who are employed in settings where the risk of infection byMDRstrains is high despite

implementation of comprehensive tuberculosis control measures. TheCDC has recommended that HIV-infected adults and children not receive BCG vaccine, although theWHO has recommended that asymptomatic HIV-infected children residing in tuberculosis-endemic areas receive BCG.

Treatment of Latent Tuberculosis Infection A major component of tuberculosis control in the United States is the treatment of selected persons with latent tuberculosis infection to prevent active disease. This intervention (formerly called preventive chemotherapy or chemoprophylaxis) is based on the results of a large number of randomized, placebo-controlled clinical trials demonstrating that a 6- to 12-month course of isoniazid reduces the risk of active tuberculosis in infected people by³90%. Analysis of available data indicates that the optimal duration of treatment is 9 to 10 months. In the absence of reinfection, the protective effect is believed to be lifelong. Clinical trials have also shown that isoniazid reduces rates of tuberculosis amongPPD-positive persons with HIV infection. Studies in HIV-infected patients have demonstrated the effectiveness of a shorter course of rifampin-based treatment.

In most cases, candidates for treatment of latent tuberculosis (Table 169-3) are identified byPPD skin testing of persons in defined high-risk groups. For skin testing, 5 tuberculin units of polysorbate-stabilized PPD should be injected intradermally into the volar surface of the forearm (Mantoux method). Multipuncture tests, which may be useful for screening large populations, are not recommended for this purpose; any positive reaction to a multipuncture test must be confirmed by Mantoux testing. Reactions are read at 48 to 72 h as the transverse diameter in millimeters of induration; the diameter of erythema is not considered. In some persons, PPD reactivity wanes with time but can be recalled by a second skin test administered 1 week or more after the first (i.e., two-step testing). For persons undergoing periodic PPD skin testing, such as health care workers and individuals admitted to long-term-care institutions, initial two-step testing may preclude subsequent misclassification of persons with boosted reactions as PPD converters.

The cutoff for a positive skin test (and thus for treatment) is related both to the probability that the reaction represents true infection and to the likelihood that the individual, if truly infected, will develop tuberculosis (Table 169-3). Thus positive reactions for close contacts of infectious cases, persons with HIV infection, and previously untreated persons whose chest radiograph is consistent with healed tuberculosis are defined as an area of induration 5 mm in diameter. A 10-mm cutoff is used to define positive reactions in most other at-risk persons. For persons with a very low risk of developing tuberculosis if infected, a cutoff of 15 mm is used. Persons with a history ofBCGvaccination may receive treatment, especially if BCG was given many years before.

SomePPD-negative individuals are also candidates for treatment. Infants and children who have come into contact with infectious cases should be treated and should have a repeat skin test 2 or 3 months after contact ends. Those whose test results remain negative should discontinue treatment. HIV-infected persons who have been exposed to an infectious tuberculosis patient should receive treatment regardless of the PPD test result.

Isoniazid is administered at a daily dose of 5 mg/kg (up to 300 mg/d) for 9 months. On the basis of cost-benefit analyses, a 6-month period of treatment has been recommended in the past and may be considered for HIV-negative adults with normal chest radiographs when financial considerations are important. When supervised treatment is desirable and feasible, isoniazid may be given at a dose of 15 mg/kg (up to 900 mg) twice weekly. There are two recommended alternative regimens for adults: 2 months of daily rifampin plus pyrazinamide and 4 months of daily rifampin. Although the 2-month regimen may be associated with increased drug intolerance, it may be useful in situations where long courses of isoniazid have not been feasible (e.g., jails). Either regimen should be considered for persons who are likely to have been infected with an isoniazid-resistant strain.

Contraindications to treatment with isoniazid and pyrazinamide include active liver disease. Since the major adverse reaction to these drugs is hepatitis, persons at increased risk of toxicity (e.g., those abusing alcohol daily and those with a history of liver disease) should undergo baseline and then monthly assessment of liver function during treatment. All patients should be carefully educated about hepatitis and instructed to discontinue use of the drug immediately should any symptoms develop. Moreover, patients should be seen and questioned monthly during therapy about adverse reactions and should be given no more than 1 month's supply of drug at each visit.

It may be more difficult to ensure compliance when treating persons with latent infection than when treating those with active tuberculosis. If family members of active cases are being treated, compliance and monitoring may be easier. When feasible, twice-weekly supervised therapy may increase the likelihood of completion. As in active cases, the provision of incentives may also be helpful.

BASICS OF CONTROL

The highest priority in any tuberculosis control program is the prompt detection of cases and the provision of directly observed short-course chemotherapy to all tuberculosis patients, with emphasis on the cure of sputum smear-positive cases. In addition, in low-prevalence countries with adequate resources, screening of high-risk groups (such as immigrants from high-prevalence countries and HIV-seropositive persons) is recommended. Identification of active cases of tuberculosis should be followed by treatment.PPD-positive high-risk persons should be treated for latent infection. Contact investigation is an important component of efficient tuberculosis control. In the United States, a great deal of attention has been given to the transmission of tuberculosis (particularly in association with HIV infection) in institutional settings such as hospitals, homeless shelters, and prisons. Measures to limit such transmission include respiratory isolation of persons with suspected tuberculosis until they are proven to be noninfectious (i.e., by sputumAFBsmear negativity), proper ventilation in rooms of patients with infectious tuberculosis, use of ultraviolet lights in areas of increased risk of tuberculosis transmission, and periodic screening of personnel who may come into contact with known or unsuspected cases of tuberculosis. In the past, radiographic surveys, especially those conducted with portable equipment and miniature films, were advocated for case finding. Today, however, the prevalence of tuberculosis in industrialized countries is sufficiently low that "mass miniature radiography" is not

cost-effective. As mentioned above, current recommendations for the prevention and treatment of tuberculosis in HIV-infected individuals have been published by theCDC.

In high-prevalence countries, tuberculosis control programs should be based on the following key elements: (1) case detection through microscopic examination of sputum from patients who present to health care facilities with cough of>3 weeks' duration; (2) administration of standard short-course chemotherapy to all sputum smear-positive patients, with direct observation of drug ingestion; (3) establishment and maintenance of a system of regular drug supply; and (4) establishment and maintenance of an effective surveillance and treatment-monitoring system allowing an analysis of treatment outcomes (e.g., cure, completion of treatment without bacteriologic proof of cure, death, treatment failure, and default) in all cases registered.

170. LEPROSY (HANSEN'S DISEASE) - *Robert H. Gelber*

Leprosy, first described in ancient Indian texts from the sixth century B.C., is a nonfatal, chronic infectious disease caused by *Mycobacterium leprae*, whose clinical manifestations are largely confined to the skin, peripheral nervous system, upper respiratory tract, eyes, and testes. The unique tropism of *M. leprae* for peripheral nerves (from large nerve trunks to microscopic dermal nerves) and certain immunologically mediated reactional states are the major causes of morbidity in leprosy. The propensity of the disease, when untreated, to result in certain characteristic deformities and the recognition in most cultures that the disease is communicable from person to person have resulted historically in a profound social stigma. Today, with early diagnosis and the institution of appropriate and effective antimicrobial therapy, patients can lead productive lives in the community, and deformities and other visible manifestations can largely be prevented.

ETIOLOGY

M. leprae is an obligate intracellular bacillus (0.3 to 1 um wide and 1 to 8 um long) that is acid-fast, indistinguishable microscopically from other mycobacteria, ideally detected in tissue sections by a modified Fite stain, and without demonstrable strain variability. *M. leprae* produces no known toxins and is well adapted to penetrate and reside within macrophages, yet it may survive outside the body for 7 to 10 days. In untreated patients, only ~1% of *M. leprae* organisms are viable. The morphologic index, a measure of the number of acid-fast bacilli (AFB) in skin scrapings that stain uniformly bright, correlates with viability. The bacteriologic index, a logarithmic-scaled measure of the density of *M. leprae* in the dermis, may be as high as 4+ to 6+ in untreated patients, falling by one unit per year during effective therapy; the rate of fall is independent of the relative potency of effective antimicrobial therapy. A rising bacteriologic or morphologic index suggests relapse and perhaps -- if the patient is being treated -- drug resistance; the latter possibility can be confirmed or excluded in the mouse model.

The genome of *M. leprae* is only 3 million base pairs, two-thirds as large as that of *M. tuberculosis*. The bacterium's complex cell wall has a peptidoglycan backbone, which is linked to arabinogalactan and mycolic acids. Lipoarabinomannan is a key component of the cell membrane, and the outer capsule contains large amounts of an *M. leprae*-specific phenolic glycolipid (PGL-1), which is detected in serologic tests. In addition, highly conserved, usually immunogenic heat-shock proteins containing *M. leprae*-specific and mycobacterial cross-reactive epitopes are found in the cytoplasm and cell wall.

Among the mycobacteria, *M. leprae* is unique in exhibiting dopa oxidase activity and an acid-fastness that is pyridine-extractable. Although it was the first bacterium to be etiologically associated with human disease, *M. leprae* remains one of the few bacterial species that still has not been cultivated on artificial medium or tissue culture. The multiplication of *M. leprae* in mouse footpads (albeit limited, with a doubling time of ~2 weeks) has provided a means to evaluate antimicrobial agents, monitor clinical trials, and screen vaccines. *M. leprae* grows best in cooler tissues (the skin, peripheral nerves, anterior chamber of the eye, upper respiratory tract, and testes), sparing warmer areas of the skin (the axilla, groin, scalp, and midline of the back).

EPIDEMIOLOGY

Demographics Leprosy is almost exclusively a disease of the developing world, affecting areas of Asia, Africa, Latin America, and the Pacific. While Africa has the highest disease prevalence, Asia has the most cases. More than 80% of the world's cases occur in a few countries: India, China, Myanmar, Indonesia, Brazil, and Nigeria. Within endemic locales, the distribution of leprosy is quite uneven, with areas of high prevalence bordering on areas with little or no disease. In Brazil the majority of cases occur in the Amazon basin, while in Mexico leprosy is mostly confined to western states. Except as imported cases, leprosy is largely absent from the United States, Canada, and northwestern Europe. In the United States, ~4000 persons have leprosy and 100 to 200 new cases are reported annually, most of them in California, Texas, New York, and Hawaii among immigrants from Mexico, Southeast Asia, the Philippines, and the Caribbean.

The global prevalence of leprosy is difficult to assess, given that many of the locales with high prevalence lack a significant medical or public health infrastructure. Estimates range from 1.5 to 8 million affected individuals. The lower estimate includes only persons who have not completed chemotherapy, excluding those who may be physically or psychologically damaged from leprosy and who may yet relapse or develop certain immune-mediated reactions; the higher figure includes patients whose infections probably are already cured and many who have no leprosy-related deformity or disability. Although the figures on the worldwide prevalence of leprosy are debatable, it is generally agreed that the annual incidence of new cases is stable and approximates 600,000.

Leprosy is associated with poverty and rural residence. It appears not to be associated with AIDS, perhaps because of leprosy's long incubation period. Most people appear to be naturally immune to leprosy and do not develop disease manifestations following exposure. The time of peak onset is in the second and third decades of life. The most severe form, lepromatous leprosy, is twice as common among men as among women and is rarely encountered in children. The frequency of the polar forms of leprosy (see "Clinical, Histologic, and Immunologic Spectrum," below) in different countries varies widely and may in part be genetically determined; certain HLA associations are known for both lepromatous and tuberculoid leprosy (see below). In India and Africa, 90% of cases are tuberculoid; in Southeast Asia, 50% are lepromatous and 50% tuberculoid; and in Mexico, 90% are lepromatous.

Transmission *M. leprae* causes disease primarily in humans. However, in Texas and Louisiana, 15% of nine-banded armadillos are infected, and armadillo contact occasionally results in human disease. Following intravenous experimental inoculation of *M. leprae*, 60% of armadillos develop a heavy disseminated infection of the liver, spleen, lymph nodes, and skin; these experimental animals have been the source of vast quantities of *M. leprae* organisms for laboratory and clinical research.

The route of transmission of leprosy remains uncertain and may be multiple; nasal droplet infection, contact with infected soil, and even insect vectors have been considered the prime candidates. Aerosolized *M. leprae* can cause infection in

immunosuppressed mice, and a sneeze from an untreated lepromatous patient may contain>10^{10}AFB. Furthermore, both IgA antibody to *M. leprae* and genes of *M. leprae* -- demonstrable by polymerase chain reaction (PCR) -- have been found in the nose of individuals without signs of leprosy from endemic areas and in 19% of occupational contacts of lepromatous patients.

Several lines of evidence implicate soil transmission of leprosy. (1) In endemic countries such as India, leprosy is primarily a rural and not an urban disease. (2) *M. leprae* products have been demonstrated to be resident in soil in endemic locales. (3) Direct dermal inoculation (e.g., during tattooing) may transmit *M. leprae*, and common sites of leprosy in children are the buttocks and thighs, suggesting that microinoculation of infected soil may transmit the disease.

Evidence for insect vectors of leprosy includes the demonstration that bedbugs and mosquitoes in the vicinity of leprosaria regularly harbor *M. leprae* and that experimentally infected mosquitoes can transmit infection to mice. Skin-to-skin contact is generally not considered an important route of transmission.

In endemic countries, ~50% of leprosy patients have a history of intimate contact with an infected person (often a household member), while, for unknown reasons, leprosy patients in nonendemic locales can identify such contact only 10% of the time. Moreover, household contact with an infected lepromatous case carries an eventual risk of disease acquisition of ~10% in endemic areas as opposed to only 1% in nonendemic locales. Contact with a tuberculoid case carries a very low risk. Physicians and nurses caring for leprosy patients and the co-workers of these patients are not at risk for leprosy.

CLINICAL, HISTOLOGIC, AND IMMUNOLOGIC SPECTRUM

The incubation period prior to manifestation of clinical disease can vary between 2 and 40 years, although it is generally 5 to 7 years in duration. Leprosy presents as a spectrum of clinical manifestations that have pathologic and immunologic counterparts. The spectrum from polar tuberculoid (TT) to borderline tuberculoid (BT) to borderline lepromatous (BL) to polar lepromatous (LL) disease is associated with an evolution from localized to more generalized disease manifestations, an increasing bacterial load, and loss of *M. leprae*-specific cellular immunity. Where a patient presents on the clinical spectrum largely determines prognosis, complications, reactional states, and the intensity of antimicrobial therapy required.

Tuberculoid Leprosy At the less severe end of the spectrum is tuberculoid leprosy, which encompasses TT and BT disease. In general, these forms of leprosy result in symptoms confined to the skin and peripheral nerves. The initial lesion of tuberculoid leprosy is often a hypopigmented macule that is sharply demarcated and hypesthetic. Later, the lesions enlarge by peripheral spread, and the margins become elevated and circinate or gyrate. The central area in turn becomes atrophic and depressed. Fully developed lesions are densely anesthetic and devoid of the normal skin organs (sweat glands and hair follicles). Patients eventually have one or more asymmetrically distributed, hypopigmented, anesthetic, nonpruritic, well-defined macules, often with an erythematous or raised border (Fig. 170-1;Fig. 170-CD1). Skin lesions of tuberculoid

leprosy vary in diameter from one to several centimeters and are often dry, scaly, and anhidrotic. Tuberculoid leprosy patients may also have asymmetric enlargement of one or a few peripheral nerves. Indeed, leprosy and certain rare hereditary neuropathies are the only human diseases associated with peripheral-nerve enlargement. Although any peripheral nerve may be enlarged (including small digital and supraclavicular nerves), those most commonly affected are the ulnar, posterior auricular, peroneal, and posttibial nerves, with associated hypesthesia and myopathy. At times, tuberculoid leprosy may present with only nerve-trunk involvement with no skin lesions; in such cases it is termed *neural leprosy*. TT leprosy may resolve spontaneously and is not associated with lepra reactions (see "Reactional States," below). BT leprosy does not heal spontaneously and may be associated with type 1 lepra reactions but not with erythema nodosum leprosum (ENL). TT leprosy is the most common form of the disease encountered in India and Africa but is virtually absent in Southeast Asia, where BT leprosy is frequent.

In TT leprosy the epidermis may be involved histologically, while in all other forms of leprosy the epidermis and the superficial dermis are spared, with pathology confined to the deeper dermis. On hematoxylin and eosin staining, TT and BT lesions appear as well-defined noncaseating granulomas with many lymphocytes and Langhans' giant cells. In tuberculoid leprosy, T cells breach the perineurium, and destruction of Schwann cells and axons may be evident, resulting in fibrosis of the epineurium, replacement of the endoneurium with epithelial granulomas, and occasionally caseous necrosis.AFB are generally absent or few in number. Such invasion and destruction of nerves in the dermis by T cells are pathognomonic for leprosy.

Circulating lymphocytes from patients with tuberculoid leprosy readily recognize *M. leprae* and its constituent proteins, and patients have positive lepromin skin tests (see "Diagnosis" below). In tuberculoid leprosy tissue, there is a 2:1 predominance of helper CD4+ over CD8+ T lymphocytes. Tuberculoid tissues are rich in the mRNAs of the proinflammatory T_H1 family of cytokines: interleukin (IL) 2, interferon g(IFN-g), and IL-12; in contrast, IL-4, IL-5, and IL-10 mRNAs are scarce.

Lepromatous Leprosy At the more severe end of the leprosy spectrum is lepromatous disease, which encompasses the LL and BL forms. The initial skin lesions of lepromatous leprosy are skin-colored or slightly erythematous papules or nodules. In time, individual lesions grow in diameter up to 2 cm; new papules and nodules then appear and may coalesce. Patients later present with symmetrically distributed skin nodules, raised plaques, or diffuse dermal infiltration (Fig. 170-CD2), which, when on the face, results in leonine facies. Late manifestations include loss of eyebrows (initially the lateral margins only; see Plate IID-56) and eyelashes, pendulous earlobes, and dry scaling skin, particularly on the feet. Almost exclusively found in western Mexico and the Caribbean is a form of lepromatous leprosy without visible skin lesions but with diffuse dermal infiltration and a demonstrably thickened dermis, termed *diffuse lepromatosis*. In lepromatous leprosy, nerve enlargement and damage tend to be symmetric, result from actual bacillary invasion, and are more insidious but ultimately more extensive than in tuberculoid leprosy. Patients with LL leprosy have symmetric acral distal peripheral neuropathy and a tendency toward symmetric nerve-trunk enlargement. They may also have signs and symptoms related to involvement of the upper respiratory tract, the anterior chamber of the eye, and the testes.

Dermatopathology in lepromatous leprosy is confined to the dermis and particularly affects the dermal appendages. Histologically, the dermis characteristically contains highly vacuolated cells (*foam cells*) otherwise found only in certain lipid-storage disorders. Indeed, on fat staining, these vacuoles are highly positive and are seen to include large amounts of *M. leprae*-associated cell wall lipids and the *M. leprae*-specificPGL-1. The dermis in lepromatous leprosy contains few lymphocytes and giant cells, and granulomas are absent. In LL leprosy, bacilli are numerous in the skin (as many as 10^9/g), where they are often found in large clumps (*globi*), and in peripheral nerves, where they initially invade Schwann cells, resulting in foamy degenerative myelination and axonal degeneration and later in Wallerian degeneration. In addition, bacilli are plentiful in circulating blood and in all organ systems except the lungs and the central nervous system. Nevertheless, patients are afebrile, and there is no evidence of major organ system dysfunction. The dermis contains more lymphocytes and fewerAFB and exhibits less vacuolization in BL than in LL leprosy.

In untreated LL patients, lymphocytes regularly fail to recognize either *M. leprae* or its protein constituents, and lepromin skin tests are negative (see "Diagnosis," below). This loss of protective cellular immunity appears to be antigen-specific, as patients are not unusually susceptible to opportunistic infections, cancer, or AIDS and maintain delayed-type hypersensitivity to *Candida*, *Trichophyton*, mumps, tetanus toxoid, and even purified protein derivative of tuberculin. At times, *M. leprae*-specific anergy is reversible with effective chemotherapy. In LL tissues, there is a 2:1 ratio of CD8+ to CD4+ T lymphocytes. LL tissues demonstrate a T_H2 cytokine profile, being rich in mRNAs forIL-4, IL-5, and IL-10 and poor in those for IL-2,IFN-g, and IL-12. It appears that cytokines mediate a protective tissue response in leprosy, as injection of IFN-g or IL-2 into lepromatous lesions causes a loss ofAFB and histopathologic conversion toward a tuberculoid pattern. Macrophages of lepromatous leprosy patients appear to be functionally intact; circulating monocytes exhibit normal microbicidal function and responsiveness to IFN-g.

LL and BL patients may develop type 2 lepra reactions (ENL; see "Reactional States," below), while BL patients (but not LL patients) can have type 1 lepra reactions.

Reactional States Lepra reactions comprise several common immunologically mediated inflammatory states that cause considerable morbidity. Some of these reactions precede diagnosis and the institution of effective antimicrobial therapy. Indeed, these reactions may precipitate presentation for medical attention and diagnosis; others occur after the initiation of appropriate chemotherapy. In the latter circumstances, patients often lose confidence in conventional therapy, perceiving that their leprosy is worsening. Only by warning patients of the potential for these reactions and describing their manifestations can physicians treating leprosy patients ensure continued credibility.

Type 1 Lepra Reactions (Downgrading and Reversal Reactions) These reactions occur in almost half of patients with borderline forms of leprosy but not in patients with polar disease. Manifestations include classic signs of inflammation within previously involved macules, papules, and plaques and, on occasion, the appearance of new skin lesions, neuritis, and (less commonly) fever -- generally low-grade. The nerve trunk most

commonly involved in this process is the ulnar nerve at the elbow, which may be painful and exquisitely tender. If patients with affected nerves are not treated promptly with glucocorticoids (see below), irreversible nerve damage may result in as little as 24 h. The most dramatic manifestation is footdrop, which occurs when the peroneal nerve is involved.

When type 1 lepra reactions precede the initiation of appropriate antimicrobial therapy, they are termed *downgrading reactions*, and the case becomes histologically more lepromatous; when they occur after the initiation of therapy, they are termed *reversal reactions*, and the case becomes more tuberculoid. Reversal reactions often occur in the first months or years after the initiation of therapy but may also develop several years thereafter.

Edema is the most characteristic microscopic feature of type 1 lepra lesions, whose diagnosis is primarily clinical. Reversal reactions are typified by a T_H1 cytokine profile, with an influx of CD4+ helper cells and increased levels ofIFN-gandIL-2. In addition, type 1 reactions are associated with large numbers of T cells bearinggg/¶receptors -- a unique feature of leprosy.

Type 1 lepra reactions are best treated with glucocorticoids (e.g., prednisone, initially at doses of 40 to 60 mg/d). As the inflammation subsides, the glucocorticoid dose can be tapered, but steroid therapy must be continued for at least 3 months lest recurrence supervene. Because of the myriad toxicities of prolonged glucocorticoid therapy, the indications for its initiation are strictly limited to lesions whose intense inflammation poses a threat of ulceration; lesions at cosmetically important sites, such as the face; and the presence of neuritis. Mild to moderate lepra reactions that do not meet these criteria should be tolerated and glucocorticoid treatment withheld. Thalidomide is ineffective against type 1 lepra reactions; clofazimine (200 to 300 mg/d) is of questionable benefit but in any event is far less efficacious than glucocorticoids.

Type 2 Lepra Reactions (ENL) ENLoccurs exclusively in patients near the lepromatous end of the leprosy spectrum, affecting nearly 50% of this group. Although ENL may precede leprosy diagnosis and initiation of therapy -- sometimes, in fact, prompting the diagnosis -- in 90% of cases it follows the institution of chemotherapy, generally within 2 years. The most common features of ENL are crops of painful erythematous papules that resolve spontaneously in a few days to a week but may recur; malaise; and fever that can be profound. However, patients may also experience symptoms of neuritis, lymphadenitis, uveitis, orchitis, and glomerulonephritis and may develop anemia, leukocytosis, and abnormal liver function tests, particularly increased aminotransferase levels. Individual patients may have either a single bout of ENL or chronic recurrent manifestations. Bouts may be either mild or severe and generalized; in rare instances, ENL results in death.

Skin biopsy ofENLpapules reveals vasculitis or panniculitis, sometimes with many lymphocytes but characteristically with polymorphonuclear leukocytes as well.

Elevated levels of circulating tumor necrosis factor (TNF) have been demonstrated inENL; thus TNF may play a central role in the pathobiology of this syndrome. ENL is thought to be a consequence of immune complex deposition, given its T_H2 cytokine

profile and its high levels ofIL-6 and IL-8. However, in ENL tissue, the presence of HLA Dr framework antigen of epidermal cells -- considered a marker for a delayed-type hypersensitivity response -- and evidence for higher levels of IL-2 andIFN-gthan are usually seen in polar lepromatous disease suggest an alternative mechanism.

Treatment must be individualized. IfENL is mild (i.e., without fever or other organ involvement, with occasional crops of only a few skin papules), it may be treated with antipyretics alone. However, in cases with many skin lesions, fever, malaise, and other tissue involvement, brief courses (1 to 2 weeks) of glucocorticoids (initially 40 to 60 mg/d) are often effective. With or without therapy, individual inflamed papules last for£1 week. Successful therapy is defined by the cessation of skin lesion development and the disappearance of other systemic signs and symptoms. If, despite two courses of glucocorticoid therapy, ENL appears to be recurring and persisting, treatment with thalidomide (100 to 300 mg nightly) should be initiated, with the dose depending on the initial severity of the reaction. Because even a single dose of thalidomide administered early in pregnancy may result in severe birth defects, including phocomelia, the use of this drug in the United States for the treatment of fertile females is tightly regulated and requires informed consent, prior pregnancy testing, and maintenance of birth control measures. Although the mechanism of thalidomide's dramatic action against ENL is not entirely clear, the drug's efficacy is probably attributable to its reduction ofTNFlevels and IgM synthesis and its slowing of polymorphonuclear leukocyte migration. After the reaction is controlled, lower doses of thalidomide (50 to 200 mg nightly) are effective in preventing relapses of ENL. Clofazimine in high doses (300 mg nightly) has some efficacy against ENL, but its use permits only a modest reduction of the glucocorticoid dose necessary for ENL control.

Lucio's Phenomenon This unusual reaction is seen exclusively in patients from the Caribbean and Mexico who have the diffuse lepromatosis form of lepromatous leprosy, most often those who are untreated. Patients with this reaction develop recurrent crops of large, sharply marginated, ulcerative lesions -- particularly on the lower extremities -- that may be generalized and, when so, are frequently fatal as a result of secondary infection and consequent septic bacteremia. Histologically, the lesions are characterized by ischemic necrosis of the epidermis and superficial dermis, heavy parasitism of endothelial cells withAFB, and endothelial proliferation and thrombus formation in the larger vessels of the deeper dermis. LikeENL, the Lucio reaction is probably mediated by the immune complex. Neither glucocorticoids nor thalidomide is effective against this syndrome. Optimal wound care and therapy for bacteremia are indicated. Ulcers tend to be chronic and heal poorly. In severe cases, exchange transfusion may prove useful.

Nerve Abscesses Patients with various forms of leprosy, but particularly those with the BT form, may develop abscesses of nerves (most commonly the ulnar) with an adjacent cellulitic appearance of the skin. In such conditions, the affected nerve is swollen and exquisitely tender. Although glucocorticoids may reduce signs of inflammation, rapid surgical decompression is necessary to prevent irreversible sequelae.

Complications

The Extremities Complications of the extremities in leprosy patients are primarily a consequence of neuropathy leading to insensitivity and myopathy. Insensitivity affects

fine touch, pain, and heat receptors but generally spares position and vibration appreciation. The most commonly affected nerve trunk is the ulnar nerve at the elbow, whose involvement results in clawing of the fourth and fifth fingers, loss of dorsal interosseous musculature in the affected hand, and loss of sensation in these distributions. Median nerve involvement in leprosy impairs thumb opposition and grasp, while radial nerve dysfunction, though rare in leprosy, leads to wristdrop. Tendon transfers can restore hand function but should not be performed until 6 months after the initiation of antimicrobial therapy and the conclusion of episodes of acute neuritis.

Plantar ulceration, particularly at the metatarsal heads, is probably the most frequent complication of leprous neuropathy. Plantar ulcers may become secondarily infected and lead to adjacent cellulitis and osteomyelitis. Because of the importance and critical integrity of the normal plantar fat pad, recurrent ulceration is unfortunately common once initial ulceration has occurred and the pad has been replaced by thin and less resilient fibrous scar tissue. The treatment of plantar ulceration includes debridement of devitalized and undermined tissue; discontinuation of weight-bearing, which may be accomplished by means of a total-contact cast or bed rest; and vigorous treatment of secondary infection, which most commonly is due to *Staphylococcus aureus*. Once healing takes place, walking must be limited, especially during the first week, with slow and progressive increases thereafter. Extra-depth shoes or individually fitted shoes with specially molded inserts are required to prevent recurrence.

Peroneal nerve palsies may result from leprosy itself or from one of its reactional states; the consequence is partial or complete footdrop, which causes an uneven distribution of weight on the plantar surface and hence a predilection to ulceration. Simple nonmetallic braces within the shoe may be useful, while tendon transfers can actually correct footdrop. Although uncommon, Charcot's joints, particularly of the foot and ankle, may result from leprosy.

The loss of distal digits in leprosy is a consequence of insensitivity, trauma, secondary infection, and -- in lepromatous patients -- a poorly understood and sometimes profound osteolytic process. Conscientious protection of the extremities during cooking and work and the early institution of therapy have substantially reduced the frequency and severity of distal digit loss in recent times.

The Nose In lepromatous leprosy, bacillary invasion of the nasal mucosa can result in chronic nasal congestion and epistaxis. Saline nosedrops may relieve these symptoms. Long-untreated LL leprosy may further result in destruction of the nasal cartilage, with consequent saddle-nose deformity or anosmia (more common in the preantibiotic era than at present). Nasal reconstructive procedures can ameliorate significant cosmetic defects.

The Eye Owing to cranial nerve palsies, lagophthalmus and corneal insensitivity may complicate leprosy, resulting in trauma, secondary infection, and (without treatment) corneal ulcerations and opacities. For patients with these conditions, eyedrops during the day and ointments at night provide some protection from such consequences. Furthermore, in LL leprosy, the anterior chamber of the eye is invaded by bacilli, andENL may result in uveitis, with consequent cataracts and glaucoma. Thus leprosy is a major cause of blindness in the developing world. Slit-lamp evaluation of LL patients

often reveals "corneal beading," representing globi of *M. leprae*.

The testes M. leprae invades the testes, whileENL may cause orchitis. Thus males with lepromatous leprosy often manifest mild to severe testicular dysfunction, with an elevation of luteinizing and follicle-stimulating hormones, decreased testosterone, and aspermia or hypospermia in 85% of LL patients but in only 25% of BL patients. LL patients may become impotent and infertile. Impotence is sometimes responsive to testosterone replacement.

Amyloidosis Secondary amyloidosis is a complication of LL leprosy andENL that is encountered infrequently in the antibiotic era. This complication may result in abnormalities of hepatic and particularly renal function.

DIAGNOSIS

Leprosy most commonly presents with both characteristic skin lesions and skin histopathology. Thus the disease should be suspected when a patient from an endemic area has suggestive skin lesions or peripheral neuropathy; the diagnosis should be confirmed by histopathology. In tuberculoid leprosy, lesional areas -- preferably the advancing edge -- must be biopsied because normal-appearing skin does not have pathologic features. In lepromatous leprosy, nodules, plaques, and indurated areas are optimal biopsy sites, but biopsies of normal-appearing skin are also generally diagnostic. Lepromatous leprosy is associated with diffuse hyperglobulinemia, which may result in false-positive serologic tests (e.g., VDRL, RA, ANA) and therefore can cause diagnostic confusion. On occasion, tuberculoid lesions may not (1) appear typical, (2) be hypesthetic, and (3) contain granulomas but only nonspecific lymphocytic infiltrates. In such instances, two of these three characteristics are considered sufficient for a diagnosis. It is preferable to overdiagnose leprosy rather than to allow a patient to remain untreated.

IgM antibodies toPGL-1are found in 95% of untreated lepromatous leprosy patients; the titer decreases with effective therapy. However, in tuberculoid leprosy -- the form of disease most often associated with diagnostic uncertainty owing to the absence ofAFB -- patients have significant antibodies to PGL-1 only 60% of the time; moreover, in endemic locales, exposed individuals without clinical leprosy may harbor antibodies to PGL-1. Thus PGL-1 serology is of little diagnostic utility in tuberculoid leprosy.
Heat-killed *M. leprae* (lepromin) has been used as a skin test reagent. It generally elicits a reaction in tuberculoid leprosy patients, may do so in individuals without leprosy, and gives negative results in lepromatous leprosy patients; consequently, it is likewise of little diagnostic value. Unfortunately,PCR of skin for *M. leprae*, although positive in LL and BL leprosy, yields negative results in 50% of tuberculoid leprosy cases, again offering little diagnostic assistance.

Included in the differential diagnosis of lesions that resemble leprosy are sarcoidosis, leishmaniasis, lupus vulgaris, lymphoma, syphilis, yaws, granuloma annulare, and various other disorders causing hypopigmentation. Sarcoidosis may result in perineural inflammation, but actual granuloma formation within dermal nerves is pathognomonic for leprosy. In lepromatous leprosy, sputum specimens may be loaded withAFB -- a finding that can be inappropriately interpreted as representing pulmonary tuberculosis.

TREATMENT

Active Agents Established agents used to treat leprosy include dapsone (50 to 100 mg/d), clofazimine (50 to 100 mg/d, 100 mg three times weekly, or 300 mg monthly), and rifampin (600 mg daily or monthly). Of these drugs, only rifampin is bactericidal. The sulfones (folate antagonists), the foremost of which is dapsone, were the first antimicrobials found to be effective for the treatment of leprosy and are still the mainstay of therapy. With sulfone treatment, skin lesions resolve and numbers of viable bacilli in the skin are reduced. Although primarily bacteriostatic, dapsone monotherapy results in only a 10% resistance-related relapse rate; after ³18 years of therapy and subsequent discontinuation, only another 10% of patients relapse, developing new, usually asymptomatic, shiny, "histoid" nodules. Dapsone is generally safe and inexpensive. Individuals with glucose-6-phosphate dehydrogenase deficiency who are treated with dapsone may develop severe hemolysis; those without this deficiency also have reduced red cell survival and a hemoglobin decrease averaging 1 g/dL. Dapsone's usefulness is limited occasionally by allergic dermatitis and rarely by the sulfone syndrome (including high fever, anemia, exfoliative dermatitis, and a mononucleosis-type blood picture). It must be remembered that rifampin induces microsomal enzymes, necessitating increased doses of medications such as glucocorticoids and oral birth control regimens. Clofazimine is often cosmetically unacceptable to light-skinned leprosy patients because it causes a red-black skin discoloration that accumulates, particularly in lesional areas, and makes the patient's diagnosis obvious to members of the community.

Other antimicrobial agents active against *M. leprae* in animal models and at the usual daily doses used in clinical trials include ethionamide/prothionamide; the aminoglycosides streptomycin, kanamycin, and amikacin (but not gentamicin or tobramycin); minocycline; clarithromycin; and several fluoroquinolones, particularly ofloxacin. Next to rifampin, minocycline, clarithromycin, and ofloxacin appear to be most bactericidal for *M. leprae*, but these drugs have not been used extensively in leprosy control programs.

Choice of Regimens Antimicrobial therapy for leprosy must be individualized, depending on the clinical/pathologic form of the disease encountered. Tuberculoid leprosy, which is associated with a low bacterial burden and a protective cellular immune response, is the easier form to treat and can be reliably cured with a finite course of chemotherapy. In contrast, lepromatous leprosy may have a higher bacillary load than any other human bacterial disease, and the absence of a salutary T cell repertoire requires prolonged or even lifelong chemotherapy. Hence, careful classification of disease prior to therapy is important. In developed countries, clinical experience with leprosy classification is limited; fortunately, however, the resources needed for skin biopsy are highly accessible and pathologic interpretation is readily available. In developing countries, clinical expertise is greater, but it may now be waning as the care of leprosy patients is integrated into general health services. In addition, access to dermatopathology services is often limited. In such instances, skin smears may prove useful, but in many locales access to the resources needed for their preparation and interpretation may also be unavailable.

A reasoned approach to the treatment of leprosy is confounded by these and several other issues:

1. Even without therapy, TT leprosy may heal spontaneously, and prolonged dapsone monotherapy (even for LL leprosy) is generally curative in 80% of cases.

2. In tuberculoid disease, there are often no bacilli found in the skin prior to therapy, and thus there is no objective measure of therapeutic success. Furthermore, despite adequate treatment, TT and particularly BT lesions often resolve little or incompletely, while relapse and late type 1 lepra reactions can be difficult to distinguish.

3. LL leprosy patients commonly harbor viable persistent *M. leprae* organisms after prolonged intensive therapy; the propensity of these organisms to initiate clinical relapse is unclear. Because relapse in LL patients after discontinuation of rifampin-containing regimens usually begins only after 7 to 10 years, follow-up over the very long term is necessary to assess ultimate clinical outcomes.

4. Even though primary dapsone resistance is exceedingly rare and multidrug therapy is generally recommended (at least for lepromatous leprosy), there is a paucity of information from experimental animals and clinical trials on the optimal combination of antimicrobials, dosing schedule, or duration of therapy.

In 1982, the World Health Organization (WHO) made recommendations for "the chemotherapy of leprosy for control programs." These recommendations came on the heels of the demonstration of the relative success of long-term dapsone monotherapy and in the context of concerns about dapsone resistance. Other complicating considerations included the limited resources available for leprosy care in the very areas where it is most prevalent and the frustration and discouragement of patients and program managers with the previous requirement for lifelong therapy for many leprosy patients. The WHO delineated for the first time a finite duration of therapy for all forms of leprosy, and -- given the prohibitive cost of daily rifampin treatment in developing countries -- encouraged the monthly administration of this agent as part of a multidrug regimen.

Over the ensuing years, theseWHOrecommendations have been broadly implemented, and the duration of therapy required, particularly for lepromatous leprosy, has been progressively shortened. For treatment purposes, the WHO classifies patients as paucibacillary and multibacillary. Previously, patients without demonstrableAFB in the dermis were classified as paucibacillary and those with AFB as multibacillary. Currently, owing to the perceived unreliability of skin smears in the field, patients are classified as multibacillary if they have five or more skin lesions and as paucibacillary if they have fewer than five skin lesions. The WHO recommends that paucibacillary adults be treated with 100 mg of dapsone daily and 600 mg of rifampin monthly (supervised) for 6 months (Table 170-1). Multibacillary adults should be treated with 100 mg of dapsone plus 50 mg of clofazimine daily (unsupervised) and with 600 mg of rifampin plus 300 mg of clofazimine monthly (supervised). Originally, the WHO recommended that lepromatous patients be treated for 2 years or until smears became negative (generally in ~5 years); subsequently, the acceptable course was reduced to 1 year -- a change that remains controversial in the absence of clinical trials.

Several factors, including an improved economic climate, the high relapse rates (20 to 40%, depending on the initial bacterial burden) among patients with lepromatous leprosy afterWHO-recommended treatment, and the demonstrable lesional activity in fully half of tuberculoid leprosy patients after the completion of therapy, have caused many authorities to question the WHO recommendations and to favor a more intensive approach. This approach (Table 170-1) calls for tuberculoid leprosy to be treated with dapsone (100 mg/d) for 5 years and for lepromatous leprosy to be treated with rifampin (600 mg/d) for 3 years and with dapsone (100 mg/d) throughout life.

On effective antimicrobial therapy, new skin lesions and signs and symptoms of peripheral neuropathy cease appearing. Nodules and plaques of lepromatous leprosy noticeably flatten in 1 to 2 months and resolve in 1 or a few years, while tuberculoid skin lesions may disappear, improve, or remain relatively unchanged. Though the peripheral neuropathy of leprosy may improve somewhat in the first few months of therapy, rarely is it significantly ameliorated by treatment.

PREVENTION AND CONTROL

Vaccination at birth with bacille Calmette-Guerin (BCG) has proved variably effective in preventing leprosy, ranging from totally ineffective to 80% efficacious. The addition of heat-killed *M. leprae* to BCG does not increase vaccine efficacy. Because whole mycobacteria contain large amounts of lipids and carbohydrates that have proven in vitro to be immunosuppressive for lymphocytes and macrophages, *M. leprae* proteins may prove to be superior vaccines. Data from a mouse model support this possibility. Chemoprophylaxis with dapsone may reduce the number of cases of tuberculoid leprosy but not of lepromatous leprosy and hence is not recommended, even for household contacts. Because leprosy transmission appears to require close prolonged household contact, hospitalized patients need not be isolated.

(Bibliography omitted in Palm version)

171. INFECTIONS DUE TO NONTUBERCULOUS MYCOBACTERIA - *Bernard Hirschel*

Mycobacteria are slightly curved or straight, rod-shaped or coccoid bacilli traditionally identified by the property of acid-fastness: once stained, the organisms are not easily decolorized, even with acid-alcohol, because of the composition of their cell walls. The genetic relation of mycobacteria with one another is evidenced by their ribosomal RNA sequence homology, which can be used for diagnostic purposes.

Because of the overwhelming clinical importance of tuberculosis, mycobacteriologists have distinguished the *Mycobacterium tuberculosis* complex (consisting of *M. tuberculosis*, *M. bovis*, and *M. africanum*) from all other mycobacteria. Except for *M. leprae* (Chap. 170), the other mycobacteria are referred to as atypical mycobacteria, mycobacteria other than tuberculosis (MOTT), or nontuberculous mycobacteria (NTM). The most clinically important NTM are listed and described in Table 171-1. The isolation of NTM -- or the lack thereof -- from an individual patient or laboratory specimen must be interpreted with the following facts in mind:

1. SomeNTMrequire special media and/or growth conditions. The laboratory must be alerted and cultures for acid-fast bacilli requested if the diagnosis of these infections is not to be missed.

2. NTM grow slowly. Even the so-called rapid growers take 3 to 7 days to form visible colonies on solid media, whereas slow-growing mycobacteria take weeks or do not grow at all on artificial media.

3. The slow growth of mycobacteria complicates antibiotic susceptibility testing. During prolonged incubation, antibiotics may be degraded and disappear from the culture medium. Long delays reduce the clinical usefulness of whatever results are eventually obtained.

4. Data on in vitro susceptibility correlate poorly with clinical results. For example, clarithromycin and azithromycin are highly and variably concentrated in tissues; consequently, the concentrations necessary for determining resistance are difficult to establish in vitro. Sensitivity testing, based on achievable serum levels, would have predicted that these drugs would have little efficacy in vivo; in fact, the opposite is true, both in animal models and in humans.

5. In contrast to *M. tuberculosis*,NTM are ubiquitous in the environment. Therefore, isolation of NTM from a site that is not normally sterile (such as sputum, urine, skin, or feces) does not constitute proof of disease. In Switzerland between 1983 and 1988, for example, only 23 of 513 HIV-negative patients with NTM isolates had clinically significant disease. Clusters of unusual isolates are more likely to suggest contamination -- e.g., from tap water or bronchoscopy equipment -- than to represent an epidemic of disease.

The original method for the classification ofNTM, developed between 1950 and 1980, depends on speed of growth, morphology, and pigmentation of colonies on solid media as well as biochemical reactions. Although reliable and inexpensive, these procedures

take a long time; a period of 12 weeks is often required for definitive identification. Of course, such delayed results are of little use in the care of patients.

The isolation ofNTM from blood cultures requires the use of a special medium for lysis-centrifugation or broth culture. The lysis-centrifugation method (lysis of blood cells followed by centrifugation and plating of the pellet with the bacteria on solid medium) permits quantification of bacteremia; however, some mycobacteria (e.g., *M. genavense*) do not grow well on solid medium and will not be detected by this method. Culture in liquid broth, such as that used in the radiometric Bactec system, shortens the time needed to identify a positive culture but also precludes the study of colonial morphology and pigmentation. Molecular probes are now used for rapid identification of the most important species (*M. avium*, *M. intracellulare*, *M. gordonae*, *M. kansasii*, and the *M. tuberculosis* complex) in a positive culture; a color is produced upon hybridization of the probe to specific sequences of the mycobacterial ribosome.

Twenty years ago, the field of mycobacteriology was something of a backwater. Tuberculosis was incorrectly perceived as a disappearing problem, andNTM were causing only rare and chronic diseases. AIDS, however, has brought mycobacterial infections to the forefront of clinical medicine once more. HIV and *M. tuberculosis* make a volatile mixture, and disseminated infections with NTM are extremely frequent in the advanced stages of AIDS (Chap. 309). In this setting, it is fortunate that new molecular techniques based on DNA amplification accelerate diagnosis, identify common sources of infection, and reveal new types of NTM, while new antibiotics, such as the macrolides, the rifamycins, and the fluoroquinolones, offer improved options for treatment and prevention. In addition, highly active antiretroviral therapy (HAART) has had a dramatic impact. By preventing and reversing immunodeficiency, HAART (Chap. 309) also prevents and reverses NTM infections.

NTM INFECTIONS IN AIDS AND OTHER IMMUNODEFICIENCIES

DISSEMINATED INFECTIONS

Etiology The majority of mycobacterial infections in immunocompromised hosts are caused by organisms belonging to the group referred to as the *M. avium* complex (MAC). This group has always been considered to include *M. avium* and *M. intracellulare* (designated by the abbreviation *MAI*) and in the past encompassed *M. scrofulaceum* as well (hence the abbreviation *MAIS*). With the development and marketing of diagnostic probes that distinguish *M. avium* from *M. intracellulare*, it has become clear that the vast majority of disseminated "MAC" infections in AIDS are actually caused by *M. avium*. Thus, from a microbiologic standpoint, this designation is now obsolete. However, it is still used in clinical practice and will be employed in that context herein.

M. genavense causes systemic infections similar to those caused byMACorganisms. *M. genavense* does not grow well in culture and may therefore be missed in some instances. However, in a series of nearly 200 disseminatedNTMinfections from Switzerland, 13% of cases were due to *M. genavense*. Other NTM, including *M. xenopi*, *M. simiae*, *M. scrofulaceum*, *M. malmoense*, and *M. celatum*, may also be involved in such cases. In addition, AIDS patients with localized NTM diseases (see "Localized

Infections," below) often have positive blood cultures (e.g., patients with skin disease due to *M. haemophilum* or with lung disease due to *M. kansasii*).

Epidemiology and Host Factors Because gastrointestinal symptoms often predominate inNTMinfection and because the intestinal submucosa is intensely involved, ingestion seems logical as a primary route of infection. Many environments and animals teem with NTM (especiallyMACorganisms), including swamps in the southeastern United States, swine almost everywhere, piped water in New England and in Finland, and soil from potted plants in San Francisco. Birds are frequently infected with *M. genavense*. Skin-test data and humoral antibody patterns point to widespread exposure. However, a direct connection of the environment to the patient is often lacking, and it is not always clear whether strains found in the environment are pathogenic in humans. In an exhaustive study of dietary factors, patients with NTM were found to have consumed more hard cheese than controls without NTM, but no NTM could be found in samples of cheese. At present, the epidemiologic evidence is not strong enough to serve as a basis for dietary recommendations in persons at high risk of NTM infection. There is no evidence for nosocomial spread of NTM from patient to patient; however, hospital hot-water systems have been suspected as the source of isolated clusters of cases. Whereas regional variations in the environmental frequency of NTM are striking, it is difficult to correlate these variations with the frequency of NTM infection among HIV-infected patients.

Disseminated infections with NTMoccur almost exclusively in severely immunosuppressed patients, usually those with AIDS. Rarely, such infections are found in patients immunosuppressed for other reasons, including transplant recipients, and patients with leukemia (in particular, hairy cell leukemia) or lymphoma. Cases in children may suggest the presence of a congenital immunodeficiency disease, such as a deficiency in the receptors for interferon g(IFN-g) or interleukin (IL) 12. Finally, rare cases of dissemination occur in immunocompetent patients who have extensive pulmonary disease (see "NTM Infections in Immunocompetent Patients," below).

In patients with AIDS, the risk ofNTMinfection correlates well with the degree of depletion of CD4+ lymphocytes. Disseminated NTM disease is rare among patients with >100 CD4+ cells per microliter; however, among patients with <10 CD4+ lymphocytes per microliter, the actuarial probability of having a blood culture positive for NTM reaches 40% after 1 year.HAARThas greatly diminished the overall incidence of NTM disease in AIDS. Current treatment recommendations suggest starting HAART when the CD4+ count falls below 500/uL. At these levels, NTM disease does not occur. In extremely immunosuppressed patients who start HAART, the CD4+ count typically rises above 100/uL within a few months; such patients are again unlikely to develop NTM disease.

Clinical Manifestations As has already been mentioned, disseminated infection withNTM is essentially a disease of advanced immunodeficiency. In HIV-infected patients, the median CD4+ lymphocyte count at the time of diagnosis is ~10/uL. Certainly, other diagnoses should be considered first when a patient with symptoms suggestive of NTM infection has>100 CD4+ cells per microliter. Prospective monthly blood cultures have shown that NTM bacteremia often causes few or no symptoms. In clinical practice, however, cultures are not performed if the patient is asymptomatic.

DisseminatedNTMinfection should be suspected on the basis of prolonged fever (sometimes of varying intensity -- particularly at first -- and accompanied by night sweats) and weight loss. Signs of abdominal involvement that may be evident on computed tomography or ultrasonography include enlargement of the liver and spleen and swelling of abdominal lymph nodes, which may result in diarrhea and/or abdominal pain. Anemia and leukopenia are frequently documented; although it is tempting to relate these abnormalities to infection of bone marrow by NTM, multiple factors are usually involved.

In short, the clinical picture of infection withNTM is not distinctive. Many other conditions, including abdominal lymphoma, the HIV wasting syndrome, *Salmonella* or *Campylobacter* infection, cryptosporidiosis, or microsporidiosis, may mimic (and coexist with) disseminated NTM infection. As stated earlier, suspicion of such infection should prompt a request for blood cultures.

Diagnosis Blood cultures on special media are the cornerstone of the diagnosis ofNTMinfection, both in patients with organ involvement and in those without. In most symptomatic patients, the intensity of mycobacteremia is such that most or all blood cultures are positive. Therefore, the performance of multiple, repetitive cultures at short intervals is not worthwhile. Rather, in clinical practice, two or three blood cultures are sufficient. In one study, the results of prospective cultures varied, and these variations (positive followed by negative or vice versa) were unrelated to symptom status. As mentioned above, liquid cultures (e.g., the Bactec system) are likely to become positive earlier (within 7 to 14 days) and are therefore preferred to cultures on solid medium. In patients infected with *M. genavense* or *M. xenopi* and in patients being treated forMACinfection, the interval to culture positivity may be much longer. In rare cases, organ involvement in NTM infection may be found to be widespread at autopsy despite multiple negative blood cultures during life.

Because the liver and bone marrow are often involved in disseminatedNTMinfection, the bacteria may be visible in acid-fast-stained biopsy samples from these sites. Presumptive diagnosis by examination of a biopsied liver specimen saves time. The yield has been as high as 50% in patients with clearly abnormal values in liver function tests. However, the yield of this method has been disappointing in patients with suspected NTM infection, negative blood cultures, and normal or nearly normal results in liver function tests.

TREATMENT

Compared with *M. tuberculosis*,NTM are of low virulence. NTM tend to affect severely immunosuppressed patients, who usually have many other medical problems. Treatment is complex, relies on the use of multiple drugs with numerous adverse effects, and may interfere with antiretroviral therapy.

The drugs used for the treatment of disseminatedNTMinfection are different from those used against tuberculosis (Table 171-1;Chaps. 168 and169). In particular, isoniazid has little effect onMACorganisms. The best method for antibiotic sensitivity testing of NTM is controversial, and the question of what relation -- if any -- exists between in vitro

resistance and treatment failure remains unanswered. From the clinician's viewpoint, growth inhibition in liquid cultures is preferred to other methods of sensitivity testing because the results become available within 7 days.

The agents most active againstMACorganisms are the macrolides clarithromycin and azithromycin. Both of these drugs are well absorbed from the gastrointestinal tract and well concentrated in macrophages and tissues, where their levels exceed those in plasma by more than 10-fold. Given alone, either drug can render blood cultures negative in a substantial proportion of cases. However, resistance (due to a single point mutation in the gene coding for the large ribosomal subunit) invariably develops, andNTMreappear in the bloodstream.

A majority ofMACstrains are sensitive to ethambutol, ciprofloxacin, clofazimine, amikacin, rifampin, and rifabutin; that is, the concentrations of these drugs attainable in serum are inhibitory in vitro. However, none of these drugs consistently reduces the intensity of mycobacteremia when used alone. The preferred regimen for treatment of disseminatedNTMinfections is the combination of rifabutin (300 to 600 mg/d), clarithromycin (1 g twice daily), and ethambutol (900 mg/d). In a randomized trial, this regimen was superior to the combination of rifampin, clofazimine, ciprofloxacin, and ethambutol, with more rapid resolution of bacteremia and increased survival. The higher dose of rifabutin was more effective but frequently caused uveitis. This side effect is of special concern when rifabutin is used in combination with ritonavir, which increases the concentration of a toxic metabolite. Among the HIV protease inhibitors, indinavir and nelfinavir may be used in combination with rifabutin.

The inclusion of intravenous amikacin in multidrug regimens has not conferred additional benefit. Nonetheless, this drug may be useful in certain cases -- e.g., when resistance to clarithromycin develops or when severe gastrointestinal symptoms interfere with oral therapy. In addition, amikacin may prevent the emergence of resistance to clarithromycin when the two drugs are used concurrently.

It is not clear how long therapy needs to be administered. Older regimens did not eradicateMAC, and many experts recommended lifelong treatment. Unfortunately, multidrug regimens are often poorly tolerated. In patients whose symptoms have lessened, whose blood cultures have become negative, and whose CD4+counts have recovered to >100/uL withHAART, it is reasonable to discontinue antimycobacterial treatment.

In vitro and in experimental animals, cytokines such asIL-12, granulocyte-macrophage colony-stimulating factor, andIFN-gact synergistically with antibiotics againstMAC. In a small-scale pilot trial including seven HIV-negative patients, IFN-g was beneficial.

Encapsulation of many drugs into liposomes enhances their effect in animal models because both liposomes andMAC are ingested by macrophages. Relevant data from studies of humans are still scarce, however.

Disseminated infections caused byNTMother than MAC have been too rare for therapy to be evaluated in controlled trials. The presently recommended treatment for these infections is the same as that for disseminated MAC infections. In particular, *M.*

genavense seems to be sensitive to clarithromycin and rifabutin.

Prevention As has been discussed, disseminated infection withMACoccurs almost exclusively in persons severely immunocompromised by HIV infection. Therefore, the best approach to the prevention of MAC infections is the prevention and reversal of immunodeficiency byHAART. In patients whose HIV is resistant to HAART and who are severely immunosuppressed, with CD4+ counts<100/uL, prophylaxis with rifabutin (300 mg/d), clarithromycin (500 mg once or twice daily), or azithromycin (1200 mg weekly) is likely to decrease the incidence of positive blood cultures by ~60%. Patients receiving prophylaxis have also had less fever, experienced less fatigue, and survived longer than patients not receiving prophylaxis. Although breakthrough bacteremia involving resistant organisms is a concern, this condition has not developed with rifabutin prophylaxis and is rare with clarithromycin. However, it is standard practice to rule out preexisting disseminatedNTMinfection (by blood culture) before starting prophylaxis.

LOCALIZED INFECTIONS

Pulmonary Disease The significance of isolation ofNTM from the airways of AIDS patients merits special discussion. In general, HIV-infected patients who have NTM in sputum or bronchoalveolar lavage fluid but have little evidence of lung damage require no treatment. *M. avium* only rarely causes significant pulmonary disease in AIDS; its isolation from sputum in the absence of radiographic changes is usually without clinical significance. In contrast, the isolation of *M. kansasii* from the lung is clinically significant: this organism causes a disease -- often predominant in the upper lobes -- that resembles pulmonary tuberculosis, with fever, cough, infiltrates, and cavities. Blood cultures are often positive. Drugs active against *M. tuberculosis*, such as rifampin (600 mg/d) and isoniazid (300 mg/d), are also effective against *M. kansasii*; treatment is generally continued for 18 to 24 months, although some data suggest that 12 months may be adequate.

Skin Disease MACorganisms, which frequently cause disseminated disease with positive blood cultures in AIDS, are also rarely associated with heterogeneous skin manifestations, such as nodules, ulcers, areas of erythema, pustules, abscesses, or panniculitis. Skin biopsies and blood cultures establish the diagnosis.

M. haemophilum In contrast toMACorganisms, *M. haemophilum* has a tendency to involve the skin, bones, joints, and lungs, although most patients also have positive blood cultures. Skin lesions are nodular, may ulcerate, and are disseminated. In the absence of specific data, treatment should follow the guidelines for MAC infection.

NTM INFECTIONS IN IMMUNOCOMPETENT PATIENTS

PULMONARY DISEASE

Etiology TheNTM most frequently causing pulmonary infections are *M. intracellulare*, *M. avium*, and *M. kansasii*. Many other species, such as *M. xenopi*, *M. malmoense*, and *M. interjectum*, can also be involved in these infections. Identification of the specific pathogen is important in the choice among the various therapeutic strategies. For example, *M. kansasii* responds to antituberculosis drugs, including isoniazid.

Epidemiology and Host Factors As has already been noted,NTM are ubiquitous in the environment, but their pathogenicity is low. Preexisting lung disease (e.g., chronic obstructive airway disease, cancer, previous tuberculosis, bronchiectasis, cystic fibrosis, and silicosis, with cavities and bronchiectases) is the main predisposing factor for pulmonary disease due to NTM.

Anecdotal evidence suggests that the proportion of patients without underlying lung pathology who are developing pulmonary disease due toNTM is increasing. These patients are usually elderly; many are women with pectus excavatum or scoliosis. In the latter elderly women, the lingula and the right middle lobes are particularly involved. Somewhat whimsically, the disease in these patients has been called "Lady Windermere syndrome" after the main character in Oscar Wilde's play *Lady Windermere's Fan*, who went to extremes to refrain from coughing.

Clinical Manifestations Most immunocompetent patients with pulmonaryNTMinfection present with chronic cough, low-grade fever, and malaise; some present with hemoptysis. These symptoms may be masked by those of the underlying disease process.

Diagnosis In contrast to the isolation of *M. tuberculosis*, of which even a single colony -- whatever its origin -- is clinically significant, the isolation of NTMfrom the sputum never in itself proves the existence of disease. NTM are frequently commensals and colonize both diseased and normal airways. Because treatment of NTM infection is complicated, it is important that the diagnosis be certain. The American Thoracic Society has formulated the following minimal guidelines for the diagnosis of pulmonary NTM disease: "evidence, such as an infiltrate visible on a chest roentgenogram, of disease, the cause of which has not been determined by careful clinical and laboratory studies, and...isolation of multiple colonies of the same strain of mycobacteria repeatedly, usually in the absence of other pathogens." For patients who have pulmonary infiltrates but not cavities, these criteria may not be specific enough; some patients are found to have cleared NTM after a 1-month trial of bronchial hygiene alone (inhalation of saline and bronchodilators to induce cough and sputum production). The detection by computed tomography of bronchiectases and nodular infiltrates in the same lobe may be particularly suggestive of NTM infection.

TREATMENT

Lung disease due toNTM may be managed by follow-up without treatment, by resection, or by drug therapy. No randomized trial has determined which is the best option. In retrospectively analyzed case series, patients undergoing surgery have had a better outcome than those treated only with drugs. However, selection bias has probably influenced these results since patients with extensive lung disease are poor candidates for surgery.

As in HIV-infected patients, immunocompetent patients with minimal disease do not need treatment at all. Likewise,NTMdisease may present as a solitary pulmonary nodule that, once resected (to confirm or exclude a diagnosis of cancer), requires no further drug treatment.

Most other patients with pulmonaryNTMdisease are treated with antimicrobials; in addition, they may or may not undergo surgery. The drugs available for the treatment of infection with *M. avium* or *M. intracellulare* have already been discussed. The regimens recommended for disseminatedMACinfection are preferred, although large doses of clarithromycin are often poorly tolerated by elderly patients. *M. intracellulare* may be easier to treat and eradicate than *M. avium*. In two small open studies, single-agent treatment with clarithromycin (500 mg twice daily) led to improvements detected by chest radiography and sputum culture.

Indications for surgery are difficult to establish but include a disappointing response to antibiotics, the presence of localized disease, and the absence of contraindications (especially impaired respiratory functions). Ideally, drug treatment should begin before surgery and should render the sputum negative by the time of the operation.

In contrast toMACorganisms, *M. kansasii* is predictably sensitive to antituberculosis agents. Treatment should consist of isoniazid (300 mg/d), rifampin (600 mg/d), and ethambutol (15 to 25 mg/kg per day). The optimal duration of therapy is unknown, but most patients have been treated for 18 to 24 months; 12 months may suffice. Sulfamethoxazole is recommended for the occasional patient whose infection relapses after *M. kansasii* becomes resistant to rifampin.

LYMPHADENITIS

NTMare among the causes of localized lymphadenitis. This disease occurs mostly in children between the ages of 1 and 5 years. Painless swelling of one node or a group of nodes usually affects the anterior cervical chain. Nodes may rapidly increase in size, with the formation of fistulas to the skin. *M. scrofulaceum* orMACorganisms most commonly cause NTM lymphadenitis, although many other species may be involved. Once tuberculosis has been excluded, the treatment of choice is excision without chemotherapy. When excision is dangerous because of proximity to the facial nerve, aspiration combined with chemotherapy may be effective.

SKIN DISEASE DUE TO NTM

Swimming-Pool and Fish-Tank Granuloma (Fig. 171-CD1) Between 1 week and 2 months (usually 2 to 3 weeks) after contact with contaminated tropical fish tanks, swimming pools, or saltwater fish, a small violet nodule or pustule may appear at a site of minor trauma. This lesion may evolve to form a crusted ulcer or small abscess or may remain warty. Lesions are multiple and disseminated on occasion -- particularly, but not exclusively, in immunosuppressed patients. The causative organism is *M. marinum*. The patient's clinical history, combined with the isolation of *M. marinum* after biopsy and culture, establishes the diagnosis. Lesions often heal spontaneously. In cases of persistence or dissemination, rifampin (300 to 600 mg/d) in combination with ethambutol (15 to 25 mg/kg per day), trimethoprim-sulfamethoxazole (160/800 mg twice daily), or minocycline (100 mg/d) may be tried for a period of at least 3 months. Very rarely, a similar clinical picture is produced by *M. gordonae*, a frequently isolated but usually nonpathogenic species.

Buruli Ulcer In many tropical areas throughout the world, *M. ulcerans* may cause an itching nodule on the arms or legs, which then breaks down to form a shallow ulcer of variable size (Fig. 171-CD2). The course of this condition is usually prolonged. *M. ulcerans* is difficult to culture; plates need to be incubated at low temperature. Excision constitutes the usual therapy. Treatment with rifampin, clofazimine, or trimethoprim-sulfamethoxazole has met with variable success.

NTMINFECTIONS OF SOFT TISSUE, TENDONS, BONES, AND JOINTS

Infections Linked to Injections and Surgery Occasionally, mycobacteria are isolated from nodular skin lesions of hospitalized patients, particularly those who are immunosuppressed (Fig. 171-CD3); in some instances there is associated lymphatic spread. Many cases are linked to injection; diabetic patients are at especially high risk. In ophthalmology, mycobacteria may cause keratitis and corneal ulceration after surgery or injury. Epidemics of mycobacterial infection following cardiac surgery have been linked to contaminated ice packs and contaminated porcine heart valves. These infections are usually due to *M. fortuitum*, *M. chelonae*, or *M. abscessus*, which are referred to collectively as the *M. fortuitum* complex. These are the so-called rapidly growing mycobacteria: colonies on solid medium appear 3 to 7 days after inoculation. As organisms may fail to grow at 37°C, incubation at 30 to 33°C is recommended. These mycobacteria are notoriously resistant to most antituberculosis drugs. Debridement is best combined with administration of two or three of the antibiotics mentioned inTable 171-1.

Infections of Tendons, Joints, and Bones In rare cases, mycobacteria invade deep tissues after direct inoculation, via contiguous spread from superficial sites of infection, or through the bloodstream.MACorganisms and *M. ulcerans* are most often cited in these instances. *M. szulgai* seems to be involved particularly frequently in olecranon bursitis.

SECTION 9 -SPIROCHETAL DISEASES

172. SYPHILIS - *Sheila A. Lukehart*

DEFINITION

Syphilis, a chronic systemic infection caused by *Treponema pallidum* subspecies *pallidum*, is usually sexually transmitted and is characterized by episodes of active disease interrupted by periods of latency. After an incubation period averaging 2 to 6 weeks, a primary lesion appears, often associated with regional lymphadenopathy. A secondary bacteremic stage, associated with generalized mucocutaneous lesions and generalized lymphadenopathy, is followed by a latent period of subclinical infection lasting many years. In about one-third of untreated cases, the tertiary stage is characterized by progressive destructive mucocutaneous, musculoskeletal, or parenchymal lesions; aortitis; or symptomatic central nervous system (CNS) disease.

ETIOLOGY

The Spirochaetales include three genera that are pathogenic for humans and for a variety of other animals: *Leptospira*, which causes human leptospirosis; *Borrelia*, which causes relapsing fever and Lyme disease; and *Treponema*, which causes the diseases known as treponematoses. The genus *Treponema* includes *T. pallidum* subspecies *pallidum*, which causes venereal syphilis; *T. pallidum* subspecies *pertenue*, which causes yaws; *T. pallidum* subspecies *endemicum*, which causes endemic syphilis or bejel; and *T. carateum*, which causes pinta (Chap. 173). Other *Treponema* species found in the human mouth, genital mucosa, and gastrointestinal tract have no proven pathogenic role in human disease. These spirochetes can be confused with *T. pallidum* on dark-field examination. An oral treponeme that is very closely related to *T. pallidum* antigenically has been found to be significantly associated with periodontitis and acute necrotizing ulcerative gingivitis; its etiologic role in these gum diseases is unknown. None of the four pathogenic treponemes has yet been cultured in quantity. Until recently, the subspecies were distinguished primarily by the clinical syndromes they produce. Recent studies have identified molecular signatures that can differentiate *T. pallidum* subspecies *pallidum* from the other pathogenic *T. pallidum* subspecies by culture-independent, polymerase chain reaction (PCR)-based methods.

T. pallidum subspecies *pallidum* (hereafter referred to simply as *T. pallidum*), a thin delicate organism with 6 to 14 spirals and tapered ends, measures 6 to 15 um in total length and 0.2 um in width. The cytoplasm is surrounded by a trilaminar cytoplasmic membrane, which in turn is surrounded by a delicate peptidoglycan layer providing some structural rigidity. This layer is surrounded by a lipid-rich outer membrane that contains relatively few integral membrane proteins. Six endoflagella wind around the cell body in a space between the inner cell wall and the outer membrane and may be the elements responsible for motility.

The sequencing of the genome of *T. pallidum* has yielded information about the organism's metabolic capabilities. *T. pallidum* lacks the genes required to synthesize enzyme cofactors, fatty acids, and nucleotides de novo. In addition, it lacks genes encoding the enzymes of the Krebs cycle and oxidative phosphorylation. To

compensate, the organism contains numerous genes predicted to code for transporters of amino acids, carbohydrates, and cations. In addition, the genome analyses and other studies have revealed the existence of a 12-member gene family (called *tpr*) that bears similarities to variable outer-membrane antigens of other spirochetes. Although the role of these encoded molecules has not yet been defined, the TprK antigen appears to be preferentially expressed and serves as a target of opsonic antibody.

The only known natural host for *T. pallidum* is the human. *T. pallidum* can infect many mammals, but only humans, higher apes, and a few laboratory animals regularly develop syphilitic lesions. Virulent strains of *T. pallidum* are grown and maintained in rabbits.

EPIDEMIOLOGY

Nearly all cases of syphilis are acquired by sexual contact with infectious lesions (i.e., the chancre, mucous patch, skin rash, or condyloma latum). Less common modes of transmission include nonsexual personal contact and infection in utero or following blood transfusions.

The total number of cases of syphilis reported annually in the United States fell steadily from 575,593 in 1943 to a low of 64,621 in 1987 -- an 88% decrease -- but then increased to 134,255 in 1990. The number of new cases of infectious syphilis reached a peak in 1947 and then fell to approximately 6000 in 1956; since then, a rather steady increase in infectious syphilis has been punctuated by four cycles of 7 to 10 years, each with a rapid rise and fall in incidence (with peaks in 1965, 1975, 1982, and 1990). Since 1990, the number of reported cases of infectious syphilis has again declined by >80%. In 1997, there were 8550 reported cases of primary and secondary syphilis and 46,540 cases of all stages.

The populations at highest risk for acquiring syphilis have changed. Between 1977 and 1982, approximately half of all patients with early syphilis in the United States were homosexual or bisexual men. Largely because of changing sexual practices in this population due to the AIDS epidemic, this proportion has decreased. The most recent epidemic of syphilis predominantly involved African-American heterosexual men and women and occurred largely in urban areas, where infectious syphilis has been correlated significantly with the exchange of sex for "crack" cocaine. The incidence of syphilis peaks at 15 to 34 years of age. The reported incidence is much higher among African Americans than in other ethnic groups and is higher in urban than in rural areas; 80% of infectious syphilis cases are reported from 15% of the counties in the United States.

The incidence of congenital syphilis roughly parallels that of infectious syphilis in females. The number of reported cases of congenital syphilis in infants£1 year of age was lowest (107 cases) in 1978, when infectious syphilis was most prevalent among homosexual and bisexual men. The dramatic increase in the incidence of primary and secondary syphilis among women from 1986 to 1990 resulted in a proportionate increase in the number of infants born with congenital syphilis -- to 3275 infants in 1991. The incidence of early syphilis among men and women has declined since 1991, as has the number of reported cases of congenital syphilis in infants (with 1049 cases in 1997).

It is important to note, however, that the case definition for congenital syphilis was broadened in 1989 and now includes all live or stillborn infants delivered to women with untreated or inadequately treated syphilis at delivery.

Approximately one of every two individuals named as sexual contacts of persons with infectious syphilis becomes infected. Many sexual contacts will already have developed manifestations of syphilis when they are first seen, and about 30% of apparently uninfected contacts who are examined within 30 days of exposure actually have incubating infection and will later develop infectious syphilis if not treated. Thus, the identification and "epidemiologic" treatment of all recently exposed sexual contacts constitute an important aspect of syphilis control. Also important is the identification of infected persons by serologic testing of pregnant women, persons admitted to hospitals, military inductees, and persons undergoing examination in physicians' offices. Still controversial are laws and regulations requiring routine premarital serologic testing for syphilis, where -- though national data are not available -- the yield is undoubtedly lower.

NATURAL COURSE AND PATHOGENESIS OF UNTREATED SYPHILIS

T. pallidum rapidly penetrates intact mucous membranes or microscopic abrasions in skin and within a few hours enters the lymphatics and blood to produce systemic infection and metastatic foci long before the appearance of a primary lesion. Blood from a patient with incubating or early syphilis is infectious. The generation time of *T. pallidum* during early active disease in vivo is estimated to be 30 to 33 h, and the incubation period of syphilis is inversely proportional to the number of organisms inoculated. The concentration of treponemes generally reaches at least 10^7 per gram of tissue before the appearance of a clinical lesion. On the basis of intradermal injection of graded doses of *T. pallidum* into eight volunteers, the 50% infectious dose was calculated to be 57 organisms. The median incubation period in humans (about 21 days) suggests an average inoculum of 500 to 1000 infectious organisms for naturally acquired disease. The incubation period (from inoculation until the primary lesion becomes discernible) rarely exceeds 6 weeks. Subcurative therapy during the incubation period may delay the onset of the primary lesion, but it is not certain that such treatment reduces the probability that symptomatic disease will ultimately develop.

The primary lesion appears at the site of inoculation, usually persists for 4 to 6 weeks, and then heals spontaneously. Histopathologic examination of primary lesions shows perivascular infiltration, chiefly by lymphocytes (including CD8+ and CD4+ cells), plasma cells, and macrophages, with capillary endothelial proliferation and subsequent obliteration of small blood vessels. The CD4+ infiltration displays a T_H1-type cytokine profile consistent with the activation of macrophages. At this time *T. pallidum* is demonstrable in the chancre in spaces between epithelial cells; within invaginations or phagosomes of epithelial cells, fibroblasts, plasma cells, and the endothelial cells of small capillaries; within lymphatic channels; and in the regional lymph nodes. Phagocytosis of organisms by activated macrophages ultimately causes their destruction, which results in spontaneous resolution of the chancre.

The generalized parenchymal, constitutional, and mucocutaneous manifestations of secondary syphilis usually appear about 6 to 8 weeks after healing of the chancre,

although 15% of patients with secondary syphilis still have persisting or healing chancres. In other patients, secondary lesions may appear several months after the chancre has healed, and some patients may enter the latent stage without ever recognizing secondary lesions. The histopathologic features of secondary maculopapular skin lesions are hyperkeratosis of the epidermis; capillary proliferation with endothelial swelling in the superficial corium; and dermal papillae with transmigration of polymorphonuclear leukocytes and, in the deeper corium, perivascular infiltration by monocytes, plasma cells, and lymphocytes. Treponemes are found in many tissues, including the aqueous humor of the eye and the cerebrospinal fluid (CSF). Invasion of theCNS by *T. pallidum* occurs during the first weeks or months of infection, and CSF abnormalities are detected in as many as 40% of patients during the secondary stage. Clinical hepatitis and immune complex-induced membranous glomerulonephritis are relatively rare but recognized manifestations of secondary syphilis; liver function tests may yield abnormal results in up to a quarter of patients with early syphilis. Generalized nontender lymphadenopathy is noted in 85% of patients with secondary syphilis. The paradoxical appearance of secondary manifestations despite high titers of antibody (including immobilizing antibody) to *T. pallidum* is unexplained but may result from changes in expression of surface antigens. Secondary lesions subside within 2 to 6 weeks, and the infection enters the latent stage, which is detectable only by serologic testing. In the preantibiotic era, up to 25% of untreated patients experienced at least one generalized or localized mucocutaneous relapse, usually during the first year; therefore, identification and examination of sexual contacts are most important for patients with syphilis of<1 year's duration. Recurrent generalized rash is now rare.

In the preantibiotic era, about one-third of patients with untreated latent syphilis developed clinically apparent tertiary disease (Fig. 128-CD5); today, in industrialized countries, specific treatment and coincidental therapy for early and latent syphilis have all but eliminated tertiary disease except for sporadic cases of neurosyphilis in persons infected with HIV. In the past, the most common type of tertiary disease was the gumma, a usually benign granulomatous lesion. Today, gummas are very uncommon. Cardiovascular syphilis, now also rare, is caused by obliterative small-vessel endarteritis, usually involving the vasa vasorum of the ascending aorta and resulting in aneurysm. AsymptomaticCNSinvolvement is demonstrable in up to 25% of patients with late latent syphilis. The factors that contribute to the development and progression of tertiary disease are unknown.

The course of untreated syphilis was studied retrospectively in a group of nearly 2000 patients with primary or secondary disease diagnosed clinically (the Oslo Study, 1891-1951) and prospectively in 431 African-American men with seropositive latent syphilis of 3 or more years' duration (the notorious Tuskegee Study, 1932-1972). In the Oslo Study, 24% of patients developed relapsing secondary lesions within 4 years, and 28% eventually developed one or more manifestations of tertiary syphilis. Cardiovascular syphilis, including aortitis, was detected in 10% of patients, none of whom had been infected before age 15; 7% of patients developed symptomatic neurosyphilis, and 16% developed benign tertiary syphilis (gummas of the skin, mucous membranes, and skeleton). Syphilis was the primary cause of death in 15% of men and 8% of women. Cardiovascular syphilis was documented in 35% of men and 22% of women who eventually came to autopsy. In general, serious late complications were nearly twice as common among men as among women.

The Tuskegee Study showed that the death rate among untreated African-American men with syphilis (25 to 50 years old) was 17% higher than that among uninfected subjects and that 30% of all deaths were attributable to cardiovascular orCNSsyphilis. By far the most important factor in increased mortality was cardiovascular syphilis. Anatomic evidence of aortitis was found in 40 to 60% of autopsied subjects with syphilis (versus 15% of control subjects), while CNS syphilis was found in only 4%. Rates of hypertension were also higher among the infected subjects. The ethical issues eventually raised by this study, begun in the preantibiotic era but continuing into the early 1970s, had a major influence on the development of current guidelines for human medical experimentation, and the history of the study may still contribute to a reluctance of some African Americans to participate as subjects in clinical research.

These two studies both showed that about one-third of patients with untreated syphilis develop clinical or pathologic evidence of tertiary syphilis, that about one-fourth die as a direct result of tertiary syphilis, and that there is additional excess mortality not directly attributable to tertiary syphilis.

MANIFESTATIONS

Primary Syphilis The typical primary chancre usually begins as a single painless papule that rapidly becomes eroded and usually becomes indurated, with a characteristic cartilaginous consistency on palpation of the edge and base of the ulcer (see Plate IID-47,Fig. 172-CD1). In heterosexual men the chancre is usually located on the penis, whereas in homosexual men it is often found in the anal canal or rectum, in the mouth, or on the external genitalia. In women, common primary sites are the cervix and labia. Consequently, primary syphilis goes unrecognized in women and homosexual men more often than in heterosexual men.

Atypical primary lesions are common. The clinical appearance depends on the number of treponemes inoculated and on the immunologic status of the patient. A large inoculum produces a dark-field-positive ulcerative lesion in nonimmune volunteers but may produce a small dark-field-negative papule, an asymptomatic but seropositive latent infection, or no response at all in individuals with a history of syphilis. A small inoculum may produce only a papular lesion, even in nonimmune individuals. Therefore, syphilis should be considered even in the evaluation of trivial or atypical dark-field-negative genital lesions. The genital lesions that most commonly must be differentiated from those of primary syphilis include traumatic superinfected lesions, lesions of herpes simplex virus infection (Chap. 182), and lesions of chancroid (Chap. 149). *Primary genital herpes* may produce inguinal adenopathy, but the nodes are tender and the lesions consist of multiple painful vesicles, which later ulcerate and are often accompanied by systemic symptoms, including fever. *Recurrent genital herpes* typically begins with a unilateral cluster of painful vesicles, usually without associated adenopathy. *Chancroid* produces painful, superficial, exudative, nonindurated ulcers, more often multiple than in syphilis (seePlate IID-54); adenopathy is common, can be either unilateral or bilateral, is tender, and may be suppurative.

Regional lymphadenopathy usually accompanies the primary syphilitic lesion, appearing within 1 week of the onset of the lesion. The nodes are firm, nonsuppurative, and

painless. Inguinal lymphadenopathy is bilateral and may occur with anal as well as with external genital chancres. Rectal chancres result in perirectal lymphadenopathy, while chancres of the cervix and vagina result in iliac or perirectal adenopathy. The chancre generally heals within 4 to 6 weeks (range, 2 to 12 weeks), but lymphadenopathy may persist for months.

Secondary Syphilis The protean manifestations of the secondary stage usually include localized or diffuse symmetric mucocutaneous lesions and generalized nontender lymphadenopathy. The healing primary chancre is still present in 15% of cases. The skin rash consists of macular, papular, papulosquamous, and occasionally pustular syphilides; often more than one form is present simultaneously. The eruption may be very subtle. Approximately 25% of patients with a discernible rash of secondary syphilis may be unaware that they have dermatologic manifestations. Initial lesions are bilaterally symmetric, pale red or pink, nonpruritic, discrete, round macules that measure 5 to 10 mm in diameter and are distributed on the trunk and proximal extremities (see Plate IID-50). After several days or weeks, red papular lesions 3 to 10 mm in diameter also appear. These lesions, which may progress to necrotic lesions (resembling pustules) in association with increasing endarteritis and perivascular mononuclear infiltration, are distributed widely, frequently involve the palms and soles (see Plate IID-48), and may occur on the face and scalp. Tiny papular *follicular syphilides* involving hair follicles may result in patchy alopecia (alopecia areata), with loss of scalp hair, eyebrows, or beard in up to 5% of cases. Progressive endarteritis obliterans and ischemia result in superficial scaling of papules (*papulosquamous syphilides*) and eventually may lead to central necrosis (*pustular syphilides*).

In warm, moist, intertriginous body areas, including the perianal area, vulva, scrotum, inner thighs, axillae, and skin under pendulous breasts, papules can enlarge and become eroded to produce broad, moist, pink or gray-white, highly infectious lesions called *condylomata lata* (see Plate IID-49); these lesions develop in 10% of patients with secondary syphilis. Superficial mucosal erosions, called *mucous patches*, occur in 10 to 15% of patients and may involve the lips, oral mucosa, tongue (Fig. 172-1), palate, pharynx, vulva and vagina, glans penis, or inner prepuce. The typical mucous patch is a painless silver-gray erosion surrounded by a red periphery. During relapses of secondary syphilis, condylomata lata are particularly common, and skin lesions tend to be asymmetrically distributed and more infiltrated, resembling skin lesions of late syphilis. These characteristics may reflect increasing cellular immunity.

Constitutional symptoms that may accompany or precede secondary syphilis include sore throat (15 to 30%), fever (5 to 8%), weight loss (2 to 20%), malaise (25%), anorexia (2 to 10%), headache (10%), and meningismus (5%). *Acute meningitis* occurs in only 1 to 2% of cases, but numbers of cells and levels of protein in CSF are increased in ³30% of cases. *T. pallidum* has been recovered from CSF during primary and secondary syphilis in 30% of cases; this finding is often but not always associated with other CSF abnormalities.

Less common complications of secondary syphilis include hepatitis, nephropathy, gastrointestinal involvement (hypertrophic gastritis, patchy proctitis, ulcerative colitis, or a rectosigmoid mass), arthritis, and periostitis. Ocular findings that suggest secondary syphilis include otherwise-unexplained pupillary abnormalities, optic neuritis, and a

retinitis pigmentosa syndrome as well as the classic iritis (especially granulomatous iritis) or uveitis. The diagnosis of secondary syphilis is often considered only after the patient fails to respond to steroid therapy. Anterior uveitis has been reported in 5 to 10% of patients with secondary syphilis, and *T. pallidum* has been demonstrated in the aqueous humor from these patients. *Syphilitic hepatitis* is distinguished by an unusually high serum level of alkaline phosphatase and by a nonspecific histologic appearance that is unlike that of viral hepatitis and includes moderate inflammation with polymorphonuclear leukocytes and lymphocytes, some hepatocellular damage, and no cholestasis. *Renal involvement* produces proteinuria associated with an acute nephrotic syndrome (or rarely with hemorrhagic glomerulonephritis) and is characterized by subepithelial electron-dense deposits and glomerular immune complexes -- findings suggesting immune-complex glomerulonephritis.

Latent Syphilis Positive serologic tests for syphilis, together with a normalCSFexamination and the absence of clinical manifestations of syphilis, indicate a diagnosis of latent syphilis. The diagnosis is often suspected on the basis of a history of primary or secondary lesions, a history of exposure to syphilis, or the delivery of an infant with congenital syphilis. A previous negative serologic test or a history of lesions or exposure may help establish the duration of latent infection. *Early latent* syphilis encompasses the first year after infection, while *late latent* syphilis (beginning³1 year after infection in the untreated patient) is associated with relative immunity to infectious relapse and with increasing resistance to reinfection. *T. pallidum* may still seed the bloodstream intermittently during this stage. Pregnant women with latent syphilis may infect the fetus in utero. Moreover, syphilis has been transmitted through the transfusion of blood from patients with latent syphilis of many years' duration. It was previously thought that untreated late latent syphilis had three possible outcomes: (1) it could persist throughout the lifetime of the infected individual, (2) it could end in the development of late syphilis, or (3) it could end with the spontaneous cure of infection, with reversion of serologic tests to negative. It is now apparent, however, that the more sensitive treponemal antibody tests rarely, if ever, become negative without treatment. About 70% of untreated patients with latent syphilis never develop clinically evident late syphilis, but the occurrence of spontaneous cure is in doubt.

Late Syphilis The slowly progressive inflammatory disease leading to tertiary manifestations begins early during the pathogenesis of syphilis, although these manifestations may not become clinically apparent for years. Early syphilitic aortitis becomes evident soon after secondary lesions subside, and patients who developCSFabnormalities during the early stages of syphilis appear to be at highest risk of late neurologic complications.

Asymptomatic Neurosyphilis CNSsyphilis represents a continuum comprising early invasion, usually within the first weeks or months of infection, and asymptomatic involvement, which may or may not lead to neurologic manifestations. Traditionally, the diagnosis of asymptomatic neurosyphilis has been made in patients who lack neurologic symptoms and signs and who haveCSFabnormalities including mononuclear pleocytosis, increased protein concentrations, or a reactive Venereal Disease Research Laboratory (VDRL) slide test. Such abnormalities are found in up to one-quarter of patients with untreated late latent syphilis, and it is these patients who are known to be at risk for neurologic complications. However, in primary and secondary syphilis, *T.*

pallidum can be isolated from CSF of 40% of patients even in the absence of other CSF abnormalities. Although the therapeutic implications of these findings in early syphilis are uncertain, it seems appropriate to conclude that even patients with early syphilis who have such findings do indeed have asymptomatic neurosyphilis and should be treated for neurosyphilis. In patients with untreated asymptomatic neurosyphilis, the overall cumulative probability of progression to clinical neurosyphilis is about 20% in the first 10 years but increases with time; the likelihood is highest among patients with the greatest degree of pleocytosis or protein elevation. Patients with untreated latent syphilis and normal CSF probably run no risk of subsequent neurosyphilis.

Symptomatic Neurosyphilis Although mixed features are common, the major clinical categories of symptomatic neurosyphilis include meningeal, meningovascular, and parenchymatous syphilis. The last category includes general paresis and tabes dorsalis. The onset of symptoms usually comes <1 year after infection for meningeal syphilis, at 5 to 10 years for meningovascular syphilis, at 20 years for general paresis, and at 25 to 30 years for tabes dorsalis. However, symptomatic neurosyphilis, particularly in the antibiotic era, often presents not as a classic picture but rather as mixed and subtle or incomplete syndromes.

Meningeal syphilis may involve either the brain or the spinal cord, and patients may present with headache, nausea, vomiting, neck stiffness, cranial nerve palsies, seizures, and changes in mental status. *Meningovascular syphilis* reflects diffuse inflammation of the pia and arachnoid together with evidence of focal or widespread arterial involvement of small, medium, or large vessels. The most common presentation is a stroke syndrome involving the middle cerebral artery of a relatively young adult; however, unlike the usual thrombotic or embolic stroke syndrome of sudden onset, meningovascular syphilis often becomes manifest after a subacute encephalitic prodrome (with headaches, vertigo, insomnia, and psychological abnormalities), which is followed by a gradually progressive vascular syndrome.

The manifestations of *general paresis* reflect widespread parenchymal damage and include abnormalities corresponding to the mnemonic *paresis*: *p*ersonality, *a*ffect, *r*eflexes (hyperactive), *e*ye (e.g., Argyll Robertson pupils), *s*ensorium (illusions, delusions, hallucinations), *i*ntellect (a decrease in recent memory and in the capacity for orientation, calculations, judgment, and insight), and *s*peech. *Tabes dorsalis* presents as symptoms and signs of demyelination of the posterior columns, dorsal roots, and dorsal root ganglia. Symptoms include ataxic wide-based gait and footslap; paresthesia; bladder disturbances; impotence; areflexia; and loss of position, deep pain, and temperature sensations. Trophic joint degeneration (Charcot's joints) and perforating ulceration of the feet can result from loss of pain sensation. The small, irregular Argyll Robertson pupil, a feature of both tabes dorsalis and paresis, reacts to accommodation but not to light. *Optic atrophy* also occurs frequently in association with tabes.

Cardiovascular Syphilis Cardiovascular manifestations are attributable to endarteritis obliterans of the vasa vasorum, which provide the blood supply to large vessels. This condition produces medial necrosis with destruction of elastic tissue, particularly in the ascending and transverse segments of the aortic arch, resulting in uncomplicated aortitis, aortic regurgitation, saccular aneurysm, or coronary ostial stenosis. Symptoms appear from 10 to 40 years after infection. Cardiovascular complications occur more

often and at an earlier age among men than among women and may be more common among African Americans than among whites. In the preantibiotic era, symptomatic cardiovascular complications developed in about 10% of persons with late untreated syphilis, and aortic regurgitation was two to four times as common as aneurysm. However, syphilitic aortitis was demonstrated at autopsy in about one-half of African-American men with untreated syphilis.

Linear calcification of the ascending aorta on chest x-ray films suggests asymptomatic syphilitic aortitis, as arteriosclerosis seldom produces this sign. Aortic dilation and a tambour quality to the sound of aortic closure are unreliable signs of aortitis. Syphilitic aneurysms -- usually saccular, occasionally fusiform -- do not lead to dissection. Approximately 1 in 10 aortic aneurysms of syphilitic origin involves the abdominal aorta, but these aneurysms tend to occur above the renal arteries, whereas arteriosclerotic abdominal aneurysms are usually found below the renal arteries. With increasing age, the nervous system is also affected in up to 40% of patients with cardiovascular syphilis.

Late Lesions of the Eyes Iritis associated with pain, photophobia, and dimness of vision or chorioretinitis occurs not only during secondary syphilis but also as a relatively common manifestation of late syphilis. Adhesions of the iris to the anterior lens may produce a fixed pupil, not to be confused with Argyll Robertson pupil.

Late Benign Syphilis (Gumma) Gummas may be multiple or diffuse but are usually solitary lesions that range from microscopic size to several centimeters in diameter. From a histologic perspective, gummas consist of a granulomatous inflammation with a central area of necrosis surrounded by mononuclear, epithelioid, and fibroblastic cells; occasional giant cells; and perivasculitis. Although rarely demonstrated microscopically, *T. pallidum* has reportedly been recovered from these lesions. The most commonly involved sites include the skin and skeletal system, the mouth and upper respiratory tract, the larynx, the liver, and the stomach; however, any organ may be involved. Gummas of the skin produce painless and indurated nodular, papulosquamous, or ulcerative lesions that form characteristic circles or arcs, with peripheral hyperpigmentation. Gummas are usually indolent and may heal spontaneously with scarring, but they may also be explosive in onset and are often destructive. These lesions may resemble those of many other chronic granulomatous conditions, including tuberculosis and sarcoidosis, leprosy, and deep fungal infections. Skeletal gummas most frequently involve the long bones of the legs, although any bone may be affected. Trauma may predispose a specific site to involvement. Presenting symptoms usually include focal pain and tenderness. Radiographic abnormalities with advanced gummas of bone include periostitis or destructive or sclerosing osteitis. Upper respiratory gummas can lead to perforation of the nasal septum or palate. Gummatous hepatitis may produce epigastric pain and tenderness as well as low-grade fever and may be associated with splenomegaly and anemia.

The histopathology and extensive tissue necrosis associated with gummas suggest delayed hypersensitivity to *T. pallidum*. Certain individuals appear to develop an exaggerated delayed-hypersensitivity response to *T. pallidum*, which presumably is mediated by sensitized T lymphocytes and macrophages. Because the histologic changes may be suggestive but are nonspecific, the diagnosis of late benign syphilis is confirmed by serologic testing and by therapeutic trial. Treatment with penicillin results

in rapid healing of active gummatous lesions.

Congenital Syphilis Transmission of *T. pallidum* from a syphilitic woman to her fetus across the placenta may occur at any stage of pregnancy, but the lesions of congenital syphilis generally develop after the fourth month of gestation, when fetal immunologic competence begins to develop. This timing suggests that the pathogenesis of congenital syphilis depends on the immune response of the host rather than on a direct toxic effect of *T. pallidum*. The risk of infection of the fetus during untreated early maternal syphilis is estimated to be 75 to 95%, decreasing to about 35% for maternal syphilis of>2 years' duration. Adequate treatment of the mother before the 16th week of pregnancy should prevent fetal damage. Untreated maternal infection may result in a rate of fetal loss of up to 40% (with stillbirth more common than abortion because of the late onset of fetal pathology), prematurity, neonatal death, or nonfatal congenital syphilis. Among infants born alive, only fulminant congenital syphilis is clinically apparent at birth, and these babies have a very poor prognosis. The most common clinical problem is the healthy-appearing baby born to a mother with a positive serologic test. Routine serologic testing in early pregnancy is considered cost-effective in virtually all populations, even in areas with a low prenatal prevalence of syphilis. Where the prevalence of syphilis is high and when the patient is at high risk, syphilis serology should be repeated in the third trimester and at delivery.

The manifestations of congenital syphilis can be divided into three types according to their timing: (1) early manifestations, which appear within the first 2 years of life (often between 2 and 10 weeks of age), are infectious and resemble the manifestations of severe secondary syphilis in the adult; (2) late manifestations, which appear after 2 years and are noninfectious; and (3) residual stigmata. The earliest sign of congenital syphilis is usually rhinitis, or "snuffles" (23%), which is soon followed by other mucocutaneous lesions (35 to 41%). These may include bullae (syphilitic pemphigus), vesicles, superficial desquamation, petechiae, and (later) papulosquamous lesions, mucous patches, and condylomata lata. The most common early manifestations are bone changes (61%), including osteochondritis, osteitis, and periostitis. Hepatosplenomegaly (50%), lymphadenopathy (32%), anemia (34%), jaundice (30%), thrombocytopenia, and leukocytosis are common.

Neonatal congenital syphilis must be differentiated from other generalized congenital infections, including rubella, cytomegalovirus or herpes simplex virus infection, and toxoplasmosis, as well as from erythroblastosis fetalis. Neonatal death is usually due to pulmonary hemorrhage, secondary bacterial infection, or severe hepatitis.

Late congenital syphilis is that which remains untreated after 2 years of age. In perhaps 60% of cases, the infection remains subclinical; the clinical spectrum in the remainder of cases differs in certain respects from that of acquired late syphilis in the adult. For example, cardiovascular syphilis rarely develops in late congenital syphilis, whereas interstitial keratitis is much more common and occurs between the ages of 5 and 25. Other manifestations associated with interstitial keratitis are eighth-nerve deafness and recurrent arthropathy. Bilateral knee effusions are known as *Clutton's joints*. Asymptomatic neurosyphilis is present in about one-third of untreated patients, and clinical neurosyphilis occurs in one-quarter of untreated individuals over 6 years of age. Gummatous periostitis occurs between the ages of 5 and 20 and, as in nonvenereal

endemic syphilis, tends to cause destructive lesions of the palate and nasal septum.

Characteristic stigmata include *Hutchinson's teeth* -- centrally notched, widely spaced, peg-shaped upper central incisors -- and "mulberry" molars -- sixth-year molars with multiple, poorly developed cusps. The abnormal facies of patients with congenital syphilis include frontal bossing, saddle nose, and poorly developed maxillae. Saber shins, characterized by anterior tibial bowing, are rare. *Rhagades* are linear scars at the angles of the mouth and nose that are caused by secondary bacterial infection of the early facial eruption. Other stigmata include unexplained nerve deafness, old chorioretinitis, optic atrophy, and corneal opacities due to past interstitial keratitis.

LABORATORY EXAMINATIONS

Demonstration of the Organism Dark-field microscopic examination of lesion exudate is useful in evaluating moist cutaneous lesions, such as the chancre of primary syphilis or the condylomata lata of secondary syphilis. The identification of a single characteristic motile organism by a trained observer is sufficient for diagnosis. Examination of oral lesions and anal ulcers by this method is not recommended, as it is difficult to differentiate *T. pallidum* from other spirochetes that may be present.

Most syphilis is diagnosed in settings where dark-field microscopy is not available. The direct fluorescent antibody *T. pallidum* (DFA-TP) test, an alternative available at central laboratories, uses fluorescein-conjugated polyclonal antitreponemal antibody for the detection of *T. pallidum* in fixed smears prepared from suspect lesions. More sensitivePCRtests have been developed but are available only in research laboratories.

T. pallidum can be found in tissue with appropriate silver stains, although these results should be interpreted with caution because artifacts resembling *T. pallidum* are often seen. Treponemes can be demonstrated more reliably in tissue by immunofluorescent or immunohistochemical methods using specific monoclonal or polyclonal antibodies to *T. pallidum*.

Serologic Tests for Syphilis There are two types of serologic tests for syphilis: nontreponemal and treponemal. Both types of tests are reactive in persons with any treponemal infection, including yaws, pinta, and endemic syphilis.

The nontreponemal tests measure IgG and IgM directed against a cardiolipin-lecithin-cholesterol antigen complex. The most widely used nontreponemal antibody tests for syphilis are the rapid plasma reagin (RPR) test, which can be automated (ART), and theVDRLslide test. In these tests, antibody is detected by the microscopic or macroscopic flocculation of the antigen suspension. The RPR test may be more expensive than the VDRL test, but it is easier to perform and uses unheated serum; it is the test of choice for rapid serologic diagnosis in a clinic or office setting. The VDRL test, however, remains the standard for use withCSF.

TheRPR andVDRLtests are equally sensitive and may be used for initial screening or for quantitation of serum antibody. The titer reflects the activity of the disease. A fourfold or greater rise in titer may be seen during the evolution of early syphilis. VDRL titers usually reach 1:32 or higher in secondary syphilis. A persistent fall of two dilutions

(fourfold) or greater following treatment of early syphilis provides essential evidence of an adequate response to therapy. VDRL titers do not correspond directly to RPR titers, and sequential quantitative testing (as for response to therapy) must employ a single test.

Two standard treponemal tests are used for confirmation of reactive nontreponemal results: the fluorescent treponemal antibody-absorbed (FTA-ABS) test and the agglutination assays for antibodies to *T. pallidum*. The microhemagglutination assay for *T. pallidum* (MHA-TP) has been replaced by the Serodia TP-PA test (Fujirebio, Tokyo), which is more sensitive for primary syphilis. The *T. pallidum* hemagglutination test (TPHA) is widely used in Europe but is not available in the United States. Both the agglutination assays and the FTA-ABS tests are very specific and, when used for confirmation of positive non-treponemal tests, have a very high positive predictive value for the diagnosis of syphilis. However, even these tests give false-positive results at rates as high as 1 to 2% when used for the screening of normal populations. New enzyme-linked immunosorbent assays have also been approved as confirmatory tests.

The relative sensitivities of theVDRLtest, theFTA-ABStest, and theMHA-TPin the various stages of untreated syphilis are shown inTable 172-1. The nontreponemal tests are nonreactive in about one-quarter of patients presenting with primary syphilis. In early primary syphilis, the detection of antibody can be maximized either by the performance of an FTA-ABS test or simply by repetition of a VDRL test after 1 to 2 weeks if the initial VDRL result is negative. All treponemal and nontreponemal tests are reactive during secondary syphilis, and a nonreactive result virtually excludes syphilis in a patient with otherwise-compatible mucocutaneous lesions. (Fewer than 1% of patients with secondary syphilis have a VDRL test that is nonreactive or weakly reactive with undiluted serum but is positive at higher serum dilutions -- the *prozone phenomenon*.) While the nontreponemal tests will become nonreactive or will be reactive in lower titers following therapy for early syphilis, the treponemal tests often remain reactive after therapy and therefore are not helpful in determining the infection status of persons with past syphilis.

For practical purposes, most clinicians need to be familiar with the three uses of serologic tests for syphilis: (1) testing of large numbers of sera for screening or diagnostic purposes (e.g., theRPR orVDRLtest), (2) quantitative measurement of the antibody titer to assess the clinical activity of syphilis or to monitor the response to therapy (e.g., the VDRL or RPR test), and (3) confirmation of the diagnosis of syphilis in a patient with a positive nontreponemal antibody test or with a suspected clinical diagnosis of syphilis (e.g., theFTA-ABStest or Serodia TP-PA).

For measurement of IgM in neonates in whom congenital syphilis is suspected, the syphilis Captia-M test (Trinity Biotech, Jamestown, NY) and the 19S IgMFTA-ABStest are available.

False-Positive Serologic Tests for Syphilis Because the antigen used in nontreponemal tests is found in other tissues, the tests may be reactive in persons without treponemal infection, although rarely do titers exceed 1:8 in such patients. In a population selected for screening because of clinical suspicion, history of exposure, or increased risk for sexually transmitted infections, fewer than 1% of reactive tests are

falsely positive. The modernVDRL andRPRtests are 97 to 99% specific, and false-positive reactions are now limited largely to those conditions listed inTable 172-2. False positivity is common among persons with autoimmune disorders. The prevalence of false-positive nontreponemal tests increases with advancing age; 10% of people over 70 years of age have false-positive reactions. In the patient with a false-positive nontreponemal test, syphilis is excluded by a nonreactive treponemal test.

Evaluation for Neurosyphilis Asymptomatic involvement of theCNS is detected by examination ofCSF for pleocytosis, increased protein concentration, andVDRLactivity. CSF abnormalities can be demonstrated in up to 40% of cases of primary or secondary syphilis and in 25% of cases of latent syphilis. In older asymptomatic seropositive individuals, the yield of lumbar puncture is relatively low. *T. pallidum* has been recovered by CSF inoculation into rabbits from up to 30% of patients with primary or secondary syphilis but rarely from those with latent syphilis. The demonstration of *T. pallidum* in CSF is often associated with other CSF abnormalities; however, organisms can be recovered from patients with otherwise-normal CSF. Before the advent of penicillin, the risk of developing clinical neurosyphilis was roughly proportional to the intensity of CSF changes in early syphilis. CSF examination is essential in the evaluation of any seropositive patient with neurologic signs and symptoms and is recommended for all patients with untreated syphilis of unknown duration or of >1 year's duration. The possibility of asymptomatic neurosyphilis in some patients with early disease is not addressed by these recommendations. Because standard therapy with penicillin G benzathine (benzathine benzylpenicillin) for early syphilis fails to result in treponemicidal levels in the CSF, some experts advise lumbar puncture in secondary and early latent syphilis, particularly in patients with HIV infection.

In short, lumbar puncture should be performed in the evaluation of latent syphilis of>1 year's duration, in suspected neurosyphilis, and in late complications other than symptomatic neurosyphilis (since asymptomatic neurosyphilis may coexist with other late complications).CSFexamination is most clearly indicated in the following situations: neurologic signs or symptoms, treatment failure, a serum reagin titer³ 1:32, HIV antibody positivity, other evidence of active syphilis (e.g., aortitis, gumma, visual or hearing changes), or plans to administer nonpenicillin therapy.

TheCSFVDRLtest is highly specific but relatively insensitive and may be nonreactive even in cases of progressive symptomatic neurosyphilis. The degree of sensitivity is highest in meningovascular syphilis and paresis and is lower in asymptomatic neurosyphilis and tabes dorsalis. The unabsorbed FTA test on CSF is reactive far more often than the CSF VDRL test in all stages of syphilis, but FTA reactivity may reflect passive transfer of serum antibody into the CSF. A nonreactive CSF FTA test, however, may be used to rule out neurosyphilis.

Evaluation for Syphilis in Patients Infected with HIV Because persons at highest risk for syphilis (inner-city populations, homosexually active men, and people in many developing countries) are also at increased risk for HIV infection, these two infections frequently coexist in the same patient. There is evidence that syphilis and other genital-ulcer diseases may be important risk factors for the acquisition and transmission of HIV infection.

The manifestations of syphilis may be altered in patients with concurrent HIV infection, and multiple cases of neurologic relapse following standard therapy have been reported in HIV-infected patients. *T. pallidum* has been isolated from theCSF of several patients after therapy for early syphilis with penicillin G benzathine. A recent multicenter U.S. study of early syphilis found similar therapeutic responses in persons with and without concurrent HIV infection, although the study lacked sufficient statistical power to exclude an effect of HIV and 41% of subjects were lost to follow-up. This investigation confirmed the high rate ofCNSinvasion in early syphilis and the persistence of *T. pallidum* after standard therapy: 11 of 43 HIV-infected patients and 21 of 88 HIV-uninfected patients had *T. pallidum* detectable in CSF before therapy; 7 of the 35 patients who underwent lumbar puncture after therapy (some HIV-infected and others uninfected) still had *T. pallidum* detectable in CSF.

The frequency of unusual clinical and laboratory manifestations of syphilis among patients co-infected with HIV is unknown. Such changes may be dependent on the stage of HIV infection and the degree of immunosuppression. There is no clear evidence that the sensitivity of serologic tests for syphilis or the serologic response to therapy in the vast majority of HIV-infected patients with early syphilis differs from the corresponding findings in patients not infected with HIV. Interpretation of serologic results should be the same for the two groups.

Persons with newly diagnosed HIV infection should be tested for syphilis. Some authorities, persuaded by reports of the persistence of *T. pallidum* in theCSF of HIV-infected persons after standard penicillin benzathine therapy for early syphilis, recommend examination of CSF for evidence of neurosyphilis for all co-infected patients, regardless of the clinical stage of syphilis, with treatment for neurosyphilis if CSF abnormalities are found or if CSF examination is not performed. Others do not recommend routine CSF examination for HIV-co-infected patients with early syphilis and believe that standard therapy is sufficient. Serologic testing after treatment is important for all patients with syphilis, particularly those also infected with HIV.

TREATMENT

Treatment of Acquired Syphilis Penicillin G is the drug of choice for all stages of syphilis. *T. pallidum* is killed by very low concentrations of penicillin G, although a long period of exposure to penicillin is required because of the unusually slow rate of multiplication of the organism. The efficacy of penicillin for syphilis remains undiminished after 50 years of use. Other antibiotics effective in syphilis include the tetracyclines, erythromycin, and the cephalosporins. Aminoglycosides and spectinomycin inhibit *T. pallidum* only in very large doses, and the sulfonamides and the quinolones are inactive.

Serum levels of penicillin G of^{3}0.03 ug/mL for at least 7 days are considered necessary for the cure of early syphilis. Recurrence rates for a given regimen increase as infection progresses from incubating to seronegative primary to seropositive primary to secondary to late syphilis. Therefore, it is probable, but unproven, that a longer duration of therapy is required to effect cure as the infection progresses. For these reasons, some authorities use more prolonged penicillin therapy than that recommended by the U.S. Public Health Service when treating secondary, latent, or late syphilis.

The treatment regimens recommended for syphilis are summarized in Table 172-3 and are discussed below.

Early Syphilis Preventive (abortive, "epidemiologic") treatment is recommended for seronegative individuals without signs of syphilis who have been exposed to infectious syphilis within the previous 3 months. Before treatment is given, every effort should be made to establish a diagnosis by examination and serologic testing. *The regimens recommended for prevention are the same as those recommended for early syphilis*.

Penicillin G benzathine is the most widely used agent for the treatment of early syphilis (including primary, secondary, and early latent syphilis), although it is more painful on injection than penicillin G procaine. A single dose of 2.4 million units cures more than 95% of cases of primary syphilis. Because the drug's efficacy in secondary syphilis may be slightly lower, some physicians administer a second dose of 2.4 million units 1 week after the initial dose at this stage of disease. Clinical relapse can follow treatment with penicillin G benzathine in patients with both HIV infection and early syphilis. Because the risk of neurorelapse may be higher in HIV-infected patients, examination ofCSF from HIV-seropositive individuals with syphilis of any stage is recommended by some experts; therapy appropriate for neurosyphilis should be given if there is any evidence ofCNSsyphilis.

For penicillin-allergic patients with early syphilis, a 2-week course of therapy with doxycycline or tetracycline is recommended. These regimens appear to be effective, although no well-controlled studies have been performed and poor compliance may be problematic. Although ceftriaxone and azithromycin have shown activity against *T. pallidum* in animals, human trials have not been of sufficient scope to permit the recommendation of either drug for any stage of syphilis.

Late latent and late syphilis (normal CSF) IfCSFabnormalities are found, the patient should be treated for neurosyphilis. The recommended treatment for late latent syphilis with normal CSF, for cardiovascular syphilis, and for late benign syphilis (gumma) is penicillin G benzathine, 2.4 million units intramuscularly once a week for 3 successive weeks (7.2 million units total). Doxycycline or tetracycline (given for 1 month) offers an untested alternative for penicillin-allergic patients with latent or late syphilis and normal CSF. The clinical response to treatment for benign tertiary syphilis is usually impressive; however, responses to therapy for cardiovascular syphilis are not dramatic because aortic aneurysm and aortic regurgitation cannot be reversed by antibiotic treatment.

Neurosyphilis The 1998 neurosyphilis treatment guidelines of the Centers for Disease Control and Prevention (CDC) are presented inTable 172-3. Penicillin G benzathine, given in total doses of up to 7.2 million units to adults or 50,000 units per kilogram to infants, does not produce detectable concentrations of penicillin G inCSF, and asymptomatic neurosyphilis may relapse in patients treated with 2.4 million units; the risk may be higher in HIV-infected patients. Therefore, the use of penicillin G benzathine alone for the treatment of neurosyphilis is not recommended. On the other hand, administration of intravenous penicillin G in doses of ³12 million units per day for 10 days or longer is thought to ensure treponemicidal concentrations of penicillin G in CSF and occasionally cures infection in patients who fail to respond to other therapy. The

clinical response to penicillin therapy for meningeal syphilis is dramatic, but the response to treatment for parenchymal neurosyphilis is variable. In general, treatment of neurosyphilis in which damage has already been done may produce no clinical change but may arrest disease progression.

Several recent publications have reported neurologic relapse after high-dose intravenous penicillin therapy for neurosyphilis in HIV-infected patients. No alternative therapies have been explored, but careful follow-up is essential, and re-treatment is warranted in such patients.

No data support the use of antibiotics other than penicillin G for the treatment of neurosyphilis; however, some of the third-generation cephalosporins may deserve further evaluation. In patients with penicillin allergy demonstrated by skin testing, desensitization may be the best course (Chap. 126).

Management of Syphilis in Pregnancy Every pregnant woman should undergo a nontreponemal test at her first prenatal visit, and women at high risk of exposure should have a repeat test in the third trimester and at delivery. In the pregnant patient with presumed syphilis (evidenced by a reactive serology, with or without clinical manifestations) and with no history of treatment for syphilis, expeditious evaluation and initiation of treatment are essential. Therapy should be administered according to the stage of the disease, as for nonpregnant patients. Patients should be warned of the risk of a Jarisch-Herxheimer reaction, which may be associated with mild premature contractions but rarely results in premature delivery.

Penicillin is the only recommended therapy for syphilis in pregnancy. If the patient has a well-documented penicillin allergy, desensitization and penicillin treatment should be undertaken in a hospital according to the 1998 sexually transmitted diseases treatment guidelines issued by theCDC. After treatment, a quantitative nontreponemal test should be repeated monthly throughout pregnancy. Treated women whose titers rise fourfold or who do not show a fourfold decrease in titer in a 3-month period should be re-treated.

Evaluation and Management of Congenital Syphilis Newborn infants of mothers with reactiveVDRL orFTA-ABStests may themselves have reactive tests, whether or not they have become infected, because of transplacental transfer of maternal IgG antibody. Rising or persistent titers indicate infection, and the infant should be treated. Neonatal IgM antibody can be detected in cord or neonatal serum with the syphilis Captia-M or 19S IgM FTA-ABS test. Alternatively, monthly quantitative nontreponemal tests may be performed on asymptomatic infants born to women treated adequately with penicillin during pregnancy.

An infant should be treated at birth if the seropositive mother has received penicillin therapy in the third trimester, inadequate penicillin treatment, or therapy with a drug other than penicillin; if her treatment status is unknown; or if the infant may be difficult to follow. It is unwise to require proof of diagnosis before treatment in such cases. TheCSFshould be examined to obtain baseline values before treatment. Penicillin is the only recommended drug for syphilis in infants. The penicillin dosage used for the treatment of the patient with late congenital syphilis is calculated in the same way as for the infant, until dosage based on weight reaches that used for adult neurosyphilis.

Specific recommendations for the treatment of infants are included in theCDC's 1998 guidelines.

Jarisch-Herxheimer Reaction A dramatic though usually mild reaction consisting of fever (average temperature elevation, 1.5°C), chills, myalgias, headache, tachycardia, increased respiratory rate, increased circulating neutrophil count, and vasodilation with mild hypotension may follow the initiation of treatment for syphilis. This reaction occurs in approximately 50% of patients with primary syphilis, 90% of those with secondary syphilis, and 25% of those with early latent syphilis. The onset comes within 2 h of treatment, the temperature peaks at about 7 h, and defervescence takes place within 12 to 24 h. The reaction is more delayed in neurosyphilis, with fever peaking after 12 to 14 h. In patients with secondary syphilis, erythema and edema of the mucocutaneous lesions increase; occasionally, subclinical or early mucocutaneous lesions may first become apparent during the reaction. The pathogenesis of this reaction is undefined, although recent studies have demonstrated the induction of inflammatory mediators such as tumor necrosis factor by treponemal lipoproteins. Patients should be warned to expect such symptoms, which can be managed by bed rest and aspirin. Steroid and other anti-inflammatory therapy is not required for this mild transient reaction.

Follow-Up Evaluation of Responses to Therapy The response of early syphilis to treatment should be determined by monitoring of the quantitativeVDRL orRPRtiter 1, 3, 6, and 12 months after treatment. More frequent serologic examination (1, 2, 3, 6, 9, and 12 months) is recommended for patients concurrently infected with HIV. Because theFTA-ABSand agglutination tests remain positive in most patients treated for seropositive syphilis, these tests are not useful in following the response to therapy. After successful treatment of seropositive first-episode primary or secondary syphilis, the VDRL titer progressively declines, becoming negative by 12 months in 40 to 75% of seropositive primary cases and in 20 to 40% of secondary cases. Patients with a history of syphilis have less rapid declines in titer and are less likely to become VDRL- or RPR-negative. If the VDRL test becomes negative or if VDRL titers drop to a fixed low value within 1 or 2 years, lumbar puncture is unnecessary since theCSFexamination is almost invariably normal and there is little risk of subsequent neurosyphilis. However, if a VDRL titer ³1:8 fails to fall by at least fourfold within 12 months, if the VDRL titer rises by fourfold, or if clinical symptoms persist or recur, re-treatment is indicated. Every effort should be made to differentiate treatment failure from reinfection, and the CSF should be examined. Patients in whom treatment failure is suspected, especially those with abnormal CSF, should be treated for neurosyphilis. If the patient remains seropositive but asymptomatic after such re-treatment, no further therapy is necessary. Patients treated for late latent syphilis frequently have low initial VDRL titers and may not have a fourfold drop after therapy with penicillin; about half of these patients remain seropositive (with low titers) for years after therapy. Re-treatment is not warranted unless the titer rises or signs and symptoms of syphilis appear.

The activity of neurosyphilis correlates best with the degree ofCSFpleocytosis, and this measure provides the most sensitive index of response to treatment. CSF should be examined every 6 months for 3 years after the treatment of asymptomatic or symptomatic neurosyphilis or until CSF findings return to normal. An elevated CSF cell count falls to£10/uL in 3 to 12 months in 95% of adequately treated cases and becomes normal in all cases within 2 to 4 years. Elevated levels of CSF protein fall more slowly,

and the CSF VDRL titer declines gradually over a period of several years.

Persistence of *T. pallidum* The persistence of *T. pallidum* in the aqueous humor,CSF, lymph nodes, brain, inflamed temporal arteries, and other tissues after "adequate" penicillin treatment has been suggested by dark-field microscopy, immunofluorescent antibody and silver staining techniques, rabbit inoculation, and PCR. Because the data on persisting treponemes are scanty, no modification of the treatment recommendations seems warranted for HIV-uninfected persons. Adherence to recommendations regarding CSF examination before the selection of therapy should minimize the possibility that *T. pallidum* will persist in the CSF.

IMMUNITY TO AND PREVENTION OF SYPHILIS

About 60% of contacts of patients with primary and secondary syphilis become infected, with lower risk in contacts exposed to early latent syphilis. The rate of development of acquired resistance to *T. pallidum* after natural or experimental infection is related to the size of the antigenic stimulus, which depends on both the size of the infecting inoculum and the duration of infection before treatment. The role of serum antibody in conferring immunity to syphilis remains controversial. Passively administered antibody prevents or delays the appearance of clinical manifestations of syphilis in the rabbit model; it does not prevent infection. Cellular immunity is considered to be of major importance in the healing of early lesions and the control of syphilitic infection. The cellular infiltration of early lesions predominantly involves T lymphocytes and macrophages. The cytokine milieu of primary and secondary lesions is of the T_H1 type, consistent with the clearance of organisms by activated macrophages. Specific antibody enhances phagocytosis and is required for macrophage-mediated killing of *T. pallidum*.

Inability to cultivate pathogenic treponemes in vitro has hindered the analysis of treponemal antigens. Attempts to induce immunity to syphilis by vaccination have shown limited promise, although repeated injection of rabbits withg-irradiated motile treponemes has conferred immunity to rechallenge. The outer membrane of *T. pallidum* contains few integral membrane proteins, and none has been definitively identified. Several newly described antigens of *T. pallidum*, including TprK, have induced partial immunity to challenge in the rabbit model, and syphilis vaccine development is being actively pursued.

ACKNOWLEDGEMENT

The author wishes to acknowledge the substantive contributions of the former coauthor, Dr. King K. Holmes, to the content and organization of this chapter. His original framework continues to serve as the structure for this revision.

173. ENDEMIC TREPONEMATOSES - *Sheila A. Lukehart*

The endemic, or nonvenereal, treponematoses are bacterial infections that are caused by close relatives of *Treponema pallidum* subspecies *pallidum*, the etiologic agent of venereal syphilis (Chap. 172). Yaws, pinta, and endemic syphilis are distinguished from venereal syphilis by mode of transmission, age of acquisition, geographic distribution, and clinical features. These infections are limited primarily to rural areas of developing nations and are seen in the United States and Europe only in recent immigrants from endemic regions. Much of our "knowledge" about the endemic treponematoses is based upon impressions and observations of health care workers who have visited endemic areas; virtually no well-designed studies of the natural history, diagnosis, or treatment of these infections have been conducted. A comparison of the treponemal infections is shown in Table 173-1.

EPIDEMIOLOGY

The endemic treponematoses are chronic diseases acquired during childhood and, like syphilis, can cause severe late manifestations years after initial infection. These infections were very common in Africa, Asia, and South America when the World Health Organization (WHO) and UNICEF embarked on a highly successful mass eradication campaign. From 1952 to 1969, it is estimated that over 160 million people were examined for treponemal infections and over 50 million cases, contacts, and latent infections were treated. This categorical program is one of WHO's outstanding successes in that the prevalence of active yaws was reduced from >20% to <1% in many rural areas and endemic syphilis was eradicated in Bosnia. In the decades since the eradication programs, lack of focused surveillance and diversion of resources to other pressing needs have resulted in a resurgence of these infections in some regions, particularly in Africa. The estimated geographic distribution of the endemic treponematoses in the 1990s is shown inFig. 173-1. In the early 1980s, WHO sponsored a series of regional meetings on the endemic treponematoses, and areas of resurgent yaws morbidity were identified in West Africa (Ivory Coast, Ghana, Togo, Benin) and extending into the Central African Republic and rural Democratic Republic of Congo (formerly Zaire). The prevalence of endemic syphilis is estimated to be>10% in some regions of Mali, Niger, Burkina Faso, and Senegal. In Asia and the western Pacific, yaws is still prevalent in Indonesia, Papua New Guinea, and the Solomon Islands; cases have also been identified in Laos and Kampuchea. In the Americas, foci of yaws persist in Haiti and other Caribbean islands, Peru, Colombia, Ecuador, Brazil, Guyana, and Surinam. Pinta is limited to Central America and northern South America, where it is found rarely and only in remote villages.

MICROBIOLOGY

The etiologic agents of the endemic treponematoses are *T. pallidum* subspecies *pertenue* (yaws), *T. pallidum* subspecies *endemicum* (endemic syphilis), and *T. carateum* (pinta). These little-studied organisms are morphologically identical to *T. pallidum* subspecies *pallidum*, and no antigenic differences among the pathogenic treponemes have been identified to date. A controversy has existed about whether the treponematoses are caused by different organisms or by the same organism, with clinical manifestations and routes of transmission being defined by the climate of the

region and the culture of the population. Three of the four organisms have been placed in the same species because of their genetic similarity; the fourth (*T. carateum*) remains a separate species simply because no organisms have been available for genetic studies. However, a molecular signature has been defined that can be used to differentiate *T. pallidum* subspecies *pallidum* from *T. pallidum* subspecies *pertenue* and *T. pallidum* subspecies *endemicum*, and unpublished studies have identified a number of distinct differences in the *tpr* gene family between venereal and nonvenereal treponemes. Whether these differences are related to the different clinical courses has not yet been determined.

CLINICAL FEATURES

All of the treponemal infections are characterized by defined disease stages, with a localized primary lesion, disseminated secondary lesions, periods of latency, and possible late lesions. The stages are most clearly defined in venereal syphilis, while the primary and secondary manifestations are more frequently overlapping in yaws and endemic syphilis; the late manifestations of pinta are very mild relative to the destructive lesions of the other treponematoses. The current preference is to divide the clinical course of the endemic treponematoses into "early" and "late" stages.

The major clinical features that are thought to differ between venereal syphilis and the nonvenereal infections are the lack of congenital transmission and lack of central nervous system (CNS) involvement in the nonvenereal infections. It is not known whether these distinctions are accurate. Because of the high degree of genetic relatedness among the organisms, there is little biologic reason to think that *T. pallidum* subspecies *endemicum* and *T. pallidum* subspecies *pertenue* would be unable to cross the blood-brain barrier or to invade the placenta. These organisms obviously can disseminate from the site of primary infection to other tissues, and they can persist for decades. In this respect, they are like *T. pallidum* subspecies *pallidum*. Even if invasion of the placenta or the CNS occurs in endemic treponemal infection, there are a number of reasons that these manifestations might not have been recognized. The lack of recognized congenital infection may be due to the fact that the nonvenereal treponematoses are usually acquired during childhood. The degree of spirochetemia (the presumed source of placental and fetal infection) is greatly diminished during the latent stage, and by the time an infected girl becomes sexually mature, she would be at low risk for transplacental transmission. Neurologic involvement may not have been recognized in nonvenereal treponemal infection because of the lack of trained medical personnel in endemic regions, the lag of years to decades between acquisition of infection and possible CNS manifestations, or a low rate of symptomatic CNS disease. The lack of longitudinal studies in endemic areas makes conclusions about the natural history of these infections tenuous.

Some published evidence supports congenital transmission as well as cardiovascular, ophthalmologic, andCNSinvolvement in yaws. Although the case is strong, particularly for CNS involvement, most studies that have shown a relatively high incidence (average, 24.9%) of cerebrospinal fluid (CSF) abnormalities in patients with yaws were not controlled for other possible causes of CSF abnormalities, did not include treponeme-specific tests, or did not follow patients for resolution of abnormalities after antitreponemal therapy. Thus, while no firm conclusions can be drawn about the

invasion of the CNS and placenta by the non-*pallidum* treponemes, it may be erroneous to accept unquestioningly the frequently repeated belief that these organisms fail to cause such manifestations.

Yaws Also known as *pian*, *framboesia*, or *bouba*, yaws is a chronic infection that is usually acquired in childhood and is caused by *T. pallidum* subspecies *pertenue*. The disease is characterized by the development of one or several primary lesions (called the "mother yaw"), followed by the appearance of multiple disseminated skin lesions. The early lesions may persist for many months, are infectious, and usually recur several times within the early years of infection. Late manifestations are destructive and can involve skin, bone, and joints.

The infection is transmitted by direct contact with infectious lesions, and transmission may be enhanced by disruption of the skin by insect bites or abrasions. Children with open lesions and without covering clothing are most likely to transmit infection during play or group sleeping. After an average incubation period estimated at 3 to 4 weeks, the first lesion begins as a papule, usually on an extremity, and then enlarges (particularly during moist warm weather) to become papillomatous or "raspberry-like" (thus the name "framboesia") (Fig. 173-2). Regional lymphadenopathy develops, and the lesion usually heals within 6 months; dissemination is thought to occur during the early weeks and months of infection. A generalized secondary eruption, accompanied by generalized lymphadenopathy, appears either concurrent with or following the primary lesion, may take several forms (macular, papular, or papillomatous), and may become secondarily infected with other bacteria. Painful papillomatous lesions on the soles of the feet result in a painful crablike gait ("crab yaws"), and periostitis may result in nocturnal bone pain and polydactylitis. All early skin lesions are infectious, and cutaneous relapses are common during the first 5 years. Late yaws is recognized in ~10% of untreated patients and is manifested by gummas of the skin and long bone, hyperkeratoses of the palms and soles, osteitis and periostitis, and hydrarthrosis. The late gummatous lesions are characteristically very destructive and extensive. Destruction of the nose, maxilla, palate, and pharynx is termed *gangosa* and is similar to the destructive lesions seen in leprosy and leishmaniasis.

Endemic Syphilis Endemic syphilis, also called *bejel*, *siti*, *dichuchwa*, *njovera*, or *skerljevo*, is a chronic infection caused by *T. pallidum* subspecies *endemicum*. Like other endemic treponematoses, endemic syphilis is chronic and is acquired in childhood. The early lesions are primarily localized to the mucocutaneous and mucosal surfaces, and the infection may be transmitted by direct contact or by shared drinking and eating utensils. A role for insects in transmission has been suggested but is unproved. The initial lesion often goes unrecognized, and the first noticeable lesion is usually an intraoral mucous patch or a mucocutaneous lesion resembling the condylomata lata of secondary syphilis (Fig. 173-2). This eruption may last for months or even years, and treponemes can readily be demonstrated in early lesions. Periostitis and regional lymphadenopathy are common. After a variable period of latency, late manifestations may appear, including osseous and cutaneous gummas. Destructive gummas, osteitis, and gangosa are more common in endemic syphilis than in late yaws. Gummas of the nipples develop in women who have previously had endemic syphilis and who breast-feed infants with oral lesions. Thus, it appears that the late lesion may result from repeated exposure of a sensitized host.

Pinta Pinta (also called *mal del pinto*, *carate*, *azul*, or *purupuru*) is the most benign of the treponemal infections and is caused by *T. carateum*. This disease has three stages that are characterized by marked changes in skin color, but it does not appear to cause destructive lesions or to involve other tissues. Transmission occurs by direct contact, usually during late childhood. The initial papule is most often located on the extremities or face and is pruritic. After one to many months of infection, numerous disseminated secondary lesions (*pintides*) appear. These lesions are initially red but become deeply pigmented, ultimately turning a dark slate blue. The secondary lesions are infectious and highly pruritic and may persist for years. Late pigmented lesions are called *dyschromic macules* and contain treponemes. Over time, most pigmented lesions show varying degrees of depigmentation, becoming brown and eventually white and giving the skin a mottled appearance. The white achromic lesions are characteristic of the late stage.

DIAGNOSIS

Diagnosis of the endemic treponematoses is based upon clinical manifestations and, when available, serologic testing. The same tests that are used for venereal syphilis (Chap. 172) become reactive during all treponemal infections, and there is no serologic test than can discriminate among the different infections. The nonvenereal treponemal infections should be considered in the evaluation of a reactive syphilis serology in any person who has immigrated from an endemic area.

TREATMENT

The recommended therapy for patients and their contacts is benzathine penicillin at a dose of 1.2 million units intramuscularly; that for children under 10 years of age is 600,000 units. This is half the dose recommended for patients and contacts with early venereal syphilis. There have been no controlled studies to show that the lower dose is effective in stopping relapse or progression to late disease. Definitive evidence of resistance to penicillin is lacking. However, because failure to heal existing lesions and frequent relapse following treatment for yaws have been described in Papua New Guinea, some health workers have suggested doubling the recommended dose of benzathine penicillin. Solely on the basis of experience with venereal syphilis, it is thought that doxycycline, tetracycline, and erythromycin (at doses appropriate for syphilis;Chap. 172) are therapeutic alternatives for patients allergic to penicillin. A Jarisch-Herxheimer reaction (Chap. 172) may follow treatment of endemic treponematoses.

CONTROL

The endemic treponematoses can be controlled with inexpensive therapy. However, the often-remote locations of the affected populations limit availability of medical care. Although the mass treatment programs of three decades ago were widely successful, time has shown that sustained control requires vigilance in regular screening and in the investigation of outbreaks -- luxuries that are often impossible in countries with more pressing medical needs. There is concern that, as HIV spreads throughout developing countries, it may markedly affect the manifestations and transmission of the endemic

treponematoses.

ACKNOWLEDGEMENT

The author gratefully acknowledges the substantial contributions of Dr. Peter Perine, the author of previous editions of this chapter, to the framework of the current chapter and to our insight into these little-studied infections.

174. LEPTOSPIROSIS - *Peter Speelman*

Leptospirosis is an infectious disease caused by pathogenic leptospires and characterized by a broad spectrum of clinical manifestations, varying from inapparent infection to fulminant, fatal disease. In its mild form, leptospirosis may present as an influenza-like illness with headache and myalgias. Severe leptospirosis, characterized by jaundice, renal dysfunction, and hemorrhagic diathesis, is referred to as *Weil's syndrome*.

ETIOLOGIC AGENTS

Leptospires are spirochetes belonging to the order Spirochaetales and the family Leptospiraceae. Traditionally, the genus *Leptospira* comprised two species: the pathogenic *L. interrogans* and the free-living *L. biflexa*. Although seven species of pathogenic leptospires are now recognized on the basis of their DNA relatedness, it is more practical clinically and epidemiologically to use a classification based on serologic differences. The pathogenic leptospires are divided into serovars according to their antigenic composition. More than 200 serovars make up the 23 serogroups.

Leptospires are coiled, thin, highly motile organisms with hooked ends and two periplasmic flagella that permit burrowing into tissue. These organisms are 6 to 20 um long and about 0.1 um wide; they stain poorly but can be seen microscopically by dark-field examination and after silver impregnation staining. Leptospires require special media and conditions for growth; it may take weeks for cultures to become positive.

EPIDEMIOLOGY

Leptospirosis is a zoonosis with a worldwide distribution that affects at least 160 mammalian species. Rodents, especially rats, are the most important reservoir, although other wild mammals, dogs, fish, and birds may also harbor these microorganisms. Leptospires establish a symbiotic relationship with their host and can persist in the renal tubules for years. Some serovars are associated with particular animals -- e.g., icterohaemorrhagiae/copenhageni with rats, grippotyphosa with voles, hardjo with cattle, canicola with dogs, and pomona with pigs.

Transmission of leptospires may follow direct contact with urine, blood, or tissue from an infected animal or exposure to a contaminated environment; human-to-human transmission is rare. Since leptospires are excreted in the urine and can survive in water for many months, water is an important vehicle in their transmission. Epidemics of leptospirosis may result from exposure to flood waters contaminated by urine from infected animals, as has been reported from Nicaragua. Leptospirosis occurs most commonly in the tropics because the climate as well as the sometimes poor working and hygienic conditions favor the pathogen's survival.

Humans are not commonly infected with leptospires. However, in the United States, the 40 to 120 cases reported annually to the Centers for Disease Control and Prevention certainly represent a significant underestimation of the total number. Certain occupational groups are at especially high risk; included are veterinarians, agricultural workers, sewage workers, slaughterhouse employees, and workers in the fishing

industry. Such individuals may acquire leptospirosis through direct exposure to or contact with contaminated water and soil. Leptospirosis has also been recognized in deteriorating inner cities where rat populations are expanding. One report described leptospirosis in urban residents of Baltimore who were sporadically exposed to rat urine.

In western countries, recreational exposure and domestic animal contact are also prominent sources of leptospirosis. Recreational water activities, such as canoeing, windsurfing, swimming, and waterskiing, place persons at risk for leptospirosis. Sometimes the infection is acquired during travel abroad. In a recent study in the Netherlands, 14% of patients with confirmed leptospirosis had acquired the infection while traveling in tropical countries, mostly in Southeast Asia. Transmission via laboratory accidents has been reported but is rare. Occasionally, leptospirosis develops after unanticipated immersion in contaminated water (e.g., in an automobile accident). Most cases occur in men, with a peak incidence during the summer and fall in western countries and during the rainy season in the tropics.

PATHOGENESIS

The pathogenesis of leptospirosis is incompletely understood. Leptospires may enter the host through abrasions in the skin or through intact mucous membranes, especially the conjunctiva and the lining of the oro- and nasopharynx. Drinking of contaminated water may introduce leptospires through the mouth, throat, or esophagus. After entry of the organisms, leptospiremia develops, with subsequent spread to all organs. Multiplication takes place in blood and in tissues, and leptospires can be isolated from blood and cerebrospinal fluid (CSF) during the first 4 to 10 days of illness. It is not clear why the presence of leptospires in the CSF does not cause damage. All forms of leptospires can damage the wall of small blood vessels; this damage leads to vasculitis with leakage and extravasation of cells, including hemorrhages. The most important known pathogenic properties of leptospires are adhesion to cell surfaces and cellular toxicity.

Vasculitis is responsible for the most important manifestations of the disease. Although leptospires mainly infect the kidneys and liver, any organ may be affected. In the kidney, leptospires migrate to the interstitium, renal tubules, and tubular lumen, causing interstitial nephritis and tubular necrosis. Hypovolemia due to dehydration or altered capillary permeability may contribute to the development of renal failure. In the liver, centrilobular necrosis with proliferation of Kupffer cells may be found. However, severe hepatocellular necrosis is not a feature of leptospirosis. Pulmonary involvement is the result of hemorrhage and not of inflammation. Invasion of skeletal muscle by leptospires results in swelling, vacuolation of the myofibrils, and focal necrosis. In severe leptospirosis, vasculitis may ultimately impair the microcirculation and increase capillary permeability, resulting in fluid leakage and hypovolemia.

When antibodies are formed, leptospires are eliminated from all sites in the host except the eye, the proximal renal tubules, and perhaps the brain, where they may persist for weeks or months. The persistence of leptospires in the aqueous humor occasionally causes chronic or recurrent uveitis. The systemic immune response is effective in eliminating the organism but may also produce symptomatic inflammatory reactions. A rise in antibody titer coincides with the development of meningitis; this association

suggests that an immunologic mechanism is responsible.

After the start of antimicrobial treatment for leptospirosis, a Jarisch-Herxheimer reaction similar to that seen in other spirochetal diseases may develop. Although frequently described in older publications, this reaction seems to be a rare event in leptospirosis and is certainly less frequent in this infection than in other spirochetal diseases.

CLINICAL MANIFESTATIONS

It is important to try to obtain a history of exposure to contaminated materials. Serologic evidence of past inapparent infection is found in 15 to 40% of persons who have been exposed but have not become ill. In symptomatic cases of leptospirosis, clinical manifestations vary from mild to serious or even fatal. More than 90% of symptomatic persons have the relatively mild and usually anicteric form of leptospirosis, with or without meningitis. Severe leptospirosis with profound jaundice (Weil's syndrome) develops in 5 to 10% of infected individuals.

The incubation period is usually 1 to 2 weeks but ranges from 2 to 26 days. Typically, an acute leptospiremic phase is followed by an immune leptospiruric phase. The distinction between the first and second phases is not always clear, and milder cases do not always include the second phase.

Anicteric Leptospirosis Leptospirosis may present as an acute influenza-like illness, with fever, chills, severe headache, nausea, vomiting, and myalgias. Muscle pain, which especially affects the calves, back, and abdomen, is an important feature of leptospiral infection. Less common features include sore throat and rash. The patient usually has an intense headache (frontal or retroorbital) and sometimes develops photophobia. Mental confusion may be evident. Pulmonary involvement, manifested in most cases by cough and chest pain and in a few cases by hemoptysis, is not uncommon.

The most common finding on physical examination is fever with conjunctival suffusion. Less common findings include muscle tenderness, lymphadenopathy, pharyngeal injection, rash, hepatomegaly, and splenomegaly. The rash may be macular, maculopapular, erythematous, urticarial, or hemorrhagic. Mild jaundice may be present.

Most patients become asymptomatic within 1 week. After an interval of 1 to 3 days, the illness recurs in a number of cases. The start of this second (immune) phase coincides with the development of antibodies. Symptoms are more variable than during the first (leptospiremic) phase. Usually the symptoms last for only a few days, but occasionally they persist for weeks. Often the fever is less pronounced and the myalgias are less severe than in the leptospiremic phase. An important event during the immune phase is the development of aseptic meningitis. Although no more than 15% of all patients have symptoms and signs of meningitis, many patients may haveCSFpleocytosis. Meningeal symptoms usually disappear within a few days but may persist for weeks. Similarly, pleocytosis generally disappears within 2 weeks but occasionally persists for months. Iritis, iridocyclitis, and chorioretinitis -- late complications that may persist for years -- can become apparent as early as the third week but often present several months after the initial illness. One epidemic of uveitis among patients with leptospirosis has been reported.

Severe Leptospirosis (Weil's Syndrome) Weil's syndrome, the most severe form of leptospirosis, is characterized by jaundice, renal dysfunction, hemorrhagic diathesis, and high mortality. This syndrome is frequently but not exclusively associated with infection due to serovar icterohaemorrhagiae/copenhageni. The onset of illness is no different from that of less severe leptospirosis; however, after 4 to 9 days, jaundice as well as renal and vascular dysfunction generally develop. Although some degree of defervescence may be noted after the first week of illness, a biphasic disease pattern like that seen in anicteric leptospirosis is lacking. The jaundice of Weil's syndrome, which can be profound and give an orange cast to the skin, is usually not associated with severe hepatic necrosis. Death is rarely due to liver failure. Hepatomegaly and tenderness in the right upper quadrant are usually detected. Splenomegaly is found in 20% of cases.

Renal failure may develop, often during the second week of illness. Hypovolemia and decreased renal perfusion contribute to the development of acute tubular necrosis with oliguria or anuria. Dialysis is sometimes required, although a fair number of cases can be managed without dialysis. Renal function may be completely regained.

Pulmonary involvement occurs frequently, resulting in cough, dyspnea, chest pain, and blood-stained sputum, and sometimes in hemoptysis or even respiratory failure. Hemorrhagic manifestations are seen in Weil's syndrome: epistaxis, petechiae, purpura, and ecchymoses are found commonly, while severe gastrointestinal bleeding and adrenal or subarachnoid hemorrhage are detected rarely.

Rhabdomyolysis, hemolysis, myocarditis, pericarditis, congestive heart failure, cardiogenic shock, adult respiratory distress syndrome, and multiorgan failure have all been described during severe leptospirosis.

LABORATORY AND RADIOLOGIC FINDINGS

The kidneys are invariably involved in leptospirosis (Fig. 174-CD1). Related findings range from urinary sediment changes (leukocytes, erythrocytes, and hyaline or granular casts) and mild proteinuria in anicteric leptospirosis to renal failure and azotemia in severe disease.

The erythrocyte sedimentation rate is usually elevated. In anicteric leptospirosis, peripheral leukocyte counts range from 3000 to 26,000/uL, with a left shift; in Weil's syndrome, leukocytosis is often marked. Mild thrombocytopenia occurs in up to 50% of patients and is associated with renal failure.

In contrast to patients with acute viral hepatitis, those with leptospirosis typically have elevated serum levels of bilirubin and alkaline phosphatase as well as mild increases (up to 200 U/L) in serum levels of aminotransferases. In Weil's syndrome, the prothrombin time may be prolonged but can be corrected with vitamin K. Levels of creatine phosphokinase, which are elevated in up to 50% of patients with leptospirosis during the first week of illness, may help to differentiate this infection from viral hepatitis.

When a meningeal reaction develops, polymorphonuclear leukocytes predominate

initially and the number of mononuclear cells increases later. The protein concentration in theCSF may be elevated; CSF glucose levels are normal.

In severe leptospirosis, pulmonary radiographic abnormalities are more common than would be expected on the basis of physical examination. These abnormalities most frequently develop 3 to 9 days after the onset of illness. The most common radiographic finding is a patchy alveolar pattern that corresponds to scattered alveolar hemorrhage. Radiographic abnormalities most often affect the lower lobes in the periphery of the lung fields.

DIAGNOSIS

A definite diagnosis of leptospirosis is based either on isolation of the organism from the patient or on seroconversion or a rise in antibody titer in the microscopic agglutination test (MAT). For a presumptive diagnosis of leptospirosis, an antibody titer of ³1:100 in the MAT or a positive macroscopic slide agglutination test in the presence of a compatible clinical illness is required. Antibodies generally do not reach detectable levels until the second week of illness. The antibody response can be affected by early treatment.

The macroscopic slide agglutination test with killed antigen is useful for screening but is not specific. TheMAT, which uses a battery of live leptospiral strains, and the enzyme-linked immunosorbent assay (ELISA), which uses a broadly reacting antigen, are the standard serologic procedures. These tests usually are available only in specialized laboratories and are used for the determination of the antibody titer and for the tentative identification of the serovar involved (thus the importance of using antigens representative of the serovars prevalent in the particular geographic area). Since cross-reactions occur frequently, however, it is often impossible to identify the infecting serovar. Serologic testing cannot be used as the basis for a decision about whether to start treatment.

In addition to theMAT and theELISA, various other tests with diagnostic value have been developed. Some tests, such as an indirect hemagglutination test, a microcapsule agglutination test, and an IgM ELISA, are commercially available. Dot-ELISA, gold immunoblot, and polymerase chain reaction techniques have been developed but are not yet used for routine diagnosis.

Leptospires can be isolated from blood and/orCSFduring the first 10 days of illness and from urine for several weeks beginning at around 1 week. Cultures may become positive after 2 to 4 weeks, with a range of 1 week to 4 months. Sometimes urine cultures remain positive for months or years after the start of illness. For isolation of leptospires from body fluids or tissues, Ellinghausen-McCullough-Johnson-Harris (EMJH) medium is useful; other possibilities are Fletcher medium and Korthoff medium. Specimens can be mailed to a reference laboratory for culture, since leptospires remain viable in anticoagulated blood (heparin, EDTA, or citrate) for up to 11 days. Isolation of leptospires is important since it is the only way the infecting serovar can be correctly identified. Dark-field examination of blood or urine frequently results in misdiagnosis and should not be used.

DIFFERENTIAL DIAGNOSIS

Leptospirosis should be differentiated from other febrile illnesses associated with headache and muscle pain, such as malaria, enteric fever, viral hepatitis, dengue, *Hantavirus* infections, and rickettsial diseases. In light of the strong similarity in epidemiology and clinical presentation between leptospirosis and *Hantavirus* infections and given the reported occurrence of dual infections, it is advisable to conduct serologic testing for *Hantavirus* in cases of suspected leptospirosis. When patients have a flulike disease with disproportionately severe myalgia or aseptic meningitis, a diagnosis of leptospirosis should be considered.

TREATMENT

The effectiveness of antimicrobial therapy for the mild febrile form of leptospirosis is controversial, but such treatment is indicated for more severe forms. Treatment should be initiated as early as possible; nevertheless, contrary to previous reports, treatment started after the first 4 days of illness is effective.

For severe cases of leptospirosis, intravenous administration of penicillin G, amoxicillin, ampicillin, or erythromycin is recommended (Table 174-1). In milder cases, oral treatment with tetracycline, doxycycline, ampicillin, or amoxicillin should be considered. Although several other antibiotics, including newer cephalosporins, are highly active against leptospires in vitro, no clinical experience has yet been gained with these drugs.

In rare cases, a Jarisch-Herxheimer reaction develops within hours after the start of antimicrobial therapy (see "Pathogenesis" above). Although so far the only effective mode of management is supportive, the role of antibodies to tumor necrosis factor in the treatment of this reaction deserves further study. A beneficial effect of the use of such antibodies for the modulation of the reaction has been demonstrated in patients with louse-borne relapsing fever. Patients with severe leptospirosis and renal failure may require dialysis. Those with Weil's syndrome may need transfusions of whole blood and/or platelets. Intensive care may be necessary.

PROGNOSIS

Most patients with leptospirosis recover. Mortality is highest among patients who are elderly and those who have Weil's syndrome. Leptospirosis during pregnancy is associated with high fetal mortality. Long-term follow-up of patients with renal failure and hepatic dysfunction has documented good recovery of renal and hepatic function.

PREVENTION

Individuals who may be exposed to leptospires through their occupations or their involvement in recreational water activities should be informed about the risks. Measures for controlling leptospirosis include avoidance of exposure to urine and tissues from infected animals, vaccination of animals, and rodent control. The animal vaccine used in a given area should contain the serovars known to be present in that area. Unfortunately, some vaccinated animals still excrete leptospires in their urine. Vaccination of humans against a specific serovar prevalent in an area has been

undertaken in some European and Asian countries and has proved effective. Chemoprophylaxis with doxycycline (200 mg once a week) has appeared to be efficacious in military personnel but is indicated only in rare instances of sustained short-term exposure.

175. RELAPSING FEVER - *David T. Dennis*, *Grant L. Campbell*

DEFINITION

The term *relapsing fever* describes two distinct borrelial disease entities: louse-borne relapsing fever (LBRF) and tick-borne relapsing fever (TBRF). Both are characterized by recurrent acute episodes of spirochetemia and fever alternating with spirochetal clearance and apyrexia.

ETIOLOGY

The worldwide distribution of relapsing spirochetal fevers was recognized in the early part of the twentieth century, and the causative agents were shown to be transmitted by lice and ticks. *Borrelia recurrentis* was identified as the cause ofLBRF; differing strains of borreliae causingTBRFwere usually named according to the species of *Ornithodoros* tick responsible for their transmission (Table 175-1). Sequencing of both flagellin and 16S ribosomal RNA genes reveals homogeneity among LBRF strains and considerable heterogeneity between Old World and New World TBRF strains.

Relapsing-fever borreliae are gram-negative bacteria that belong to the family Spirochaetaceae. They are helical in shape and average 0.2 to 0.5 um in width and 5 to 20 um in length. They comprise an outer membrane, an intermediate peptidoglycan layer, and an inner cytoplasmic membrane, which encloses the protoplasmic cylinder. Periplasmic flagella (variable numbers have been described) are situated beneath the outer membrane. Relapsing-fever borreliae are slow-growing and microaerophilic; they grow best at 30 to 35°C. BothTBRF andLBRFspirochetes grow well in Barbour-Stoenner-Kelly (BSK II) medium.

Relapsing-fever borreliae are distinguished by remarkable antigenic variability and strain heterogeneity. New *Borrelia* serotypes spontaneously emerge at a high rate, resulting from a unique process of DNA rearrangement within genes located on linear plasmids. These genes code for variable major proteins (VMPs) found on the spirochete's outer-membrane surface. This antigenic variation, generated by sequential expression of previously silent *vmp* genes for serotype-specific VMPs, allows the borreliae to escape the immune response of the host and results in the relapse phenomenon characteristic of infection with these organisms. Borrelial *vmp* gene expression also varies between mammalian and arthropod hosts.

EPIDEMIOLOGY

Louse-Borne Relapsing Fever Body lice (*Pediculus humanus* var. *corporis*) become infected with *B. recurrentis* by feeding on spirochetemic humans, the only reservoirs of infection. In lice, *B. recurrentis* spirochetes are found almost exclusively in the hemolymph; humans acquire infection when infected body lice are crushed and their fluids contaminate mucous membranes or breaks in the skin (such as abrasions caused by scratching of pruritic louse bites). Spirochetes are not transmitted directly by the bite of a louse (anterior station transmission) or by inoculation of louse feces (posterior station transmission). Lice have a life span of only a few weeks, feed at frequent intervals, and survive only a few days off the human host.

LBRFhas severely affected military and civilian populations disrupted by war and other disasters. During the Industrial Revolution, the disease was common among slum dwellers, prisoners, and others living in impoverished, overcrowded, and unhygienic conditions. In the first half of the twentieth century, during periods of war and famine, both LBRF and louse-borne typhus were epidemic in eastern Europe, the Balkans, and the former Soviet Union. LBRF has disappeared from its former global range as improvements have been made in standards of living, sanitation, and hygiene; it is now an important disease only in northeastern Africa, especially the highlands of Ethiopia, where an estimated 10,000 cases occur annually. In Ethiopia, the disease affects mostly homeless men crowded together in unhygienic circumstances, especially during the cool rainy season, when it is more difficult for them to change and wash their clothing. LBRF has repeatedly spilled out of Ethiopia into neighboring Somalia and Sudan, especially affecting displaced persons. LBRF does not pose a significant risk to tourists or other casual visitors but can be acquired from lice by persons (such as relief workers) in intimate contact with those affected as well as through accidental needle stick or mucocutaneous contact with infected blood.

Tick-Borne Relapsing Fever Soft ticks (Argasidae, *Ornithodoros* spp.) transmitTBRF. The ticks become infected by feeding on spirochetemic hosts. Except for *B. duttoni* (a prominent cause of TBRF in sub-Saharan Africa), TBRF borreliae are zoonotic disease agents found naturally in rodents (rats, mice, chipmunks, and squirrels) and in lagomorphs (rabbits and hares). The spirochetes are transmitted by ticks to humans and animals via saliva and excretory fluids when the tick feeds. Infection in ticks is transmitted vertically from one stage to the next; in some species, infection is transmitted transovarially over several generations. Soft ticks are hardy and can survive for 10 years or more with only an occasional blood meal. These ticks feed painlessly, relatively quickly (for 20 to 45 min), and usually at night while hosts are sleeping. Thus patients with TBRF are often unaware of tick exposures.

TBRFborreliae are widely distributed throughout the world. Human infection with these organisms is generally underrecognized and underreported. TBRF is most highly endemic in sub-Saharan Africa but is also found in countries of the Mediterranean littoral, Middle Eastern states, southern Russia, the Indian subcontinent, and China. In the United States, this disease occurs west of the Mississippi River, especially in mountainous areas, where *B. hermsii* is the causative agent. TBRF is reported at low frequency throughout Latin America. The disease typically occurs sporadically or in small -- often familial -- clusters. Infected soft ticks may cause repeated infections among persons living or sleeping in the same dwelling. In sub-Saharan Africa, *O. moubata*, the vector of *B. duttoni*, infests native huts and rest houses, hiding in crevices of floors and walls during the day and emerging at night to feed on sleeping inhabitants. In the United States, *B. hermsii* infections most often occur during spring and summer months among persons sleeping in rustic mountain cabins. Infections of humans are sometimes precipitated by the disappearance of rodents (e.g., as a result of epizootic plague) that nest in foundations, wall spaces, and attics and that serve as the usual maintenance hosts for *O. hermsi* ticks. Outbreaks caused by *B. hermsii* have taken place among persons staying in cabins along the north rim of the Grand Canyon and in the mountains of California, Idaho, and Colorado. Rodent-infested caves in southwestern states are associated with occasional cases of relapsing fever caused by

B. turicatae.

PATHOGENESIS AND PATHOLOGY

In humans, relapsing-fever borreliae penetrate the skin or mucous membranes, multiply in the blood, and circulate in great numbers during febrile periods. The organisms also may be found in the liver, spleen, central nervous system, bone marrow, and other tissues and may be sequestered at these sites during periods of remission. The severity of disease is positively related to spirochete density in the blood. Even though the pathophysiologic manifestations of the disease resemble responses to endotoxin, and although plasma from some patients with relapsing fever coagulates *Limulus* amebocyte lysates, borreliae and other spirochetes have not been shown to express a true lipopolysaccharide (endotoxin) molecule. Infection with *B. recurrentis* does, however, activate protein mediators of inflammation, such as Hageman factor, prekallikrein, and proteins of the complement system; furthermore, a spirochetal heat-stable pyrogenic factor stimulates mononuclear phagocytes to express increased amounts of leukocyte pyrogen and thromboplastin.

The Jarisch-Herxheimer reaction in patients withLBRF is associated with a release of various cytokines into the plasma, including interleukin 6, interleukin 8, C-reactive protein, and enormous amounts of tumor necrosis factor a (TNF-a). Pretreatment of LBRF patients with antibody to TNF-asuppresses the Jarisch-Herxheimer reactions that follow penicillin treatment and reduces the plasma concentrations of certain other cytokines.

Findings at autopsy of patients with relapsing fever most often include hepatosplenomegaly and variable edema and swelling of other organs, such as the brain, lungs, and kidneys. On microscopic examination, the spleen is congested and contains multiple microabscesses composed of mononuclear cells that replace the white pulp, the myocardium displays diffuse histiocytic inflammation and interstitial edema, and the liver has areas of midzonal necrosis. Petechial hemorrhages are commonly evident over the surfaces of the meninges, pleura, heart, spleen, liver, kidneys, and mesentery. Subcapsular and parenchymal hemorrhagic infarcts of the spleen, heart, liver, and brain are sometimes grossly visible. Icterus is a common finding in severe and fatal cases of relapsing fever.

CLINICAL MANIFESTATIONS

The clinical manifestations of LBRFand TBRFare similar. The mean incubation period is 7 days (range, 2 to 18 days), and the onset of illness is sudden, with fever, headache, shaking chills, sweats, myalgias, and arthralgias. The arthralgia of relapsing fever can be severe, involving small and large joints, but there is no evidence of arthritis. Dizziness, nausea, and vomiting are common. Sleep may be difficult and is sometimes accompanied by disturbing dreams. The patient is coherent but withdrawn, thirsty, and disinterested in food and other outside stimuli. The fever is high from the first, with a usual temperature of³40°C (³104°F); fever is most often irregular in pattern and is sometimes accompanied by delirium. Patients become progressively prostrate as the disease advances. The pulse is rapid and the patient is mildly tachypneic. Meningism may be found. The conjunctivae are often injected, and the patient usually exhibits

photophobia. The sclerae are sometimes icteric, most commonly in the later stages of illness. The mucous membranes are often dry, and the patient is usually dehydrated. Scattered petechiae develop on the trunk, extremities, and mucous membranes in one-third or more of patients with LBRF and in fewer patients with TBRF. A nonproductive cough is common, but chest sounds are usually normal; pleuritic pain and an accompanying pleuritic rub are sometimes noted. Cardiac findings are compatible with a high-output state; tachycardia and summation gallop are common. Tender enlargement of the spleen and liver frequently characterizes the acute phase of illness.

Epistaxis and blood-tinged sputum are common complications, and gastrointestinal and central nervous system hemorrhage can occur. Because of this coagulopathy, oneLBRFoutbreak in southern Sudan was thought to be viral hemorrhagic fever. Other complications of variable incidence include iridocyclitis, optic neuritis, meningitis, coma, isolated cranial-nerve palsy, pneumonitis, myocarditis, and rupture of the spleen. Infection during pregnancy can result in spontaneous abortion, stillbirth, or neonatal infection. Life-threatening complications are unusual in otherwise healthy persons given supportive care, especially if the illness is diagnosed and treated early.

Without treatment, symptoms intensify over a 2- to 7-day period (average, 5 days inLBRF and 3 days inTBRF), ending in a spontaneous crisis during which spirochetes disappear from the circulation. Treatment with one of the rapidly acting antibiotics, such as erythromycin, a tetracycline, or chloramphenicol, regularly precipitates a Jarisch-Herxheimer reaction within 1 to 4 h. The severity of this reaction is positively correlated with the density of spirochetes in the blood at the time of treatment. In the first phase of the crisis or reaction (the *chill phase*), rigors and rising fever are accompanied by an increasing metabolic rate, alveolar hyperventilation, high cardiac output, increasing peripheral vascular resistance, and decreased pulmonary arterial pressure. The body temperature commonly rises to³41°C (³105.8°F). This high fever is accompanied often by agitation and confusion and sometimes by delirium. Fever can be partially controlled by the use of a cooling blanket and ice packs and by sponging of the patient with tepid water and alcohol. The chill phase terminates after 10 to 30 min, giving way to a *flush phase* characterized by a fall in body temperature, drenching sweats, and sometimes (more commonly in LBRF) a potentially dangerous fall in systemic arterial pressure and rise in pulmonary arterial pressure. Although cardiac output is maintained at high levels, the effective circulating blood volume decreases as peripheral vascular resistance falls. Vital signs must be monitored carefully during this period of the reaction, which usually lasts£8 h. Clinical and electrocardiographic evidence of myocarditis and myocardial dysfunction includes a prolonged QT_cinterval, a third heart sound (S_3), elevated central venous pressure, arterial hypotension, and pulmonary edema.

The crisis is followed by a period of exhaustion, sleep, and an uneventful recovery. Not uncommonly, in the first week of convalescence, patients experience 1 or 2 days of mild fever unassociated with detectable spirochetemia. In untreated patients, spirochetemia and symptoms may recur after a period of several days or weeks (average interval to first relapse, 9 days inLBRF and 7 days inTBRF). Only one or two relapses characteristically occur in untreated patients with LBRF, whereas as many as 10 (average, three) can occur in untreated patients with TBRF. In most cases, the illness

becomes shorter and milder and the afebrile intervals longer with each relapse. Because of the great antigenic variation among *Borrelia* strains, infection confers only partial immunity, and repeated infections of the same individual have been recorded.

Diseases that should be considered in the differential diagnosis of relapsing fever or that may complicate relapsing fever include typhus fever, typhoid, nontyphoid salmonellosis, malaria, dengue and other arboviral illnesses, tuberculosis, leptospirosis, and viral hemorrhagic fevers. In the United States, the geographic distribution of Colorado tick fever overlaps that ofTBRF, and the two diseases have similar manifestations early in their courses.

LABORATORY FINDINGS AND DIAGNOSIS

The diagnosis of relapsing fever is confirmed most easily by the detection of spirochetes in blood, bone marrow aspirates, or cerebrospinal fluid. Motile spirochetes can be seen when fresh blood is examined by dark-field microscopy; and fixed organisms are clearly visible in Wright-, Giemsa-, or acridine orange-stained preparations of thin or dehemoglobinized thick smears of peripheral blood or buffy-coat preparations (Fig. 175-1). Organisms are found in blood taken during periods of fever preceding the crisis; smears from³70% of patients withLBRF and from fewer patients withTBRF are positive. In reference laboratories, relapsing-fever spirochetes are cultured from blood by the inoculation of BSK II medium or by the intraperitoneal inoculation of immature laboratory mice. The detection of agglutinins against *Proteus* OX-K (Weil-Felix reaction) in convalescent-phase serum supports the diagnosis. Serum antibodies to *Borrelia* can be detected by enzyme immunoassays, but these tests are unstandardized and subject to insensitivity due to antigenic variations among strains. Serologic cross-reactions occur with other spirochetes, including *B. burgdorferi* (the agent of Lyme disease) and *Treponema pallidum*.

Other laboratory findings in relapsing fever are generally nonspecific. The leukocyte count is normal or moderately elevated, with an unremarkable cell differential. Serum bilirubin levels are generally only slightly elevated. Thrombocytopenia (mean platelet count, about 50,000/uL) is evident in patients withLBRFduring the acute phase of the illness; platelet counts rebound during early convalescence. Prothrombin and partial thromboplastin times are moderately prolonged during acute illness, as are standardized bleeding times. Fibrinogen concentrations in the blood are normal, and fibrinolysis is mild or absent. Results of the Rumpel-Leede tourniquet test are negative, despite the presence of petechiae.

TREATMENT

Relapsing-fever borreliae are exquisitely sensitive to antibiotics. Treatment with erythromycin, a tetracycline, chloramphenicol, or penicillin produces rapid clearance of spirochetes and a remission of symptoms (Table 175-2). Although a single dose of erythromycin, a tetracycline, or chloramphenicol is highly effective in the treatment ofLBRF, less is known about the efficacy of single-dose treatment ofTBRF. Empirical treatment of TBRF for 7 days is therefore recommended to reduce the risk of persisting or relapsing borreliosis. For children<8 years of age and for pregnant women, erythromycin and penicillin are the preferred drugs.

The use of delayed-release intramuscular penicillin may prolong or delay the clearance of spirochetes and thereby attenuate the accompanying Jarisch-Herxheimer reaction, but this response is not predictable; furthermore, single-dose penicillin treatment sometimes results in relapse of spirochetemia and symptoms. Glucocorticoids and nonsteroidal anti-inflammatory agents do not prevent or significantly modify the cardiopulmonary disturbances of the Jarisch-Herxheimer reaction, although hydrocortisone and acetaminophen given at the same time as antibiotics reduce peak body temperature. Although pretreatment with antibody toTNF-amay moderate the Jarisch-Herxheimer reaction in treated patients withLBRF, its widespread use in LBRF is impractical and its use inTBRF(whose treatment is associated with a relatively mild Jarisch-Herxheimer reaction) is not warranted. Close monitoring of fluid balance, arterial and venous pressures, and myocardial function is advised in supportive management of the Jarisch-Herxheimer reaction in patients with LBRF.

The management of patients with myocardial dysfunction requires caution in the administration of intravenous fluids and, in some cases, rapid digitalization. Bleeding is not controlled by heparin, and clinical studies do not suggest that disseminated intravascular coagulopathy is important. Vitamin K and other soluble vitamins are sometimes given to counter dietary deficiencies in patients withLBRF. Because postural hypotension is often pronounced during the acute phase of relapsing fever and in the early stage of recovery, patients should be assisted when arising from bed.

UntreatedLBRF has a high case-fatality rate, especially among persons in otherwise poor health, such as those in famine-affected populations. The fatality rate among treated persons is usually <5%. In general,TBRF is a milder disease than LBRF: the spontaneous crisis and the Jarisch-Herxheimer reactions are less pronounced and the case-fatality rates are lower for TBRF than for LBRF.

PREVENTION AND CONTROL

LBRFcan be prevented by elimination of circumstances that promote louse infestation (crowding, poverty, homelessness, poor personal hygiene), by use of practices that eliminate or reduce numbers of body lice (washing clothes, drying clothes in direct sunlight, changing clothes at frequent intervals), and by application of acaricides. Secondary complications and the spread of infection can be prevented by early case detection and treatment of infected persons and close contacts. Historically, outbreaks of LBRF have been controlled by mass delousing. In situations like those in refugee camps, individuals, their clothes, and their bedding should be deloused with appropriate acaricides, such as 0.5% permethrin dust. Impregnation of clothing with liquid permethrin, a residual acaricide, can provide long-term protection against infestation. In outbreaks of fever that involve louse-infested populations, empirical single-dose treatment with doxycycline will be effective against typhus as well as LBRF. *B. recurrentis* has a fragile life cycle and is eradicable.

TBRFcan be prevented by the avoidance of rodent- and tick-infested dwellings and infested natural sites. Limiting rodent access to the foundations and attics of homes and vacation cabins and eliminating harborage for rodents in and around these dwellings reduce the potential for tick exposure. Rodents and rodent nests should be removed

from infested buildings and their surroundings. Tick harborages of infested buildings or other circumscribed sites, such as rodent burrows and nests in hollow logs surrounding dwellings and in rodent-infested caves, can be chemically treated by pest-control specialists using various acaricides, such as carbaryl, diazinon, chlorpyrifos, pyrethrins, and malathion. Persons who enter tick-infested sites can protect themselves by wearing clothing that denies ticks access to the skin, by applying repellents to exposed skin and to clothing, and by applying an acaricide containing permethrin to clothing. Reporting of suspected cases of relapsing fever to public health authorities is important so that an epidemiologic investigation and control measures can be initiated promptly.

176. LYME BORRELIOSIS - *Allen C. Steere*

DEFINITION

Lyme borreliosis, a tick-transmitted spirochetal illness, usually begins with a characteristic expanding skin lesion, erythema migrans (EM; stage 1, localized infection). After several days or weeks, the spirochete may spread hematogenously to many different sites (stage 2, disseminated infection). Possible manifestations of disseminated infection include secondary annular skin lesions, meningitis, cranial or peripheral neuritis, carditis, atrioventricular nodal block, or migratory musculoskeletal pain. Months to years later (usually after periods of latent infection), intermittent or chronic arthritis, chronic encephalopathy or polyneuropathy, or acrodermatitis may develop (stage 3, persistent infection). Most patients experience early symptoms of the illness during the summer, but the infection may not become symptomatic until it progresses to stage 2 or 3. Despite regional variations, the basic stages of the illness are similar worldwide.

ETIOLOGIC AGENT

Borrelia burgdorferi, the causative agent of the disease, is a fastidious, microaerophilic bacterium. The organism contains many immunogenic proteins, including a number of differentially expressed lipoproteins, most of which are encoded by plasmid DNA. The spirochete grows best at 33°C in a complex liquid medium called Barbour, Stoenner, Kelly (BSK) medium. Culture of the organism from clinical specimens (except for biopsy samples of skin at sites ofEM or acrodermatitis) has been difficult. Three groups of pathogenic *B. burgdorferi* organisms, together referred to as *B. burgdorferi sensu lato*, have been identified, and more groups surely exist. To date, North American strains have belonged to the first group, *B. burgdorferi sensu stricto*. Although all three of the identified groups have been found in Europe and Asia, most isolates there have been strains of group 2 (*B. garinii*) or group 3 (*B. afzelii*). These differences may well account for the clinical variations in the disease in different geographic regions.

EPIDEMIOLOGY

The distribution of Lyme borreliosis correlates closely with the geographic ranges of ticks of the *Ixodes ricinus* complex: *I. scapularis* (also called *I. dammini*), *I. pacificus*, *I. ricinus*, and *I. persulcatus*. *I. scapularis* is the principal vector in the northeastern United States from Massachusetts to Maryland and in the midwestern states of Wisconsin and Minnesota. Surveys in these regions have documented infection in at least 20% of *I. scapularis* ticks; most cases of Lyme disease in the United States have occurred in these areas. *I. pacificus* is the vector in the western states of California and Oregon. The disease is acquired throughout Europe (from Great Britain to Scandinavia to European Russia), where *I. ricinus* is the vector, and in Asian Russia, China, and Japan, where *I. persulcatus* is the vector. These ticks transmit other diseases that may have similar symptoms. In the United States, *I. scapularis* also transmits babesiosis and ehrlichiosis; in Europe and Asia, *I. ricinus* and *I. persulcatus* also transmit tick-borne encephalitis.

Ticks of the *I. ricinus* complex feed once during each of the three stages of their usual

2-year life cycle. Typically, larval ticks take one blood meal in the late summer, nymphs (Fig. 176-CD1) feed during the following spring and early summer, and adults feed during autumn. For *I. scapularis* in the northeast, the white-footed mouse is the preferred host of the immature larval and nymphal ticks. It is critical that both of the tick's immature stages feed on the same host, because the life cycle of the spirochete depends on horizontal transmission: in early summer from infected nymphs to mice and in late summer from infected mice to larvae, which then molt to become the infected nymphs that will begin the cycle again the following year. It is the tiny nymphal tick that is primarily responsible for transmission of the disease to humans during the early summer months. White-tailed deer, which are not involved in the life cycle of the spirochete, are the preferred host for the adult stage of *I. scapularis* and seem to be critical to the tick's survival. The adult tick occasionally transmits the spirochete to humans during the fall, but at this stage the tick is considerably larger and easier to recognize.

Lyme disease is now the most common vector-borne infection in the United States. Since surveillance was begun in 1982, more than 100,000 cases have been reported to the Centers for Disease Control and Prevention (CDC); during the 1990s, more than 10,000 new cases have been reported each summer. Cases have been noted in 48 states, but the life cycle of *B. burgdorferi* has been identified in only 19 states. Cases have occurred in association with hiking, camping, or hunting trips and with residence in wooded or rural areas. Persons of all ages and both sexes are affected.

PATHOGENESIS

To maintain its complex enzootic cycle, *B. burgdorferi* must adapt to two markedly different environments: the tick and the mammalian host. The spirochete expresses outer-surface proteins A and B (OspA and OspB) in the midgut of the tick, whereas OspC is upregulated as the organism travels to the tick's salivary gland and thence to the mammalian host.

After injection into the human skin, *B. burgdorferi* may migrate outward, producingEM, and may spread hematogenously to other organs. Spread within the human host is probably facilitated through binding to the spirochete's surface by human plasminogen and urokinase-type plasminogen activator, which activates plasmin, a potent protease. The spirochete can adhere to many types of mammalian cells; it binds specifically to certain ubiquitous host integrin receptors in the extracellular matrix, to vitronectin and fibronectin, and to matrix glycosaminoglycans. *B. burgdorferi* seems to have a particular tropism for tissues of the skin, nervous system, atrioventricular node, and joints, from all of which it has been cultured, seen in histologic sections, or (more commonly) detected (via its DNA) by the polymerase chain reaction (PCR). These findings and the response of all stages of the disease to antibiotic therapy suggest that the organism persists in affected tissues throughout the illness, but the mechanisms of persistent infection are not yet clear.

The immune response in Lyme disease develops gradually. After the first several weeks of infection, mononuclear cells generally exhibit heightened responsiveness to *B. burgdorferi* antigens, and evidence of B cell hyperactivity is found, including elevated total serum IgM levels, cryoprecipitates, and circulating immune complexes. Titers of

specific IgM antibody to *B. burgdorferi* peak between the third and sixth week after disease onset. The specific IgG response develops gradually over months, with response to an increasing array of 12 or more spirochetal polypeptides and maximal expansion during the period of arthritis. The spirochete is a potent inducer of proinflammatory cytokines, including tumor necrosis factor a and interleukin 1b. Histologic examination of all affected tissues reveals an infiltration of lymphocytes and plasma cells with some degree of vascular damage (including mild vasculitis or hypervascular occlusion), suggesting that the spirochete may have been present in or around blood vessels.

CLINICAL MANIFESTATIONS

Early Infection: Stage 1 (Localized Infection) After an incubation period of 3 to 32 days,EM, which occurs at the site of the tick bite, usually begins as a red macule or papule that expands slowly to form a large annular lesion, most often with a bright red outer border and partial central clearing (Plate IID-46,Fig. 176-CD2). Because of the small size of ixodid ticks, most patients do not remember the preceding tick bite. The center of the lesion sometimes becomes intensely erythematous and indurated, vesicular, or necrotic. In other instances, the expanding lesion remains an even, intense red; several red rings are found within an outside ring; or the central area turns blue before the lesion clears. Although EM can be located anywhere, the thigh, groin, and axilla are particularly common sites. The lesion is warm but not often painful. Perhaps as many as 25% of patients do not exhibit this characteristic skin manifestation.

Early Infection: Stage 2 (Disseminated Infection) Within days or weeks after the onset ofEM, the organism often spreads hematogenously to many sites. In these cases patients frequently develop secondary annular skin lesions similar in appearance to the initial lesion. Skin involvement is commonly accompanied by severe headache, mild stiffness of the neck, fever, chills, migratory musculoskeletal pain, arthralgias, and profound malaise and fatigue. Less common manifestations include generalized lymphadenopathy or splenomegaly, hepatitis, sore throat, nonproductive cough, conjunctivitis, iritis, or testicular swelling. Except for fatigue and lethargy, which are often constant, the early signs and symptoms of Lyme disease are typically intermittent and changing. Even in untreated patients, the early symptoms usually become less severe or disappear within several weeks.

Symptoms suggestive of meningeal irritation may develop early in Lyme disease whenEM is present but usually are not associated with cerebrospinal fluid (CSF) pleocytosis or an objective neurologic deficit. After several weeks or months, about 15% of untreated patients develop frank neurologic abnormalities, including meningitis, subtle encephalitic signs, cranial neuritis (including bilateral facial palsy), motor or sensory radiculoneuropathy, mononeuritis multiplex, or myelitis -- alone or in various combinations. In the United States, the usual pattern consists of fluctuating symptoms of meningitis accompanied by facial palsy and peripheral radiculoneuropathy. Lymphocytic pleocytosis (about 100 cells per microliter) is found in CSF, often along with elevated protein levels and normal or slightly low glucose concentrations. In Europe and Asia, the first neurologic sign is characteristically radicular pain, which is followed by the development of CSF pleocytosis (called *Bannwarth's syndrome*), but meningeal or encephalitic signs are frequently absent. These early neurologic abnormalities usually

resolve completely within months, but chronic neurologic disease may occur later.

Within several weeks after the onset of illness, about 8% of patients develop cardiac involvement. The most common abnormality is a fluctuating degree of atrioventricular block (first-degree, Wenckebach, or complete heart block). Some patients have more diffuse cardiac involvement, including electrocardiographic changes indicative of acute myopericarditis, left ventricular dysfunction evident on radionuclide scans, or (in rare cases) cardiomegaly or pancarditis. Cardiac involvement usually lasts for only a few weeks but may recur. Chronic cardiomyopathy caused by *B. burgdorferi* has been reported in Europe.

During this stage, musculoskeletal pain is common. The typical pattern consists of migratory pain in joints, tendons, bursae, muscles, or bones (usually without joint swelling) lasting for hours or days and affecting one or two locations at a time.

Late Infection: Stage 3 (Persistent Infection) Months after the onset of infection, about 60% of patients in the United States who have received no antibiotic treatment develop frank arthritis. The typical pattern comprises intermittent attacks of oligoarticular arthritis in large joints (especially the knees), lasting for weeks to months in a given joint. Small joints and periarticular sites also may be affected, primarily during early attacks. The number of patients who continue to have recurrent attacks decreases each year. However, in a small percentage of cases, involvement of large joints -- usually one or both knees -- becomes chronic and may lead to erosion of cartilage and bone. These patients have a higher frequency of the class II major histocompatibility complex alleles associated with rheumatoid arthritis, particularly HLA-DRBI*0401 or *0101 alleles, than patients with brief Lyme arthritis or normal control subjects. Moreover, they may have persistent arthritis for months or even several years after the apparent eradication of spirochetes from the joints with antibiotic therapy. In these genetically susceptible individuals, autoimmunity may develop within the proinflammatory milieu of the joints because of molecular mimicry between the dominant T cell epitope of OspA and human lymphocyte function-associated antigen 1 (hLFA-1).

White cell counts in joint fluid range from 500 to 110,000/uL (average, 25,000/uL); most of these cells are polymorphonuclear leukocytes. Tests for rheumatoid factor or antinuclear antibodies usually give negative results. Examination of synovial biopsy samples reveals fibrin deposits, villous hypertrophy, vascular proliferation, microangiopathic lesions, and a heavy infiltration of lymphocytes and plasma cells.

Although less common, chronic neurologic involvement may also become apparent months or years after the onset of infection, sometimes following long periods of latent infection. The most common form of chronic central nervous system involvement is subtle encephalopathy affecting memory, mood, or sleep and often accompanied by axonal polyneuropathy manifested as either distal paresthesia or spinal radicular pain. Patients with encephalopathy frequently have evidence of memory impairment in neuropsychological tests and abnormal results inCSFanalyses. In cases with polyneuropathy, electromyography generally shows extensive abnormalities of proximal and distal nerve segments. Encephalomyelitis or leukoencephalitis, a rare manifestation of Lyme borreliosis reported primarily in Europe, is a severe neurologic disorder that may include spastic paraparesis, upper motor-neuron bladder dysfunction, and lesions

in the periventricular white matter. The prolonged course of chronic neuroborreliosis following periods of latent infection is reminiscent of tertiary neurosyphilis.

Acrodermatitis chronica atrophicans (Fig. 176-CD3), the late skin manifestation of the disorder, has been associated primarily with *B. afzelii* infection in Europe and Asia. It has been observed primarily in elderly women. The skin lesions, which are usually found on the acral surface of an arm or leg, begin insidiously with reddish-violaceous discoloration; they become sclerotic or atrophic over a period of years.

DIAGNOSIS

Lyme disease is usually diagnosed by the recognition of a characteristic clinical picture with serologic confirmation. Although serologic testing may yield negative results during the first several weeks of infection, most patients have a positive antibody response to *B. burgdorferi* after that time. The limitation of serologic tests is that they do not clearly distinguish between active and inactive infection. Patients with previous Lyme disease -- particularly in cases progressing to late stages -- often remain seropositive for years, even after adequate antibiotic treatment. In addition, some patients are seropositive because of asymptomatic infection. If these individuals subsequently develop another illness, the positive serologic test for Lyme disease may cause diagnostic confusion. On the other hand, a few patients who receive inadequate antibiotic therapy during the first several weeks of infection develop subtle joint or neurologic symptoms but are seronegative. The important point is that seronegative Lyme disease is usually a mild, attenuated illness.

For serologic analysis in Lyme disease, theCDCrecommends a two-step approach in which samples are first tested by enzyme-linked immunosorbent assay (ELISA) and equivocal or positive results are then tested by western blotting. During the first month of infection, both IgM and IgG responses to the spirochete should be determined, preferably in both acute- and convalescent-phase serum samples. Approximately 20 to 30% of patients have a positive response detectable in acute-phase samples, whereas about 70 to 80% have a positive response during convalescence (2 to 4 weeks later). After that time, the great majority of patients continue to have a positive IgG antibody response, and a single test (that for IgG) is usually sufficient. In persons with illness of longer than 1 month's duration, a positive IgM test result alone is likely to be false-positive; therefore, a positive IgM test should not be used to support the diagnosis in such patients. According to current criteria adopted by the CDC, an IgM western blot is considered positive if two of the following three bands are present: 23, 39, and 41 kDa. However, the combination of the 23- and 41-kDa bands may still represent a false-positive result. An IgG blot is considered positive if 5 of the following 10 bands are present: 18, 23, 28, 30, 39, 41, 45, 58, 66, and 93 kDa.

Because serologic tests do not distinguish between active and inactive infection, tests that detect the spirochete directly are being researched. *B. burgdorferi* may be cultured from skin lesions of patients with the disorder, but its culture from other sites has been a low-yield proposition. Detection of spirochetal DNA byPCR may serve as a substitute for culture in cases of Lyme arthritis. In one study, *B. burgdorferi* DNA was detected in synovial fluid samples from 75 (85%) of 88 patients and in none of 64 control samples. However, the sensitivity of PCR determinations inCSF from patients with

neuroborreliosis has been much lower. There seems to be little if any role for PCR in the detection of *B. burgdorferi* DNA in blood or urine samples.

DIFFERENTIAL DIAGNOSIS

ClassicEM is a slowly expanding erythema with partial central clearing. If the lesion expands little, it may represent the red papule of an uninfected tick bite. If the lesion expands rapidly, it may represent cellulitis (e.g., streptococcal cellulitis) or an allergic reaction, perhaps to tick saliva. Patients with secondary annular lesions may be thought to have erythema multiforme, but neither the development of blistering mucosal lesions nor the involvement of the palms or soles is a feature of *B. burgdorferi* infection. In the southeastern United States, an EM-like skin lesion, sometimes with mild systemic symptoms, may be associated with *Amblyomma americanum* tick bites, but the cause of this illness has not yet been identified.

Later in the infection, the most common problem in diagnosis is to mistake Lyme disease for chronic fatigue syndrome or fibromyalgia. This difficulty is compounded by the fact that a small percentage of patients do in fact develop these chronic pain or fatigue syndromes in association with or soon after Lyme disease. Compared with Lyme disease, chronic fatigue syndrome (Chap. 384) or fibromyalgia tends to produce more generalized and disabling symptoms, including marked fatigue, severe headache, diffuse musculoskeletal pain, multiple symmetric tender points in characteristic locations, pain and stiffness in many joints, diffuse dysesthesia, difficulty with concentration, and sleep disturbances. Patients with chronic fatigue syndrome or fibromyalgia lack evidence of joint inflammation; they have normal results in neurologic tests; and they usually have a greater degree of anxiety and depression than patients with chronic neuroborreliosis.

TREATMENT

As outlined in the algorithm in Fig. 176-1, the various manifestations of Lyme disease can usually be treated successfully with orally administered antibiotics; the exceptions are objective neurologic abnormalities and third-degree atrioventricular heart block, which seem to require intravenous therapy. For early Lyme disease, doxycycline is effective in men and in nonpregnant women. An advantage of this regimen is that it is also effective against the agent of human granulocytic ehrlichiosis, which is transmitted by the same tick that transmits the Lyme disease agent. Amoxicillin, cefuroxime axetil, and erythromycin or its congeners are second-, third-, and fourth-choice alternatives, respectively. In children, amoxicillin is effective (not more than 2 g/d); in cases of penicillin allergy, cefuroxime axetil or erythromycin may be used. For patients with infection localized to the skin, a 20-day course of therapy is generally sufficient; in contrast, for patients with disseminated infection, a 30-day course is recommended. Approximately 15% of patients experience a Jarisch-Herxheimer-like reaction during the first 24 h of therapy.

These oral antibiotic regimens, when given for 30 to 60 days, are effective for the treatment of Lyme arthritis. However, the response to oral therapy may be slower than that to intravenous therapy. In the small percentage of patients with arthritis in whom arthritic symptoms persist for months or even years after the apparent eradication of

spirochetes from the joints with antimicrobial therapy, treatment with anti-inflammatory agents or synovectomy may be successful.

For objective neurologic abnormalities (with the possible exception of facial palsy alone), parenteral antibiotic therapy seems to be necessary. Intravenous ceftriaxone, given for 4 weeks, is most commonly used for this purpose, but intravenous cefotaxime or intravenous penicillin G for the same duration may also be effective. In patients with high-degree atrioventricular block or a PR interval of greater than 0.3 s, intravenous therapy for at least part of the course and cardiac monitoring are recommended. Prior to the use of antibiotics for the treatment of Lyme disease, the degree of heart block was found to decrease rapidly with prednisone (40 to 60 mg/d). Although rarely used today, glucocorticoids may be of benefit in patients with complete heart block or congestive heart failure if antimicrobial therapy alone does not result in improvement within 24 h.

It is unclear how and whether asymptomatic infection should be treated, but patients with such infection are often given a course of oral antibiotics. The appropriate treatment for Lyme disease during pregnancy is also unclear. Because the risk of maternal-fetal transmission seems to be very low, standard therapy for the documented stage and manifestation of the illness may be sufficient. Relapse may follow the use of any of the antibiotic regimens for Lyme disease, and a second course of therapy may be necessary. On the other hand, in patients who develop chronic fatigue syndrome or fibromyalgia after Lyme disease, further antibiotic therapy does not seem to be of benefit.

The risk of infection with *B. burgdorferi* after a recognized tick bite is so low that antibiotic prophylaxis is not routinely indicated. However, if the tick is engorged, if follow-up is difficult, or if the patient is quite anxious, therapy with amoxicillin or doxycycline for 10 days is likely to prevent Lyme disease.

PROGNOSIS

The response to treatment is best early in the disease. Later treatment of Lyme borreliosis is still effective, but convalescence may be longer. Eventually, most patients recover with minimal or no residual deficits.

ALGORITHM FOR TESTING AND THERAPY

According to guidelines recently published by the American College of Physicians, empirical antibiotic therapy without serologic testing is recommended for patients with a high pretest probability of Lyme disease (such as those withEM); two-step testing (byELISAand, if positive, by western blot) is recommended for patients with an intermediate pretest probability (such as those with recurrent oligoarticular arthritis); and neither testing nor treatment is recommended for patients with a low pretest probability (such as those with nonspecific symptoms of myalgias, arthralgias, or fatigue).

REINFECTION

Reinfection may occur afterEM when patients are treated with antimicrobial agents. In such cases, the immune response is not adequate to provide protection from

subsequent infection. However, patients who develop an expanded immune response to the spirochete over a period of months (such as those with Lyme arthritis) have protective immunity for a period of years and do not acquire the infection again.

VACCINATION

A vaccine is now available for the prevention of Lyme disease in the United States. It consists of a recombinant outer-surface lipoprotein A (L-OspA) with adjuvant. High-titered antibody to OspA is necessary for protection. In a phase 3 efficacy trial in which subjects were given three doses of vaccine or placebo on a 0-, 1-, and 12-month schedule, vaccine efficacy in preventing definite cases of Lyme disease was 49% during the first year (after two doses) and 76% in year 2 (after three doses). Equivalent antibody titers may be obtained if the three doses are given on a 0-, 1-, and 2-month schedule. The third dose should be given in April so that the vaccine recipient will have peak antibody titers during the summer tick-transmission season. Although long-term data are not yet available, yearly booster injections may be necessary. Vaccine injection may cause a mild to moderate local or systemic reaction usually lasting for only a few days. Vaccination should be considered for individuals who live in areas that are highly endemic for the infection and who have frequent exposure to tick habitats.

SECTION 10 -*RICKETTSIA, MYCOPLASMA,* AND *CHLAMYDIA*

177. RICKETTSIAL DISEASES - *David Walker*, *Didier Raoult*, *J. Stephen Dumler*, *Thomas Marrie*

The rickettsiae make up a family of gram-negative coccobacilli and short bacilli that grow strictly in eukaryotic cells. Characteristics of these organisms include their obligately intracellular location and persistence. The pathogenic rickettsiae move through mammalian reservoirs; they are transmitted by insect or tick vectors. Except for louse-borne typhus, humans are incidental hosts. Among rickettsiae, *Coxiella burnetii* (the agent of Q fever) is notorious for its ability to survive for an extended period outside of the reservoir or vector and for its extreme infectiousness: inhalation of a single microorganism can cause pneumonia. Clinical infections with rickettsiae can be classified into five general groups: (1) tick- and gamasid mite-borne, spotted fever group (SFG) rickettsial diseases; (2) flea- and louse-borne typhus group rickettsial diseases; (3) chigger-borne scrub typhus; (4) ehrlichioses; and (5) Q fever. The rickettsiae that cause spotted fevers, typhus, and scrub typhus are listed along with their vectors, geographic ranges, and associated diseases inTable 177-1.

TICK- AND MITE-BORNE SPOTTED FEVERS

ROCKY MOUNTAIN SPOTTED FEVER

Rocky Mountain spotted fever (RMSF), the most severe of the rickettsial diseases, is caused by *Rickettsia rickettsii*. This organism possesses two major immunodominant surface-exposed proteins, rOmpA and rOmpB, which have species-specific conformational epitopes. rOmpA functions as an adhesin for the host cell; rOmpB, the most abundant outer-membrane protein, shares genetic sequences and limited antigens with typhus group rickettsiae. This small (0.3 um by 1.0 um) bacillus has a gram-negative cell wall structure; its lipopolysaccharide shares antigens mainly within theSFG and is not endotoxic in the quantities found in human infections.

Discovered in the American West in the late nineteenth century,RMSF is at present documented in 48 states, Canada, Mexico, Costa Rica, Panama, Colombia, and Brazil. It is transmitted by *Dermacentor variabilis*, the American dog tick, in the eastern two-thirds of the United States and California; by *D. andersoni*, the Rocky Mountain wood tick, in the western United States; by *Rhipicephalus sanguineus* in Mexico; and by *Amblyomma cajennense* in Central and South America. Maintained principally by transovarian transmission from one generation of ticks to the next, *R. rickettsii* can be acquired by uninfected ticks through the ingestion of a blood meal from rickettsemic small mammals.

Humans become infected during the active season of the vector tick species. In northern areas, cases occur mainly in the spring; in warmer southern states, most cases occur from May to September, although some cases are reported in the winter. Although 4% of *D. variabilis* ticks contain rickettsiae, the vast majority of these are nonpathogenic species such as *R. montana* and *R. bellii*. The likelihood of an individual tick's containing *R. rickettsii* is remote. From 1988 to 1997, the reported incidence ofRMSF has been in the range of 0.16 to 0.26 cases per 100,000 population in the

United States. This rate is probably an underestimate, since the diagnosis is difficult and reporting incomplete. The 5- to 9-year-old age group has the highest incidence. The mortality rate was 20 to 25% in the preantibiotic era and now remains at about 5% because of delayed diagnosis and treatment. The case-fatality ratio is higher for males than females and increases with each decade of life above age 20.

Pathogenesis *R. rickettsii* organisms are inoculated into the dermis along with secretions of the tick's salivary glands after ³6 h of feeding. Rickettsiae spread lymphohematogenously throughout the body, attach via rOmpA to the endothelial cell membrane, and induce their own engulfment. Once intracellularly located, they escape rapidly from the phagosome, replicate in the cytosol by binary fission, and spread from cell to cell, propelled by polar polymerization of the host cell's actin. The result is numerous foci of contiguous infected endothelial cells that are extensive enough to manifest clinically after a dose-dependent incubation period of approximately 1 week (range, 2 to 14 days). *R. rickettsii* is more invasive than other rickettsiae, routinely spreading to infect vascular smooth-muscle cells. Despite frequent statements to the contrary, occlusive thrombosis and ischemic necrosis are not the fundamental pathologic basis for tissue and organ injury inRMSF. Instead, increased vascular permeability, with resulting edema, hypovolemia, and ischemia, is responsible. Indeed, immunohistologic studies of severely infected humans and animals have demonstrated numerous zones of infected endothelium, only a small proportion of which contain thrombi. The thrombi are usually located to one side of the lumen, which is not occluded. These hemostatic plugs appear to be an appropriate host response rather than a pathogenic process. Consumption of platelets results in thrombocytopenia in 32 to 52% of patients, but disseminated intravascular coagulation with hypofibrinogenemia is rare. Activation of platelets, generation of thrombin, and activation of the fibrinolytic system all appear to be homeostatic physiologic responses to endothelial injury.

Clinical Manifestations Early in the illness, when medical attention usually is first sought,RMSF is difficult to distinguish from many self-limiting viral illnesses. Fever, headache, malaise, myalgia, nausea, vomiting, and anorexia are the most frequent symptoms during the first 3 days. The patient becomes progressively more ill as vascular infection and injury advance. In one large series, only one-third of patients were diagnosed with presumptive RMSF early in the clinical course and treated appropriately as outpatients. In the tertiary care setting, RMSF is all too often recognized only when its late severe manifestations, developing at the end of the first week or in the second week of illness in patients without appropriate treatment, prompt admission to the intensive care unit.

The progressive nature of the infection is clearly manifested in the skin. Rash is evident in only 14% of patients on the first day of illness and in only 49% during the first 3 days. Macules (1 to 5 mm) appear first on the wrists and ankles (Figs. 177-CD1,177-CD2) and then on the remainder of the extremities and the trunk. Later, more severe vascular damage results in frank hemorrhage at the center of the maculopapule (Fig. 177-CD3), a petechia that does not disappear upon compression (Plate IID-45). This sequence of events is sometimes delayed or aborted by effective treatment. In fact, rash appears on day 6 or later in 20% of cases and does not appear at all in 9 to 16% of cases, including some with severe visceral lesions that result in death. Petechiae occur in 41 to 59% of cases, appearing on or after day 6 in 74% of cases that include a rash. Involvement of

the palms and soles, often considered diagnostically important, usually occurs relatively late in the course (after day 5 in 43% of cases) and does not occur at all in 18 to 64% of cases.

The microcirculation, both systemic and pulmonary, is the target of intracellular rickettsial infection, and the clinical manifestations reflect the ensuing vascular changes. Widespread increased vascular permeability results in edema, decreased plasma volume, hypoalbuminemia, reduced serum oncotic pressure, and prerenal azotemia. Hypotension occurs in 17% of cases. Extensive infection of the pulmonary microcirculation is associated with noncardiogenic pulmonary edema. Cardiac involvement is most frequently manifested as dysrhythmia, which is detected in 7 to 16% of cases. Pulmonary involvement, often a major factor in fatal cases, is observed in 17% of cases, of which 12% are considered to represent severe respiratory disease and 8% require mechanical ventilation.

Central nervous system (CNS) involvement is the other important determinant of the outcome ofRMSF. Encephalitis, presenting as confusion or lethargy, is apparent in 26 to 28% of cases. Progressively severe encephalitis manifests as stupor or delirium in 21 to 26% of cases, as ataxia in 18%, as coma in 9 to 10%, and as seizures in 8%. Cranial nerve palsy, hearing loss, severe vertigo, nystagmus, dysarthria, aphasia, unilateral corticospinal signs, ankle clonus, extensor toe signs, hyperreflexia, spasticity, fasciculations, athetosis, neurogenic bladder, hemiplegia, paraplegia, and complete paralysis have been reported. Meningoencephalitis results in cerebrospinal fluid (CSF) pleocytosis in 34 to 38% of cases; usually there are 10 to 100 cells per microliter with a mononuclear predominance, but occasionally there are more than 100 cells per microliter and a polymorphonuclear predominance. The CSF protein concentration is increased in 30 to 35% of cases, but the CSF glucose concentration is usually normal.

Renal failure, which occurs in more severely ill patients, is often reversible with rehydration. However, in the most severe cases, shock results in acute tubular necrosis-induced renal failure, which often requires hemodialysis.

Hepatic injury is manifested in 38% of cases as mildly or moderately increased serum aminotransferase concentrations and is due to focal death of individual hepatocytes, but hepatic failure does not occur. Jaundice is recognized in 8 to 9% of cases and an elevated serum bilirubin concentration in 18 to 30%. Marked hyperbilirubinemia occasionally occurs, probably as a consequence of both hemolysis and hepatocytic injury.

Bleeding is a potentially life-threatening effect of severe vascular damage. Anemia develops in 30% of cases and is severe enough to require red blood cell transfusions in 11%. Blood is detected in the stools or vomitus of 10% of patients, and death has followed massive upper gastrointestinal hemorrhage.

Other characteristic clinical laboratory findings include a normal white blood cell count with increased numbers of immature myeloid cells, increased plasma levels of proteins of the acute-phase response (C-reactive protein, fibrinogen, ferritin, and others), and hyponatremia (in 56% of cases) due to the appropriate secretion of antidiuretic hormone in response to the hypovolemic state. Skeletal muscle injury, clinically manifested as

myositis, has been documented in several individual cases by the detection of marked elevations in serum creatine kinase or of histopathologic evidence of vascular injury in skeletal muscle and multifocal rhabdomyonecrosis. Ocular involvement includes conjunctivitis in 30% of cases and retinal vein engorgement, flame hemorrhages, arterial occlusion, and papilledema with normalCSFpressure in some instances.

In untreated cases, death usually occurs 8 to 15 days after the onset of illness. A rare presentation, fulminantRMSF, is fatal within 5 days after onset. This fulminant presentation has been associated with RMSF in black males who have glucose-6-phosphate dehydrogenase (G6PD) deficiency and is thought to be related to an undefined effect of hemolysis on the rickettsial infection. Although survivors of RMSF usually appear to return to their previous state of health, permanent sequelae, including neurologic deficits and amputation of gangrenous extremities, may follow severe illness.

Diagnosis The diagnosis ofRMSFduring the acute stage is more difficult than is generally appreciated. Clinical and epidemiologic considerations are more important than laboratory features early in the illness. The most important epidemiologic factor is a history of exposure within the 12 days preceding disease onset to a potentially tick-infested environment during a season of possible tick activity. However, only 60% of patients actually recall being bitten by a tick during the incubation period.

The differential diagnosis for early clinical manifestations ofRMSF(fever, headache, and myalgia without a rash) includes influenza, enteroviral infection, infectious mononucleosis, viral hepatitis, leptospirosis, typhoid fever, gram-negative or -positive bacterial sepsis, human monocytic or granulocytic ehrlichiosis, murine typhus, sylvatic flying-squirrel typhus, and rickettsialpox. Enterocolitis may be suggested by nausea, vomiting, and abdominal pain; prominence of abdominal tenderness has resulted in exploratory laparotomy.CNSinvolvement may masquerade as bacterial and viral meningoencephalitis, with seizures, coma, neurologic signs, andCSFabnormalities. Cough, pulmonary signs, and chest roentgenographic opacities may lead to a diagnostic consideration of bronchitis or pneumonia.

During the first 3 days of illness, only 3% of patients exhibit the classic triad of fever, rash, and history of tick exposure. When a rash appears, a diagnosis ofRMSFshould certainly be considered. However, many illnesses considered in the differential diagnosis may also be associated with a rash, including rubeola, rubella, meningococcemia, disseminated gonococcal infection, secondary syphilis, toxic shock syndrome, drug hypersensitivity, idiopathic thrombocytopenic purpura, thrombotic thrombocytopenic purpura, Kawasaki syndrome, and immune complex vasculitis. The converse is also true: any person in an endemic area with a provisional diagnosis of one of the above illnesses may have RMSF.

The most common serologic test for confirmation of the diagnosis is the indirect immunofluorescence assay. Between 7 and 10 days after onset, a diagnostic titer of^{3}1:64 is usually detectable. Latex agglutination and a solid-state enzyme immunoassay are also available commercially. Latex agglutination usually yields a diagnostic titer of^{3}1:128 at 7 to 9 days after onset. The sensitivity and specificity of the indirect immunofluorescence assay are 94 to 100% and 100%, respectively, and the latex agglutination test has a sensitivity of 71 to 94% and a specificity of 96 to 99%. The

performance of the solid-state immunoassay has not been reported. It is important to understand that serologic tests forRMSF are usually negative at the time of presentation for medical care and that treatment should not be delayed while a positive serologic result is awaited.

The only diagnostic test that is useful during the acute illness is immunohistologic examination (immunofluorescence or immunoenzyme staining) of a cutaneous biopsy of a rash lesion for *R. rickettsii*. Examination of a 3-mm punch biopsy of such a lesion is 70% sensitive and 100% specific. Polymerase chain reaction (PCR) amplification and detection of *R. rickettsii* DNA in peripheral blood is an insensitive approach except in the preterminal state; rickettsiae are present in large quantities in heavily infected foci of endothelial cells but in relatively low quantities in the circulation. Cultivation of rickettsiae in cell culture is technically feasible but is seldom undertaken because of biohazard and technologic concerns.

TREATMENT

The drug of choice for the treatment of both children and adults withRMSF is doxycycline, except when the patient is pregnant or allergic to the drug. Doxycycline is administered orally (or, in the presence of coma or vomiting, intravenously) at 200 mg/d in two divided doses. For children with RMSF reinfection, up to five courses of doxycycline may be administered with minimal risk of dental staining. Other regimens include oral tetracycline (25 to 50 mg/kg per day) in four divided doses. b-Lactam antibiotics, erythromycin, and aminoglycosides have no role in the treatment of RMSF, and sulfa-containing drugs are likely to exacerbate this infection. There is not enough clinical experience to comment on the use of fluoroquinolones in this setting. The most seriously ill patients are managed in intensive care units, with careful administration of fluids to achieve optimal tissue perfusion without precipitating noncardiogenic pulmonary edema. In some severely ill patients, hypoxemia requires intubation and mechanical ventilation; oliguric or anuric acute renal failure requires hemodialysis; seizures necessitate the use of antiseizure medication; anemia or severe hemorrhage necessitates transfusions of packed red blood cells; and bleeding with severe thrombocytopenia requires platelet transfusions. Heparin is not a useful component of treatment, and there is no evidence that glucocorticoids, although frequently administered, affect outcome.

Prevention Avoidance of tick bites is the only available preventive approach. Protective clothing and tick repellents, which could reduce the risk, are seldom actually used. After possible tick exposure, it is wise to inspect the body once or twice a day and remove ticks before they can inoculate rickettsiae.

MEDITERRANEAN SPOTTED FEVER (BOUTONNEUSE FEVER) AND OTHER SPOTTED FEVERS

The etiologic agent of Mediterranean spotted fever, *R. conorii*, is prevalent in southern Europe (below the 45th parallel), all of Africa, and southwestern and south-central Asia. The tick vector and reservoir is *R. sanguineus*, the dog brown tick. The name of this disease varies with the region in which it occurs; examples include Kenya tick typhus, Indian tick typhus, Israeli spotted fever, and Astrakhan spotted fever. Whatever the

designation, the disease is characterized by a high fever, rash, and -- in most geographic locales -- an inoculation eschar (*tache noire*) at the site of the tick bite. A severe form of the disease, associated with a 50% mortality rate, has been observed in patients with diabetes, alcoholism, or heart failure.

African tick-bite fever, which is caused by *R. africae* and has been recognized since the beginning of the twentieth century, was first documented in the modern era in Zimbabwe in 1992. The disease occurs in rural areas and follows bites by ticks of cattle and wild animals. *R. africae* is prevalent in *Amblyomma hebraeum* and *A. variegatum* ticks, which readily feed on humans. Cases have been confirmed not only in Zimbabwe but also in Tanzania and South Africa, and the disease is prevalent in the Caribbean islands of Guadeloupe. The incubation period is 7 days. The illness is mild and consists of headache, fever, eschar at the tick bite site, and regional lymphadenopathy. *Amblyomma* ticks often feed in groups, and several ticks may be found on one patient, with the subsequent development of multiple eschars. Rash is frequently lacking or transient and may be vesicular. African tick-bite fever is the most prevalent rickettsiosis worldwide, and, as tourism to sub-Saharan Africa increases, it is expected that more cases will be seen in non-African countries.

Rickettsia japonica causes *Japanese spotted fever* or *Oriental spotted fever*. Patients present with fever, cutaneous eruption, and an inoculation eschar. In Australia, two spotted fevers have been described. *Queensland tick typhus* is due to *R. australis* and is transmitted by *Ixodes holocyclus*. The skin rash in this disease is usually maculopapular but is sometimes vesicular, and there is an inoculation eschar. *Flinders Island spotted fever*, observed on an island close to Tasmania, is due to *R. honei*. In France, a case of *atypical Lyme disease* caused by *R. slovaca* and two cases of infection with *R. mongolotimonae* have been reported.

Diagnosis The diagnosis of these tick-borne spotted fevers is based on clinical and epidemiologic findings and is confirmed by cell-culture isolation of rickettsiae, byPCR of skin biopsies (a method not available in most laboratories), or by serology. The identification of specific species requires cross-adsorption (Table 177-2). In an endemic area, patients presenting with fever, rash, and/or a skin lesion consisting of a black necrotic area or a crust surrounded by erythema should be considered to have one of these rickettsial spotted fevers.

TREATMENT

SeeTable 177-2.

RICKETTSIALPOX

Rickettsialpox was first described in 1946 by a general practitioner in New York City and soon afterwards was shown to be caused by a distinct species, *R. akari*. This organism was isolated from mice and their mites (*Liponyssoides sanguineus*), which maintain the organisms by transovarian transmission. *R. akari* shares lipopolysaccharide antigens with other members of theSFG.

Epidemiology More than 100 cases of rickettsialpox were diagnosed annually in the

northeastern United States in the late 1940s and the 1950s, and outbreaks occurred in the Ukraine in the 1950s. However, few cases are diagnosed currently. Recently, a culture-confirmed case of rickettsialpox was documented in southern Europe. This case was initially misdiagnosed as Mediterranean spotted fever on the basis of the development of serum antibodies cross-reactive with *R. conorii*. Cases have also been reported in Arizona, Utah, and Ohio.

Clinical Manifestations A papule forms at the site of the mite bite. This lesion develops a central vesicle that becomes a 1- to 2.5-cm painless black crusted eschar surrounded by an erythematous halo (Fig. 177-CD4). Enlargement of the lymph nodes draining the region of the eschar suggests initial lymphogenous spread. After a 10-day incubation period, during which the eschar and regional lymphadenopathy frequently go unnoticed, the onset of illness is marked by malaise, chills, fever, headache, and myalgia. A macular rash appears 2 to 6 days after onset and evolves sequentially into papules, vesicles, and crusts that heal without scarring. In some cases the rash remains macular or maculopapular. Some patients suffer nausea, vomiting, abdominal pain, cough, conjunctivitis, or photophobia. Untreated rickettsialpox is not fatal, with fever lasting 6 to 10 days.

Diagnosis and Treatment SeeTable 177-2.

FLEA- AND LOUSE-BORNE RICKETTSIAL DISEASES

ENDEMIC MURINE TYPHUS (FLEA-BORNE)

Murine typhus was postulated to be a distinct disease, with rats as the reservoir and fleas as the vector, by Maxcy in 1926. Dyer isolated the etiologic agent, *R. typhi*, from rats and fleas in 1931. By the end of World War II, murine typhus was known to be a global disease. A novel typhus group *Rickettsia* has now been shown to be maintained vertically in cat fleas and to cause human infection. This flea-transmitted species, *R. felis*, reportedly contains antigens most closely resembling typhus group rickettsiae but genetically is anSFGorganism. *R. felis* has been found in 4% of cat fleas and in 33% of opossums collected in the vicinity of human murine typhus-like cases in southern Texas.

Epidemiology *R. typhi* is maintained in mammalian host/flea cycles, with rats (*Rattus rattus* and *R. norvegicus*) and the Oriental rat flea (*Xenopsylla cheopis*) as the classic zoonotic niche. Fleas acquire *R. typhi* from rickettsemic rats and carry the organism throughout the rest of their lifespan. Nonimmune rats and humans are infected when rickettsia-laden flea feces are "scratched" into pruritic bite lesions; less frequently, the flea bite itself transmits the organisms. Yet another possible route of transmission is the inhalation of aerosolized flea feces. Infected rats appear healthy, although they are rickettsemic for approximately 2 weeks.

Currently, fewer than 100 cases of endemic typhus are reported annually in the United States. These cases occur mainly in southern Texas and southern California, where the classic rat-flea cycle is absent and an opossum-cat flea (*Ctenocephalides felis*) cycle is prominent. Although *X. cheopis* fleas are inefficient at the transovarian maintenance of *R. felis*, cat fleas are highly effective at vertical transmission of this organism, whose natural occurrence has been detected in fleas in California, Texas, and Oklahoma.

Infected opossums and cat fleas as well as a case of human infection were reported from Corpus Christi, Texas, in the same environment where humans, opossums, and cat fleas are infected with *R. typhi*. Cases of endemic typhus occur year-round, mainly in warm (often coastal) areas. This infection has also been reported from Greece, Spain, and Indonesia. The peak prevalence in southern Texas is from April through June and elsewhere is during the warm months of summer and early fall. Patients seldom recall a flea bite or exposure to fleas, although exposure to animals such as cats, opossums, raccoons, skunks, and rats is reported by nearly 40% of those who are questioned.

Clinical Manifestations The incubation period of experimental murine typhus in volunteers averages 11 days, with a range of 8 to 16 days. Close observation during this period reveals prodromal symptoms of headache, myalgia, arthralgia, nausea, and malaise developing 1 to 3 days before the abrupt onset of chills and fever. Nearly all patients experience nausea and vomiting early in the illness.

The duration of untreated illness averages 12 days, with a range of 9 to 18 days. Rash is present in only 13% of patients at the time of presentation for medical care (usually about 4 days after onset of symptoms), appearing an average of 2 days later in half of the remaining patients and never appearing in the other half. The initial macular rash is often detected by careful inspection of the axilla or the inner surface of the arm. Subsequently, the rash becomes maculopapular, involving the trunk more often than the extremities; it is seldom petechial and rarely involves the face, palms, or soles. A rash is detected in only 20% of patients with dark brown or black skin.

Pulmonary involvement is frequently prominent in murine typhus; 35% of patients have a hacking, nonproductive cough, and 23% of patients who undergo chest radiography have pulmonary densities due to interstitial pneumonia, pulmonary edema, and pleural effusions. Bibasilar rales are the most common pulmonary sign. Less common clinical symptoms and signs include abdominal pain, confusion, stupor, seizures, ataxia, coma, and jaundice. Clinical laboratory studies frequently reveal anemia and leukopenia early in the course, leukocytosis late in the course, thrombocytopenia, hyponatremia, hypoalbuminemia, mildly increased serum levels of hepatic aminotransferases, and prerenal azotemia. Complications may include respiratory failure requiring intubation and mechanical ventilation, hematemesis, cerebral hemorrhage, and hemolysis (in patients with G6PD deficiency and some hemoglobinopathies). The illness is severe enough to necessitate the admission of 10% of hospitalized patients to an intensive care unit. Greater severity is generally associated with old age, underlying disease, and treatment with a sulfa drug; the case-fatality rate is 1%. In a study of children with murine typhus, 50% suffered only nocturnal fevers, feeling well enough for active daytime play.

Diagnosis and Treatment See Table 177-2.

EPIDEMIC TYPHUS (LOUSE-BORNE)

Epidemic typhus due to infection with *R. prowazekii* is transmitted by the human body louse (*Pediculus humanus corporis*), which lives on clothes and is found in poor hygienic conditions (especially in jails, where the disease it causes is called *jail fever*)

and usually in cold areas. Lice acquire *R. prowazekii* when they ingest a blood meal from a rickettsemic patient. The rickettsiae multiply in the midgut epithelial cells of the louse and spill over into the louse feces. The infected louse defecates during its blood meal, and the patient autoinoculates the organisms by scratching. The fact that the louse abandons dead hosts and patients with high fever (>40°C) improves its efficiency as a vector. Since the louse does not pass *R. prowazekii* to its offspring, the disease is usually spread from person to person by the louse-borne route. Lice die within 1 to 2 weeks after infection, turning red just prior to death -- hence the name *red louse disease*. This epidemic form of typhus is related to poverty, cold weather, war, and disasters and is currently prevalent in mountainous areas of Africa, South America, and Asia. A large outbreak involving 100,000 people in refugee camps in Burundi occurred in 1997, a small focus was reported in Russia for the first time in 1998, and sporadic cases have been reported from Algeria and from Peru. The global reemergence of the disease is due to proliferation of body lice. In the United States, sporadic cases of epidemic typhus are transmitted by flying-squirrel fleas. Eastern flying-squirrel (*Glaucomys volans*) lice and fleas have been found to be infected with *R. prowazekii*. The flying-squirrel fleas occasionally bite humans.

Brill-Zinsser disease is a recrudescent, mild form of epidemic typhus occurring years after the acute disease, probably as a result of immunosuppression or old age. Nathan Brill first identified recrudescent typhus in New York in 1898. In 1933 Hans Zinsser noted that more than 90% of patients with recrudescent typhus had emigrated from typhus-endemic areas of Europe. Strains of *R. prowazekii* indistinguishable from classic strains were isolated from patients with recrudescent typhus. Furthermore, *R. prowazekii* was isolated from the lymph nodes of patients undergoing elective surgery who had had typhus years earlier. Thus the typhus rickettsiae can remain dormant for years and can reactivate with waning immunity.

Clinical Manifestations After an incubation period of 1 week, the onset of illness is abrupt, with prostration, severe headache, and rapidly rising fever of 38.8 to 40.0°C (102 to 104°F). Cough is frequently prominent, occurring in 70% of patients. Myalgias are usually severe. In the outbreak in Burundi, the disease was referred to as *sutama* ("crouching"), the myalgias being so severe that patients crouched in an attempt to alleviate the pain. A rash begins on the upper trunk, usually on the fifth day, and then becomes generalized, involving all of the body except the face, palms, and soles. Initially, this rash is macular; without treatment, it becomes maculopapular, petechial, and confluent (Fig. 177-CD5). The rash is frequently absent or not detected on black skin in Africa, where 60% of patients have *spotless epidemic typhus*. Photophobia, with considerable conjunctival injection and eye pain, is frequent. The tongue may be dry, brown, and furred. Confusion and coma are common. Skin necrosis and gangrene of the digits as well as interstitial pneumonia have been noted in severe cases (Fig. 177-CD6). Untreated disease is fatal in 7 to 40% of cases, with outcome depending primarily on the condition of the host. Patients with untreated infections develop renal insufficiency and multiorgan involvement in which neurologic manifestations are frequently prominent. Overall, 12% of patients with epidemic typhus have neurologic involvement. North American *R. prowazekii* infection transmitted by flying-squirrel ectoparasites is a milder illness; whether this milder disease is due to host factors (e.g., better health status) or organism factors (e.g., attenuated virulence) is unknown.

Prevention Prevention of epidemic typhus involves control of body lice. Clothes should be changed regularly, and insecticides should be used every 6 weeks to control the louse population.

Diagnosis and Treatment See Table 177-2. Epidemic typhus is sometimes misdiagnosed as typhoid fever in tropical countries.

SCRUB TYPHUS

The etiologic agent of scrub typhus is a small, obligately intracellular bacterium of the family Rickettsiaceae that differs substantially from other family members in its genetic makeup and in the composition of its cell wall (which, for example, lacks lipopolysaccharide and peptidoglycan). Consequently, this organism has been classified as a species in a separate genus, *Orientia tsutsugamushi*.

O. tsutsugamushi is maintained in nature by transovarian transmission in trombiculid mites, mainly of the genus *Leptotrombidium*. After hatching, infected larval mites (chiggers, the only stage that feeds on an animal host) inoculate organisms into the skin while feeding. Scrub typhus is found in environments that harbor the infected chiggers, particularly areas of heavy scrub vegetation -- e.g., where the forest is regrowing after being cleared and along riverbanks. Infections occur during the wet season, when the mites lay their eggs. The disease is endemic in eastern and southern Asia, northern Australia, and islands of the western Pacific Ocean. Scrub typhus is also found in tropical areas of India, Sri Lanka, Bangladesh, Myanmar, Thailand, Malaysia, Laos, Vietnam, Kampuchea, China, Taiwan, the Philippines, Indonesia, Papua New Guinea, northern Australia, and islands of the South Pacific Ocean; in temperate areas of Japan, Korea, far-eastern Russia, Tadzhikistan, the mountains of northern India, Pakistan, and Nepal; and in nontropical areas of China, such as Tibet and Shangdong Province. Those infected include indigenous rural workers, residents of suburban areas, and westerners visiting endemic areas for professional or recreational purposes. Infections are more prevalent than the number of clinical diagnoses would suggest; in some areas more than 3% of the population is infected or reinfected each month. Immunity wanes over 1 to 3 years, and there is remarkable antigenic diversity.

Clinical Manifestations The illness varies in severity from mild and self-limiting to fatal. After an incubation period of 6 to 21 days (usually 8 to 10 days), the onset of disease is characterized by fever, headache, myalgia, cough, and gastrointestinal symptoms. Some patients develop no further signs or symptoms and recover spontaneously after a few days. The classic case description includes an eschar at the site of chigger feeding, regional lymphadenopathy, and a maculopapular rash -- signs that are seldom observed in indigenous patients. Fewer than 50% of westerners develop an eschar, and fewer than 40% develop a rash (on day 4 to 6 of illness). Severe cases typically include prominent encephalitis and interstitial pneumonia as key features of vascular injury. Severe illness in persons withG6PDdeficiency has been accompanied by hemolysis. The case-fatality rate for untreated classic cases is 7% but would probably be lower if all relatively mild cases (which are underdiagnosed) were included.

Diagnosis and Treatment SeeTable 177-2. One report has described cases of scrub typhus in Thailand that do not respond to treatment with doxycycline or

chloramphenicol.

EHRLICHIOSES

Ehrlichiae are small, obligately intracellular bacteria with a gram-negative-type cell wall that grow in cytoplasmic vacuoles to form clusters called *morulae* (Fig. 177-1). Two distinct *Ehrlichia* species cause human infections that can be severe and frequent (Table 177-3). *E. chaffeensis*, the agent of human monocytotropic ehrlichiosis (HME), infects predominantly mononuclear phagocytic cells in tissues and blood monocytes. A member of the *E. phagocytophila* group that infects cells of myeloid lineage is the agent of human granulocytotropic ehrlichiosis (HGE). Both *E. chaffeensis* and *E. phagocytophila* are tick-borne but are transmitted by distinct vectors with little geographic overlap. *E. ewingii* is a newly recognized agent of human ehrlichiosis. Identified in four patients to date by means of a broad-rangePCRassay, *E. ewingii* has previously been reported as a cause of granulocytotropic ehrlichiosis in dogs.

Ehrlichiae were discovered by veterinarians during the investigation of hemolytic anemia of cattle before 1910. Researchers thereafter discerned that "marginal points" within erythrocytes were infectious and named the agent *Anaplasma marginale*. Subsequently, several other species now known as ehrlichiae were detected as veterinary infectious agents, including *Cowdria ruminantium*, *E. canis*, *E. phagocytophila*, and *E. risticii*. In 1953, *E. sennetsu* was identified in humans with mononucleosis-like syndromes in Japan.

The current taxonomic positions are determined by nucleic acid sequences of conserved and unique genes among these species. By analysis of 16S ribosomal RNA sequences, the genus and related organisms can be divided into two major clades: the *E. canis* group (including *E. chaffeensis*) and the *E. phagocytophila* group (including *E. equi* and the agent ofHGE). The *E. sennetsu* group is as distantly related to both of these clades as it is to the genus *Rickettsia* and is not tick-borne. Given the lack of transovarian transmission in ticks, the natural maintenance of the tick-borne ehrlichiae clearly depends in part upon transient or persistent infections in wild and feral mammalian reservoirs. Thus, these bacteria are propagated by horizontal transmission that relies upon a tick-mammal-tick cycle; humans are inadvertently infected when they impinge upon the natural habitats occupied by the ticks and the reservoir hosts.

HUMAN MONOCYTOTROPIC EHRLICHIOSIS

Epidemiology Infections caused by *E. chaffeensis* have been documented in more than 500 cases reported to the Centers for Disease Control and Prevention (CDC). However, sinceHME is not a reportable disease in most states, this figure is a gross underestimate. Most infections have been identified in the south-central, southeastern, and mid-Atlantic states, but cases have also been recognized in California, the Pacific northwest, New England, Europe, and Africa. The vector is the Lone Star tick (*Amblyomma americanum*), which in all its life stages feeds upon white-tailed deer, a major reservoir host. Dogs have been discovered to be subclinically infected and may also be an important reservoir. Tick bites and exposures are reported by patients, frequently in rural areas and especially in the months May through July. The median age of HME patients is 44 years, and 75% of the affected individuals are male; however,

severe and fatal infections in children are also well recognized.

Clinical Manifestations *E. chaffeensis* is inoculated into the dermal blood pool created by the feeding tick and subsequently disseminates via the blood to tissues. After a median incubation period of 8 days, illness develops; only about one-third of individuals who seroconvert develop a consistent clinical illness. The classic clinical manifestations are not specific and include fever (97% of cases), headache (81%), myalgia (68%), and malaise (84%); less frequently observed are gastrointestinal involvement (nausea, vomiting, diarrhea; 25 to 68%), cough (25%), rash (36% overall, 6% at presentation) (Fig. 177-CD7), and confusion (20%).HME may be severe: 62% of patients with documented cases are hospitalized, and about 2% die. Severe complications include a toxic shock-like or septic shock-like syndrome, respiratory insufficiency and adult respiratory distress, meningoencephalitis, fulminant infection (in immunocompromised patients), severe opportunistic and nosocomial infections, and hemorrhage. Laboratory findings may be of value in the differential diagnosis; 60 to 74% of patients with HME have leukopenia (initially lymphopenia, later neutropenia), 72% have thrombocytopenia, and nearly 90% have elevations in serum levels of hepatic aminotransferases. With effective therapy, rebound lymphocytosis is common. In spite of abnormal blood counts, examinations reveal hypercellular bone marrow, and noncaseating granulomas may be present. Vasculitis is not a component of HME.

Diagnosis BecauseHME can be rapidly fatal, empirical antibiotic therapy should be instituted on the basis of a clinical diagnosis. This diagnosis may be suggested by fever in the setting of known tick exposure during the preceding 3 weeks, leukopenia and/or thrombocytopenia, and increased aminotransferase concentrations in serum. Morulae are rarely demonstrated in peripheral blood smears unless an intensive examination is performed; even then, an experienced microscopist is required. The active phase of HME may be diagnosed byPCRamplification of *E. chaffeensis* nucleic acids from EDTA-anticoagulated blood obtained before the start of doxycycline therapy. Retrospective serologic diagnosis requires a consistent clinical picture and detection of a fourfold increase in *E. chaffeensis* antibody titer (to^{3}1:64) by indirect immunofluorescence in paired serum samples obtained approximately 30 days apart. It must be underscored that separate specific diagnostic tests for HME andHGE are necessary.

TREATMENT

Tetracycline is effective therapy forHME. Either tetracycline (250 to 500 mg given orally every 6 h) or doxycycline (100 mg given orally or intravenously twice daily) is associated with a lowered rate of hospitalization and a shortened duration of fever. The use of chloramphenicol is controversial, and *E. chaffeensis* is not susceptible to this drug in vitro. While a few reports document the persistence of *E. chaffeensis* in humans after the acute phase of illness, such persistence is very infrequent; most patients are cured after relatively short courses of tetracycline therapy (continuing for 3 to 5 days after defervescence).

Prevention HME is prevented by the avoidance of ticks in endemic areas. The use of protective clothing and tick repellents, careful tick searches after exposures, and prompt removal of attached ticks markedly diminish risk.

HUMAN GRANULOCYTOTROPIC EHRLICHIOSIS

Epidemiology As of 1995, approximately 150 cases ofHGE had been documented in 11 states (mostly in the upper midwest and the northeast), with a distribution similar to that of Lyme disease. Most cases have been identified within the range of various *I. ricinus*-complex ticks, particularly *I. scapularis*. White-footed deer mice in the United States and red deer in Europe appear to play a role in maintaining HGE in nature. The incidence of HGE peaks in May, June, and July, but the disease may occur throughout the year in conjunction with human exposure to *Ixodes* ticks. HGE affects predominantly males (79%) and older persons (median age, 58 years).

Clinical Manifestations Because of high seroprevalence rates in endemic regions, it seems likely that only a minority of infected individuals develop clinical manifestations. The incubation period forHGEvaries between 4 and 8 days, and the disease manifests as fever (94 to 100% of cases), myalgia (78 to 98%), headache (61 to 85%), and malaise (98%) -- findings suggestive of an influenza-like illness. A minority of patients develop gastrointestinal involvement, including nausea, vomiting, or diarrhea (22 to 39%); rash (2 to 11%); cough (27%); and confusion (17%). Severe complications occur most often in the elderly, but even children may be severely affected. Respiratory insufficiency, with adult respiratory distress syndrome, a toxic shock-like syndrome, and life-threatening opportunistic infections, are the most worrisome complications. Meningoencephalitis has not yet been conclusively recognized with HGE. The case-fatality rate is probably <1%, but nearly 7% of ill patients may require intensive care. As inHME, laboratory findings are of great assistance; most patients develop leukopenia and/or thrombocytopenia with increased serum levels of hepatic aminotransferases. The pancytopenia observed in HGE presumably relates to sequestration or destruction of platelets and leukocytes, since the bone marrow is ordinarily normo- or hypercellular. Vasculitis is not a component of HGE. Unlike HME, HGE is not associated with granulomas. While clear evidence exists for co-infections with *Borrelia burgdorferi* and *Babesia microti*, which are transmitted by the same tick vector(s), there is little evidence of comorbidity or of a persistent or chronic phase for HGE.

Diagnosis HGEshould be included in the differential diagnosis for patients who have been exposed to ticks and who develop an influenza-like illness during the season of *Ixodes* tick activity (May through December). The concurrent detection of thrombocytopenia, leukopenia, and/or elevations in serum aminotransferase activities further increases the likelihood of HGE. A substantial proportion of patients with HGE develop serologic reactions considered diagnostic of Lyme disease in the absence of clear clinical findings consistent with that diagnosis. Thus, HGE should be considered in the differential diagnosis of atypical severe presentations of Lyme disease. Although not highly sensitive, a thorough peripheral blood film examination for morulae in neutrophils may identify 20 to 75% of infections.PCR on EDTA-anticoagulated blood collected before initiation of tetracycline therapy from patients with active disease is a sensitive and specific method for early confirmation. Serodiagnosis is based mostly upon the retrospective demonstration of a fourfold increase in *E. phagocytophila* group antibody titer to a minimum of 1:80 in paired sera obtained approximately 1 month apart. IgM antibodies may be detected in many patients within the first 1.5 months after illness.

Approximately 15 to 40% of infected persons have a detectable antibody titer at presentation, but, in regions where seroprevalence is high, a single acute-phase polyvalent titer may be misleading.

TREATMENT

Doxycycline (100 mg given orally twice daily) is an effective therapeutic agent, while rifampin has been associated with clinical improvement in pregnant patients withHGE. In vitro studies suggest a role for trovafloxacin, but no prospective studies of any therapy for HGE have been conducted. Most treated patients defervesce within 24 to 48 h.

Prevention Prevention ofHGErequires tick avoidance. The Lyme disease vaccine offers no protection against HGE, and no other vaccine is available.

Q FEVER

Q fever results from infection with *C. burnetii*. This small gram-negative microorganism (0.2 um by 0.7 um) exists in two antigenic forms: phase I and phase II. When *C. burnetii* is passaged in cell cultures or embryonated eggs, its lipopolysaccharide undergoes truncation that results in an antigenic change called *phase variation*. The phase I form is extremely infectious and exists in humans and other animals. Passage in cell culture or embryonated eggs results in a shift to the phase II form, which is avirulent. The ability of *C. burnetii* to form spores allows the organism to survive in harsh environments. Indeed, it can survive for more than 40 months in skim milk at room temperature and is readily recovered from soil up to 1 month after contamination. Three different plasmids have been described in various isolates of *C. burnetii*. Q fever encompasses two broad clinical syndromes: acute and chronic infection. It is likely that the host's immune response (rather than characteristics of the infecting strain) determines whether or not chronic Q fever develops.

Epidemiology Q fever is a zoonosis. The primary sources of human infection are infected cattle, sheep, and goats. However, infected cats, rabbits, and dogs have also been shown to transmit *C. burnetii* to humans. The extensive wildlife reservoir for *C. burnetii* includes mammals, birds, and ticks. In the infected female mammal, *C. burnetii* localizes to the uterus and the mammary glands. Infection is reactivated during pregnancy, and high concentrations of *C. burnetii* are found in the placenta. At parturition, *C. burnetii* is dispersed as an aerosol, and infection follows inhalation of aerosolized organisms by a susceptible host. Infected female animals shed the organism in milk for weeks to months after parturition. In rare instances, human-to-human transmission has followed delivery of an infant to an infected woman or autopsy on an infected individual. *C. burnetii* has been transmitted via blood transfusion. Those at risk for Q fever are abattoir workers, veterinarians, and other individuals who vocationally or avocationally come into contact with infected animals. Exposure to infected newborn animals or to infected products of conception poses the highest risk. Sexual transmission has been demonstrated experimentally in mice, as has transmission during artificial insemination in cattle. Whether *C. burnetii* is sexually transmitted among humans is not yet known. While the experimental evidence on this point is contradictory, the ingestion of contaminated milk in some areas is probably a

major route of transmission to humans.

Infections due to *C. burnetii* occur in most countries. Indeed, the only areas known to be free of *C. burnetii* are New Zealand and Antarctica. The primary manifestation of acute Q fever differs from place to place: It is pneumonia in Nova Scotia (Canada) and granulomatous hepatitis in Marseille (France), while both of these manifestations are seen in the Basque country of Spain. These differences may reflect the route of infection; i.e., the ingestion of contaminated milk may result in hepatitis and the inhalation of contaminated aerosols in pneumonia.

Clinical Manifestations

Acute Q Fever The incubation period for acute Q fever ranges from 3 to 30 days. The clinical presentations include flulike syndromes, prolonged fever, pneumonia, hepatitis, pericarditis, myocarditis, meningoencephalitis, and infection during pregnancy. The symptoms of acute Q fever are nonspecific; common among them are fever, extreme fatigue, and severe headache. Other symptoms include chills, sweats, nausea, vomiting, and diarrhea, which occur in 5 to 20% of patients. Cough develops in about half of patients with Q fever pneumonia. Neurologic manifestations of acute Q fever are uncommon; however, in one outbreak in the West Midlands, United Kingdom, 23% of 102 patients had neurologic signs and symptoms as the major manifestation. A nonspecific rash may be evident in 4 to 18% of patients. The white blood cell count is usually normal. Thrombocytopenia is detected in about 25% of patients, and reactive thrombocytosis [with platelet counts of up to 1 million/uL (1×10^{12}/L)] frequently develops during recovery. This thrombocytosis may account for cases of deep vein thrombophlebitis complicating acute Q fever in some series. Uncommon manifestations of acute Q fever include optic neuritis, extrapyramidal neurologic disease, Guillain-Barre syndrome, inappropriate secretion of antidiuretic hormone, epididymitis, orchitis, priapism, hemolytic anemia, mediastinal lymphadenopathy mimicking lymphoma, pancreatitis, erythema nodosum, and mesenteric panniculitis. Chest radiography may show an opacity that is indistinguishable from those seen in pneumonia of other etiologies (Fig. 177-CD8). Multiple rounded opacities are common; in the appropriate epidemiologic setting, they are highly suggestive of Q fever pneumonia. However, right-sided endocarditis resulting in septic pulmonary emboli can produce the same radiographic appearance.

Chronic Q Fever Chronic Q fever, which is uncommon, almost always implies endocarditis. This infection usually occurs in patients with previous valvular heart disease, immunosuppression, or chronic renal insufficiency. Fever is usually absent or low grade. Patients may have nonspecific symptoms for up to 1 year before diagnosis. Valvular vegetations have been seen in only 12% of patients with transthoracic echocardiograms, but the rate of detection may be higher with the use of transesophageal echocardiography. A high index of suspicion is necessary for a correct diagnosis. The disease should be suspected in all patients with culture-negative endocarditis. In addition, all patients with valvular heart disease and an unexplained purpuric eruption, renal insufficiency, stroke, and/or progressive heart failure should be tested for *C. burnetii* infection. Patients with chronic Q fever have hepatomegaly and/or splenomegaly. These two findings, especially in combination with positive rheumatoid factor, high erythrocyte sedimentation rate, high C-reactive protein level, and/or

increased g-globulin concentrations (up to 60 to 70 g/L), suggest this diagnosis. Other manifestations of chronic Q fever include infection of vascular prostheses, aneurysms, and bone.

Diagnosis *C. burnetii* can be isolated from buffy-coat blood samples or tissue specimens by a shell-vial technique; however, most laboratories are not permitted to attempt the isolation of *C. burnetii* since it is considered highly infectious.PCR can be used to amplify *C. burnetii* DNA from tissue or biopsy specimens. This technique can also be used on paraffin-embedded tissues. Serology, however, is the most commonly used diagnostic tool. Three techniques are available: complement fixation, indirect immunofluorescence, and enzyme-linked immunosorbent assay. Indirect immunofluorescence is sensitive and specific and is the method of choice. Rheumatoid factor should be adsorbed from the specimen before testing. An IgG titer of ³1:800 to phase I antigen is suggestive of chronic Q fever. In almost all instances of chronic Q fever, the antibody titer to phase I antigen is much higher than that to phase II antigen. The reverse is true in acute Q fever. In addition, in acute Q fever, it is usually possible to demonstrate a fourfold rise in titer between acute- and convalescent-phase serum samples.

TREATMENT

Treatment of acute Q fever with doxycycline (100 mg twice daily for 14 days) is usually successful. Quinolones are also effective. Treatment of chronic Q fever should include at least two antibiotics active against *C. burnetii*. The combination of rifampin and doxycycline has been used with success. For chronic infection, doxycycline should be given as 100 mg twice daily and rifampin as 300 mg once daily. The optimal duration of antibiotic therapy for chronic Q fever remains undetermined. We recommend a minimum of 3 years of treatment, with discontinuation only if the phase I IgA antibody titer is£1:50 and the IgG phase I titer is£1:200. Another therapeutic option under investigation is the combination of doxycycline (100 mg twice daily) with hydroxychloroquine (600 mg once daily). With this combination, therapy can be completed in 18 months. It is necessary to monitor hydroxychloroquine levels and to adjust the dosage to maintain a plasma concentration of 0.8 to 1.2 ug/mL. In vitro, the addition of 1 mg of hydroxychloroquine/mL renders doxycycline bactericidal for *C. burnetii*.

Prevention A vaccine has been shown to be effective in preventing Q fever in abattoir workers in Australia.

178. *MYCOPLASMA* INFECTIONS - *William M. McCormack*

Mycoplasmas, the smallest free-living organisms known, are prokaryotes that are bounded only by a plasma membrane. Their lack of a cell wall is associated with cellular pleomorphism and resistance to cell wall-active antimicrobial agents, such as penicillins and cephalosporins. The organisms' small genome limits biosynthesis and explains the difficulties encountered with in vitro cultivation. Mycoplasmas typically colonize mucosal surfaces of the respiratory and urogenital tracts of many animal species. Sixteen species of mycoplasmas have been recovered from humans. Most are commensals. *Mycoplasma pneumoniae* causes upper and lower respiratory tract infections. *M. genitalium* and *Ureaplasma urealyticum* are established causes of urethritis and have been implicated in other genital conditions. *M. hominis* and *U. urealyticum* are part of the complex microbial flora of bacterial vaginosis.

MECHANISMS OF PATHOGENICITY

Adherence of mycoplasmas to the surface of the host cell is necessary for colonization and infection. Some pathogenic mycoplasmas are flask-shaped, with specialized tips that enhance adherence. *M. pneumoniae* adheres via a network of interactive adhesins and accessory proteins and produces hydrogen peroxide, which may cause injury to host cells. *M. hominis* metabolizes arginine, with the production of potentially cytotoxic amounts of ammonia. Ureaplasmas have been placed in a separate genus because of their unique urease activity; the metabolism of urea also produces ammonia. *M. pneumoniae* may evoke IgM autoantibodies that agglutinate human erythrocytes at 4°C. These cold agglutinins can cause anemia and other complications (Fig. 178-CD1).

MYCOPLASMA PNEUMONIAE

EPIDEMIOLOGY

M. pneumoniae causes upper and lower respiratory tract symptoms in all age groups, with the highest attack rates in 5- to 20-year-olds. The infection is acquired by inhalation of aerosols. The incubation period is 2 to 3 weeks, considerably longer than that of most other respiratory infections. Although epidemics have taken place in closed populations, such as schools and military installations, most cases occur sporadically or in families. In families, cases typically occur serially, with 2- to 3-week intervals between cases. Infections in adults are often the result of contact with children.

Infection with *M. pneumoniae* is worldwide. Cases occur throughout the year, with epidemics every few years. Some studies have noted an increase in the number of cases during the autumn months in temperate climates. Although pneumonia is the classic presentation, nonpneumonic infection is considerably more common. In very young children, most infections result only in upper respiratory symptoms, whereas children>5 and adults may have bronchitis and pneumonia.

CLINICAL PRESENTATION

After a prolonged incubation period, fever and constitutional symptoms develop along with headache and cough, both of which can be prominent and distressing. Symptoms

typically progress less rapidly than those of viral respiratory tract infections. In the minority (perhaps 5 to 10%) of infected individuals who develop tracheobronchitis or pneumonia, cough becomes more prominent. Sputum, if produced at all, is usually white and may be tinged with blood. The temperature seldom rises above 38.9 to 39.4°C (102 to 103°F). Shaking chills, myalgias, and gastrointestinal symptoms (e.g., nausea, vomiting, and diarrhea) are unusual. Chest muscle soreness may result from frequent and prolonged coughing, but true pleuritic pain is uncommon.

Pharyngeal injection is often noted. Cervical lymph node enlargement is unusual. Bullous myringitis is a unique but uncommon manifestation. As in other "atypical" pneumonias, findings on auscultation of the lung may be normal or nearly normal despite striking radiographic abnormalities. Pleural effusions develop in<20% of patients.

M. pneumoniae infection may be particularly severe in patients who have sickle cell disease and other hemoglobin S-related hemoglobinopathies. The functional asplenia seen in sickle cell disease may contribute to severe mycoplasmal disease as it does in pneumococcal infection. Severe respiratory distress and large pleural effusions may occur. Digital necrosis has been seen in patients with sickle cell disease who develop very high titers of cold agglutinins.

EXTRAPULMONARY MANIFESTATIONS

A broad array of extrapulmonary abnormalities have been associated with *M. pneumoniae* infection. Although these events are unusual, they complicate other respiratory diseases even more rarely and often provide the only clue that an otherwise unremarkable respiratory infection may be mycoplasmal.

Erythema multiforme (Stevens-Johnson syndrome; see Plate IIE-67) typically occurs in young male patients with *M. pneumoniae* infection. Other dermatologic manifestations, such as maculopapular and vesicular exanthems, erythema nodosum, and urticaria, have been reported, but none is as clearly linked to *M. pneumoniae* as is erythema multiforme.

Cardiac abnormalities reported in conjunction with *M. pneumoniae* infection include myocarditis and pericarditis, which may result in abnormalities of conduction. Of the wide variety of neurologic conditions associated with *M. pneumoniae*, most have been documented in case reports, where establishment of a cause-and-effect relationship is problematic. Central nervous system abnormalities that have been associated with *M. pneumoniae* include encephalitis, cerebellar ataxia, Guillain-Barre syndrome, transverse myelitis, and peripheral neuropathies. Arthralgias are not unusual in patients who have mycoplasmal pneumonia; mycoplasmal arthritis is rare except in patients who have hypogammaglobulinemia. Hematologic abnormalities associated with *M. pneumoniae* include hemolytic anemia and coagulopathies.

The pathogenesis of the extrapulmonary manifestations of *M. pneumoniae* infection is controversial. Occasional reports have described the identification of *M. pneumoniae* or its nucleic acids in involved tissues. The fact that most attempts at detection have been negative, however, suggests that these extrapulmonary complications have an

immunologic basis. Mycoplasmas, including *M. pneumoniae*, can nonspecifically stimulate B lymphocytes. *M. pneumoniae*-infected individuals can develop autoantibodies, including those reactive with brain, heart, and muscle.

DIAGNOSIS

Most infections with *M. pneumoniae* are not diagnosed, as they are indistinguishable from upper and lower respiratory tract infections caused by myriad other viral and bacterial pathogens. When the diagnosis is suspected, it is usually because illness is prolonged or extrapulmonary manifestations develop. The white blood cell count is generally somewhat elevated, with few immature cells. Gram's stain of sputum shows leukocytes without a predominance of any bacterial morphologic type. Since *M. pneumoniae* lacks a cell wall, it cannot be detected on Gram's stain. In patients who have pneumonia, the chest radiograph may show reticulonodular or interstitial infiltration, primarily in the lower lobes. As in other "atypical" pneumonias, radiographic abnormalities may be more prominent than would be predicted by auscultation of the chest.

M. pneumoniae can be grown on artificial media, but the process is exacting, requires special media, and takes upwards of 2 weeks. Thus, mycoplasmal cultures do not provide timely information to aid in patient management. The same, unfortunately, is true of serologic diagnosis. Specific antibodies can be detected by enzyme-linked immunoassays, indirect immunofluorescence, or complement fixation but do not develop early enough to guide decisions regarding treatment. As with most serologic tests, examination of paired acute- and convalescent-phase serum specimens is required for good sensitivity and specificity.

Cold agglutinins are nonspecific but develop within the first 7 to 10 days in more than half of patients with *M. pneumoniae* pneumonia and may be detectable when the patient presents to a health care provider. In a patient with a compatible clinical picture, a cold agglutinin titer of³1:32 supports the diagnosis of mycoplasmal pneumonia. Cold agglutinin determinations are readily available from diagnostic laboratories. The test can also be performed at the bedside by the addition of 1 mL of the patient's blood to a tube containing anticoagulant (e.g., a tube used to collect blood for determination of prothrombin activity). Before cooling, the nonaggregated red blood cells coat the sides of the inverted tube. The blood is cooled to 4°C when the tube is placed in an ice bath for 3 to 5 min or in a standard refrigerator. In a positive test, clumps of red blood cells can be observed when the tube is inverted. Rewarming of the sample to 37°C in an incubator or by exposure to body heat should reverse the agglutination. A positive "bedside" cold agglutinin test is equivalent to a laboratory titer of³1:64.

The lack of sensitive, specific, and timely diagnostic tests has prompted the development of a variety of antigen detection tests that do not involve serology or the cultivation of live organisms. Such tests include antigen capture, indirect enzyme immunoassays, DNA probing, and nucleic acid amplification. Since many viral and bacterial infections result in clinical presentations similar to that caused by *M. pneumoniae*, examination of specimens for single antigens is unlikely to be useful. Rather, tests that examine an individual specimen for multiple antigens are needed. Multiplex nucleic acid amplification tests that examine a single throat swab or sputum

sample for all of the most likely causative microorganisms are feasible with current technology. Prototype multiplex polymerase chain reaction (PCR) assays have already been developed. If such tests become available clinically, more precise etiologic diagnosis of upper and lower respiratory tract infections will be possible.

TREATMENT

Because most mycoplasmal infections are not specifically diagnosed, management is directed at one of two syndromes: upper respiratory tract infection or community-acquired pneumonia. Upper respiratory infections, whether caused by viruses or by *M. pneumoniae*, do not require antimicrobial treatment. Community-acquired pneumonia (Chap. 255) may be caused by bacteria such as *Streptococcus pneumoniae* and *Haemophilus influenzae* or by "atypical" agents such as *Chlamydia pneumoniae*, *Legionella pneumophila*, and *M. pneumoniae*. Recommended treatment regimens include a third-generation cephalosporin, such as intravenous ceftriaxone (1.0 g/d) or cefotaxime (1.0 g every 8 h), that is active against the conventional bacterial pathogens plus intravenous or oral erythromycin (500 mg four times a day) to cover atypical microorganisms. Newer agents that have antimicrobial activity against both conventional and atypical causes of community-acquired pneumonia may be prescribed as monotherapy. These drugs include oral clarithromycin (500 mg twice a day), intravenous or oral azithromycin (500 mg once daily), and intravenous or oral levofloxacin (500 mg once daily). Treatment of documented *M. pneumoniae* pneumonia is usually continued for 14 to 21 days.

Pneumonia due to *M. pneumoniae* is usually self-limited and is seldom life-threatening. Effective antimicrobial agents do shorten the duration of illness and, by reducing coughing, may conceivably render the patient less infectious. Although symptoms are alleviated by antimicrobial treatment, the organism usually is not eradicated. Cultures positive for *M. pneumoniae* may persist for months despite effective antimicrobial treatment. The beneficial effects, if any, of such treatment on extrapulmonary manifestations of *M. pneumoniae* infection are unknown.

GENITAL MYCOPLASMAS (See also Chap. 132)

EPIDEMIOLOGY

M. hominis and *U. urealyticum* are the most prevalent genital mycoplasmas. Infants may become colonized with one or both of these organisms during passage through a colonized birth canal. Neonatal colonization tends not to persist. Only about 10% of prepubertal girls and even fewer prepubertal boys are colonized with ureaplasmas. After puberty, colonization occurs mainly as a result of sexual activity. Among adults, disadvantaged populations have higher colonization rates. Ureaplasmas can be cultured from the vaginas of ~80% of women cared for in public clinics and about half of women cared for by private obstetricians and gynecologists. Similarly, vaginal *M. hominis* is found in 50% of women attending public clinics and in ~20% of private patients. Men have somewhat lower rates of genital colonization than women. Nonetheless, both *U. urealyticum* and *M. hominis* are frequently detected in genital specimens from healthy, sexually experienced adults. Evaluation of the role of these organisms in human disease must take into account their high prevalence among healthy people.

M. fermentans colonizes both the respiratory and genital tracts in>20% of adults. There is no convincing evidence that *M. fermentans* causes human disease; although it had been implicated as a possible determinant of HIV-1 disease progression, more recent data do not support such a role. *M. genitalium* is a fastidious organism that is difficult to cultivate.PCRstudies have identified the organism more successfully. Little is known about the epidemiology of *M. genitalium*.

ASSOCIATION WITH HUMAN DISEASE

Nongonococcal Urethritis *Chlamydia trachomatis* is the organism most firmly implicated in the etiology of nongonococcal urethritis (NGU). There is no doubt that both *U. urealyticum* and *M. genitalium* also cause some cases of NGU. The ubiquity of ureaplasmas among men who do not have urethritis and the difficulty of identifying *M. genitalium* do not allow precise estimation of the proportion of cases of NGU caused by each of these mycoplasmas. *U. urealyticum* and *M. genitalium* do, however, appear to cause most of the nonchlamydial cases.

Epididymitis and Prostatitis Ureaplasmas may be an occasional cause of epididymitis. *M. hominis* has not been implicated in this disease. Neither organism has been convincingly associated with prostatitis.

Pelvic Inflammatory Disease (PID) (See also Chap. 133) *M. hominis* and *U. urealyticum* are both prominent components of the complex microbial flora of bacterial vaginosis. Since bacterial vaginosis is associated with PID, it is difficult to determine whether either organism plays an independent role in this condition. Although *M. genitalium* is not associated with bacterial vaginosis, preliminary studies have linked it to PID in women who are not infected with either *Neisseria gonorrhoeae* or *C. trachomatis*.

Disorders of Reproduction Ureaplasmas have been considered as causes of involuntary infertility in both men and women, but there is no convincing evidence for such an association. These organisms have been associated with chorioamnionitis and late abortion. Given the close association of ureaplasmas with bacterial vaginosis, a condition that is strongly associated with chorioamnionitis and late abortion, it is difficult to define an independent role for ureaplasmas in this condition. In infants of very low birthweight, ureaplasmas have been shown to cause pneumonia and chronic lung disease.

Extragenital Infections Sexually acquired reactive arthritis and Reiter's disease may be triggered by ureaplasmas, although *C. trachomatis* is the usual triggering agent. Patients who have hypogammaglobulinemia may develop chronic arthritis due to ureaplasmas and some other mycoplasmal species. *M. hominis* has been identified in patients with postthoracotomy sternal wound infection and in rare instances of prosthetic heart valve and prosthetic joint infection.

DIAGNOSIS

There is seldom any reason to examine specimens from the lower genital tract (vagina, male urethra) for mycoplasmas. The ubiquity of the organisms among healthy

individuals makes a positive result uninterpretable. The organisms should be sought only in specimens from normally sterile areas, such as joint fluid with evidence of inflammation and cultures negative for conventional microorganisms.

M. hominis can replicate in many routine blood culture media without changing the appearance of the media. *M. hominis* forms nonhemolytic pinpoint colonies on blood agar; organisms cannot be visualized in gram-stained smears of these colonies. Neither *U. urealyticum* nor *M. genitalium* will grow in ordinary microbiologic media.

Microbiologic diagnosis of genital mycoplasmal infection requires specially prepared media and is beyond the capability of all but reference and research laboratories. Nucleic acid amplification tests such asPCR have been developed and may become commercially available.

TREATMENT

Ureaplasmas, *M. genitalium*, and *M. hominis* are usually susceptible to tetracyclines (e.g., doxycycline). Tetracycline-resistant ureaplasmas can be treated with erythromycin, while tetracycline-resistant strains of *M. hominis* respond to treatment with clindamycin. As noted above, a specific microbiologic diagnosis of mycoplasmal infection is seldom made. Appropriate treatment provides antimicrobial coverage for the organisms that cause the particular syndrome. Accordingly,NGU is treated with doxycycline (100 mg orally twice a day for 7 days) or azithromycin (1.0 g as a single oral dose) to provide activity against *C. trachomatis*, *U. urealyticum*, and *M. genitalium*. Recommended regimens for the treatment ofPIDprovide antimicrobial activity against gonococci, chlamydiae, and anaerobes as well as genital mycoplasmas.

179. CHLAMYDIAL INFECTIONS - *Walter E. Stamm*

The genus *Chlamydia* contains three species that infect humans: *Chlamydia psittaci*, *C. trachomatis*, and *C. pneumoniae* (formerly the TWAR agent). *C. psittaci* is widely distributed in nature, producing genital, conjunctival, intestinal, or respiratory infections in many mammalian and avian species. Genital infections with *C. psittaci* have been well characterized in several species and cause abortion and infertility. Although mammalian strains of *C. psittaci* are not known to infect humans, avian strains occasionally do so, causing pneumonia and the systemic illness known as *psittacosis*.

C. pneumoniae is a fastidious chlamydial species that appears to be a common cause of upper respiratory tract infection and pneumonia, primarily in children and young adults, and is a cause of recurrent respiratory infections in older adults. Studies have also linked *C. pneumoniae* infection to atherosclerotic cardiovascular disease and perhaps to asthma and sarcoidosis. No animal reservoir has been identified for *C. pneumoniae*; it appears to be an exclusively human pathogen spread via the respiratory route through close personal contact. To date, all strains of *C. pneumoniae* studied have been serologically homologous.

C. trachomatis is also an exclusively human pathogen and was identified as the cause of trachoma in the 1940s. Since then, *C. trachomatis* has been recognized as a major cause of sexually transmitted and perinatal infection.

Chlamydiae are obligate intracellular bacteria that are classified in their own order (Chlamydiales). They possess both DNA and RNA, have a cell wall and ribosomes similar to those of gram-negative bacteria, and are inhibited by antibiotics such as tetracycline.

A unique feature of all chlamydiae is their complex reproductive cycle. Two forms of the microorganism -- the extracellular elementary body and the intracellular reticulate body -- participate in this cycle. The elementary body is adapted for extracellular survival and is the infective form transmitted from one person to another. Elementary bodies attach to susceptible target cells (usually columnar or transitional epithelial cells) and enter the cells inside a phagosome. Within 8 h of cell entry, the elementary bodies reorganize into reticulate bodies, which are adapted to intracellular survival and multiplication. They undergo binary fission, eventually producing numerous replicates contained within the intracellular membrane-bound "inclusion body," which occupies much of the infected host cell. Chlamydial inclusions resist lysosomal fusion until late in the developmental cycle. After 24 h, the reticulate bodies condense and form elementary bodies still contained within the inclusion. The inclusion then ruptures, releasing elementary bodies from the cell to initiate infection of adjacent cells or transmission to another person.

Studies with monoclonal antibodies to and nucleotide sequencing of the major outer-membrane protein have delineated at least 20 serotypes of *C. trachomatis*. According to the classification of Wang and Grayston, strains associated with trachoma have generally been those of the A, B, Ba, and C serovars, while serovars D through K have largely been associated with sexually transmitted and perinatally acquired infections. Serovars L_1, L_2, and L_3produce lymphogranuloma venereum (LGV) and hemorrhagic proctocolitis. The LGV strains demonstrate unique biologic behavior in that

they are more invasive than the other serovars, produce disease in lymphatic tissue, grow readily in cell culture systems and macrophages, and are fatal when inoculated intracerebrally into mice and monkeys. Non-LGV strains of *C. trachomatis* characteristically produce infections involving the superficial columnar epithelium of the eye, genitalia, and respiratory tract.

C. trachomatis has been reported as an infrequent cause of endocarditis, peritonitis, pleuritis, and possibly periappendicitis and may occasionally cause respiratory infections in older children and adults. Some immunosuppressed patients with pneumonia have had either serologic or cultural evidence of *C. trachomatis* infection, but more data are necessary to define a pathogenic role for *Chlamydia* in these patients.

SEXUALLY TRANSMITTED AND PERINATAL INFECTIONS DUE TO *C. TRACHOMATIS*

SPECTRUM OF *C. TRACHOMATIS* GENITAL INFECTIONS

Genital infections caused by *C. trachomatis* represent the most common bacterial sexually transmitted diseases (STDs) in the United States. An estimated 4 million cases occur each year. In adults, the clinical spectrum of sexually transmitted *C. trachomatis* infections parallels that of gonococcal infection. Both infections have been associated with urethritis, proctitis, and conjunctivitis in both sexes; with epididymitis in men; and with mucopurulent cervicitis (MPC) (Fig. 179-CD1), acute salpingitis, bartholinitis, and the Fitz-Hugh-Curtis syndrome (perihepatitis) in women. Moreover, both types of infection can be associated with septic arthritis. In general, however, chlamydial infections produce fewer symptoms and signs than corresponding gonococcal infections at the same anatomic site; in fact, chlamydial infections are often totally asymptomatic. Increasing evidence suggests that many chlamydial infections of the genital tract, especially in women, persist for months without producing symptoms. Simultaneous infection with *C. trachomatis* often occurs in women with cervical gonococcal infection and in heterosexual men with gonococcal urethritis.

EPIDEMIOLOGY

Infections due to *C. trachomatis* are now reportable in the United States, and national incidence data show steadily rising numbers of reported infections, undoubtedly reflecting both increased testing and increased reporting. Most testing has focused upon women to date, and thus the reported incidence is severalfold greater in women than in men; this difference likely represents a surveillance artifact.

The age of peak incidence of genital *C. trachomatis* infections, as of other sexually transmitted infections, is the late teens and early twenties. The prevalence of chlamydial urethral infection among young men is at least 3 to 5% for those seen in general medical settings or in urban high schools,>10% for asymptomatic soldiers undergoing routine physical examination, and 15 to 20% for heterosexual men seen inSTDclinics. In areas where chlamydial control programs have been implemented, prevalence may be markedly reduced. In short, prevalence varies widely with the population group studied and with the geographic locale. The ratio of chlamydial to gonococcal urethritis is highest for heterosexual men and for those of high socioeconomic status and is lowest

for homosexual men and indigent populations.

The prevalence of cervical infection among women is approximately 5% for asymptomatic college students and prenatal patients in the United States, >10% for women seen in family planning clinics, and >20% for women seen inSTDclinics. As in men, prevalence varies substantially by geographic locale. However, substantial prevalences (~8%) of asymptomatic chlamydial infection were recently demonstrated in young female military recruits from all parts of the United States. In this country, the prevalence of *C. trachomatis* in the cervix of pregnant women is 5 to 10 times higher than that of *Neisseria gonorrhoeae.* The prevalence of genital infection with either agent is highest among individuals who are between the ages of 18 and 24, single, and non-Caucasian (e.g., black or hispanic). Recurrent chlamydial infections occur frequently in these same risk groups, often acquired from untreated sexual partners. Oral contraceptive pill use and the presence of cervical ectopy also confer an increased risk of chlamydial infection. The proportion of infections that are asymptomatic appears to be higher for *C. trachomatis* than for *N. gonorrhoeae*, and symptomatic *C. trachomatis* infections are clinically less severe. Mild or asymptomatic chlamydial infections of the fallopian tubes nonetheless cause ongoing tubal damage and infertility. Furthermore, because the total number of *C. trachomatis* infections exceeds the total number of *N. gonorrhoeae* infections in industrialized countries, the total morbidity caused by *C. trachomatis* genital infections in these countries equals or exceeds that caused by *N. gonorrhoeae*. The prevalence of *C. trachomatis* is higher than that of *N. gonorrhoeae* in industrialized countries, in part because measures such as treatment of sex partners and routine cultures for case detection in asymptomatic individuals have been applied much more effectively to the control of gonorrhea than to the control of *C. trachomatis* infection.

PATHOGENESIS

C. trachomatis preferentially infects the columnar epithelium of the eye and the respiratory and genital tracts. The infection induces an immune response but often persists for months or years in the absence of antimicrobial therapy. Serious sequelae often occur in association with repeated or persistent infections. The precise mechanism through which repeated infection elicits an inflammatory response that leads to tubal scarring and damage in the female upper genital tract is not yet clear. One antigen, the chlamydial 60-kDa heat-shock protein, may be involved in inducing the pathologic immune response or may elicit antibodies that cross-react with human heat-shock proteins. The recent sequencing of the chlamydial genome may soon offer further insights into the pathogenic mechanisms of *C. trachomatis*.

CLINICAL MANIFESTATIONS

Nongonococcal and Postgonococcal Urethritis Nongonococcal urethritis (NGU) is a diagnosis of exclusion that is applied to men with symptoms and/or signs of urethritis who do not have gonorrhea. Postgonococcal urethritis (PGU) refers to nongonococcal urethritis developing in men 2 to 3 weeks after treatment of gonococcal urethritis with single doses of agents such as amoxicillin or cephalosporins that lack sufficient activity against chlamydiae. Since current treatment regimens for gonorrhea also include tetracycline, doxycycline, or azithromycin for possible concomitant chlamydial infection,

both the incidence of PGU and the causative role of chlamydiae in this syndrome have declined. *C. trachomatis* causes 20 to 40% of cases of NGU in heterosexual men but is less commonly isolated from homosexual men with this syndrome. The cause of most of the remaining cases is uncertain; considerable evidence suggests that *Ureaplasma urealyticum* causes many cases of NGU, while *Trichomonas vaginalis* and herpes simplex virus (HSV) cause some cases.

NGUis diagnosed by documentation of a leukocytic urethral exudate and by exclusion of gonorrhea by Gram's staining or culture. *C. trachomatis* urethritis is generally less severe than gonococcal urethritis, although in an individual patient these two forms of urethritis cannot be reliably differentiated solely on clinical grounds. Symptoms include urethral discharge (often whitish and mucoid rather than frankly purulent), dysuria, and urethral itching. Physical examination may reveal meatal erythema and tenderness and a urethral exudate that is often demonstrable only by stripping of the urethra.

At least one-third of males with *C. trachomatis* urethral infection have no demonstrable signs or symptoms of urethritis. Use of nucleic acid amplification assays on first-void urine specimens to diagnose chlamydial infections in men has facilitated more broadly based testing for asymptomatic infection in males. As a result, asymptomatic chlamydial urethritis has been demonstrated in 5 to 10% of sexually active adolescent males screened in school-based clinics or community centers. Such patients generally have first-glass pyuria (³15 leukocytes per 400´ microscopic field in the sediment of first-void urine), a positive leukocyte esterase test, or an increased number of leukocytes on Gram-stained smear prepared from a urogenital swab inserted 1 to 2 cm into the anterior urethra. For the enumeration of leukocytes, the smear is first scanned at low power to identify areas of the slide containing the highest concentration of leukocytes. These areas are then examined under oil immersion (1000´). An average of four or more leukocytes in at least three of five 1000´ (oil-immersion) fields is indicative of urethritis and correlates with the recovery of *C. trachomatis*. To differentiate between true urethritis and functional symptoms among symptomatic patients or to make a presumptive diagnosis of *C. trachomatis* infection in a "high-risk" but asymptomatic man (e.g., male patients inSTDclinics, sex partners of women with nongonococcal salpingitis orMPC, fathers of children with inclusion conjunctivitis), the examination of an endourethral specimen for increased leukocytes is useful if specific diagnostic tests for chlamydiae are not available. Alternatively, noninvasive screening for urethritis can be accomplished by testing of a first-void urine sample for pyuria, either by microscopy or by the leukocyte esterase test. Urine can also be directly tested for chlamydiae or gonococci by DNA amplification methods, as described below.

Epididymitis *C. trachomatis* is the foremost cause of epididymitis in sexually active heterosexual men under 35 years of age, accounting for about 70% of cases. *N. gonorrhoeae* causes most of the remaining cases, and some men have simultaneous infections with both pathogens, usually accompanied by asymptomatic urethritis as defined above. In homosexual men, sexually transmitted coliform infection acquired via rectal intercourse may cause epididymitis. Coliform bacteria and *Pseudomonas aeruginosa*, usually in association with preceding urologic instrumentation or surgery, are the most common causes of epididymitis in men over 35. Men with epididymitis typically present with unilateral scrotal pain, fever, and epididymal tenderness or swelling on examination. The illness may be mild enough to treat on an outpatient basis

with oral antibiotics or severe enough to require hospitalization and parenteral therapy. Testicular torsion should be excluded promptly by radionuclide scan, Doppler flow study, or surgical exploration in a teenager or young adult who presents with acute unilateral testicular pain without urethritis. The possibility of testicular tumor or chronic infection (e.g., tuberculosis) should be excluded when a patient with unilateral intrascrotal pain and swelling does not respond to appropriate antimicrobial therapy.

Reiter's Syndrome Reiter's syndrome consists of conjunctivitis, urethritis (or cervicitis in females), arthritis, and characteristic mucocutaneous lesions (Chap. 315). *C. trachomatis* has been recovered from the urethra of up to 70% of men with untreated nondiarrheal Reiter's syndrome and associated urethritis. In the absence of overt urethritis, it is important to exclude subclinical urethritis in the men in whom this diagnosis is suspected.

The pathogenesis of Reiter's syndrome remains obscure. However, since more than 80% of affected patients have the HLA-B27 phenotype and since other mucosal infections (with *Salmonella*, *Shigella*, or *Campylobacter*, for example) produce an identical syndrome, chlamydial infection is thought to initiate an aberrant and hyperactive immune response that produces inflammation at the involved target organs in these genetically predisposed individuals. Evidence of exaggerated cell-mediated and humoral immune responses to chlamydial antigens in Reiter's syndrome supports this hypothesis. The presumptive demonstration of chlamydial elementary bodies and chlamydial DNA in the joint fluid and synovial tissue of patients with Reiter's syndrome suggests that chlamydiae may actually spread from genital to joint tissues in these patients, perhaps in macrophages.

Proctitis *C. trachomatis* strains of either the genital immunotypes D through K or theLGVimmunotypes cause proctitis in homosexual men who practice receptive anorectal intercourse. In the United States, the vast majority of cases are due to immunotypes D through K and present either as asymptomatic infection or as mild proctitis not unlike gonococcal proctitis. These infections may develop in heterosexual women as well. Patients present with mild rectal pain, mucous discharge, tenesmus, and (occasionally) bleeding. Nearly all have neutrophils in their rectal Gram's stain. Anoscopy in these non-LGV cases of chlamydial proctitis reveals mild, patchy mucosal friability and mucopurulent discharge, and the disease process is limited to the distal rectum. LGV strains produce more severe ulcerative proctitis or proctocolitis that can be confused clinically withHSVproctitis (severe rectal pain, bleeding, discharge, and tenesmus) and that histologically resembles Crohn's disease in that giant cell formation and granulomas can be seen (Chap. 287). In the United States, these cases occur almost exclusively in homosexual men.

Mucopurulent Cervicitis Although many women with *C. trachomatis* infection of the cervix have no symptoms or signs, a careful speculum examination reveals evidence ofMPC in 30 to 50% of cases. As is discussed more fully inChap. 133, MPC is associated with yellow mucopurulent discharge from the endocervical columnar epithelium and with³20 neutrophils per 1000´ microscopic field within strands of cervical mucus on a thinly smeared, Gram-stained preparation of endocervical exudate. Other characteristic findings include edema of the zone of cervical ectopy and a propensity of the mucosa to bleed on minor trauma -- e.g., when specimens are collected with a

swab. A Pap smear shows increased numbers of neutrophils as well as a characteristic pattern of mononuclear inflammatory cells, including plasma cells, transformed lymphocytes, and histiocytes. Cervical biopsy shows a predominantly mononuclear cell infiltrate of the subepithelial stroma, often with follicular cervicitis.

Pelvic Inflammatory Disease (PID) (See alsoChap. 133) *C. trachomatis* plays an important causative role in salpingitis. Infection with *C. trachomatis* has been demonstrated in laparoscopically verified salpingitis, the organism has been recovered from the fallopian tubes in the absence of other pathogens, and serologic evidence of recent *C. trachomatis* infection has been found in women with PID. In the United States, *C. trachomatis* has been identified in the fallopian tubes or endometrium of up to 50% of women with PID, and its role as an important etiologic agent in this syndrome is well accepted.

PIDoccurs via ascending intraluminal spread of *C. trachomatis* from the lower genital tract.MPC is thus followed by endometritis, endosalpingitis, and finally pelvic peritonitis. Evidence of MPC is usually found in women with laparoscopically verified salpingitis. Similarly, endometritis, demonstrated by endometrial biopsy showing plasma cell infiltration of the endometrial epithelium, is documented in most women with laparoscopically verified chlamydial (or gonococcal) salpingitis. Chlamydial endometritis can also occur in the absence of clinical evidence of salpingitis: approximately 40 to 50% of women with MPC have plasma cell endometritis. Histologic evidence of endometritis has been correlated with an "endometritis syndrome" consisting of vaginal bleeding, lower abdominal pain, and uterine tenderness in the absence of adnexal tenderness. It is not known what proportion of women who have chlamydial endometritis without adnexal tenderness also have salpingitis. However, chlamydial salpingitis produces milder symptoms than does gonococcal salpingitis and may be associated with less marked adnexal tenderness. Mild adnexal or uterine tenderness in sexually active women with cervicitis suggests PID.

Infertility associated with fallopian-tube scarring has been strongly linked to antecedent *C. trachomatis* infection in serologic studies. Since many infertile women with tubal scarring and antichlamydial antibody have no history ofPID, it appears that subclinical tubal infection ("silent salpingitis") may produce scarring. Studies in animals and humans with salpingitis and tubal scarring suggest the continuing presence of persistent, slowly replicating chlamydial infection in tubal tissue. Ectopic pregnancy, which occurs in more than 70,000 women in the United States annually, is also thought to be related to *Chlamydia*-induced tubal scarring in many cases. While the pathogenesis of *Chlamydia*-induced tubal scarring remains poorly understood, antibodies to the chlamydial 60-kDa heat-shock protein have been correlated with tubal infertility, ectopic pregnancy, and Fitz-Hugh-Curtis syndrome (see below). Thus this antigen may initiate an immune-mediated process that ultimately damages the fallopian tube. Host genetic susceptibility, as defined by HLA type, may also play an important role.

Perihepatitis, or the Fitz-Hugh-Curtis syndrome, was originally described as a complication of gonococcalPID. However, cultural and/or serologic evidence of *C. trachomatis* infection is found in three-quarters of women with this syndrome. *C. trachomatis* has also been cultured from exudate on the hepatic capsule in

laparoscopically verified cases. This syndrome should be suspected whenever a young, sexually active woman presents with an illness resembling cholecystitis (fever and right-upper-quadrant pain of subacute or acute onset). Symptoms and signs of salpingitis may be minimal. High titers of antibodies to *C. trachomatis* are generally present.

Urethral Syndrome in Women In the absence of infection with uropathogens such as coliforms or *Staphylococcus saprophyticus*, *C. trachomatis* is the pathogen most commonly isolated from college women with dysuria, frequency, and pyuria (Chap. 280). *Chlamydia* can also be isolated from the urethra of women without symptoms of urethritis, and up to 25% of femaleSTDclinic patients with chlamydial urogenital infection have cultures positive for *C. trachomatis* from the urethra only.

***C. trachomatis* Infection in Pregnancy** *C. trachomatis* in pregnancy has been associated in some studies (but not in others) with premature delivery and with postpartum endometritis. Whether these complications are in part attributable to *C. trachomatis* is not clear.

PERINATAL INFECTIONS: INCLUSION CONJUNCTIVITIS AND PNEUMONIA

Epidemiology Studies in the United States have demonstrated that 5 to 25% of pregnant women have *C. trachomatis* infections of the cervix. In these studies, approximately one-half to two-thirds of children exposed during birth have acquired *C. trachomatis* infection. Roughly half of the infected infants (or 25% of the group exposed) have developed clinical evidence of inclusion conjunctivitis. In addition to infecting the eye, *C. trachomatis* has been isolated frequently and persistently from the nasopharynx, rectum, and vagina of such infants, occasionally for periods exceeding 1 year in the absence of treatment. Pneumonia develops in about 10% of children infected perinatally, and otitis media may in some cases result from perinatally acquired chlamydial infection.

Inclusion Conjunctivitis of the Newborn (Neonatal Chlamydial Conjunctivitis) Neonatal chlamydial conjunctivitis has an acute onset 5 to 14 days after birth and often produces a profuse mucopurulent discharge. However, it is impossible to differentiate chlamydial conjunctivitis from other forms of neonatal conjunctivitis (such as that due to *N. gonorrhoeae*, *Haemophilus influenzae*, *Streptococcus pneumoniae*, orHSV) on clinical grounds; instead, laboratory diagnosis is required. Inclusions within epithelial cells are often detected in Giemsa-stained conjunctival smears, but these smears are considerably less sensitive than cultures, antigen detection tests, or nucleic acid hybridization tests for chlamydiae. Gram-stained smears may show gonococci or occasional small gram-negative coccobacilli in *Haemophilus* conjunctivitis, but smears should be accompanied by cultures for these agents.

Infant Pneumonia *C. trachomatis* causes a distinctive pneumonia syndrome in infants. Recent epidemiologic studies have linked chlamydial pulmonary infection in infants with increased occurrence of subacute lung disease (bronchitis, asthma, wheezing) in later childhood.

LYMPHOGRANULOMA VENEREUM

Definition LGV is a sexually transmitted infection caused by *C. trachomatis* strains of the L_1, L_2, and L_3serovars. In the United States, most cases are caused by L_2organisms. Acute LGV in heterosexual men is characterized by a transient primary genital lesion followed by multilocular suppurative regional lymphadenopathy. Women, homosexual men, and -- in occasional instances -- heterosexual men may develop hemorrhagic proctitis with regional lymphadenitis. Acute LGV is almost always associated with systemic symptoms such as fever and leukocytosis but is rarely associated with systemic complications such as meningoencephalitis. After a latent period of years, late complications include genital elephantiasis due to lymphatic involvement; strictures; and fistulas of the penis, urethra, and rectum.

Epidemiology LGV is usually sexually transmitted, but occasional transmission by nonsexual personal contact, fomites, or laboratory accidents has been documented. Laboratory work involving the creation of aerosols of LGV organisms (e.g., sonication, homogenization) must be conducted only with appropriate measures for biologic containment.

The peak incidence ofLGVcorresponds to the age of greatest sexual activity: the second and third decades of life. The worldwide incidence of LGV is falling, but the disease is still endemic and a major cause of morbidity in Asia, Africa, South America, and parts of the Caribbean. In the Bahamas, an apparent outbreak of LGV has been described in association with a concurrent increase in heterosexual infection with HIV. However, only 186 cases were reported in the United States in 1995, for a rate of 0.1 case per 100,000 population.

The frequency of infection following exposure is believed to be much lower than that for gonorrhea and syphilis. Early manifestations are recognized far more often in men than in women, who usually present with late complications. In the United States, where the reported male-to-female ratio of cases is 3.4:1, most cases have involved homosexually active men and persons returning from abroad (travelers, sailors, and military personnel). The main reservoir of infection, although it has not been directly demonstrated, is presumed to be asymptomatically infected individuals.

Clinical Manifestations In heterosexuals, a *primary genital lesion* develops from 3 days to 3 weeks after exposure. It is a small, painless vesicle or nonindurated ulcer or papule located on the penis in men and on the labia, posterior vagina, or fourchette in women. The primary lesion is noticed by fewer than one-third of men withLGV and only rarely by women. It heals in a few days without scarring and, even when noticed, is usually recognized as LGV only in retrospect. LGV strains of *C. trachomatis* have occasionally been recovered from genital ulcers and from the urethra of men and the endocervix of women who present with inguinal adenopathy; these areas may be the primary site of infection in some cases.

In women and homosexual men, *primary anal* or *rectal infection* develops after receptive anorectal intercourse. In women, rectal infection withLGV (or non-LGV) strains of *C. trachomatis* presumably can also arise by the contiguous spread of infected secretions along the perineum (as in rectal gonococcal infections in women) or perhaps by spread to the rectum via the pelvic lymphatics.

From the site of the primary urethral, genital, anal, or rectal infection, the organism spreads via the regional lymphatics. Penile, vulvar, or anal infection can lead to inguinal and femoral lymphadenitis. Rectal infection produces hypogastric and deep iliac lymphadenitis. Upper vaginal or cervical infection results in enlargement of the obturator and iliac nodes.

The most common presenting picture in heterosexual men is the *inguinal syndrome*, which is characterized by painful inguinal lymphadenopathy beginning 2 to 6 weeks after presumed exposure; in rare instances, the onset comes after a few months. The inguinal adenopathy is unilateral in two-thirds of cases, and palpable enlargement of the iliac and femoral nodes is often evident on the same side as the enlarged inguinal nodes (Fig. 132-CD2). The nodes are initially discrete, but progressive periadenitis results in a matted mass of nodes that becomes fluctuant and suppurative. The overlying skin becomes fixed, inflamed, and thin and finally develops multiple draining fistulas. Extensive enlargement of chains of inguinal nodes above and below the inguinal ligament ("the sign of the groove") is not specific and, although not uncommon, is documented in only a minority of cases. On histologic examination, infected nodes are initially found to have characteristic small stellate abscesses surrounded by histiocytes. These abscesses coalesce to form large, necrotic, suppurative foci. Spontaneous healing usually takes place after several months; inguinal scars or granulomatous masses of various sizes persist for life. Massive pelvic lymphadenopathy in women or homosexual men may lead to exploratory laparotomy.

As cultures and serologic tests for *C. trachomatis* are being used more often, increasing numbers of cases ofLGVproctitis are being recognized in homosexual men. Such patients present with anorectal pain and mucopurulent, bloody rectal discharge. Although these patients may complain of diarrhea, they are often referring not to diarrhea but rather to frequent, painful, unsuccessful attempts at defecation (tenesmus). Sigmoidoscopy reveals ulcerative proctitis or proctocolitis, with purulent exudate and mucosal bleeding. The histopathologic findings in the rectal mucosa include granulomas with giant cells, crypt abscesses, and extensive inflammation. These clinical, sigmoidoscopic, and histopathologic findings may closely resemble those of Crohn's disease of the rectum.

Constitutional symptoms are common during the stage of regional lymphadenopathy and, in cases of proctitis, may include fever, chills, headache, meningismus, anorexia, myalgias, and arthralgias. These findings in the presence of lymphadenopathy are sometimes mistakenly interpreted as representing malignant lymphoma. Other systemic complications are infrequent but include arthritis with sterile effusion, aseptic meningitis, meningoencephalitis, conjunctivitis, hepatitis, and erythema nodosum. Chlamydiae have been recovered from the cerebrospinal fluid and in one case were isolated from the blood of a patient with severe constitutional symptoms -- a result indicating the dissemination of infection. Laboratory-acquired infections suspected of being due to the inhalation of aerosols have been associated with mediastinal lymphadenitis, pneumonitis, and pleural effusion.

Complications of untreated anorectal infection include perirectal abscess; fistula in ano; and rectovaginal, rectovesical, and ischiorectal fistulas. Secondary bacterial infection

probably contributes to these complications. Rectal stricture is a late complication of anorectal infection and usually develops 2 to 6 cm from the anal orifice -- i.e., at a site within reach on digital rectal examination. Proximal extension of the stricture for several centimeters may lead to a mistaken clinical and radiographic diagnosis of carcinoma.

A small percentage of cases ofLGV in men present as chronic progressive infiltrative, ulcerative, or fistular lesions of the penis, urethra, or scrotum. Associated lymphatic obstruction may produce elephantiasis. When urethral stricture occurs, it usually involves the posterior urethra and causes incontinence or difficulty with urination.

APPROACH TO THE DIAGNOSIS AND TREATMENT OF *C. TRACHOMATIS* GENITAL INFECTIONS

Four types of laboratory procedure are available to confirm *C. trachomatis* infection: direct microscopic examination of tissue scrapings for typical intracytoplasmic inclusions or elementary bodies; isolation of the organism in cell culture; detection of chlamydial antigens or nucleic acid by immunologic or hybridization methods; and detection of antibody in serum or in local secretions.

Except in conjunctivitis, direct microscopic examination of Giemsa-stained cell scrapings for typical inclusions has an unacceptably low degree of sensitivity, and false-positive interpretations by inexperienced observers are common. Even for conjunctivitis, this approach has been replaced by direct fluorescent antibody staining of conjunctival smears to identify chlamydial elementary bodies with specific monoclonal antibodies (see below).

Cell culture techniques for isolation of *C. trachomatis* are available in most large medical centers but not in other clinical settings. In addition to limited availability, other disadvantages of cell culture include its low and variable level of sensitivity (60 to 80%), its requirement for rigorous transport conditions, and its high cost and technically demanding nature. Therefore, nonculture alternatives involving antigen detection or nucleic acid hybridization have been developed. In the direct immunofluorescent antibody (DFA) slide test, potentially infected genital or ocular secretions are smeared onto a slide, fixed, and stained with fluorescein-conjugated monoclonal antibody specific for chlamydial antigens. The observation of fluorescing elementary bodies confirms the diagnosis. Compared with culture, this test is 70 to 85% sensitive, and it is quite specific when used for confirmation of urethral, cervical, or ocular infection in high-risk patients with suspected *C. trachomatis* infection. The sensitivity and specificity of the test depend directly upon the skill of the microscopist. The apparently lower sensitivity of the test in low-risk populations, along with its relatively labor-intensive nature, limits its value as a screening tool.

Enzyme-linked immunosorbent assay (ELISA) techniques for the detection of chlamydial antigens provide another alternative to culture. The reported sensitivity and specificity of these tests for genital infections (as compared with culture) have been 60 to 80% and 97 to 99%, respectively, in high-risk populations. Sensitivities have generally been higher in cervical infection and lower in urethritis among males. Like theDFAslide test, the ELISA is less sensitive and less specific in low-prevalence populations and largely asymptomatic patients. ELISAs are better suited to screening

than is DFA because large numbers of specimens can easily be processed.

Assays with nucleic acid probes have also been developed for chlamydial diagnosis. One such test uses DNA-RNA hybridization and appears to be approximately equal to the bestELISAs in terms of sensitivity and specificity. Nucleic acid probes have also been developed for use in amplification assays such as ligase chain reaction and polymerase chain reaction (PCR). These tests are now the most sensitive chlamydial diagnostic methods available, being the first nonculture assays actually to surpass culture itself in sensitivity. In addition, the ability of these tests to detect chlamydial genes in urine with a high degree of sensitivity and specificity allows their use with urine specimens rather than with conventional urethral and cervical swabs for the first time. The use of urine specimens is particularly appealing for public-health chlamydial screening programs because of the ease of sample collection, even in community-based settings.

Serologic tests are of limited usefulness in the diagnosis of chlamydial oculogenital infections. The complement fixation test with heat-stable, genus-specific antigen has been used with some success to diagnoseLGV but is insensitive in infections due to non-LGV strains of *C. trachomatis*. The microimmunofluorescence (micro-IF) test with *C. trachomatis* antigens is more sensitive but is generally available only in research laboratories. The test measures antibodies by serovar specificity and by immunoglobulin class (IgM, IgG, IgA, secretory IgA) in both serum and local secretions. Serologic diagnosis by themicro-IFtest may be useful in infant pneumonia (in which high-titer IgM antibody and/or fourfold rises in titer are often demonstrated), in chlamydial salpingitis (especially Fitz-Hugh-Curtis syndrome), and in LGV. In all of these more invasive syndromes, high antibody levels are present.

Table 179-1 summarizes the diagnostic tests of choice for patients with suspected *C. trachomatis* infection. With few exceptions, the most suitable method for diagnosis is demonstration of the agent by either cell culture or one of the newer nonculture techniques. Selection of the most appropriate of these tests often depends upon local availability and expertise. However, it is clear that, in most settings and for most purposes, sensitivity and specificity will be greatest with nucleic acid amplification techniques. For patients to whom medicolegal considerations may apply (victims of sexual or child abuse), cultures or nucleic acid amplification methods should always be used. Since *C. trachomatis* is an intracellular pathogen, adequate specimens for chlamydial diagnostic testing must include epithelial cells. Cultures or nonculture tests of pus are less often positive. In urethritis, a thin-shafted urogenital swab should be inserted at least 2 cm into the urethra to obtain an appropriate specimen. Although cultures of urine for chlamydiae are less sensitive than urethral cultures, studies suggest that nucleic acid amplification testing of a first-void urine specimen from men is a more sensitive and less painful diagnostic alternative to the more invasive urethral swab-based tests, culture, or antigen detection tests. The first 30 mL of voided urine should be collected for testing. When a cervical sample is collected, the external os should first be cleaned of debris and purulent material; a plastic-shafted swab should then be inserted into the cervix, rotated slowly several times, and withdrawn. For the diagnosis of urogenital (cervical or urethral) infections in women, testing of a first-void urine specimen by nucleic acid amplification methods is at least as sensitive as testing of a cervical swab. When conjunctival specimens are sought, the epithelium should be

swabbed to remove cells rather than just purulent material. All specimens for chlamydial culture should be placed immediately into transport medium and then either refrigerated (if they will reach the laboratory within 12 to 18 h) or frozen at-70°C (if longer storage is anticipated). A major advantage of the nonculture diagnostic techniques is their less rigid transport requirements; neither refrigeration nor rapid transport is needed.

From a public health viewpoint, the most effective use of chlamydial diagnostic testing has not been unequivocally established and varies with the clinical population, local resources, and laboratory expertise. Since chlamydial diagnostic testing has become more widely available and is now more sensitive and specific than in the past, its use for specific diagnosis in patients with suspected chlamydial syndromes (such asMPC,NGU, andPID) and their partners should be promoted. High priority should be given to the screening of asymptomatic high-risk women who would not otherwise receive treatment for presumptive chlamydial infection, especially those seen in high-risk settings (e.g.,STDclinics or abortion clinics) and those with a high-risk profile (e.g., sexually active and £21 years of age, new sex partner within the preceding 2 months, or more than one current sex partner). Similar screening programs should be used to detect and treat asymptomatic urethritis in high-risk adolescent males. Where implemented, screening programs of this type have been associated with reductions in the prevalence of chlamydial infection and of its complications, such as PID.

ANTIMICROBIAL SUSCEPTIBILITY

In laboratory tests that evaluate the growth of chlamydiae in cell cultures, the tetracyclines, erythromycin, rifampin, certain fluoroquinolones (especially ofloxacin), and the macrolide azithromycin are all highly active against these organisms. Sulfonamides and clindamycin are also active against *C. trachomatis*, but to a lesser degree. Penicillin and ampicillin suppress chlamydial multiplication but do not eradicate the organism in vitro. The cephalosporins appear to be relatively ineffective against *C. trachomatis*. Streptomycin, gentamicin, neomycin, kanamycin, vancomycin, ristocetin, spectinomycin, and nystatin are not effective at concentrations inhibitory for most bacteria and fungi. There does not appear to be much strain-to-strain variation in susceptibility to antibiotics, and no clinically significant antimicrobial resistance in chlamydiae has been described. Thus antimicrobial susceptibility testing is not needed in the routine management of patients with chlamydial infection, even recurrent infection.

TREATMENT

Until the introduction of azithromycin, chlamydial infections could not be eradicated by single-dose or short-term antimicrobial regimens. In most uncomplicated infections in adults, 7 days of treatment with doxycycline or tetracycline have to be given for genital infections, but a 2-week course of therapy is recommended for complicated chlamydial infections (e.g.,PID, epididymitis) and at least a 3-week course forLGV. Failure of treatment of genital infections with a tetracycline usually indicates poor compliance or reinfection rather than the involvement of a drug-resistant strain.

Therapy for *C. trachomatis* urethritis is more efficacious than therapy for nonchlamydialNGU. *C. trachomatis* is eradicated from the urethra in nearly all cases by treatment with tetracycline hydrochloride (500 mg qid for 7 days) or doxycycline (100 mg

by mouth bid for 7 days).

Eradication of *C. trachomatis* from the cervix by tetracycline, doxycycline, and erythromycin, with doses and durations similar to those specified above for urethritis, has been demonstrated. Erythromycin base (500 mg qid for 10 to 14 days) is the regimen of choice for pregnant women with *C. trachomatis* infection. Amoxicillin (500 mg tid for 10 days) has also been used successfully in pregnant women. Tetracycline hydrochloride (500 mg qid) or doxycycline (100 mg bid) for 14 days produces clinical and microbiologic cure of epididymitis andPIDassociated with *C. trachomatis* infection, but in this situation a tetracycline should always be used together with a drug that is highly effective against gonorrhea.

Azithromycin is highly active against *C. trachomatis*, exhibits prolonged bioavailability, is concentrated intracellularly, and has offered the prospect of single-dose therapy for chlamydial infection for the first time. In comparative trials, a 1-g single dose of azithromycin has been as effective as 7 days of doxycycline for uncomplicated chlamydial infection. Azithromycin causes fewer adverse gastrointestinal reactions than do older macrolides such as erythromycin. The single-dose regimen of azithromycin has great appeal for the treatment of patients with uncomplicated chlamydial infection (especially those without symptoms and those with a likelihood of poor compliance) and of sexual partners of infected patients. These advantages must be weighed against the considerably greater cost of azithromycin than of doxycycline. Whenever possible, the single 1-g dose should be given as directly observed therapy. Although not approved by the U.S. Food and Drug Administration, the 1-g single-dose regimen of azithromycin appears to be safe and effective in the treatment of pregnant women.

Of the newer fluoroquinolones, ofloxacin (300 mg by mouth bid for 7 days) has been shown to be as effective as doxycycline for the treatment of chlamydial infection and appears to be safe and well tolerated. It cannot be used in pregnancy.

Treatment of Sex Partners The continued high prevalence of chlamydial infections in most parts of the United States is due primarily to the failure to diagnose -- and therefore treat -- patients with symptomatic or asymptomatic infection and their sex partners. *C. trachomatis* urethral or cervical infection has been well documented in a high proportion of the sex partners of patients withNGU, epididymitis, Reiter's syndrome, salpingitis, or endocervicitis. If possible, confirmatory laboratory tests for *Chlamydia* should be undertaken in these individuals, but even those without evidence of clinical disease who have recently been exposed to proven or possible chlamydial infection (e.g., NGU) should be offered therapy.

Treatment of Neonates and Infants In neonates with conjunctivitis or infants with pneumonia, erythromycin ethylsuccinate or estolate can be given orally in a dose of 50 mg/kg per day, preferably in four divided doses, for 2 weeks. Careful attention must be given to compliance with therapy -- a frequent problem. Relapses of eye infection are common following treatment with topical erythromycin or tetracycline ophthalmic ointment and may also occur after oral erythromycin therapy. Thus follow-up cultures should be performed after treatment. Both parents should be examined for *C. trachomatis* infection and, if diagnostic testing is not readily available, should be treated with doxycycline or azithromycin.

PREVENTION

Efforts to develop a vaccine for chlamydial infection have not yet been successful. Early diagnosis and treatment shorten the duration of infectiousness of the carrier and therefore constitute primary prevention of chlamydial infection. By the early 1990s, one of the 10 regions of the United States (Region X, the Pacific Northwest) had formally undertaken a chlamydial control program involving widespread screening of women attending family planning clinics. Approximately 500,000 tests per year were conducted at 150 such clinics throughout the region in women meeting the criteria for high risk. Within 5 years, the prevalence of chlamydial infection had been reduced by>30% in this population. While other regions of the United States have now initiated similar programs, many family planning andSTDclinics still do not offer chlamydial testing. The availability of highly sensitive and specific diagnostic tests that can be done with urine specimens and of single-dose therapy makes it feasible to mount an effective chlamydial control program nationwide, with screening of high-risk persons both in traditional health care settings and in novel community- and school-based settings.

TRACHOMA AND ADULT INCLUSION CONJUNCTIVITIS

DEFINITION

Trachoma is a chronic conjunctivitis associated with infection by *C. trachomatis* serovar A, B, Ba, or C. It has been responsible for an estimated 20 million cases of blindness throughout the world and remains an important cause of preventable blindness. Inclusion conjunctivitis is an acute ocular infection caused by sexually transmitted *C. trachomatis* strains (usually serovars D through K) in adults exposed to infected genital secretions and in their newborn offspring.

EPIDEMIOLOGY

Epidemiologically, two types of eye disease are caused by *C. trachomatis*. In trachoma-endemic areas where the classic eye disease is seen, transmission is from eye to eye via hands, flies, towels, and other fomites and usually involves serovar A, B, Ba, or C. In nonendemic areas, organisms of serovars D through K can be transmitted from the genital tract to the eye, usually causing only the inclusion conjunctivitis syndrome, occasionally with keratitis. Rarely, the eye disease acquired in this way progresses, with the development of pannus and scars similar to those seen in endemic trachoma. These cases may be referred to as paratrachoma to differentiate them epidemiologically from eye-to-eye-transmitted endemic trachoma.

The worldwide incidence and severity of trachoma have decreased dramatically during the past 35 years, mainly as a result of improving hygienic and economic conditions. Endemic trachoma is still the major cause of preventable blindness in northern Africa, sub-Saharan Africa, the Middle East, and parts of Asia. The endemic disease is transmitted primarily through close personal contact, particularly among young children in rural communities with limited water supplies. In endemic areas, trachoma is associated with repeated exposure and reinfection, but the infection can also become chronic and persistent. In the United States a mild form of endemic trachoma still occurs

in Mexican Americans as well as in immigrants from areas where trachoma is endemic. Acute relapse of old trachoma occasionally follows treatment with cortisone eye ointment or develops in very old persons who were exposed in their youth.

CLINICAL MANIFESTATIONS

Both endemic trachoma and adult inclusion conjunctivitis present initially as a conjunctivitis characterized by small lymphoid follicles in the conjunctiva. In regions with hyperendemic classic blinding trachoma, the disease usually starts insidiously before the age of 2 years. Reinfection is common and probably contributes to the pathogenesis of trachoma. Studies usingPCRtechniques indicate that chlamydial DNA is often present in the ocular secretions of patients with trachoma, even in the absence of positive cultures. Thus persistent infection may be more common than was previously thought.

The cornea becomes involved, with inflammatory leukocytic infiltrations and superficial vascularization (pannus formation). As the inflammation continues, conjunctival scarring eventually distorts the eyelids, causing them to turn inward so that the inturned lashes constantly abrade the eyeball (trichiasis and entropion); eventually the corneal epithelium is abraded and may ulcerate, with subsequent corneal scarring and blindness. Destruction of the conjunctival goblet cells, lacrimal ducts, and lacrimal gland may produce a "dry-eye" syndrome, with resultant corneal opacity due to drying (xerosis) or secondary bacterial corneal ulcers.

Communities with blinding trachoma often experience seasonal epidemics of conjunctivitis due to *H. influenzae* that contribute to the intensity of the inflammatory process. In such areas the active infectious process usually resolves spontaneously in affected persons between 10 and 15 years of age, but the conjunctival scars continue to shrink, producing trichiasis and entropion and subsequent corneal scarring in adults. In areas with milder and less prevalent disease, the process may be much slower, with active disease continuing into adulthood; blindness is rare in these cases.

Eye infection with genital *C. trachomatis* strains in sexually active young adults presents as the acute onset of unilateral follicular conjunctivitis and preauricular lymphadenopathy similar to that seen in acute adenovirus or herpesvirus conjunctivitis. If untreated, the disease may persist for 6 weeks to 2 years. It is frequently associated with corneal inflammation in the form of discrete opacities ("infiltrates"), punctate epithelial erosions, and minor degrees of superficial corneal vascularization. Very rarely, conjunctival scarring and eyelid distortion occur, particularly in patients treated for many months with topical glucocorticoids. Recurrent eye infections develop most often in patients whose sexual consorts are not treated with antimicrobials.

DIAGNOSIS

The clinical diagnosis of classic trachoma can be made if two of the following signs are present:

1. Lymphoid follicles on the upper tarsal conjunctiva

2. Typical conjunctival scarring

3. Vascular pannus

4. Limbal follicles or their sequelae, Herbert's pits

The clinical diagnosis of endemic trachoma should be confirmed by laboratory tests in children with more marked degrees of inflammation. Intracytoplasmic chlamydial inclusions are found in 10 to 60% of Giemsa-stained conjunctival smears in such populations, but isolation in cell cultures, newer antigen detection testing, or chlamydialPCR is more sensitive. Follicular conjunctivitis in adult Europeans or Americans living in trachomatous regions is rarely due to trachoma.

Sporadic cases of adult inclusion conjunctivitis must be differentiated from keratoconjunctivitis due to adenovirus orHSV and from bacterial conjunctivitis during the first 15 days after onset; later, they must be distinguished from other forms of chronic follicular conjunctivitis. Demonstration of chlamydiae by Giemsa- or immunofluorescent-stained smears, by isolation in cell cultures, or by newer nonculture tests constitutes definitive evidence of infection. Genital examination and tests for genital chlamydial infection are indicated. Serum antibody does not constitute evidence of chlamydial eye infection since many sexually active adults have acquired serum antibody from genital infection.

TREATMENT

Public health control programs for endemic trachoma have consisted of the mass application of tetracycline or erythromycin ointment to the eyes of all children in affected communities for 21 to 60 days or on an intermittent schedule. These programs also include surgical correction of inturned eyelids by a mobile surgical team that visits each locale. Single-dose azithromycin therapy is now being evaluated as an alternative method of mass antibiotic treatment for trachoma in young children and pregnant women.

Adult inclusion conjunctivitis responds well to treatment with full doses of systemic tetracycline or erythromycin for 3 weeks. Treatment of all sexual consorts of the patient simultaneously is also necessary to prevent ocular reinfection and to avoid genital disease due to chlamydial infection. Topical antibiotic treatment is not required for patients who receive systemic antibiotics.

PREVENTION

Efforts to develop a trachoma vaccine have not yet been successful. General hygienic measures associated with improved living standards are effective in the elimination of endemic trachoma. An adequate water supply for personal cleanliness may be a key factor. In some areas the reduction of numbers of flies in the household is important.

PSITTACOSIS

DEFINITION

Psittacosis is primarily an infectious disease of birds and mammals that is caused by *C. psittaci*. Transmission of infection from birds to humans results in a febrile illness characterized by pneumonitis and systemic manifestations. Inapparent infections or mild influenza-like illnesses may also occur. The term *ornithosis* is sometimes applied to infections contracted from birds other than parrots or parakeets, but *psittacosis* is the preferred generic term for all forms of the disease.

EPIDEMIOLOGY

Almost any avian species can harbor *C. psittaci*. Psittacine birds (parrots, parakeets, budgerigars) are most commonly infected, but human cases have been traced to contact with pigeons, ducks, turkeys, chickens, and many other birds. Psittacosis may be considered an occupational disease of pet-shop owners, poultry workers, pigeon fanciers, taxidermists, veterinarians, and zoo attendants. During the past 20 years, there has been an increase in incidence, with cases and outbreaks occurring primarily among employees of poultry-processing plants. It is suspected that many cases go undiagnosed and unreported. The disease appears to be especially common in England, where budgerigars are popular household pets and where restrictions on the importation of these birds have been eased.

The agent is present in nasal secretions, excreta, tissues, and feathers of infected birds. Although the disease can be fatal, infected birds frequently show only minor evidence of illness, such as ruffled feathers, lethargy, and anorexia. Asymptomatic avian carriers are common, and complete recovery may be followed by continued shedding of the organism for many months.

Psittacosis is almost always transmitted to humans by the respiratory route. On rare occasions the disease may be acquired from the bite of a pet bird. Prolonged contact is not essential for transmission of the disease; a few minutes spent in an environment previously occupied by an infected bird has resulted in human infection. In one outbreak, gardening rather than direct exposure to birds was associated with infection. A psittacosis-like agent has been transmitted among hospital personnel, with severe and sometimes fatal infections. There is evidence that these "human" strains are more virulent than avian organisms. There is no record of infection acquired by the ingestion of poultry products.

PATHOGENESIS

The psittacosis agent gains entrance to the body through the upper part of the respiratory tract, spreads via the bloodstream, and eventually localizes in the pulmonary alveoli and in the reticuloendothelial cells of the spleen and liver. Invasion of the lung probably takes place by way of the bloodstream rather than by direct extension from the upper air passages. A lymphocytic inflammatory response occurs on both the interstitial and the respiratory surfaces of the alveoli as well as in the perivascular spaces. The alveolar walls and interstitial tissues of the lung are thickened, edematous, necrotic, and occasionally hemorrhagic. Histologic examination of the affected areas reveals alveolar spaces filled with fluid, erythrocytes, and lymphocytes. The picture is not pathognomonic of psittacosis unless macrophages containing characteristic cytoplasmic inclusion bodies (Levinthal-Coles-Lillie bodies) can be identified. The respiratory

epithelium of the bronchi and bronchioles usually remains intact.

CLINICAL MANIFESTATIONS

The clinical manifestations and course of psittacosis are extremely variable. After an incubation period of 7 to 14 days or longer, the disease may start abruptly with shaking chills and fever, with temperatures ranging as high as 40.5°C (105°F); however, the onset is often gradual, with fever increasing over a 3- to 4-day period. Headache is almost always a prominent symptom; it is usually diffuse and excruciating and is often the patient's chief complaint.

Many patients present with a dry hacking cough that is usually nonproductive, but small amounts of mucoid or bloody sputum may be raised as the disease progresses. Cough may begin early in the course of the disease or as late as 5 days after the onset of fever. Chest pain, pleurisy with effusion, or a friction rub may all occur but are rare. Pericarditis and myocarditis have been reported. Most patients have a normal or slightly increased respiratory rate; marked dyspnea with cyanosis occurs only in severe psittacosis with extensive pulmonary involvement. In psittacosis, as in mycoplasmal pneumonias, the physical signs of pneumonitis tend to be less prominent than symptoms and x-ray findings would suggest. The initial examination may reveal fine sibilant rales, or clinical evidence of pneumonia may be completely lacking. Rales usually become audible and more numerous as the illness progresses. Signs of frank pulmonary consolidation are usually absent. Symptoms of upper respiratory tract infection are not prominent, although mild sore throat, pharyngitis, and cervical adenopathy are often documented; on occasion, the last may be the only manifestation of illness. Epistaxis is encountered early in the course of nearly one-fourth of cases. Photophobia is also a common complaint.

Patients often report generalized myalgia, and spasm and stiffness of the muscles of the back and neck may lead to an erroneous diagnosis of meningitis. Lethargy, mental depression, agitation, insomnia, and disorientation have been prominent features of the illness in some epidemics but not in others; delirium and stupor develop near the end of the first week in severe cases. Occasional patients are comatose when first seen, and the diagnosis of psittacosis may be elusive in these cases. Gastrointestinal manifestations such as abdominal pain, nausea, vomiting, or diarrhea are noted in some cases; constipation and abdominal distention sometimes occur as late complications. Icterus, the result of severe hepatic involvement, is a rare and ominous finding. A faint macular rash (Horder's spots) resembling the rose spots of typhoid fever has been described.

Patients without cough or other clinical evidence of respiratory involvement present with fever of unknown origin (Chap. 125). The pulse rate is slow in relation to the fever. When splenomegaly is noted in a patient with acute pneumonitis, psittacosis should be considered; the reported incidence of splenomegaly in this disease ranges from 10 to 70%. Nontender hepatic enlargement also occurs, but jaundice is rare. Thrombophlebitis is not unusual during convalescence; indeed, pulmonary infarction is sometimes a late complication and may be fatal.

In untreated cases of psittacosis, sustained or mildly remittent fever persists for 10 days

to 3 weeks or occasionally for as long as 3 months. Over this period, the respiratory manifestations gradually abate. Psittacosis contracted from parrots or parakeets is more likely to be a severe, prolonged illness than infection acquired from pigeons or barnyard fowl. Relapses occur but are rare. Occasional patients develop endocarditis, and *C. psittaci* infection should be considered in cases of culture-negative endocarditis. Secondary bacterial infections are uncommon. Immunity to reinfection is probably permanent.

LABORATORY FINDINGS

The chest x-ray in psittacosis is nonspecific and may show pneumonic lesions that are usually patchy in appearance but can be hazy, diffuse, homogeneous, lobar, atelectatic, wedge-shaped, nodular, or miliary. The white blood cell count is normal or moderately decreased in the acute phase of the disease but may rise in convalescence. The erythrocyte sedimentation rate frequently is not elevated. Transient proteinuria is common. The cerebrospinal fluid sometimes contains a few mononuclear cells but is otherwise normal. Despite hepatomegaly, the results of liver function tests are generally normal or mildly elevated.

The diagnosis can be confirmed only by isolation of the causative microorganism or by serologic studies. The agent is present in the blood during the acute phase of the disease and in the bronchial secretions for weeks or sometimes years after infection, but it is difficult to isolate. Further, the organism is hazardous to work with in the laboratory, and most clinical laboratories do not offer culture for *C. psittaci*. Thus psittacosis is most readily diagnosed by the demonstration of a rising titer of complement fixation antibody in the serum of a patient with a compatible clinical syndrome. Both an acute-phase and a convalescent-phase specimen should always be tested. *C. trachomatis*, *C. psittaci*, and *C. pneumoniae* all share a genus-specific "group" antigen, which is the basis of the complement fixation test. Thus acute infections with *C. trachomatis* or *C. pneumoniae* can also produce titer rises in this test. However, these three species have different major outer-membrane proteins that are the principal antigens in themicro-IFtest. If there is doubt as to the interpretation of the complement fixation test, the micro-IF test can be used to differentiate among these antigens. The prompt initiation of treatment with tetracycline has been shown to delay an antibody rise in convalescence for several weeks or months.

DIFFERENTIAL DIAGNOSIS

A history of exposure to birds may be the only clinical basis for differentiating psittacosis from a variety of infectious and noninfectious febrile disorders. The list of pulmonary diseases that may be confused with psittacosis includes *Mycoplasma* pneumonia, *C. pneumoniae* pneumonia, legionellosis, viral pneumonia, Q fever, coccidioidomycosis, tuberculosis, enterovirus infection, carcinoma of the lung with bronchial obstruction, and common bacterial pneumonias. In the early stages, before pneumonitis appears, psittacosis may be mistaken for influenza, typhoid fever, miliary tuberculosis, or infectious mononucleosis.

TREATMENT

The tetracyclines are consistently effective in the treatment of psittacosis. Defervescence and alleviation of symptoms usually take place within 24 to 48 h after the institution of therapy with 2 g daily in four divided doses. To avoid relapse, treatment should probably be continued for at least 7 to 14 days after defervescence. In severe cases, hospitalization and pulmonary intensive care may be indicated. Sulfonamides are not active against *C. psittaci*. Erythromycin can be used in patients allergic to or intolerant of tetracyclines.

C. PNEUMONIAE INFECTIONS

A third chlamydial species that causes disease in humans, *C. pneumoniae*, has been described in the past two decades. *C. pneumoniae* can be distinguished from the other two species on the basis of DNA hybridization and elementary body morphology. Although *C. pneumoniae* can be grown in a variety of cell cultures, it is considerably more difficult to culture than other chlamydiae, especially from clinical specimens. HL cells appear to be the most effective cell line for isolation of *C. pneumoniae*.

Knowledge of the epidemiology of *C. pneumoniae* infections has been derived primarily from serologic studies. Infections begin to occur in late childhood, achieve peak incidence in young adults, but continue throughout adult life. Seroprevalence in the many adult populations that have been tested throughout the world exceeds 40% -- a figure suggesting that *C. pneumoniae* infections are ubiquitous. Secondary episodes (reinfections) appear to occur commonly in older adults throughout life. *C. pneumoniae* also produces epidemics of pneumonia and respiratory illness, especially in close residential quarters such as military barracks. The incidence of infections outside of epidemics remains poorly defined. Transmission appears to be from person to person, probably primarily in schools and family units.

Little is known about the pathogenesis of *C. pneumoniae* infection. The infection begins in the upper respiratory tract and in many persons is a long-lived asymptomatic condition of the upper respiratory mucosal surfaces. However, in at least some individuals, the organism is transported to distant sites -- perhaps within macrophages -- since evidence exists for replication within arteries and synovial membranes of joints. A *C. pneumoniae* outer-membrane protein may induce host immune responses whose cross-reaction with human proteins results in an autoimmune reaction.

The clinical spectrum of *C. pneumoniae* infection includes acute pharyngitis, sinusitis, bronchitis, and pneumonitis, primarily in young adults. The clinical manifestations of primary infection appear to be more severe and prolonged than those of reinfection. The pneumonitis resembles that of *M. pneumoniae* pneumonia in that leukocytosis is frequently lacking and patients often have prominent antecedent upper respiratory tract symptoms, fever, nonproductive cough, a mild to moderate degree of illness, minimal findings on chest auscultation, and small segmental infiltrates on chest x-ray. In elderly patients, pneumonia due to *C. pneumoniae* can be especially severe and may necessitate hospitalization and respiratory support.

Epidemiologic studies have demonstrated an association between serologic evidence of *C. pneumoniae* infection and atherosclerotic disease of the coronary and other arteries. In addition, *C. pneumoniae* has been identified in atherosclerotic plaques by electron

microscopy, DNA hybridization, and immunocytochemistry. Recently, the organism has been recovered in culture from atheromatous plaque -- a result indicating the presence of viable replicating bacteria in vessels. Evidence from animal models supports the hypothesis that *C. pneumoniae* infection of the upper respiratory tract is followed by recovery of the organism from atheromatous lesions in the aorta and that the infection accelerates the process of atherosclerosis, especially in hypercholesterolemic animals. Antimicrobial treatment of the infected animals reverses the increased risk of atherosclerosis. In humans, two small trials in patients with unstable angina or recent myocardial infarction also suggested that antibiotics reduce subsequent untoward cardiac events. Larger trials have been initiated to determine more definitively whether antibiotics affect the risk of atherosclerosis.

Diagnosis of *C. pneumoniae* infection is currently difficult because cell culture techniques are not available for routine clinical use and nonculture tests using antigen detection methods or DNA probes have not been developed for commercial use. Acute- and convalescent-phase sera can be tested for chlamydial complement fixation antibody to make a retrospective diagnosis. However, this test does not distinguish *C. pneumoniae* infection from infection due to *C. trachomatis* or *C. psittaci*. Although controlled treatment trials have not been conducted, *C. pneumoniae* is inhibited in vitro by erythromycin and tetracycline. Recommended therapy consists of 2 g per day of either agent for 10 to 14 days. Other macrolides, such as azithromycin, and some fluoroquinolones, such as levofloxacin, also appear to be effective.

SECTION 11 -VIRAL DISEASES

180. MEDICAL VIROLOGY - *Fred Wang*, *Elliott Kieff*

DEFINING A VIRUS

Viruses consist of a nucleic acid surrounded by one or more proteins. Some viruses also have an outer-membrane envelope. Viruses differ from other replicating organisms in that they do not have ribosomes or enzymes for high-energy phosphate generation or for protein, carbohydrate, or lipid metabolism. Viruses are obligate intracellular parasites -- that is, they require cells in order to replicate. Typically, viral nucleic acids encode proteins necessary for replicating and packaging the nucleic acids into new viral particles.

Viruses differ from viroids, prions, and virusoids. *Virusoids* are nucleic acids that depend on helper viruses to package the nucleic acids into virus-like particles. *Viroids* are simply molecules of naked, cyclical, mostly double-stranded, small RNAs and appear to be restricted to plants, in which they spread from cell to cell and are replicated by cellular RNA polymerase II. *Prions* (Chap. 375) are protein molecules that can spread from cell to cell and effect changes in the structure of their normal counterparts (cellular proteins). Prions have been implicated in neurodegenerative conditions such as Creutzfeldt-Jakob disease, kuru, and Gerstmann-Straussler disease. Prions have also been implicated in neurodegeneration associated with human infection with bovine spongiform encephalopathy ("mad cow disease").

VIRAL STRUCTURE

Viruses have from a few to 200 genes. These genes may be embodied in a single-strand or double-strand DNA genome or in a single-strand sense, a single-strand or segmented antisense, or a double-strand segmented RNA genome. Sense-strand RNA genomes can be translated directly into protein. Sense and antisense genomes are also referred to as positive-strand and negative-strand genomes, respectively. The viral nucleic acid is usually associated with one or more virus-encoded nucleoproteins in the core of the viral particle. The viral nucleic acid is almost always enclosed in a protein shell called a *capsid*. Because of the limited genetic complexity of viruses, their capsids are usually composed of multimers of identical capsomers. Capsomers are in turn composed of one or a few proteins. Capsids have icosahedral or helical symmetry. Icosahedral structures approximate spheres but have two-, three-, and fivefold axes of symmetry, while helical structures have only a twofold axis of symmetry. The entire structural unit of nucleic acid, nucleoprotein(s), and capsid is called a *nucleocapsid*. Many human viruses have a simple nucleocapsid structure. For these viruses, the outer surface of the capsid mediates contact with uninfected cells. Other viruses are more complex and have an outer envelope that is derived from membranes of the infected cell. The piece of infected cell membrane that becomes the viral envelope has usually been modified during infection by the insertion of virus-encoded glycoproteins. These glycoproteins usually mediate contact of enveloped viruses with uninfected cells. Enveloped viruses frequently have matrix or tegument proteins that fill the space between the nucleocapsid and the envelope. In general, enveloped viruses are sensitive to solvents and nonionic detergents that can disrupt the envelope, while viruses that

consist only of nucleocapsids are usually more resistant. The schematic diagram of a large and complex herpesvirus shown in Fig. 180-1 illustrates the components of a complicated DNA virus. Prototypical pathogenic human viruses are listed in Table 180-1. The relative sizes and structures of typical pathogenic human viruses are shown in Fig. 180-2.

TAXONOMY OF PATHOGENIC HUMAN VIRUSES

As is apparent from Table 180-1 and Fig. 180-2, the classification of viruses into orders and families is based on nucleic acid composition, nucleocapsid size and symmetry, and envelopment status. Viruses of a single family have similar types of genomes and are morphologically similar in electron micrographs. Further subclassification into genus is dependent on similarities in epidemiology and biologic effects and on the degree of colinear nucleic acid sequence homology. In general, each human virus has a common name related to its pathologic effects or the circumstances of its discovery and a formal species name assigned by the International Committee on Taxonomy of Viruses. The latter designation consists of the name of the host followed by the family or genus of the virus and a number. This dual terminology has created a confusing situation in which viruses are referred to and referenced by either name -- e.g., varicella-zoster virus (VZV) or human herpesvirus (HHV) 3.

VIRAL INFECTION IN VITRO

STAGES OF INFECTION

At the cellular level, viral infection proceeds in stages.

Viral Interactions at the Cell Surface First, virus adsorbs to a receptor on the cell surface. Adsorption is the consequence of a molecular interaction of a viral surface protein with a molecule on the cell's plasma membrane. For example, a poliovirus capsid protein binds to a cell plasma-membrane protein of the immunoglobulin superfamily type; a rhinovirus capsid protein binds to intracellular adhesion molecule 1; an echovirus capsid protein binds to an integrin; the influenza A virus envelope hemagglutinin protein binds to sialic acid; the HIV envelope glycoprotein binds to CD4 and then engages one of several chemokine receptors that function as coreceptors for the virus; the herpes simplex virus (HSV) envelope glycoproteins bind to heparan sulfate on cell surfaces and then engage one of several immunoglobulin superfamily or tumor necrosis factor (TNF) receptors; and an Epstein-Barr virus (EBV) glycoprotein binds to the B lymphocyte complement receptor CD21. Adsorption characteristically proceeds almost as well at 4°C as at 37°C, and adsorbed virus can still be neutralized by antibody. Adsorption frequently initiates changes in virion surface proteins that result in destabilization and preparation for the next stage of entry into the cell.

After adsorption, viruses penetrate through or fuse with the cell membrane, lose their sensitivity to neutralizing antibody, and become uncoated as they enter the cytoplasm. For all viruses, penetration and uncoating result in viral nucleocapsid or nucleoprotein entry into the cytoplasm. Penetration and uncoating as well as subsequent steps in viral replication depend on the cell's energy metabolism and on biochemical changes in the cell's plasma membrane and cytoskeleton. Therefore, penetration proceeds slowly at

temperatures<37°C. Viruses use various strategies to penetrate and enter cells. Interaction of the viral surface protein with a cellular receptor can induce changes in viral glycoproteins or capsid proteins and in cell-surface proteins, with consequent penetration. The interaction of multiple protein molecules on the viral surface with multiple molecules on the cell-surface receptor may induce receptor aggregation at the site of viral adsorption. Receptor aggregation can trigger signaling events within the cytoplasm and changes in the plasma membrane. The cell frequently misperceives that the receptor has encountered its "normal ligand," and the aggregated receptor is internalized with the attached virus through an endocytic process that involves clathrin-coated pits. Endocytosis is important in the entry of viruses as diverse as picornaviruses, influenza viruses, HIV, adenoviruses, and herpesviruses. In many cases, entry of the virus into the cytoplasm depends on acidification of the viral endosome.

One of the best-studied examples of the effect of low pH on viral penetration is influenza virus. Influenza hemagglutinin mediates adsorption, receptor aggregation, and endocytosis. In low-pH endosomes, changes in the conformation of the hemagglutinin expose amphipathic domains that interact chemically with the cell membrane and initiate fusion of the viral and cellular membranes. Data indicate that the HIV envelope glycoprotein undergoes similar conformational changes after interaction with CD4 and chemokine receptors. For influenza virus, the M2 membrane protein also plays a key role in the uncoating of the viral envelope by providing an ion channel in the envelope. Fusion of viral and cell membranes results in the mixture of viral envelope lipids and proteins with cell membrane lipids and proteins and the penetration of the influenza nucleocapsid into the cytoplasm. Little is known about the details of the fusion processes or the subsequent biochemical interactions. With more complex viruses, such as herpesviruses, different glycoproteins interact with different receptors on different cell types or on different surfaces of polarized epithelial cells. Viral glycoproteins other than the protein that mediates initial adsorption may be critical in mediating envelope fusion with cell membranes.

Viral Gene Expression and Replication After uncoating and release of viral nucleoprotein into the cytoplasm, the viral genome is transported to a site for expression and replication. In order to produce infectious progeny, viruses must (1) replicate their nucleic acid, (2) produce structural proteins, and (3) assemble the nucleic acid and proteins into progeny virions. Different viruses use different strategies and gene repertoires to accomplish these goals. DNA viruses (except for poxviruses) replicate their nucleic acid and assemble into nucleocapsid complexes in the cell nucleus. RNA viruses (except for influenza viruses) transcribe and replicate their nucleic acid and assemble entirely in the cytoplasm. Thus, the replication strategies of DNA and RNA viruses are presented separately below. Positive-strand and negative-strand RNA viruses are discussed separately. Medically important viruses of each group are used for illustrative purposes.

Positive-Strand RNA Viruses Medically important positive-strand RNA viruses include picornaviruses, flaviviruses, togaviruses, and caliciviruses. Genomic RNA from positive-strand RNA viruses is released into the cytoplasm without associated enzymes. Cell ribosomes recognize and associate with an internal ribosome entry sequence in the viral genomic RNA and translate a polyprotein that is a fusion of many or all of the viral

proteins. The viral RNA polymerase and other viral proteins are cleaved from the polyprotein by protease components of the polyprotein. Antigenomic RNA is then transcribed from the genomic RNA template. Positive-strand genomes and mRNAs are next transcribed from the antigenomic RNA by the viral RNA polymerase. Positive-strand genomic RNA is encapsidated in the cytoplasm.

Negative-Strand RNA Viruses Medically important negative-strand RNA viruses include rhabdoviruses, filoviruses, paramyxoviruses, and bunyaviruses. Negative-strand RNA virus genomes are released into the cytoplasm with an associated RNA polymerase and one or more accessory proteins. Except for influenza viruses, negative-strand RNA viruses replicate entirely in the cytoplasm. The viral RNA polymerase transcribes messenger RNAs (mRNAs) as well as full-length antigenomic RNA, which is the template for replication of genomic RNA. The mRNAs encode for RNA polymerase and accessory factors as well as for viral structural proteins. Influenza virus is an unusual negative-strand RNA virus that transcribes its mRNAs and antigenomic RNAs in the cell's nucleus. The influenza genome RNA snatches cellular mRNA cap sequences to enhance translation of viral mRNAs and uses cell splicing machinery to encode additional viral mRNAs. All negative-strand RNA viruses, including influenza viruses, assemble in the cytoplasm.

Double-Strand Segmented RNA Viruses These viruses, which are taxonomically grouped in the reovirus family, have 10 to 12 RNA segments that make up their genome. The medically important viruses in this group are rotaviruses and Colorado tick fever virus. Reovirus virions include an RNA polymerase complex. Reoviruses replicate and assemble in the cytoplasm.

DNA Viruses Medically important DNA viruses include parvoviruses, papovaviruses, human papillomaviruses (HPVs), adenoviruses, herpesviruses, and poxviruses. Other than poxviruses, most DNA viruses must get to the cell's nucleus for DNA transcription by cellular RNA polymerase II. For example, after receptor binding and fusion, herpesvirus nucleocapsids are released into the cytoplasm along with tegument proteins. The complex is then transported along microtubules to nuclear pores, and the DNA is released into the nucleus.

Transcriptional regulation and mRNA processing for nuclear DNA viruses depend on both viral and cellular proteins. For herpesviruses, the viral tegument protein can activate transcription of viral immediate-early genes, a class of genes expressed immediately after infection. Transcription of immediate-early genes requires the virus tegument protein and preexisting cellular transcription factors. One of the key preexisting cellular factors forHSV-1 immediate-early gene transcription is docked in the cytoplasm in neurons; this fact may explain why HSV-1 goes into a latent state in neurons.

Transcription is often regulated into an organized cascade of viral gene expression. Herpesvirus immediate-early genes turn on the promoters for early genes. Other DNA viruses are not as dependent on transactivators encoded from the viral genome for early-gene transcription. Most early genes encode proteins that are necessary for viral DNA synthesis and for the turn-on of late-gene transcription. Late genes encode mostly viral structural proteins or viral proteins necessary for the assembly and egress of the

virus from the infected cell. Late-gene transcription is continuously dependent on DNA replication. Therefore, inhibitors of DNA replication also stop late-gene transcription.

Each DNA virus family uses unique mechanisms for replicating its DNA. Herpesvirus DNAs are linear in the virion but circularize in the infected cell. In lytic virus infection, circular herpesvirus genomes are replicated into linear concatemers through a "rolling-circle" mechanism. Herpesviruses encode a DNA polymerase and at least six other viral proteins necessary for viral DNA replication; these viruses also encode several enzymes that increase the pool of precursor deoxynucleotide triphosphates. Adenovirus genomes are linear in the virion and are replicated into complementary linear copies by a virus-encoded DNA polymerase and an initiator protein complex. The double-strand circular papovavirus genomes are replicated into progeny circular DNA molecules by cellular DNA replication enzymes. Two viral early proteins contribute to viral DNA replication and to the persistence of papovavirus DNA in latently infected cells. Other early papovavirus proteins stimulate cells to remain in cycle, thus facilitating viral DNA replication. Occasionally,HPVsintegrate into the host chromosome; overexpression of viral early proteins and excessive stimulation of cellular growth result. Sometimes the consequence is the development of malignancies such as cervical cancer (see "Persistent Viral Infections and Cancer," below). Parvoviruses are the smallest DNA viruses: their genomes are half the size of the papovavirus genomes and include only two genes. Parvoviruses have negative single-strand DNA genomes. The replication of autonomous parvoviruses, such as B19, depends on cellular DNA replication and requires the virus-encoded Rep protein. Other parvoviruses, such as adeno-associated virus (AAV), are not autonomous and require helper viruses of the adenovirus or herpesvirus family for their replication. AAV has been touted as a potentially safe human gene vector because its Rep protein causes its integration at a single chromosomal site.

Poxviruses are the largest DNA viruses and are unique among these viruses in replicating and assembling in the cytoplasm. Poxviruses encode transcription factors and an RNA polymerase as well as enzymes for RNA capping and polyadenylation and for DNA synthesis. Poxvirus DNA also has a unique structure. The two strands of the double-strand linear DNA are covalently linked at the ends so that the genome is also a covalently closed single-strand circle. In addition, there are inverted repeats at the ends of the DNA. During DNA replication, the genome is cleaved within the terminal inverted repeat, and the inverted repeats self-prime complementary-strand synthesis by the virus-encoded DNA polymerase. Like herpesviruses, poxviruses encode several enzymes that increase deoxynucleotide triphosphate precursor levels and thus facilitate viral DNA synthesis.

Viruses with Both RNA and DNA Genomes Retroviruses, lentiviruses, and hepatitis B virus (HBV) are not purely RNA or DNA viruses.

Retroviruses and lentiviruses are enveloped RNA viruses with two identical sense-strand genomes and associated reverse transcriptase and integrase enzymes. Retroviruses and lentiviruses differ from all other viruses in that they reverse-transcribe themselves into partially duplicated double-strand DNA copies and then routinely integrate into the host genome as part of their replication strategy. Cellular RNA polymerase II and transcription factors regulate transcription from the integrated

provirus genome. Some retroviruses also encode for regulators of transcription and RNA processing, such as Tax and Rex in the human T-lymphotropic virus (HTLV) types I and II and Tat and Rev in HIV-1 and HIV-2. Full-length proviral transcripts are made from a promoter in the viral terminal repeat and serve as both genomic RNAs that will be packaged in the nucleocapsids and mRNAs that encode for the viral Gag protein, polymerase/integrase protein, and envelope glycoprotein. The Gag protein includes a protease that cleaves it into several components, including a viral matrix protein that coats the viral RNA. Viral RNA polymerase/integrase, matrix protein, and cellular tRNA are key components of the viral nucleocapsid. The HIV Gag protease has been an important target for inhibition of HIV replication. Remnants of simple retroviral DNA in the human genome suggest that there may be replication-competent simple human retroviruses, but little other evidence supports the existence of these viruses.

HBVreplication is unique because the virus encodes and packages in the virion a reverse transcriptase and genomic RNA, which is then copied into an incomplete double-strand circular DNA genome before the virion matures in the infected cell. On entry into the cytoplasm, the virion reverse transcriptase/DNA polymerase completes DNA synthesis, and the covalently closed circular genome resides in the nucleus. Viral mRNAs are transcribed from the closed circular viral episome by cellular RNA polymerase II. A capped and polyadenylated, full-genome-length, terminally redundant transcript is packaged into virus core particles in the cytoplasm of infected cells. This RNA associates with the viral reverse transcriptase. The reverse transcriptase converts the full-length, terminally redundant, core-particle, encapsidated RNA genome into partially double-strand DNA. HBV is believed to mature by budding through the cell's plasma membrane, which has been modified by the insertion of viral surface antigen protein.

Viral Assembly and Egress For most viruses, nucleic acid and structural protein synthesis are accompanied by the assembly of protein and nucleic acid complexes. The assembly and egress of mature infectious virus mark the end of the eclipse phase of infection, during which infectious virus cannot be recovered from the infected cell. Nucleic acids from RNA viruses and poxviruses assemble into nucleocapsids in the cytoplasm. For all DNA viruses except poxviruses, viral DNA assembles into nucleocapsids in the nucleus. In general, the capsid proteins of viruses with icosahedral nucleocapsids can self-assemble into densely packed and highly ordered capsid structures. Herpesviruses require an assemblin protein as a scaffold for capsid assembly. Viral nucleic acid then spools into the assembled capsid. For herpesviruses, a full unit of the viral DNA genome is packaged into the capsid, and a capsid-associated nuclease cleaves the viral DNA at both ends. In the case of viruses with helical nucleocapsids, the protein component appears to assemble around the nucleic acid, which contributes to capsid organization.

Viruses must egress from the infected cell and not bind back to its plasma membrane. In many cases, enveloped viruses simply egress and acquire their envelope by budding through the cell's plasma membrane. Excess viral membrane glycoproteins are synthesized to saturate cell receptors and facilitate viral egress. Some viruses encode membrane proteins with enzymatic activity for receptor destruction. Influenza virus, for example, encodes a glycoprotein with neuraminidase activity, which destroys sialic acid on the infected cell's plasma membrane. Herpesvirus nucleocapsids acquire their initial

envelope by assembling in the nucleus and then budding through the nuclear membrane into the endoplasmic reticular space. The enveloped herpesvirus is then released from the cell either by maturation in cytoplasmic vesicles, which fuse with the plasma membrane and release the virus by exocytosis, or by "de-envelopment" into the cytoplasm and "re-envelopment" at the plasma membrane. In most instances, nonenveloped viruses appear to depend on the death and dissolution of the infected cell for their release.

FIDELITY OF VIRAL REPLICATION

Cells grow by doubling their genome and dividing, whereas viruses typically make large quantities of viral nucleic acid and structural proteins, and thousands of progeny may be produced from a single infected cell. Many particles partially assemble and never mature into virions. Many mature-appearing virions are imperfect and have only incomplete or nonfunctional genomes. Despite the inefficiency of assembly, a typical virus-infected cell releases 10 to 1000 infectious progeny. Some of these progeny may contain genomes that differ from those of the virus that infected the cell. Smaller, "defective" virus genomes have been noted with the replication of many RNA and DNA viruses. Virions with defective genomes can be produced in large numbers through packaging of incompletely synthesized nucleic acid. Adenovirus packaging is notoriously inefficient, and a high particle-to-infectious virus ratio may limit the amount of recombinant adenovirus that can be administered for gene therapy. Mutant viral genomes are also produced and can be of medical significance. In general, viral nucleic acid replication is more error-prone than cellular nucleic acid replication. RNA polymerases and reverse transcriptases are intrinsically more error-prone than DNA polymerases. Mutant viruses can be virulent and may preferentially cause disease through evasion of the host immune response or through resistance to antiviral drugs. Persistent hepatitis C virus (HCV) infection appears to be due to genome mutation and persistent immune escape. Changes in viral nucleic acid can also take place through infection by and recombination or reassortment between two related viruses in a single cell. While this occurrence is highly unusual, the changes could be substantial and could significantly alter virulence or epidemiology. Reassortment of an avian or mammalian influenza A hemagglutinin gene into a human influenza background is believed to play a role in the emergence of new epidemic influenza A strains.

VIRAL GENES NOT REQUIRED FOR VIRAL REPLICATION

Viruses frequently have genes encoding proteins that are not directly involved in replication or packaging of the viral nucleic acid, in virion assembly, or in regulation of the transcription of viral genes involved in those processes. Most of these proteins fall into four classes: (1) proteins that directly or indirectly alter cell growth; (2) proteins that inhibit cellular DNA, RNA, or protein synthesis so that viral mRNA can be efficiently transcribed or translated; (3) proteins that promote the cell's survival or inhibit apoptosis so that progeny virus can mature and escape from the infected cell; and (4) proteins that downregulate host inflammatory or immune responses so that virus infection can proceed in an infected person to the maximum extent consistent with virus survival and efficient transmission to a new host. More complex viruses of the poxvirus or herpesvirus family encode many proteins that serve these functions. Some of these viral proteins have motifs similar to those of cell proteins, while others are quite novel.

Virology has increasingly focused on these more sophisticated strategies evolved by viruses to permit the establishment of long-term infection in humans and other animals. These strategies often provide unique insights into the control of cell growth, cell survival, macromolecular synthesis, proteolytic processing, immune or inflammatory suppression, immune resistance, cytokine mimicry, or cytokine blockade.

HOST RANGE

The concept of host range was originally based on the cell types in which a virus replicated in tissue culture. For the most part, the host range is limited by specific cell-surface proteins required for viral adsorption or penetration. Another common basis for host-range limitation is transcription from viral promoters. Most DNA viruses depend not only on cellular RNA polymerase II and the basal components of the cellular transcription complex but also on activated components and transcriptional accessory factors, both of which differ among differentiated tissues, among cells at various phases of the cell cycle, and between resting and cycling cells.

The concept of host range for virus infection in humans includes these factors and others since (1) most viruses infect more than one cell type in vivo and (2) the virus life cycle and extent of viral replication can be affected by the differentiation and activated state of a given cell type. This point is particularly relevant for human papovavirus, herpesvirus, and lentivirus infections, in which vigorous replication during initial infection may be followed by quiescent or latent infection -- a situation that allows the virus to persist.

VIRAL CYTOPATHIC EFFECTS AND INHIBITORS OF APOPTOSIS

The replication of almost all viruses has adverse effects on the infected cell, inhibiting cellular synthesis of DNA, RNA, or proteins. This inhibitory effect probably stems from the viruses' need to prevent or limit nonspecific, innate host resistance factors, including interferon (IFN). Most commonly, viruses specifically inhibit host protein synthesis by attacking a component of the translational initiation complex -- frequently, a component that is not required for efficient translation of viral RNAs. Poliovirus protease 2A, for example, cleaves a cellular component of the complex that ordinarily facilitates translation of cell mRNAs by interacting with their 5¢ cap structure. Poliovirus RNA is efficiently translated without a 5¢ cap since it has an internal ribosome entry sequence. Influenza virus inhibits the processing of mRNA by snatching 5¢ cap structures from nascent cellular RNAs and using them as primers in the synthesis of viral mRNA.HSV has a virion tegument protein that inhibits cellular mRNA translation.

Apoptosis is the expected consequence of virus-induced inhibition of cellular macromolecular synthesis and viral nucleic acid replication. While the induction of apoptosis may be important for the release of some viruses (particularly nonenveloped viruses), many viruses have acquired genes or parts of genes that enable them to forestall infected-cell apoptosis. This delay may be advantageous in allowing the completion of viral replication. Adenoviruses and herpesviruses encode analogues of the cellular Bc12 protein, which blocks mitochondrial enhancement of proapoptotic stimuli. Poxviruses and some herpesviruses encode caspase inhibitors. Many viruses, includingHPVs and adenoviruses, encode proteins that inhibit p53 or its downstream

proapoptotic effects.

VIRAL INFECTION IN VIVO

The capsid and envelope of a virus protect its genome and permit its transmission from cell to cell and to prospective hosts. Most common viral infections are spread by aerosolized particles, by ingestion of contaminated water or food, or by direct contact. In all these situations, infection begins on an epithelial or mucosal surface and spreads along it or from it to deeper tissues. Infection may then spread through the body via the bloodstream, lymphatics, or neural circuits. Parenteral inoculation also serves to transmit some viral infections among humans or from animals (including insects) to humans.

PRIMARY INFECTION

The first (primary) episode of viral infection usually lasts from several days to several weeks. During this period, the concentration of virus at sites of infection rises and then falls, usually to unmeasurable levels. The rate at which the intensity of viral infection rises and falls at a given site depends on the accessibility of that organ or tissue to both the virus and systemic immune effectors, the intrinsic ability of the virus to replicate at that site, and endogenous nonspecific and specific resistance. Typically, infections with enterovirus, mumps virus, measles virus, rubella virus, rotavirus, influenza virus, adenovirus,HSV, andVZV are cleared from almost all sites within 3 to 4 weeks. Some of these viruses are especially proficient in altering or evading the innate and acquired immune responses; thus primary infection with these viruses can last for several months. Characteristically extending beyond several weeks are primary infections due toHBV,HCV, hepatitis D virus (HDV),EBV, cytomegalovirus (CMV), HIV,HPV, and molluscum contagiosum virus. For some of these viruses (e.g., HPV, HBV, HCV, HDV, and molluscum contagiosum virus), the primary phase of infection is almost indistinguishable from the persistent phase.

Disease manifestations usually arise as a consequence of viral replication at a specific site but do not necessarily correlate with levels of replication at that site. For example, the clinical manifestations of limited infection with poliovirus, enterovirus, rabies virus, measles virus, mumps virus, orHSV in neural cells are severe relative to the level of viral replication at mucosal surfaces. Similarly, significant morbidity may accompany in utero fetal infection with rubella virus orCMV.

Primary infections are cleared by specific and nonspecific immune responses. Thereafter, an immunocompetent host is usually immune to the disease manifestations of reinfection by the same virus. Immunity may not prevent transient surface colonization on reexposure, or even persistent colonization.

PERSISTENT AND LATENT INFECTIONS

Relatively few viruses cause persistent or latent infections.HBV,HCV, rabies virus, measles virus, HIV,HTLV,HPV, herpesviruses, and some poxviruses are notable exceptions. The mechanisms for persistent infection vary widely. In persistent HCV infection and to a lesser extent in HIV infection, the high mutation rates in viral genome

replication significantly facilitate persistent infection, continuously yielding mutant viruses that have lost antigenic determinants to which the host has developed effective immune responses. HIV is directly immunosuppressive, depleting CD4+ T lymphocytes and compromising CD8+ cytotoxic T cell immune responsiveness. Moreover, HIV encodes a Nef protein that downmodulates major histocompatibility complex (MHC) class I expression, rendering HIV-infected cells partially resistant to immune CD8+ cytolysis. The high mutation rate and the magnitude of virus load conspire to promote persistent infection with drug-resistant HIV mutants.

In contrast, herpesviruses and papovaviruses have much lower mutation rates. Their persistence is due to their ability to establish latent infection and to reactivate from latency. In this instance, *latency* is defined as a state of infection with a full viral genome replicated by cellular DNA polymerase in conjunction with the cell genome; there is no expression of viral genes associated with lytic infection and therefore no production of infectious virus. ForHPVs, latently infected basal epithelial cells replicate. Some of the progeny cells provide a stable supply of latently infected basal cells, while others go on to squamous differentiation and in the process become permissive for lytic virus infection. For herpesviruses, latent infection is established in nonreplicating neural cells (HSV andVZV) and in replicating cells of early hematopoietic lineages [EBV and probablyCMV,HHV-6, HHV-7, and Kaposi's sarcoma-associated herpesvirus (KSHV, also known as HHV-8)]. Reactivation from neural latency appears to be an intermittent process provoked by external stimuli, whereas reactivation from hematopoietic precursors appears to be a more continuous process. In their latent stage, HPV and herpesvirus genomes are hidden from the normal immune response. It is still not fully understood how latent and reactivated HPV and herpesvirus infections escape immediate and effective immune responses in highly immune hosts. HPV, HSV, and VZV may be somewhat protected because of their replication in middle and upper layers of the squamous epithelium. HSV and CMV are also known to encode proteins that downregulateMHCclass I expression and antigenic peptide presentation on infected cells, thereby enabling these cells to escape CD8+ T lymphocyte cytotoxicity. Latent infection and intermittent reactivation perpetuate HPV and herpesvirus infections in human populations by allowing the viruses to persist in immune hosts and to be transmitted to the next generation of naive hosts.

Like other poxviruses, molluscum contagiosum virus cannot establish latent infection but rather causes persistent infection in hypertrophic lesions that last for months or years. This virus encodes a chemokine homologue that probably blocks inflammatory responses and anMHCclass I analogue that may block cytotoxic T lymphocyte attack.

PERSISTENT VIRAL INFECTIONS AND CANCER

Persistent viral infection is estimated to be the root cause of as many as 20% of human malignancies. For the most part, cancer is an accidental and highly unusual or long-term effect of infection with oncogenic human viruses. In these malignancies, viral infection is a critical and ultimately determinative early step, and an unusual virus-infected cell undergoes the subsequent genetic changes that permit the enhanced autonomous growth and survival characteristic of a malignant cell. Most hepatocellular carcinoma is now believed to be caused by chronic inflammatory, immune, and regenerative responses toHBV orHCVinfection. Epidemiologic data firmly link HBV and HCV infection

to hepatocellular carcinoma, and studies in murine experimental models indicate that chronic liver injury and repair induced by virus-encoded proteins can result in hepatocellular cancer. In rare instances, HBV DNA integrates into cellular DNA -- an event that probably contributes to the development of some tumors.

Almost all cervical carcinoma is caused by long-term persistent replication of "high-risk" genitalHPVstrains. An infrequent consequence of persistent HPV replication is the integration of a small fragment of the HPV genome encoding the HPV E6 and E7 proteins into chromosomal DNA. Overexpression of these proteins of HPV type 16 or 18 eliminates at least two major tumor-suppressive mechanisms in the infected cell and causes profound changes in cellular growth and survival. Nevertheless, subsequent chromosomal changes must occur over ensuing cycles of cell growth if a sufficiently malignant cell is to invade the surrounding tissues.

Similarly, long-termEBVinfection and expression of the EBV oncogene LMP1 in a clone of latently infected epithelial cells appears to be a critical early step in the evolution of anaplastic nasopharyngeal carcinoma, a common malignancy in Chinese and North African populations. High-level LMP1 expression is a hallmark of many cases of Hodgkin's disease. Among younger age groups, >50% of Hodgkin's disease tumors are clonally derived from an EBV-infected cell. TheHTLV-I Tax and Rex proteins appear to be critical to the initiation of cutaneous adult T cell lymphoma/leukemias that may occur long after primary HTLV-I infection.

A newEBV-related herpesvirus,KSHV, was identified in a search for the postulated sexually transmitted etiologic agent of Kaposi's sarcoma in HIV-infected individuals. Molecular data confirm the presence of KSHV DNA in all Kaposi's tumors, including those associated with HIV infection, transplantation, and familial transmission.

Evidence supporting a causal role of viral infection in these malignancies includes epidemiologic data, the presence of viral DNA in all tumor cells, the ability of the viruses to transform human cells in culture, the results of in vitro assays for transforming effects of specific viral genes on cell growth, and pathologic data indicating the expression of transforming viral genes in premalignant or malignant cells in vivo.

EBVis a unique example of a human virus that relies on the normal immune response to contain the potentially unrestrained growth of infected B lymphocytes. In the initial stages of normal primary EBV infection, EBV "latently" infects B lymphocytes and expresses at least eight viral proteins that cause continuous cell proliferation. The infected cells grow indefinitely in vitro or in T cell-deficient mice. Most of the viral proteins are highly antigenic, and these virus-infected cells, which can transiently constitute 10% of the circulating B lymphocyte population, are met with an overwhelming helper and cytotoxic T cell response during primary infection. The number of virus-infected cells then falls rapidly, and the one EBV-infected cell in a million that persists does not express most of the viral proteins that cause B cell proliferation. These persisting cells are the site of normal latent infection. Breakthrough growth of the EBV-infected B lymphocytes almost never occurs in immunocompetent hosts. However, in immunosuppressed AIDS patients or organ transplant recipients, EBV-infected B lymphocytes expressing the full set of growth-transforming genes may grow, uncontrolled by the immune system, and cause self-sustained and potentially fatal

lymphoproliferative disease. Clinical investigation has resulted in novel strategies for treating these virus-induced malignancies by increasing T cell responsiveness through ex vivo expansion and readministration of EBV-specific T cells and by attacking the proliferating B cells with antibody coupled to toxins.

RESISTANCE TO VIRAL INFECTIONS

Resistance to viral infection is initially provided by factors that are not virus-specific. Physical protection is afforded by the cornified layers of the skin and by mucous secretions that continuously sweep over mucosal surfaces. Once the first cell is infected, viral infection inducesIFNs, which are important local resistance factors. Viral infection may also cause the release of other cytokines from infected cells. Viral protein epitopes expressed on the cell surface in the context ofMHCclass I and II HLA proteins attract T cells with appropriate receptors. Cytokines, inflammatory agents, and antigens released by virus-induced cell death attract inflammatory cells, dendritic cells, granulocytes, natural killer (NK) cells, and B lymphocytes to the sites of initial infection. IFNs and NK cells are particularly important in containing viral infection for the first several days. Granulocytes and macrophages are also important in the phagocytosis and degradation of viruses, especially after an initial antibody response.

Some 7 to 10 days after infection, virus-specific antibody responses, virus-specific HLA class II-restricted CD4+ helper T lymphocyte responses, and virus-specific HLA class I-restricted CD8+ cytotoxic T lymphocyte responses are detected. These responses, whose magnitude typically increases over the second and third weeks of infection, are important in rapid recovery. Between the second and third weeks of infection, the antibody type usually changes from IgM to IgG, and IgA antibody is detected at initially infected mucosal surfaces. Antibody may directly neutralize virus by binding to its surface and preventing its adsorption or penetration. Complement usually enhances virus neutralization. Antibody and complement can also lyse virus-infected cells that express viral proteins on their surface. A cell infected with an enveloped virus usually expresses viral envelope glycoprotein components on its surface and is thus rendered subject to destruction by antibodies and complement.

The antibody and CD4+/CD8+ T lymphocyte responses tend to persist for several months after primary infection. Antibody-producing lymphocytes persist in small numbers as memory cells and begin to proliferate rapidly in response to a second infection, providing an early barrier to reinfection with the same virus. Immunologic memory for T cell responses appears to be less long-lived, and redevelopment of T cell immunity may take longer than secondary antibody responses, particularly when many years have elapsed between primary infection and reexposure.

Some viruses have genes that alter innate and acquired host defenses. Adenoviruses encode small RNAs that inhibitIFNshutoff of infected-cell protein synthesis. Adenovirus E1A inhibits IFN-mediated changes in cell gene transcription. Adenovirus E3 proteins preventTNF-induced cytolysis and block HLA class I antigen synthesis by the infected cell.HSVICP47 andCMV US11 block class I antigen presentation.EBVencodes an interleukin (IL) 10 homologue that inhibitsNK and T cell responses. Vaccinia virus B15R is an IL-1 receptor decoy. Vaccinia virus B8R is a soluble TNF receptor that blocks the effects of TNF. Vaccinia virus CrmA inhibits the ability of CD8+ cytotoxic cells to kill

virus-infected cells. Some poxviruses and herpesviruses encode blockers of chemokines and thereby inhibit cellular inflammatory responses. The adoption of these strategies by viruses highlights the importance of these host resistance factors in containing viral infection as well as that of redundancy in host resistance. The ultimate success of a virus requires a live host to help it disseminate.

Much has been written about the role of specific aspects of the host immune response in containment of specific virus infections. Certainly, T lymphocyte disorders are associated with severe primary and reactivated herpesvirus infections, and antibody responses are important in resistance to many RNA virus infections. However, antibody responses are also important in resistance to herpesvirus infections, as is exemplified by the utility of immunoglobulin therapy in early amelioration of these infections. T lymphocyte responses play a significant role in resistance to RNA virus infections, as is illustrated by the presence of cytotoxic T cells specific for influenza virus nucleoprotein.

Host resistance does not come without a price. Clearly, aspects of the host response contribute to the pathophysiologic manifestations and symptoms of viral infection. Inflammation at sites of viral infection can increase rates of local cell death. Immune responses to viral infection can target related epitopes on normal cells. While such effects have been demonstrated in experimental models, their role in the autoimmune manifestations of primary or recurrent human viral infections is uncertain.

INTERFERONS

All human cells can synthesizeIFN-aor -b in response to viral infection. The IFN response is usually induced by the presence of double-strand viral RNA, which can be made by both RNA and DNA viruses. IFN-g is not directly related to IFN-a or -b and is produced mainly byNK cells and by immune T lymphocytes responding toIL-12. IFN-a and -b bind to the IFN-a receptor, while IFN-gbinds to a different but related receptor. Both receptors signal through receptor-associated JAK kinases and other cytoplasmic proteins, including "STAT" proteins. These proteins are tyrosine phosphorylated by JAK kinases, translocate to the nucleus, and transactivate promoters for specific cell genes. Three types of antiviral effects are induced by IFN at the transcriptional level. The first effect is attributable to the induction of 2¢-5¢ oligo(A) synthetases, which require double-strand RNA for their activation. Activated synthetase polymerizes oligo(A) and thereby activates RNAse L, which in turn degrades single-strand RNA. The second effect takes place through the induction of PKR, a serine and threonine kinase that is also activated by double-strand RNA. PKR phosphorylates and negatively regulates the translational initiation factor eIF2-a, shutting down protein synthesis in the infected cell. A third effect is initiated through the induction of Mx proteins, a family of GTPases that is particularly important in inhibiting influenza virus and vesicular stomatitis virus replication. None of these IFN effects is directed specifically against the virus; infected-cell RNA and protein synthesis are globally inhibited. IFN probably contributes to the death of the infected cell.

DIAGNOSTIC VIROLOGY

A wide variety of methods are now used to diagnose viral infection, but serology and viral isolation in tissue culture remain the backbone of diagnostic virology. Acute- and

convalescent-phase sera with rising antibody titers to virus-specific antigens and a shift from IgM to IgG antibodies are generally accepted as diagnostic of acute viral infection. Traditionally, virus-specific antibodies have been detected by hemadsorption, hemagglutination, or indirect immunofluorescence. Immunofluorescence assays use fixed virus-infected cells as a target for serum antibodies. Hemadsorption and hemagglutination assays measure the ability of serum antibodies to the hemagglutinin proteins of RNA viruses to inhibit virus-induced adsorption or agglutination. Serologic diagnosis is based on a greater-than-fourfold rise in IgG antibody concentration when acute- and convalescent-phase serum samples are analyzed at the same time. A simultaneous fall in IgM antibody confirms recent primary viral infection. Immunofluorescence, hemadsorption, and hemagglutination assays are labor-intensive and are being replaced by enzyme-linked immunosorbent assays (ELISAs). ELISAs generally use specific viral proteins purified from virus-infected cells or produced by recombinant DNA technology. These viral antigens are attached to a solid phase, where they can be incubated with serum, washed to eliminate nonspecific antibodies, and reacted with an enzyme-linked reagent to detect human IgG or IgM antibody specifically adhering to the viral antigen on the solid phase. The amount of antibody can then be quantitated by the intensity of a color reaction mediated by the linked enzyme. ELISAs can be automated and can have enhanced sensitivity. Western blots measure antibody to multiple viral proteins simultaneously. The proteins are separated by size and transferred to an inert membrane, where they are incubated with serum antibodies. Western blots have an internal specificity control, since the level of reactivity for viral proteins can be compared with that for cellular proteins in the same sample. Western blots are a useful confirmatory test but require individual evaluation and are inherently difficult to quantitate.

Viral isolation in tissue culture is dependent on the infection of susceptible cells and amplification through viral replication in infected cells. Virus growing in tissue culture cells can frequently be identified by its effect under light microscopy. For example,HSVproduces a typical cytopathic effect in rabbit kidney cells within 3 days. Other viral cytopathic effects may not be as diagnostically useful. Identification may require confirmation by staining with virus-specific monoclonal antibodies. Viruses growing in tissue culture can also be identified by hemadsorption, by interference (e.g., rubella virus-infected cells resist lysis by echovirus), or by electron microscopy (assuming that the specimen has altered cell morphology, as observed by ordinary light microscopy).

The efficiency and speed of virus identification can be enhanced by combining short-term culture with immune detection. In assays with "shell vials" of tissue culture cells growing on a coverslip, viral infection can be detected by staining of the culture with a monoclonal antibody to a specific viral protein expressed early in viral replication. Thus, virus-infected cells can be detected within hours or days of inoculation -- before the several rounds of infection that would be required to produce a visible cytopathic effect.

The sensitivity of virus isolation depends on the collection of specimens from the appropriate site and the rapid transport of these specimens in the appropriate medium to the virology laboratory. Rapid transport maintains viral viability and limits bacterial and fungal overgrowth. Lipid-enveloped viruses are generally much more sensitive to

freezing and thawing than nonenveloped viruses. The most appropriate site for culture depends on the pathogenesis of the virus in question. Nasopharyngeal, tracheal, or endobronchial aspirates are most appropriate for the identification of respiratory viruses. Sputum cultures generally are not appropriate because bacterial contamination and viscosity threaten tissue-culture cell viability. Aspirates of vesicular fluid are useful for isolation ofHSV andVZV. Nasopharyngeal aspirates and stool specimens may be useful when the patient has fever and a rash and an enteroviral infection is suspected. Adenoviruses can be cultured from the urine of patients with hemorrhagic cystitis.CMV can frequently be isolated from cultures of urine or buffy coat. Biopsy material can be effectively cultured when viruses infect major organs, as in HSV encephalitis or adenovirus pneumonia. Unlike serology, the isolation of a virus does not establish the time of primary infection. Many viruses persistently or intermittently colonize normal human mucosal surfaces. Saliva is not infrequently positive for herpesviruses, and 1% of normal urine samples are positive for CMV. Isolations from blood, cerebrospinal fluid (CSF), or biopsy specimens are more often diagnostic of significant virus infection.

Another method aimed at increasing the speed of viral diagnosis is direct antigen testing. Virus-infected cells obtained directly from the patient are detected by staining with virus-specific monoclonal antibodies; for example, epithelial cells obtained by nasopharyngeal aspiration can be stained with a variety of monoclonal antibodies to respiratory viruses. The Tzanck preparation used to detect multinucleated giant cells inHSV- orVSV-induced lesions was the predecessor of these direct antigen tests and can be enhanced by the use of HSV- or VZV-specific monoclonal antibodies. Similarly, monoclonal antibodies can be applied to histopathology specimens to identify virus-infected cells.

Advances in nucleic acid technology are revolutionizing diagnostic virology. The speed and sensitivity of tests that directly amplify minute amounts of viral nucleic acids present in specimens mean that detection no longer depends on viable virus and its replication. For example, amplification and detection ofHSVnucleic acids leaking into theCSF of patients with HSV encephalitis can be more sensitive than culture of virus from CSF. The extreme sensitivity of these tests can be a problem, since trivial amounts of contamination can lead to false-positive results. In addition, detection of viral nucleic acids does not necessarily indicate virus-induced disease, especially in cases where viruses (e.g., herpesviruses) can cause persistent asymptomatic infection.

Measurement of the amount of viral RNA or DNA in peripheral blood is becoming an important means for determining which patients are at increased risk for virus-induced disease and for evaluating clinical responses to antiviral chemotherapy. Direct staining withCMV-specific monoclonal antibodies to quantitate virus-infected cells in the peripheral blood or CMV antigenemia can be useful in identifying which immunosuppressed patients may be at risk for CMV-induced disease. New CMV assays using nucleic acid technologies for the same purpose have been approved for clinical use. RNA viral-load measurements by nucleic acid technologies are now routinely used in AIDS patients to evaluate responses to an increasing number of antiviral agents. Viral-load measurements may also be useful for evaluating the treatment of patients withHBV andHCVinfections.

The use of antiviral agents for the treatment of herpesvirus and HIV infections has been

highly effective. However, the emergence of drug-resistant HIV strains in treated patients can limit efficacy in some cases. The increased number of antiviral agents and drug classes with different viral targets has made the identification of drug-resistant viruses clinically relevant, especially for HIV infection. Drug resistance in herpesviruses is a more unusual problem.

Viral genotyping is a new and faster method for the identification of drug-resistant viruses. Rising viral loads despite antiviral chemotherapy may indicate emergence of resistant HIV strains. Resistance to reverse transcriptase or protease inhibitors has been associated with specific mutations in the reverse transcriptase or protease genes. Identification of these mutations by polymerase chain reaction amplification and nucleic acid sequencing can be clinically useful for determining which antiviral agents may still be effective. Genotyping ofHCV may also help identify patients who can benefit from combination chemotherapy.

Viral phenotyping may also be useful for identifying resistant viruses associated with new or unrecognized genetic mutations. These labor-intensive assays are not routinely available, but technical advances and continued evolution of drug-resistant viruses may make these tests more clinically relevant in the near future.

IMMUNIZATION FOR THE PREVENTION OF VIRAL INFECTIONS

Viral vaccines were among the outstanding accomplishments of twentieth-century science. The scourge of smallpox has been eradicated. Poliovirus eradication may soon follow. Rabies and measles can be contained or eliminated. Excess mortality due to influenza virus epidemics can be contained, and the threat of influenza pandemics has decreased. WidespreadHBVvaccination has dramatically lessened the frequency of acute and chronic hepatitis and is expected to lead to a dramatic decrease in the incidence of hepatocellular carcinoma. The ease with which some viruses are attenuated in tissue culture has led to widespread immunization against rubella, measles, mumps, and chickenpox. Recombinant DNA-based strategies will make it possible to prevent severe infections with many other viruses by using purified proteins or genetically engineered live virus vaccines. Unfortunately, there are limits to these prospects. The evolutionary divergence of HIV andHCV, for example, complicates the development of highly effective immunogens for the prevention of infection with these agents. Modestly effective immunogens that incorporate multiple B and T cell epitopes may prove useful for low-level exposures.

181. ANTIVIRAL CHEMOTHERAPY, EXCLUDING ANTIRETROVIRAL DRUGS - *Raphael Dolin*

The development of drugs for antiviral chemotherapy and chemoprophylaxis is a relatively recent but now very active area of biomedical research. Significant progress has been made in recent years on new drugs for several viral infections. Despite these advances, the field of antiviral therapy -- both the number of antiviral drugs and our understanding of their optimal use -- continues to lag behind the field of antibacterial drug treatment, in which more than 60 years of experience have now been accumulated.

The development of antiviral drugs poses several challenges. Viruses replicate intracellularly and often employ host cell enzymes, macromolecules, and organelles for synthesis of viral particles. Therefore, useful antiviral compounds must discriminate between host and viral functions with a high degree of specificity; agents without such selectivity are likely to be too toxic for clinical use.

The development of laboratory assays to assist clinicians in the appropriate use of antiviral drugs is also in its infancy. Phenotypic and genotypic assays for resistance to antiviral drugs are becoming more widely available, and correlations of laboratory results with clinical outcomes in various settings are beginning to be defined. Of particular note has been the development of highly sensitive and specific methods to measure the concentration of virus in blood (*virus load*), which permit direct assessment of the antiviral effect of a given drug regimen in the host. Virus load measurements have been useful in recognizing the risk of disease progression in patients with certain viral infections and in identifying patients in whom antiviral chemotherapy might be of greatest benefit. Like any in vitro laboratory test, these tests yield results that are highly dependent on (and likely to vary with) the laboratory techniques employed.

Information regarding the pharmacokinetics of some antiviral drugs, particularly in diverse clinical settings, is limited. Assays to measure the concentrations of these drugs, especially of their active moieties within cells, are not widely available. Thus, there are relatively few guidelines for adjusting dosages of antiviral agents to maximize antiviral activity and minimize toxicity. Clinical use of antiviral drugs must therefore be accompanied by particular vigilance with regard to unanticipated adverse effects.

Like that of other infections, the course of viral infections is profoundly affected by an interplay of the pathogen with a complex set of host defenses. The presence or absence of preexisting immunity and the ability to mount humoral and/or cell-mediated immune responses are important determinants of the outcome of viral infections. The state of the host's defenses needs to be considered when antiviral agents are utilized or evaluated.

As with any therapy, the optimal use of antiviral compounds requires a specific and timely diagnosis. For some viral infections, such as herpes zoster, the clinical manifestations are so characteristic that a diagnosis can be made on clinical grounds alone. For other viral infections, such as influenza A, epidemiologic information (e.g., the documentation of a community-wide outbreak) can be used to make a presumptive diagnosis with a high degree of accuracy. However, for most other viral infections, including herpes simplex encephalitis, cytomegaloviral infections other than retinitis, and

enteroviral infections, diagnosis on clinical grounds alone cannot be accomplished with certainty. For such infections, rapid viral diagnostic techniques are of great importance. Considerable progress has been made in recent years in the development of such tests, which are now widely available for a number of viral infections.

Despite these complexities, the efficacy of a number of antiviral compounds has been clearly established in rigorously conducted and controlled studies. As summarized inTable 181-1, this chapter reviews the antiviral drugs that are currently approved or are likely to be considered for approval in the near future for use against viral infections other than those caused by HIV. Antiretroviral drugs are reviewed inChap. 309.

ANTIVIRAL DRUGS ACTIVE AGAINST RESPIRATORY INFECTIONS

AMANTADINE AND RIMANTADINE

Amantadine and the closely related compound rimantadine are primary symmetric amines. Their antiviral activity is limited to influenza A viruses, whose replication they inhibit by interfering with the uncoating of virus after infection of the cell. This interference is attributable to the agents' interaction with the influenza A M2 matrix protein, during which the ion channel function of M2 is inhibited. A substitution of a single amino acid in the M2 protein can result in a virus that is resistant to amantadine and rimantadine.

Amantadine and rimantadine have been demonstrated to be effective in the prophylaxis of influenza A in large-scale studies of young adults and in less extensive studies of children and elderly subjects. In such studies, efficacy rates of 55 to 80% in the prevention of influenza-like illness were noted, and even higher rates were reported when virus-specific attack rates were calculated. Amantadine and rimantadine have also been demonstrated to be effective in the treatment of influenza A infection in studies involving predominantly young adults and, to a lesser extent, children. Administration of these compounds within 24 to 72 h after the onset of illness has resulted in a reduction of the duration of signs and symptoms by ~50% from that in a placebo-treated group. The effect on signs and symptoms of illness is superior to that of commonly used antipyretic-analgesics. Only anecdotal reports are available concerning the efficacy of amantadine or rimantadine in the prevention or treatment of complications of influenza (e.g., pneumonia).

Amantadine and rimantadine are available only in oral formulations and are ordinarily administered to adults once or twice daily in a dose of 100 to 200 mg/d. Despite their structural similarities, the pharmacokinetics of the two compounds are different. Amantadine is not metabolized and is excreted almost entirely by the kidney, with a half-life of 12 to 17 h and peak plasma concentrations of 0.4 ug/mL. Rimantadine is extensively metabolized to hydroxylated derivatives and has a half-life of 30 h. Only 30 to 40% of an orally administered dose is recovered in the urine. The peak plasma levels of rimantadine are approximately half those of amantadine, but rimantadine is concentrated in respiratory secretions to a greater extent than amantadine. For prophylaxis, the compounds must be administered daily for the period at risk (i.e., the peak duration of the outbreak). For therapy, amantadine or rimantadine is generally administered for 5 to 7 days.

Although these compounds are generally well tolerated, 5 to 10% of amantadine recipients experience mild central nervous system side effects consisting primarily of dizziness, anxiety, insomnia, and difficulty in concentrating. These effects are rapidly reversible upon cessation of the drug's administration. At a dose of 200 mg/d, rimantadine is better tolerated than amantadine; in a large-scale study of young adults, adverse effects were no more frequent among rimantadine recipients than among placebo recipients. Seizures and worsening of congestive heart failure have also been reported in patients treated with amantadine, although a causal relationship has not been established. The dosage of amantadine should be reduced to £100 mg/d in patients with renal insufficiency [i.e., a creatinine clearance (Cr_{Cl}) rate of <50 mL/min] and in the elderly. A rimantadine dose of 100 mg/d should be used for patients with a Cr_{Cl} of<10 mL/min and in the elderly. Resistance to amantadine and rimantadine can be induced readily in vitro. The emergence and probable transmission of virus resistant to these drugs have also been noted in vivo after their use for the treatment of children or adults. In the United States, both amantadine and rimantadine are approved for the prophylaxis and treatment of influenza A in adults and for prophylaxis in children. Amantadine is also approved for the treatment of influenza A in children.

RIBAVIRIN

Ribavirin is a synthetic nucleoside analogue that inhibits a wide range of RNA and DNA viruses. The mechanism of action of ribavirin is not completely defined and may be different for different groups of viruses. Ribavirin-5¢-monophosphate blocks the conversion of inosine-5¢-monophosphate to xanthosine-5¢-monophosphate and interferes with the synthesis of guanine nucleotides as well as that of both RNA and DNA. Ribavirin-5¢-monophosphate also inhibits capping of virus-specific messenger RNA in certain viral systems. In studies demonstrating the effectiveness of ribavirin, the compound has been administered as a small-particle aerosol. It has been used to treat respiratory syncytial virus (RSV) infections in infants and -- less extensively -- to treat parainfluenza virus infections in children and influenza A and B virus infections in young adults. In infants with RSV infection who were given ribavirin by continuous aerosol for 3 to 6 days, illness and lower respiratory tract signs resolved more rapidly and arterial oxygen desaturation was less pronounced than in placebo-treated groups. Ribavirin has also had a beneficial clinical effect in infants with RSV infection who require mechanical ventilation. Aerosolized ribavirin has been administered to older children and adults with severe RSV and parainfluenza virus infections (including immunosuppressed patients), but the benefit of this treatment, if any, is unclear. In RSV infections, ribavirin is often given in combination with immunoglobulins.

Orally administered ribavirin has not been effective in the treatment of influenza A virus infections. Intravenous or oral ribavirin has reduced mortality among patients with Lassa fever; it has been particularly effective in this regard when given within the first 6 days of illness. Intravenous ribavirin has been reported to be of clinical benefit in the treatment of hemorrhagic fever with renal syndrome caused by Hantaan virus and as therapy for Argentinian hemorrhagic fever. Moreover, oral ribavirin has been recommended for the treatment and prophylaxis of Congo-Crimean hemorrhagic fever. Intravenous ribavirin is being evaluated as therapy for the hemorrhagic fever with pulmonary syndrome caused by newly described hantaviruses in the United States. Oral administration of ribavirin

reduces serum aminotransferase levels in patients with chronic hepatitis C virus (HCV) infection; since it appears not to reduce serum HCV RNA levels, the mechanism of this effect is unclear. Given in doses of 1000 to 1200 mg/d in combination with interferon (IFN)a (see below), ribavirin has been approved for the treatment of patients with chronic HCV infection.

Large doses of ribavirin administered orally (800 to 1000 mg/d) have been associated with reversible hematopoietic toxicity. This effect has not been observed with aerosolized ribavirin, apparently because little drug is absorbed systemically. Aerosolized administration of ribavirin is generally well tolerated but occasionally is associated with bronchospasm, rash, or conjunctival irritation. Aerosolized ribavirin has been licensed for treatment ofRSVinfection in infants and should be administered under close supervision -- particularly in the setting of mechanical ventilation, where precipitation of the drug is possible. Health care workers exposed to the drug have experienced minor toxicity, including eye and respiratory tract irritation. Because ribavirin is mutagenic, teratogenic, and embryotoxic, its use is generally contraindicated in pregnancy. Its administration as an aerosol poses a risk to pregnant health care workers.

ZANAMIVIR AND OSELTAMIVIR

Influenza viral neuraminidase is essential for release of the virus from infected cells and for its subsequent spread throughout the respiratory tract of the infected host. The enzyme cleaves terminal sialic acid residues, thus destroying the cellular receptors recognized by the viral hemagglutinin. Zanamivir, a sialic acid analogue, is a highly active and specific inhibitor of the neuraminidases of influenza A and B viruses. Oseltamivir is another neuraminidase inhibitor that is a transition-state analogue of sialic acid cleavage. Its antineuraminidase activity is similar to that of zanamivir. Oseltamivir phosphate is an ethyl ester prodrug that is converted to oseltamivir carboxylate by esterases in the liver. Both zanamivir and oseltamivir act through competitive and reversible inhibition of the active site of influenza A and B viral neuraminidases and have relatively little effect on mammalian cell enzymes. As would be expected from their different mechanisms of action, zanamivir and oseltamivir are active against strains of influenza A virus that are resistant to amantadine and rimantadine.

Zanamivir has low oral bioavailability. It is inhaled orally via a hand-held inhaler. By this route, ~15% of the dose is deposited in the lower respiratory tract, and low plasma levels of the drug are detected. Orally administered oseltamivir has an oral bioavailability of >60% and a plasma half-life of 7 to 9 h. The drug is excreted unmetabolized, primarily by the kidney.

Intranasal inhaled zanamivir is generally well tolerated. The most frequent toxicities encountered with orally administered oseltamivir are nausea, gastrointestinal discomfort, and (less commonly) vomiting. Gastrointestinal discomfort is usually transient and is less likely if the drug is administered with food. No serious clinical or laboratory toxicities have yet been reported with zanamivir or oseltamivir in clinical trials.

Inhaled zanamivir and orally administered oseltamivir have been effective in the treatment of naturally occurring influenza A or B in otherwise healthy adults. In

placebo-controlled studies, illness has been shortened by 1 to 1.5 days of therapy with either of these drugs. Once-daily inhaled zanamivir or orally administered oseltamivir provides effective prophylaxis against laboratory-documented influenza A-associated illness. The emergence of viruses resistant to zanamivir or oseltamivir appears to be infrequent in clinical studies carried out thus far.

As of this writing, zanamivir and oseltamivir have been approved by the U.S. Food and Drug Administration (FDA) for treatment of influenza in adults (and -- in the case of zanamivir -- in children³7 years of age) who have been symptomatic for£2 days. Indications for prophylactic use are under review.

ANTIVIRAL DRUGS ACTIVE AGAINST HERPESVIRUS INFECTIONS

ACYCLOVIR AND VALACYCLOVIR

Acyclovir is a highly potent and selective inhibitor of the replication of certain herpesviruses, including herpes simplex virus (HSV) types 1 and 2, varicella-zoster virus (VZV), and Epstein-Barr virus (EBV). It is relatively ineffective in the treatment of human cytomegalovirus (CMV) infections; however, some studies have indicated its effectiveness in the prevention of CMV-associated disease in immunosuppressed patients. Valacyclovir, the L-valyl ester of acyclovir, is converted almost entirely to acyclovir after oral administration. Valacyclovir has pharmacokinetic advantages over orally administered acyclovir: it exhibits significantly greater oral bioavailability, results in higher blood levels, and can be given less frequently than acyclovir.

The high degree of selectivity of acyclovir is related to its mechanism of action, which requires that the compound first be phosphorylated to acyclovir monophosphate. This phosphorylation occurs efficiently in herpesvirus-infected cells by means of a virus-coded thymidine kinase. In uninfected mammalian cells, little phosphorylation of acyclovir occurs, and the drug is therefore concentrated in herpesvirus-infected cells. Acyclovir monophosphate is subsequently converted by host cell kinases to a triphosphate that is a potent inhibitor of virus-induced DNA polymerase but has relatively little effect on host cell DNA polymerase. Acyclovir triphosphate can also be incorporated into viral DNA, with early chain termination.

Acyclovir is available in intravenous, oral, and topical forms, while valacyclovir is available in an oral formulation. Intravenous acyclovir is markedly effective in the treatment of mucocutaneousHSVinfections in immunocompromised hosts, reducing time to healing, duration of pain, and virus shedding. When administered prophylactically during periods of intense immunosuppression (e.g., related to chemotherapy for leukemia or transplantation) and before the development of lesions, intravenous acyclovir reduces the frequency of HSV-associated disease. After prophylaxis is discontinued, HSV lesions recur. Intravenous acyclovir is also effective in the treatment of HSV encephalitis; two comparative trials have indicated that acyclovir is more effective than vidarabine for this indication (see below). BecauseVZV is generally less sensitive to acyclovir than is HSV, higher doses of acyclovir must be used to treat VZV infections. In immunocompromised patients with herpes zoster, intravenous acyclovir reduces the frequency of cutaneous dissemination and visceral complications and -- in one comparative trial -- was more effective than vidarabine. Acyclovir,

administered orally at doses of 800 mg five times a day, had a modest beneficial effect on localized herpes zoster lesions in both immunocompromised and immunocompetent patients. Combination of acyclovir with a tapering regimen of prednisone appeared to be more effective than acyclovir alone in terms of quality-of-life outcomes in immunocompetent herpes zoster patients over age 50. A comparative study of acyclovir (800 mg orally five times daily) and valacyclovir (1 g orally tid) in immunocompetent patients with herpes zoster indicated that the latter drug may be more effective in eliciting the resolution of zoster-associated pain. Orally administered acyclovir (600 mg five times a day) reduced complications of herpes zoster ophthalmicus in a placebo-controlled trial.

In normal children with chickenpox, acyclovir -- administered at 20 mg/kg qid, up to a maximum of 800 mg qid, within 24 h of the onset of rash -- resulted in a modest overall clinical benefit. Intravenous acyclovir has also been reported to be effective in the treatment of immunocompromised children with chickenpox.

The most widespread use of acyclovir is in the treatment of genitalHSVinfections. Intravenous or oral acyclovir or oral valacyclovir has shortened the duration of symptoms, reduced virus shedding, and accelerated healing when employed for the treatment of primary genital HSV infections. Oral acyclovir and valacyclovir have also had a modest effect in treatment of recurrent genital HSV infections. However, the failure of treatment of either primary or recurrent disease to reduce the frequency of subsequent recurrences has indicated that acyclovir is ineffective in eliminating latent infection. Chronic oral administration of acyclovir for periods of 1 to 6 years or longer or of valacyclovir for up to 1 year has reduced the frequency of recurrences markedly during therapy; once the drug is discontinued, lesions recur. In AIDS patients, chronic or intermittent administration of acyclovir has been associated with the development of HSV andVZVstrains resistant to the action of the drug and with clinical failures. The most common mechanism of resistance is a deficiency of the virus-induced thymidine kinase. Patients with HSV or VZV infections resistant to acyclovir have frequently responded to foscarnet.

With the availability of the oral and intravenous forms, there are few indications for topical acyclovir, although treatment with this formulation has been modestly beneficial in primary genitalHSVinfections and in mucocutaneous HSV infections in immunocompromised hosts.

Overall, acyclovir is remarkably well tolerated and is generally free of toxicity. The most frequently encountered form of toxicity is renal dysfunction, particularly after rapid intravenous administration or with inadequate hydration. Central nervous system changes, including lethargy and tremors, are occasionally reported, primarily in immunosuppressed patients. However, whether these changes are related to acyclovir, to concurrent administration of other therapy, or to underlying infection remains unclear. Acyclovir is excreted primarily unmetabolized by the kidney, via both glomerular filtration and tubular secretion. Approximately 15% of a dose of acyclovir is metabolized to 9-[(carboxymethoxy)methyl]guanine or other minor metabolites. Reduction in dosage is indicated in patients with a Cr_{Cl} of<50 mL/min per 1.73 m_2. The half-life of acyclovir is ~3 h in normal adults, and the peak plasma concentration after a 1-h infusion of a dose of 5 mg/kg is 9.8 ug/mL. Approximately 22% of an orally administered acyclovir dose is

absorbed, and peak plasma concentrations of 0.3 to 0.9 ug/mL are attained after administration of a 200-mg dose. Acyclovir penetrates relatively well into the cerebrospinal fluid (CSF), with concentrations approaching half of those found in plasma.

Acyclovir causes chromosomal breakage at high doses, but its administration to pregnant women has not been associated with fetal abnormalities. Nonetheless, the potential risks and benefits of acyclovir should be carefully assessed before the drug is used in pregnancy.

Valacyclovir exhibits three to five times greater bioavailability than acyclovir. The concentration-time curve for valacyclovir, given as 1 g orally tid, is similar to that for acyclovir, given as 5 mg/kg intravenously every 8 h. The safety profiles of valacyclovir and acyclovir are similar, although thrombotic thrombocytopenic purpura/hemolytic-uremic syndrome has been reported in immunocompromised patients who have received high doses of valacyclovir. Valacyclovir is approved for the treatment of herpes zoster and for initial and recurrent episodes of genitalHSVinfections in immunocompetent adults as well as for suppressive treatment of genital herpes. It is being studied for use against other herpesvirus infections in various clinical settings.

CIDOFOVIR

Cidofovir is a phosphonate nucleotide analogue of cytosine. Its major use is inCMVinfections, particularly retinitis, but it is active against a broad range of herpesviruses, includingHSV, human herpesvirus (HHV) type 6, HHV-8, and certain other DNA viruses such as polyomaviruses, papillomaviruses, and adenoviruses. Cidofovir does not require initial phosphorylation by virus-induced kinases; the drug is phosphorylated by host cell enzymes to cidofovir diphosphate, which is a competitive inhibitor of viral DNA polymerases and, to a lesser extent, of host cell DNA polymerases. Incorporation of cidofovir diphosphate slows or terminates nascent DNA chain elongation. Cidofovir is active against HSV isolates that are resistant to acyclovir because of absent or altered thymidine kinase and against CMV isolates that are resistant to ganciclovir because of UL97 mutations. Cidofovir is usually active against foscarnet-resistant CMV, although cross-resistance to foscarnet as well as to ganciclovir has been described.

Cidofovir has poor oral availability and is administered intravenously. It is excreted primarily by the kidney and has a plasma half-life of 2.6 h. Cidofovir diphosphate's intracellular half-life of >48 h is the basis for the recommended dosing regimen of 5 mg/kg twice a week for the initial 2 weeks and then 5 mg/kg once a week. The major toxic effect of cidofovir is proximal renal tubular injury, as manifested by elevated serum creatinine levels and proteinuria. The risk of nephrotoxicity can be reduced by vigorous saline hydration and by concomitant oral administration of probenecid. Neutropenia, rashes, and gastrointestinal tolerance may also occur.

Intravenous cidofovir has been approved for the treatment ofCMVretinitis in AIDS patients who are intolerant of ganciclovir or foscarnet or in whom those drugs have failed. In a controlled study, a maintenance dosage of 5 mg/kg a week administered to AIDS patients reduced the progression of CMV retinitis from that seen at 3 mg/kg.

Intravenous cidofovir has been reported anecdotally to be effective therapy for acyclovir-resistant mucocutaneousHSVinfections. Likewise, topically administered cidofovir is reportedly beneficial against these infections in HIV patients; it is also being studied for the treatment of anogenital warts. Intravenous cidofovir is being evaluated as therapy for progressive multifocal leukoencephalopathy and for Kaposi's sarcoma. An ophthalmic formulation is being studied as treatment for adenoviral keratoconjunctivitis. Intravitreal cidofovir has been used to treat CMV retinitis but has been associated with significant toxicity.

FOMIVIRSEN

Fomivirsen is the first antisense oligonucleotide approved by the U.S. Food and Drug Administration (FDA) for therapy in humans. This phosphorothioate oligonucleotide, 21 nucleotides in length, inhibitsCMVreplication through interaction with CMV messenger RNA. Fomivirsen is complementary to messenger transcripts of the major immediate early region 2 (IE2) of CMV, which codes for proteins regulating viral gene expression. In addition to its antisense mechanism of action, fomivirsen may exert activity against CMV through inhibition of viral adsorption to cells as well as direct inhibition of viral replication. Because of its different mechanism of action, fomivirsen is active against CMV isolates that are resistant to nucleoside or nucleotide analogues, such as ganciclovir, foscarnet, or cidofovir.

Fomivirsen has been approved for intravitreal administration in the treatment ofCMVretinitis in AIDS patients who have failed to respond to other treatments or cannot tolerate them. Injections of 330 mg every 2 weeks have resulted in significant reductions in the rate of progression of CMV retinitis. The major toxicity is ocular inflammation, including vitritis and iritis, which usually responds to topically administered glucocorticoids.

GANCICLOVIR

An analogue of acyclovir, ganciclovir is active againstHSV andVZV and is markedly more active than acyclovir againstCMV. Ganciclovir triphosphate inhibits CMV DNA polymerase and can be incorporated into CMV DNA, whose elongation it eventually terminates. In HSV- and VZV-infected cells, ganciclovir is phosphorylated by virus-encoded thymidine kinases; in CMV-infected cells, it is phosphorylated by a viral kinase encoded by the UL97 gene. Ganciclovir triphosphate is present in tenfold higher concentrations in CMV-infected cells than in uninfected cells. Ganciclovir is approved for the treatment of CMV retinitis in immunosuppressed patients and for the prevention of CMV disease in transplant recipients. It is widely used for the treatment of other CMV-associated syndromes, including pneumonia, esophagogastrointestinal infections, hepatitis, and "wasting" illness.

Ganciclovir is available for intravenous or oral administration. Because its oral bioavailability is low (5 to 9%), relatively large doses (1 g tid) must be administered by this route. Oral bioavailability is enhanced if the drug is administered with food, as recommended. The serum half-life of ganciclovir is 3.5 h after intravenous administration and 4.5 h after oral administration. The drug is excreted primarily by the kidney in unmetabolized form, and its dosage should be reduced in cases of renal

failure. The most commonly employed dosage for initial therapy -- 5 mg/kg intravenously every 12 h for 14 to 21 days -- is followed by a maintenance dose of 5 mg/kg intravenously per day or 5 times per week, possibly for as long as immunosuppression persists. Oral ganciclovir is approved as an alternative to the intravenous preparation in maintenance therapy forCMVretinitis, where it appears to be somewhat less effective although more convenient than intravenous therapy. Intraocular ganciclovir, given by either intravitreal injection or intraocular implantation, has also been used to treat CMV retinitis.

Ganciclovir is effective as prophylaxis againstCMV-associated disease in organ and bone marrow transplant recipients. Oral ganciclovir administered prophylactically to AIDS patients with CD4+ counts of<100/uL provided protection against the development of CMV retinitis in one large-scale study and was subsequently approved for that indication. However, the long-term benefits of this approach to prophylaxis are unestablished, and most experts do not recommend the use of oral ganciclovir for that purpose.

The administration of ganciclovir has been associated with profound bone marrow suppression, particularly neutropenia, which significantly limits the drug's use in many patients. Bone marrow toxicity is potentiated when other bone marrow suppressants, such as zidovudine, are used concomitantly.

Resistance has been noted inCMVisolates obtained after therapy with ganciclovir, especially in patients with AIDS. Such resistance may develop through a mutation in either the viral UL97 gene or the viral DNA polymerase. Ganciclovir-resistant isolates are usually sensitive to foscarnet (see below).

FAMCICLOVIR AND PENCICLOVIR

Famciclovir is the diacetyl 6-deoxyester of the guanosine analogue penciclovir. Famciclovir is well absorbed orally, with a bioavailability of 77%, and is rapidly converted by deacetylation and oxidation to penciclovir. Penciclovir's spectrum of activity and mechanism of action are similar to those of acyclovir; thus penciclovir is not active against acyclovir-resistant viruses. Penciclovir is phosphorylated initially by a virus-encoded thymidine kinase and subsequently by cellular kinases to penciclovir triphosphate, which inhibitsHSV-1, HSV-2, andVZV DNA polymerases as well as hepatitis B virus (HBV). The serum half-life of penciclovir is 2 h, but the intracellular half-life of penciclovir triphosphate is 7 to 20 h -- markedly longer than that of acyclovir triphosphate. Penciclovir is eliminated primarily in the urine by both glomerular filtration and tubular secretion. The usually recommended dosage interval should be adjusted for renal insufficiency.

Clinical trials involving immunocompetent adults with herpes zoster showed that famciclovir was superior to placebo in eliciting the resolution of skin lesions and virus shedding and in shortening the duration of postherpetic neuralgia; moreover, it was at least as effective as acyclovir administered orally at a dose of 800 mg five times daily. Famciclovir was also effective in the treatment of herpes zoster in immunosuppressed patients. Clinical trials have demonstrated its effectiveness in suppression of genitalHSVinfections for up to 1 year and in the treatment of initial and recurrent

episodes of genital herpes. Famciclovir is effective as therapy for mucocutaneous HSV infections in HIV-infected patients. Application of a 1% penciclovir cream reduces the duration of signs and symptoms of herpes labialis in immunocompetent patients (by 0.5 to 1.0 day) and has been approved for that purpose by theFDA. Famciclovir is generally well tolerated, with occasional headache, nausea, and diarrhea reported in frequencies similar to those among placebo recipients. The administration of high doses of famciclovir for 2 years was associated with an increased incidence of mammary adenocarcinomas in female rats, but the clinical significance of this effect is unknown. Intravenous penciclovir is being investigated for the treatment of mucocutaneous HSV infections in immunosuppressed patients.

FOSCARNET

Foscarnet (phosphonoformic acid) is a pyrophosphate-containing compound that potently inhibits herpesviruses, includingCMV. This drug inhibits DNA polymerases at the pyrophosphate binding site at concentrations that have relatively little effect on cellular polymerases. Foscarnet does not require phosphorylation to exert its antiviral activity and is therefore active againstHSV andVZVisolates that are resistant to acyclovir because of deficiencies in thymidine kinase as well as against most ganciclovir-resistant strains of CMV. Foscarnet also inhibits the reverse transcriptase of HIV and is active against HIV in vivo.

Foscarnet is poorly soluble and must be administered intravenously via an infusion pump in a dilute solution over 1 to 2 h. The plasma half-life of foscarnet is 3 to 5 h and increases with decreasing renal function, since the drug is eliminated primarily by the kidneys. It has been estimated that 10 to 28% of a dose may be deposited in bone, where it can persist for months. The most common initial dosage of foscarnet -- 60 mg/kg every 8 h for 14 to 21 days -- is followed by a maintenance dose of 90 to 120 mg/kg once a day.

Foscarnet is approved for the treatment ofCMVretinitis in patients with AIDS and of acyclovir-resistant mucocutaneousHSVinfections. In a comparative clinical trial, the drug appeared to be about as efficacious as ganciclovir against CMV retinitis but was associated with a longer survival period, possibly because of its anti-HIV activity. Intraocular foscarnet has been used to treat CMV retinitis. Foscarnet has also been employed to treat acyclovir-resistant HSV andVZVinfections as well as ganciclovir-resistant CMV infections, although resistance to foscarnet has been reported in CMV isolates obtained during therapy.

The major form of toxicity associated with foscarnet is renal impairment. Thus renal function should be monitored closely, particularly during the initial phase of therapy. Since foscarnet binds divalent metal ions, hypocalcemia, hypomagnesemia, hypokalemia, and hypo- or hyperphosphatemia can develop. Saline hydration and slow infusion appear to protect the patient against nephrotoxicity and electrolyte disturbances. Although hematologic abnormalities have been documented (most commonly anemia), foscarnet is not generally myelosuppressive and may be administered concomitantly with myelosuppressive medications such as zidovudine.

IDOXURIDINE

Idoxuridine inhibits the replication of herpesviruses and poxviruses. It was formerly used systemically to treat herpesvirus infections, but, because of associated toxicity and lack of proven efficacy, its systemic use has largely been abandoned. Topical idoxuridine is effective in the treatment ofHSVkeratitis, particularly in superficial infections, but has been supplanted by topically applied trifluridine and vidarabine (see below).

TRIFLURIDINE

Trifluridine is a pyrimidine nucleoside active againstHSV-1, HSV-2, andCMV. Trifluridine monophosphate irreversibly inhibits thymidylate synthetase, and trifluridine triphosphate inhibits viral and, to a lesser extent, cellular DNA polymerases. Because of systemic toxicity, its use is limited to topical therapy. Trifluridine is approved for treatment of HSV keratitis, for which trials have shown that it is more effective than topical idoxuridine but similarly effective to topical vidarabine. The drug has benefited some patients with HSV keratitis who have failed to respond to idoxuridine or vidarabine. Topical application of trifluridine to sites of acyclovir-resistant HSV mucocutaneous infections has also been beneficial in some cases.

VIDARABINE

Vidarabine is a purine nucleoside analogue with activity againstHSV-1, HSV-2,VZV, andEBV. Vidarabine inhibits viral DNA synthesis through its 5¢-triphosphorylated metabolite, although its precise molecular mechanisms of action are not completely understood. Intravenously administered vidarabine has been shown to be effective in the treatment of herpes simplex encephalitis, mucocutaneous HSV infections and herpes zoster in immunocompromised patients and of neonatal HSV infections. Its use has been supplanted by intravenous acyclovir, which is more effective and easier to administer. Production of the intravenous preparation has been discontinued by the manufacturer, but vidarabine is available as an ophthalmic ointment, which is effective in the treatment of HSV keratitis.

OTHER ANTIVIRAL DRUGS

Lamivudine is a pyrimidine nucleoside analogue that is used primarily in combination therapy against HIV infection (Chap. 309). It is also active againstHBVthrough inhibition of the viral DNA polymerase and has been approved for the treatment of chronic HBV infection. In one study, at doses of 100 mg/d for³1 year, lamivudine was well tolerated and resulted in suppression of HBV DNA levels, normalization of serum aminotransferase levels in most patients, and reduction of hepatic inflammation and fibrosis. Loss of hepatitis B e antigen (HBeAg) occurred in a minority of patients. Resistance to lamivudine developed in 15 to 36% of patients treated for 1 year and was associated with changes in the YMDD motif of HBV DNA polymerase. This is an important limitation of monotherapy with the drug. Studies of lamivudine as a component of combination therapy for hepatitis B are under way. Lamivudine also appears to be useful in the prevention or suppression of HBV infection associated with liver transplantation.

Lobucavir is a synthetic cyclobutane nucleoside analogue with activity against a broad

range of herpesviruses, HIV, andHBV. It is currently under investigation in clinical trials. Its mechanism of action is through inhibition of viral DNA synthesis. Lobucavir is initially phosphorylated by virus-induced kinases, and lobucavir triphosphate is a potent inhibitor ofHSV,CMV, and HBV DNA polymerases. Lobucavir can be administered orally or intravenously. It is excreted largely unmetabolized via the kidney and has a plasma half-life of 2 h after intravenous administration. Its oral availability is dose-dependent, ranging from 25 to 40% at doses of £200 mg and decreasing at higher doses. The preclinical toxicity profile of lobucavir appears to be similar to that of ganciclovir. However, neutropenia has been uncommonly encountered in studies in humans. Aminotransferase elevations have been documented after intravenous and (less commonly) oral administration. The most frequent adverse effects after oral administration are headache, insomnia, and gastrointestinal discomfort. In clinical trials to date, oral lobucavir has demonstrated antiviral effects in CMV- and HBV-infected patients as well as clinical benefits against HSV infections in immunocompetent patients. Short-term (1-month) oral administration of 200 mg of lobucavir bid or qid reduced serum HBV DNA levels in chronically infected patients. HBV DNA levels returned to pretreatment values when the drug was stopped, and studies of longer-term administration are under way. Lobucavir is under clinical investigation for use in HIV infection and in several herpesvirus infections.

Pleconaril is an investigational drug active in vitro against picornavirus replication, including over 90% of the most commonly isolated enterovirus types and 80% of rhinovirus serotypes. Its mechanism of action is through binding to a specific hydrophobic pocket in the viral capsid, which prevents attachment and/or uncoating of the virus. Pleconaril is poorly water soluble and is formulated as an oral suspension. After oral administration of 200- and 400-mg doses to adults, peak plasma concentrations are 1.1 and 2.4 ug/mL, respectively, and the terminal plasma half-life is 25 h. Pleconaril is generally well tolerated; the most frequently reported adverse effects are headache, nausea, diarrhea, and gastrointestinal discomfort, which have occurred at rates similar to those among placebo recipients. Orally administered pleconaril, given before and after experimental infection of healthy volunteers with coxsackievirus A21, reduced peak viral titers by >100-fold and decreased the subsequent rate of development of illness. Pleconaril treatment of adults with enteroviral meningitis decreased the overall duration of illness and headache and reduced the use of analgesics from that by placebo recipients. Clinical studies of pleconaril in other enterovirus-induced diseases are in progress.

INTERFERONS

Interferons are cytokines that exhibit a broad spectrum of antiviral activities as well as immunomodulating and antiproliferative properties. TheIFNs are not available for oral administration but must be given intramuscularly, subcutaneously, or intravenously. Early studies with human leukocyte IFN demonstrated an effect in the prophylaxis of experimentally induced rhinovirus infections in humans and in the treatment ofVZVinfections in immunosuppressed patients. DNA recombinant technology has made available highly purified a,b, and g IFNs that have been evaluated in a variety of viral infections. Results of such trials have confirmed the effectiveness of intranasally administered IFN in the prophylaxis of rhinovirus infections, although its use has been associated with nasal mucosal irritation. Studies have also demonstrated a beneficial

effect of intralesionally or systemically administered IFNs on genital warts. The effect of systemic administration consists primarily of a reduction in the size of lesions, and this mode of therapy may be useful in individuals who have numerous warts that cannot easily be treated by individual intralesional injection. However, lesions frequently recur after intralesional or systemic IFN therapy is discontinued.

Interferons have undergone extensive study in the treatment of chronicHBVinfection. The administration ofIFN-a2b (5 million units daily for 16 weeks) to patients with stable chronic HBV infection resulted in loss of markers of HBV replication, such asHBeAgand HBV DNA, in 33 to 37% of cases; 10 to 20% of patients also became negative for hepatitis B surface antigen. In >80% of patients who lose HBeAg and HBV DNA markers, serum aminotransferases return to normal levels, and both short- and long-term improvements in liver histopathology have been described. Predictors of a favorable response to therapy include low pretherapy levels of HBV DNA, high pretherapy serum levels of alanine aminotransferase (ALT), a short duration of chronic HBV infection, and active liver histopathology. Poor responses are seen in immunosuppressed patients, including those with HIV infection. Adverse effects of the above dose of IFN are common and include fever, chills, myalgia, fatigue, neurotoxicity (primarily manifested as somnolence and confusion), and leukopenia. Approximately 25% of patients receiving a daily dose of 5 million units require dose reduction, but fewer than 5% require discontinuation of therapy.

SeveralIFNpreparations, including a2a,a2b, alfacon-1, and am1 (lymphoblastoid), have been studied as therapy for chronicHCVinfections. A variety of regimens have been employed, of which the most common is IFN-a2b or -a2a at 3 million units three times per week for 12 months. A complete biochemical response, defined as a return to normal serumALTvalues at the end of treatment, has been documented in ~54% of patients. In addition, liver biopsies have shown decreases in lobular and periportal inflammation. However, relapse has occurred in approximately half of all cases upon discontinuation of therapy, so that sustained responses were documented in 28% of cases. The addition of oral ribavirin to IFN-a2b -- either as initial therapy or after failure of interferon therapy alone -- resulted in significantly higher rates of sustained response (40 to 50%) than were obtained with monotherapy. Prognostic factors for a favorable response include an age of<45 years, a short duration of disease, low levels of HCV RNA, and infection with HCV genotypes other than 1. IFN alfacon, a synthetic "consensus" a interferon, appears to produce response rates similar to those elicited by IFN-a2a or -a2b and has recently been approved in the United States for the treatment of chronic hepatitis C.

Treatment of chronic hepatitis D withIFN-aapparently requires higher doses (5 million units daily or 10 million units three times per week) and is less effective than treatment of chronic hepatitis B or C. After 12 months of therapy, biochemical and virologic responses were detected in ³50% of patients, but few responses were sustained once therapy was stopped.

SECTION 12 -DNA VIRUSES

182. HERPES SIMPLEX VIRUSES - *Lawrence Corey*

DEFINITION

Herpes simplex viruses (HSV-1, HSV-2; *Herpesvirus hominis*) produce a variety of infections involving mucocutaneous surfaces, the central nervous system (CNS), and -- on occasion -- visceral organs. The advent of effective chemotherapy for HSV infections has made prompt recognition of these syndromes even more clinically important than in the past.

ETIOLOGIC AGENT

The genome ofHSV is a linear, double-stranded DNA molecule (molecular weight, ~100´10_6) that encodes more than 75 gene products. The genomic structures of the two HSV subtypes are similar, and the overall sequence homology between HSV-1 and HSV-2 is ~50%. The homologous sequences are distributed over the entire genome map, and most of the polypeptides specified by one viral type are antigenically related to polypeptides of the other viral type. Many type-specific regions unique to HSV-1 and HSV-2 proteins do exist, however, and a number of them appear to be important in host immunity. These type-specific regions have been used to develop serologic assays that distinguish between the two viral subtypes. Restriction endonuclease analysis of viral DNA can be used to distinguish between the two subtypes and among strains of each subtype. The variability of nucleotide sequences from clinical strains of HSV-1 and HSV-2 is such that HSV isolates obtained from two individuals can be differentiated by restriction enzyme patterns unless the isolates are from epidemiologically related sources, such as sexual partners, mother-infant pairs, or persons involved in a common-source outbreak.

The viral genome is packaged in a regular icosahedral protein shell (capsid) composed of 162 capsomers. The outer covering of the virus is a lipid-containing membrane (envelope) derived from modified cell membrane and acquired as the DNA-containing capsid buds through the inner nuclear membrane of the host cell. Between the capsid and lipid bilayer of the envelope is the tegument. Viral replication has both nuclear and cytoplasmic phases. The initial steps of replication include attachment, fusion between the viral envelope and the cell membrane to liberate the nucleocapsid into the cytoplasm of the cell, and disassembly of the nucleocapsid to release the viral DNA. Replication ofHSV is highly regulated. After fusion of the virion envelope with the host cell membrane, several viral proteins are released from the HSV virion. Some shut off host protein synthesis (by increasing cellular RNA degradation), while others "turn on" transcription of early genes of HSV replication. These early gene products, designated *a genes*, are required for synthesis of the subsequent polypeptide group, theb polypeptides, many of which are regulatory proteins and enzymes required for DNA replication. Most current antiviral drugs interfere with b proteins, such as the viral DNA polymerase enzyme. The third (g) class of HSV genes requires viral DNA replication for expression and constitutes most of the structural proteins specified by the virus.

After replication of the viral genome and synthesis of structural proteins, nucleocapsids

are assembled in the nucleus of the cell. Envelopment occurs as the nucleocapsids bud through the inner nuclear membrane into the perinuclear space. In some cells, viral replication in the nucleus forms two types of inclusion bodies: type A basophilic Feulgen-positive bodies that contain viral DNA and an eosinophilic inclusion body that is devoid of viral nucleic acid or protein and represents a "scar" of viral infection. Virions are then transported via the endoplasmic reticulum and the Golgi apparatus to the cell surface.

HSVinfection of some neuronal cells does not result in cell death. Instead, viral genomes are maintained by the cell in a repressed state compatible with survival and normal activities of the cell, a condition called *latency*. Latency is associated with transcription of only a limited number of virus-encoded proteins. Subsequently, the viral genome may become activated, resulting in the normal pattern of regulated viral gene expression, replication, and release of HSV. The release of virus from the neuron and its subsequent entry into epithelial cells result in viral replication. This process is termed *reactivation*. Whereas infectious virus rarely can be recovered from sensory or autonomic nervous system ganglia dissected from cadavers, maintenance and growth of the neural cells in tissue culture result in production of infectious virions (*explantation*) and in subsequent permissive infection of susceptible cells (*cocultivation*). The fact that HSV replication was first detected in neurons during reactivation in vitro suggested that the neuron harbors the latent virus in vivo. Viral DNA and RNA have since been found in neural tissue at times when infectious virus cannot be isolated. Two RNA "latency-associated" transcripts that overlap the immediate early (a) gene products, called ICP-O, are found in abundance in the nuclei of latently infected neurons. These latency-associated transcripts code proteins in an antisense direction. Deletion mutants of this region that can become latent have been made. However, the efficiency of their later reactivation is reduced; thus, the antisense transcripts may play a role in maintaining rather than in establishing latency. At present, the molecular mechanisms of the latency of HSV-1 and HSV-2 are not well understood, and strategies to interrupt latency or to maintain molecular latency in neurons are not available.

PATHOGENESIS

Exposure to HSVat mucosal surfaces or abraded skin sites permits entry of the virus and initiation of its replication in cells of the epidermis and dermis. Investigators have identified several cell receptors that are ligands for HSV attachment proteins. Studies to define how these receptors influence viral replication and pathogenesis are under way. Initial HSV infection is often subclinical -- i.e., without clinically apparent lesions. Both clinical acquisition and subclinical acquisition are associated with sufficient viral replication to permit infection of either sensory or autonomic nerve endings. On entry into the neuronal cell, the virus -- or, more likely, the nucleocapsid -- is transported intraaxonally to the nerve cell bodies in ganglia. In humans, the interval from inoculation of virus in peripheral tissue to spread to the ganglia is unknown. During the initial phase of infection, viral replication occurs in ganglia and contiguous neural tissue. Virus then spreads to other mucosal skin surfaces through centrifugal migration of infectious virions via peripheral sensory nerves. This mode of spread helps explain the large surface area involved, the high frequency of new lesions distant from the initial crop of vesicles that is characteristic in patients with primary genital or oral-labial HSV infection, and the recovery of virus from neural tissue distant from neurons innervating the

inoculation site. Contiguous spread of locally inoculated virus also may take place and allow further mucosal extension of disease.

After the resolution of primary disease, infectiousHSV can no longer be recovered in the ganglia. However, viral DNA can be found in 10 to 50% of ganglion cells in the anatomic region of the initial infection. Only ~1% of such cells express latency-associated transcripts of RNA detectable by current techniques. The mechanisms controlling the reactivation of HSV infection are unknown. Alterations in cellular transcripts that "maintain" latency are suspected, and several cellular protein kinases are under investigation. Experimentally, ultraviolet light, systemic and local immunosuppression, and trauma to the skin or ganglia are associated with reactivation.

Analysis of the DNA from sequentially isolated strains ofHSV or from isolates from multiple infected ganglia in any one individual has revealed identical restriction endonuclease patterns in most persons. Occasionally (most frequently in immunocompromised persons), multiple strains of the same viral subtype are detected in one individual. This finding suggests that exogenous infection with different strains of the same subtype is possible although very uncommon.

IMMUNITY

Host responses to infection withHSVinfluence the acquisition of disease, the severity of infection, resistance to the development of latency, the maintenance of latency, and the frequency of recurrences. Both antibody-mediated and cell-mediated reactions are clinically important. Immunocompromised patients with defects in cell-mediated immunity experience more severe and more extensive HSV infections than those with deficits in humoral immunity, such as agammaglobulinemia. Experimental ablation of lymphocytes indicates that T cells play a major role in preventing lethal disseminated disease, although antibodies help reduce virus titers in neural tissue. Some of the clinical manifestations of HSV disease appear to be related to the host immune response (e.g., stromal opacities associated with recurrent herpetic keratitis). The surface viral glycoproteins have been shown to be antigens recognized by antibodies mediating neutralization and immune-mediated cytolysis (antibody-dependent cell-mediated cytotoxicity). Monoclonal antibodies specific for each of the known viral glycoproteins have, in experimental infections, conferred protection against subsequent neurologic disease or ganglionic latency. However, the use of subunit glycoprotein vaccines in humans has not been successful in reducing acquisition of infection, despite high titers of type-specific antibodies. Multiple cell populations, including natural killer cells, macrophages, a variety of T lymphocytes, and lymphokines generated by these cells, play a role in host defenses against HSV infections. In animals, passive transfer of primed lymphocytes confers protection from subsequent challenge. Maximum protection usually requires the activation of multiple T cell subpopulations, including cytotoxic T cells and T cells responsible for delayed hypersensitivity. The latter cells may confer protection by the antigen-stimulated release of lymphokines (e.g., interferons), which may have a direct antiviral effect and may activate and enhance a variety of specific and nonspecific effector cells. Increasing evidence suggests that HSV-specific CD8+ T cell responses are critical for clearance of virus from lesions. In addition, immunosuppressed patients with frequent and prolonged HSV lesions have fewer functional CD8+ T cells directed at HSV. The HSV virion contains a gene called unique

long gene no. 12 (UL-12) that can bind to the cellular transporter-activating protein TAP-1 and reduce the ability of this protein to bind HSV peptides to HLA class I, thereby reducing recognition of viral proteins by cytotoxic T cells of the host. This effect can be overcome by the addition of interferon g, but this requires 24 to 48 h; thus, the virus has time to replicate and invade other host cells. Prior HSV-1 infection does not appear to reduce the frequency of acquisition of HSV-2 as measured by seroconversion. However, persons with prior HSV-1 infection who acquire HSV-2 appear to have a greater frequency of subclinical acquisition. These data suggest that type-specific immune responses are central to the control of HSV infection.

EPIDEMIOLOGY

Seroepidemiologic studies have documentedHSVinfections worldwide. Much of the humoral immune response to HSV is to type-common antigenic determinants. Serologic assays with whole-virus antigen preparations, such as complement fixation, neutralization, indirect immunofluorescence, passive hemagglutination, radioimmunoassay, and enzyme-linked immunosorbent assay, do not reliably distinguish between the two viral subtypes. Such assays are useful for differentiating uninfected (seronegative) persons from those with past HSV-1 or HSV-2 infection, but they do not reliably distinguish between the two subtypes. Serologic assays that identify antibodies to type-specific surface proteins of the two subtypes have been developed. These assays, which are based on the demonstration of antibodies to type-specific epitopes of the virus, can reliably distinguish between the human antibody responses to HSV-1 and HSV-2. The most commonly used assays are those that measure antibodies to glycoprotein G of HSV-1 (gG1) and HSV-2 (gG2). A western blot assay that can detect several HSV type-specific proteins can also be used.

Infection withHSV-1 is acquired more frequently and earlier than infection with HSV-2. More than 90% of adults have antibodies to HSV-1 by the fifth decade of life. In populations of low socioeconomic status, most persons acquire HSV-1 infection before the third decade of life.

Antibodies toHSV-2 are not detected routinely until puberty. Antibody prevalence rates correlate with past sexual activity and vary greatly among different population groups. Serosurveys indicate that nearly 22% of the United States population has antibodies to HSV-2 -- a 30% increase in the past 12 years. In most routine obstetric and family planning clinics, 25% of women have HSV-2 antibodies, although only 10% report a history of genital lesions. As many as 50% of heterosexual adults attending sexually transmitted disease clinics have antibodies to HSV-2. Antibody prevalence rates average about 5% higher among women than among men. Several studies suggest that much of this "asymptomatic" infection is largely unrecognized in that when "asymptomatic" seropositive persons are shown pictures of genital lesions,>60% subsequently identify episodes of symptomatic reactivation. Most important, these asymptomatic seropositive persons with reactivation shed virus on mucosal surfaces as frequently as those with symptomatic disease. The large reservoir of unidentified carriers of HSV-2 and the frequent asymptomatic reactivation of virus from the genital tract have fostered the continued spread of genital herpes throughout the world. HSV-2 infection is an independent risk factor for the acquisition and transmission of infection with HIV type 1. Among coinfected persons, HIV-1 virions can be shed from herpetic

lesions of the genital region. This shedding may facilitate the spread of HIV through sexual contact.

HSVinfections occur throughout the year. The incubation period ranges from 1 to 26 days (median, 6 to 8 days). Transmission can result from contact with persons with active ulcerative lesions or with persons without clinical manifestations of infection who are shedding HSV or on whose mucosal surfaces the virus is replicating. Studies using the polymerase chain reaction (PCR) have shown that HSV reactivation on mucosal surfaces is much more frequent than previously recognized. Among immunocompetent adults, HSV-2 can be isolated from the genital tract on 2 to 3% of days, and HSV DNA can be detected on 20 to 30% of days. Corresponding figures for HSV-1 in oral secretions are similar. Shedding rates are highest during the initial years of acquisition and may be as high as 30 to 50% of days during this period. Immunosuppressed patients shed HSV on mucosal sites at even higher frequency (20 to 50% of days). Daily antiviral chemotherapy can markedly reduce shedding rates. These data indicate that potential exposure to HSV from sexual or other close contact (kissing, sharing of glasses or silverware) is more common than has been thought. These shedding-rate data are consistent with the high seroprevalence of HSV infections worldwide.

CLINICAL SPECTRUM

HSVhas been isolated from nearly all visceral or mucocutaneous sites. The clinical manifestations and course of HSV infection depend on the anatomic site involved, the age and immune status of the host, and the antigenic type of the virus. Primary HSV infections (i.e., first infections with either HSV-1 or HSV-2 in which the host lacks HSV antibodies in acute-phase serum) are frequently accompanied by systemic signs and symptoms, involve both mucosal and extramucosal sites, and have a longer duration of symptoms, a longer duration of virus isolation from lesions, and a higher rate of complications than recurrent episodes of disease. Both viral subtypes can cause genital and oral-facial infections, and the infections caused by the two subtypes are clinically indistinguishable. However, the frequency of reactivation of infection is influenced by anatomic site and virus type. Genital HSV-2 infection is twice as likely to reactivate and recurs 8 to 10 times more frequently than genital HSV-1 infection. Conversely, oral-labial HSV-1 infection recurs more frequently than oral-labial HSV-2 infection. Asymptomatic shedding rates follow the same pattern.

Oral-Facial Infections Gingivostomatitis (Fig. 182-CD1) and pharyngitis are the most frequent clinical manifestations of first-episodeHSV-1 infection, while recurrent herpes labialis (Fig. 182-CD2) is the most frequent clinical manifestation of reactivation HSV infection. HSV pharyngitis and gingivostomatitis usually result from primary infection and are most commonly seen in children and young adults. Clinical symptoms and signs, which include fever, malaise, myalgias, inability to eat, irritability, and cervical adenopathy, may last from 3 to 14 days. Lesions may involve the hard and soft palate, gingiva, tongue, lip, and facial area. HSV-1 or HSV-2 infection of the pharynx usually results in exudative or ulcerative lesions of the posterior pharynx and/or tonsillar pillars. Lesions of the tongue, buccal mucosa, or gingiva may occur later in the course in one-third of cases. Fever lasting from 2 to 7 days and cervical adenopathy are common. It can be difficult to differentiate HSV pharyngitis clinically from bacterial pharyngitis, *Mycoplasma pneumoniae* infections, and pharyngeal ulcerations of noninfectious

etiologies (e.g., Stevens-Johnson syndrome). No substantial evidence suggests that reactivation oral-labial HSV infection is associated with symptomatic recurrent pharyngitis.

Reactivation of HSVfrom the trigeminal ganglia may be associated with asymptomatic virus excretion in the saliva, development of intraoral mucosal ulcerations, or herpetic ulcerations on the vermilion border of the lip or external facial skin. About 50 to 70% of seropositive patients undergoing trigeminal nerve root decompression and 10 to 15% of those undergoing dental extraction develop oral-labial HSV infection a median of 3 days after these procedures.

In immunosuppressed patients, infection may extend into mucosal and deep cutaneous layers (Fig. 182-CD3). Friability, necrosis, bleeding, severe pain, and inability to eat or drink may result. The lesions ofHSVmucositis are clinically similar to mucosal lesions caused by cytotoxic drug therapy, trauma, or fungal or bacterial infections. Persistent ulcerative HSV infections are among the most common infections in patients with AIDS. HSV and *Candida* infections often occur concurrently. Systemic antiviral therapy speeds the rate of healing and relieves the pain of mucosal HSV infections in immunosuppressed patients. The frequency of HSV reactivation during the early phases of transplantation or induction chemotherapy is high (50 to 90%), and prophylactic systemic antivirals such as intravenous acyclovir or penciclovir are used to reduce reactivation rates. Patients with atopic eczema also may develop severe oral-facial HSV infections (eczema herpeticum), which may rapidly come to involve extensive areas of skin and occasionally disseminate to visceral organs. Extensive eczema herpeticum has resolved promptly with the administration of intravenous acyclovir. Erythema multiforme (EM) also may be associated with HSV infections (Plate IIE-67); some evidence suggests that HSV infection is the precipitating event in ~75% of cases of cutaneous EM. HSV antigen has been demonstrated both in circulatory immune complexes and in skin lesion biopsy samples from these patients. Patients with severe HSV-associated EM are candidates for chronic suppressive oral antiviral therapy.

HSV-1 has been implicated in the etiology of Bell's palsy (flaccid paralysis of the mandibular portion of the facial nerve). Whether antiviral chemotherapy can alter the clinical course and complications of this infection is unclear.

Genital Infections First-episode primary genital herpes is characterized by fever, headache, malaise, and myalgias. Pain, itching, dysuria, vaginal and urethral discharge, and tender inguinal lymphadenopathy are the predominant local symptoms. Widely spaced bilateral lesions of the external genitalia are characteristic. Lesions may be present in varying stages, including vesicles, pustules, or painful erythematous ulcers. The cervix and urethra are involved in>80% of women with first-episode infections. First episodes of genital herpes in patients who have had priorHSV-1 infection are associated with less frequent systemic symptoms and faster healing than primary genital herpes. The clinical courses of acute first-episode genital herpes among patients with HSV-1 and HSV-2 infections are similar. However, the recurrence rates of genital disease (Figs. 182-CD4,182-CD5,182-CD6) differ with the viral subtype: the 12-month recurrence rates among patients with first-episode HSV-2 and HSV-1 infections are ~90% and ~55%, respectively (median number of recurrences, 4 and <1, respectively). Recurrence rates for genital HSV-2 infections vary greatly among individuals and over

time within the same individual. HSV has been isolated from the urethra and urine of men and women without external genital lesions. A clear mucoid discharge and dysuria are characteristics of symptomatic HSV urethritis. HSV has been isolated from the urethra of 5% of women with the dysuria-frequency syndrome. Occasionally, HSV genital tract disease is manifested by endometritis and salpingitis in women and by prostatitis in men. About 15% of cases of HSV-2 acquisition are associated with these nonlesional clinical syndromes, such as aseptic meningitis, cervicitis, or urethritis.

BothHSV-1 and HSV-2 can cause symptomatic or asymptomatic rectal and perianal infections. HSV proctitis is usually associated with rectal intercourse. However, subclinical perianal shedding of HSV is detected both in heterosexual men and in women who report no rectal intercourse. This phenomenon is due to the establishment of latency in the sacral dermatome from prior genital tract infection, with subsequent reactivation in epithelial cells in the perianal region. Such reactivations are often subclinical. Symptoms of HSV proctitis include anorectal pain, anorectal discharge, tenesmus, and constipation. Sigmoidoscopy reveals ulcerative lesions of the distal 10 cm of the rectal mucosa. Rectal biopsies show mucosal ulceration, necrosis, polymorphonuclear and lymphocytic infiltration of the lamina propria, and (in occasional cases) multinucleated intranuclear inclusion-bearing cells. Perianal herpetic lesions are also found in immunosuppressed patients receiving cytotoxic therapy. Extensive perianal herpetic lesions and/or HSV proctitis is common among patients with HIV infection.

Herpetic Whitlow (Fig. 182-CD7) Herpetic whitlow -- HSVinfection of the finger -- may occur as a complication of primary oral or genital herpes by inoculation of virus through a break in the epidermal surface or by direct introduction of virus into the hand through occupational or some other type of exposure. Clinical signs and symptoms include the abrupt onset of edema, erythema, and localized tenderness of the infected finger. Vesicular or pustular lesions of the fingertip that are indistinguishable from lesions of pyogenic bacterial infection are seen. Fever, lymphadenitis, and epitrochlear and axillary lymphadenopathy are common. The infection may recur. Prompt diagnosis (to avoid unnecessary and potentially exacerbating surgical therapy and/or transmission) is essential. Antiviral chemotherapy (to speed the healing of the process) is usually recommended (see below).

Herpes Gladiatorum HSV may infect almost any area of skin. Mucocutaneous HSV infections of the thorax, ears, face, and hands have been described among wrestlers. Transmission of these infections is facilitated by trauma to the skin sustained during wrestling. Prompt diagnosis and therapy are required to contain the spread of this infection.

Eye Infections HSVinfection of the eye is the most frequent cause of corneal blindness in the United States. HSV keratitis presents with an acute onset of pain, blurring of vision, chemosis, conjunctivitis, and characteristic dendritic lesions of the cornea. Use of topical glucocorticoids may exacerbate symptoms and lead to involvement of deep structures of the eye. Debridement, topical antiviral treatment, and/or interferon therapy hastens healing. However, recurrences are common, and the deeper structures of the eye may sustain immunopathologic injury. Stromal keratitis due to HSV appears to be related to T cell-dependent destruction of deep corneal tissue. An HSV-1 epitope that is

autoreactive with T cell-targeting corneal antigens has been postulated to be a factor in this infection. Chorioretinitis, usually a manifestation of disseminated HSV infection, may occur in neonates or in patients with HIV infection. HSV and varicella-zoster virus can cause acute necrotizing retinitis as an uncommon but severe manifestation.

Central and Peripheral Nervous System Infections HSVaccounts for 10 to 20% of all cases of sporadic viral encephalitis in the United States. The estimated incidence is about 2.3 cases per million persons per year. Cases are distributed throughout the year, and the age distribution appears to be biphasic, with peaks at 5 to 30 and >50 years of age. Subtype 1 virus causes >95% of cases of HSV encephalitis.

The pathogenesis ofHSVencephalitis varies. In children and young adults, primary HSV infection may result in encephalitis; presumably, exogenously acquired virus enters theCNS by neurotropic spread from the periphery via the olfactory bulb. However, most adults with HSV encephalitis have clinical or serologic evidence of mucocutaneous HSV-1 infection before the onset of the CNS symptoms. In ~25% of the cases examined, the HSV-1 strains from the oropharynx and brain tissue of the same patient differ; thus some cases may result from reinfection with another strain of HSV-1 that reaches the CNS. Two theories have been proposed to explain the development of actively replicating HSV in localized areas of the CNS in persons whose ganglionic and CNS isolates are similar. Reactivation of latent HSV-1 infection in trigeminal or autonomic nerve roots may be associated with extension of virus into the CNS via nerves innervating the middle cranial fossa. HSV DNA has been demonstrated by DNA hybridization in brain tissue obtained at autopsy -- even from healthy adults. Thus, reactivation of long-standing latent CNS infection may be another mechanism for the development of HSV encephalitis.

The clinical hallmark ofHSVencephalitis has been the acute onset of fever and focal neurologic (especially temporal-lobe) symptoms. Clinical differentiation of HSV encephalitis from other viral encephalitides, focal infections, or noninfectious processes is difficult. The most sensitive noninvasive method for early diagnosis of HSV encephalitis is the demonstration of HSV DNA in cerebrospinal fluid (CSF) byPCR. Although titers of CSF and serum antibodies to HSV increase in most cases of HSV encephalitis, they rarely do so earlier than 10 days into the illness and therefore, while useful retrospectively, are generally not helpful in establishing an early clinical diagnosis. Demonstration of HSV antigen, HSV DNA, or HSV replication in brain tissue obtained by biopsy is highly sensitive and has a low complication rate; examination of such tissue also provides the best opportunity to identify alternative, potentially treatable causes of encephalitis. Antiviral chemotherapy reduces the rate of death from HSV encephalitis. Intravenous acyclovir is more effective than vidarabine. Even with therapy, however, neurologic sequelae are frequent, especially in persons over 35 years of age. Most authorities recommend the administration of intravenous acyclovir to patients with presumed HSV encephalitis until the diagnosis is confirmed or an alternative diagnosis is made.

HSVhas been isolated from theCSF of 0.5 to 3% of patients presenting to the hospital with aseptic meningitis. HSV meningitis, which is usually seen in association with primary genital HSV infection, is an acute, self-limited disease manifested by headache, fever, and mild photophobia and lasting from 2 to 7 days. Lymphocytic pleocytosis in the

CSF is characteristic. Neurologic sequelae of HSV meningitis are rare. HSV is the most commonly identified cause of recurrent lymphocytic meningitis (Mollaret's meningitis). Demonstration of HSV antibodies in CSF or persistence of HSV DNA in CSF can establish the diagnosis. Daily administration of antiviral therapy aimed at reducing the likelihood of clinical HSV reactivation has been successful in such cases.

Autonomic nervous system dysfunction, especially of the sacral region, has been reported in association with bothHSV and varicella-zoster virus infections. Numbness, tingling of the buttocks or perineal areas, urinary retention, constipation,CSFpleocytosis, and (in males) impotence may occur. Symptoms appear to resolve slowly over days to weeks. Occasionally, hypesthesia and/or weakness of the lower extremities may persist for many months. Rarely, transverse myelitis manifested by a rapidly progressive symmetric paralysis of the lower extremities or a Guillain-Barre syndrome may follow HSV infection. Similarly, peripheral nervous system involvement (Bell's palsy) or cranial polyneuritis also may be related to reactivation of HSV-1 infection. Transitory hypesthesia of the area of skin innervated by the trigeminal nerve and vestibular system dysfunction as measured by electronystagmography are the predominant signs of disease. Studies to determine whether antiviral chemotherapy may abort these signs or reduce their frequency and severity are unavailable.

Visceral Infections HSVinfection of visceral organs usually results from viremia, and multiple-organ involvement is common. Occasionally, however, the clinical manifestations of HSV infection involve only the esophagus, lung, or liver. HSV esophagitis may result from direct extension of oral-pharyngeal HSV infection into the esophagus or may occur de novo by reactivation and spread of HSV to the esophageal mucosa via the vagus nerve. The predominant symptoms of HSV esophagitis are odynophagia, dysphagia, substernal pain, and weight loss. There are multiple oval ulcerations on an erythematous base with or without a patchy white pseudomembrane. The distal esophagus is most commonly involved. With extensive disease, diffuse friability may spread to the entire esophagus. Neither endoscopic nor barium examination can differentiate HSV esophagitis from *Candida* esophagitis or from esophageal ulcerations due to thermal injury, radiation, or corrosives. Endoscopically obtained secretions for cytologic examination and culture provide the most useful material for diagnosis. Systemic antiviral chemotherapy usually reduces symptoms and heals esophageal ulcerations.

HSVpneumonitis is uncommon except in severely immunosuppressed patients and may result from extension of herpetic tracheobronchitis into lung parenchyma. Focal necrotizing pneumonitis usually ensues. Hematogenous dissemination of virus from sites of oral or genital mucocutaneous disease also may occur and produce bilateral interstitial pneumonitis. Bacterial, fungal, and parasitic pathogens are commonly present in HSV pneumonitis. The mortality rate from untreated HSV pneumonia in immunosuppressed patients is high (>80%). HSV has also been isolated from the lower respiratory tract of persons with adult respiratory distress syndrome (ARDS). However, the relationship between the isolation of HSV and the pathogenesis of ARDS is unclear.

HSVis an uncommon cause of hepatitis in immunocompetent patients. HSV infection of the liver is associated with fever, abrupt elevations of bilirubin and serum aminotransferase levels, and leukopenia (<4000 white blood cells per microliter).

Disseminated intravascular coagulation also may develop.

Other reported complications ofHSVinfection include monarticular arthritis, adrenal necrosis, idiopathic thrombocytopenia, and glomerulonephritis. Disseminated HSV infection (Fig. 182-CD8) in immunocompetent patients is rare. In immunocompromised, burned, or malnourished patients, HSV occasionally disseminates to other visceral organs, such as the adrenal glands, pancreas, small and large intestines, and bone marrow. Rarely, primary HSV infection in pregnancy disseminates and may be associated with the death of both mother and fetus. This uncommon event is usually related to the acquisition of primary infection in the third trimester.

Neonatal HSV Infection Neonates (infants younger than 6 weeks) have the highest frequency of visceral and/orCNSinfection of anyHSV-infected patient population. Without therapy, the overall rate of death from neonatal herpes is 65%; fewer than 10% of neonates with CNS infection develop normally. Although skin lesions are the most commonly recognized features of disease, many infants do not develop lesions until well into the course of disease. Neonatal infection is usually acquired perinatally from contact with infected genital secretions at the time of delivery. Congenitally infected infants have been reported. In most series, 30% of neonatal HSV infections are due to HSV-1 and 70% to HSV-2. The risk of developing neonatal HSV infection is 10 times higher for an infant born to a mother who has recently acquired HSV than for other infants. Guidelines to evaluate routine serologic testing for HSV in pregnancy are being drafted and will serve as a basis on which to counsel "susceptible" (HSV-2-uninfected) women regarding the dangers of unprotected coitus and HSV-2 infection near term. Neonatal HSV-1 infections may also be acquired through postnatal contact with immediate family members who have symptomatic or asymptomatic oral-labial HSV-1 infection or through nosocomial transmission within the hospital. Antiviral chemotherapy has reduced the rate of death from neonatal herpes to 25%. However, the rate of morbidity, especially in infants with HSV-2 infection involving the CNS, is still very high.

DIAGNOSIS

Both clinical and laboratory criteria are useful for establishing the diagnosis ofHSVinfections. A clinical diagnosis can be made accurately when characteristic multiple vesicular lesions on an erythematous base are present. However, it is increasingly being recognized that herpetic ulcerations may clinically resemble skin ulcerations of other etiologies. Mucosal HSV infections may also present as urethritis or pharyngitis without cutaneous lesions. Thus, laboratory studies to confirm the diagnosis and to guide therapy are recommended. Staining of scrapings from the base of the lesions with Wright's, Giemsa's (Tzanck preparation; Fig. 182-CD9), or Papanicolaou's stain demonstrates characteristic giant cells or intranuclear inclusions of herpesvirus infection. These cytologic techniques are often useful as quick office procedures to confirm the diagnosis. Limitations of the cytologic method are that it does not differentiate between HSV and varicella-zoster virus infections, that it is relatively insensitive, and that the correct identification of giant cells requires experience.

HSVinfection is best confirmed in the laboratory by isolation of virus in tissue culture or by demonstration of HSV antigens or DNA in scrapings from lesions. HSV causes a discernible cytopathic effect in a variety of cell culture systems, and most specimens

can be identified within 48 to 96 h after inoculation. Spin-amplified culture with subsequent staining for HSV antigen has shortened the time needed to identify HSV to <24 h. The sensitivity of viral isolation depends on the stage of lesions (with higher sensitivity in vesicular than in ulcerative lesions), on whether the patient has a first or a recurrent episode of the disease (with higher sensitivity in first than in recurrent episodes), and on whether the sample is from an immunosuppressed or an immunocompetent patient (with more antigen in immunosuppressed patients). Antigen detection procedures have approached viral isolation in terms of sensitivity in detecting HSV in genital or oral-labial lesions; however, antigen detection appears to be only ~50% as sensitive as viral isolation for the identification of HSV in cervical or salivary secretions of asymptomatic patients.PCRtechniques appear to be more sensitive for HSV than viral isolation, especially for the diagnosis ofCNSinfections and for the detection of HSV as a cause of late-stage ulcerative lesions. Laboratory confirmation permits subtyping of the virus; information on subtype may be useful epidemiologically and may help to predict the frequency of reactivation after first-episode oral-labial or genital HSV infection.

Acute- and convalescent-phase serum can be useful in demonstrating seroconversion during primaryHSV-1 or HSV-2 infection. However, only 5% of patients with recurrent mucocutaneous HSV infections have a fourfold or greater rise in titer of antibody to HSV in the interval between the collection of the first and second samples. Serologic assays, especially type-specific assays, should be used to identify asymptomatic carriers of HSV-1 or HSV-2 infection.

Several studies have shown that persons seropositive forHSV-2 to whom the clinical manifestations of HSV have been explained are able to identify symptomatic reactivations. Individuals seropositive for HSV-2 should be told about the high frequency of subclinical reactivation in mucosal surfaces not visible to the eye (e.g., cervix, urethra, perianal skin) or in microscopic ulcerations that may not be clinically symptomatic. Transmission of infection during such episodes is well established. HSV-2-seropositive persons should be educated about the high likelihood of subclinical shedding and the role condoms (male or female) may play in reducing transmission. Chronic antiviral therapy is being studied as a means of reducing the transmission of infection.

TREATMENT

Many aspects of mucocutaneous and visceralHSVinfections are amenable to antiviral chemotherapy. For mucocutaneous infections, acyclovir and its congeners famciclovir and valacyclovir have been the mainstay of therapy. Several antiviral agents are available for topical use in HSV eye infections: idoxuridine, trifluorothymidine, topical vidarabine, and cidofovir. For HSV encephalitis and neonatal herpes, intravenous acyclovir is the treatment of choice.

All licensed antivirals forHSVinhibit the viral DNA polymerase. One class of drugs, typified by the drug acyclovir, is made up of substrates for the HSV enzyme thymidine kinase. Acyclovir, ganciclovir, famciclovir, and valacyclovir are all selectively phosphorylated to the monophosphate form in virus-infected cells. Cellular enzymes convert the monophosphate form of the drug to the triphosphate, which is then

incorporated into the viral DNA chain.

Acyclovir is the most frequently used agent for the treatment ofHSVinfections and is available in intravenous, oral, and topical formulations. Famciclovir, the oral formulation of penciclovir, is clinically effective in the treatment of a variety of HSV-1 and HSV-2 infections. Intravenous penciclovir is also available. Valacyclovir is the valyl ester of acyclovir and has greater bioavailability than acyclovir. Ganciclovir has activity against both HSV-1 and HSV-2; however, it is more toxic than acyclovir, valacyclovir, and famciclovir and is generally not recommended for the treatment of HSV infections.

All three compounds -- acyclovir, valacyclovir, and famciclovir -- have proven effective in shortening the duration of symptoms and lesions of mucocutaneousHSVinfections in both immunocompromised and immunocompetent patients (Table 182-1). Intravenous and oral formulations prevent reactivation of HSV in seropositive immunocompromised patients during induction chemotherapy or in the period immediately after bone marrow or solid organ transplantation. Chronic daily suppressive therapy reduces the frequency of reactivation disease among patients with frequent genital or oral-labial herpes.

Intravenous acyclovir (30 mg/kg per day, given as a 10-mg/kg infusion over 1 h at 8-h intervals) is effective in reducing rates of death and morbidity fromHSVencephalitis. Early initiation of therapy is a critical factor in outcome. The major side effect associated with intravenous acyclovir is transient renal insufficiency, usually due to crystallization of the compound in the renal parenchyma. This adverse reaction can be avoided if the medication is given slowly over 1 h and the patient is well hydrated. BecauseCSFlevels of acyclovir average only 30 to 50% of plasma levels, the dosage of acyclovir used for treatment ofCNSinfection (30 mg/kg per day) is double that used for treatment of mucocutaneous or visceral disease (15 mg/kg per day).

Acyclovir-resistant strains ofHSV have been identified. Most of these strains have an altered substrate specificity for phosphorylating acyclovir. Thus, cross-resistance to famciclovir and valacyclovir is usually found. Occasionally, an isolate with altered thymidine kinase (TK) specificity arises and is sensitive to famciclovir but not to acyclovir. In some patients infected with TK-deficient virus, higher doses of acyclovir are associated with clearing of lesions. In others, clinical disease progresses despite high-dose therapy. Almost all clinically significant acyclovir resistance has been seen in immunocompromised patients, and HSV-2 isolates are more often resistant than HSV-1 strains. A study by the Centers for Disease Control and Prevention indicated that ~5% of isolates from HIV-positive persons exhibit some degree of in vitro resistance to acyclovir. Isolation of HSV from persisting lesions despite adequate dosages and blood levels of acyclovir should raise the suspicion of acyclovir resistance. Therapy with the antiviral drug foscarnet is useful (Chap. 181). Because of its toxicity and cost, this drug is usually reserved for patients with extensive mucocutaneous infections. Cidofovir is a nucleotide analogue and exists as a phosphonate or monophosphate form. Most TK-deficient strains of HSV are sensitive to cidofovir. Cidofovir ointment speeds healing of acyclovir-resistant lesions. No well-controlled trials of systemic cidofovir have been reported. True TK-negative variants of HSV appear to have a reduced capacity to spread because of altered neurovirulence -- a feature important in the relatively infrequent presence of such strains in immunocompetent populations, even with increasing use of antivirals.

PREVENTION

The large reservoir of persons with asymptomaticHSV-1 and HSV-2 infections indicates that the success of efforts to control HSV disease through suppressive antiviral chemotherapy and/or educational programs will be limited. Rather, control of HSV infection will require the prevention of infection -- a goal most likely to be attained by vaccination. Several candidate vaccines are under investigation, and the prevention of HSV infection has been assigned a high public health priority.

Barrier forms of contraception, especially condoms, decrease the likelihood of transmission ofHSVinfection, especially during periods of asymptomatic viral excretion. When lesions are present, HSV infection may be transmitted by skin-to-skin contact despite the use of a condom. Nevertheless, the available data suggest that consistent condom use is an effective means of reducing the risk of genital HSV-2 transmission. Prevention of neonatal HSV requires the prevention of acquisition of HSV in the third trimester of pregnancy. Identification of women or couples susceptible to acquisition of HSV in pregnancy through serologic screening is receiving increasing attention, and such screening is being used with increasing frequency.

183. VARICELLA-ZOSTER VIRUS INFECTIONS - *Richard J. Whitley*

DEFINITION

Varicella-zoster virus (VZV) causes two distinct clinical entities: varicella (chickenpox) and herpes zoster (shingles). Chickenpox, a ubiquitous and extremely contagious infection, is usually a benign illness of childhood characterized by an exanthematous vesicular rash. With reactivation of latent VZV (which is most common after the sixth decade of life), herpes zoster presents as a dermatomal vesicular rash, usually associated with severe pain.

ETIOLOGY

A clinical association between varicella and herpes zoster has been recognized for nearly 100 years. Early in the twentieth century, similarities in the histopathologic features of skin lesions resulting from varicella and herpes zoster were demonstrated. Viral isolates from patients with chickenpox and herpes zoster produced similar alterations in tissue culture -- specifically, the appearance of eosinophilic intranuclear inclusions and multinucleated giant cells. These results suggested that the viruses were biologically similar. Restriction endonuclease analyses of viral DNA from a patient with chickenpox who subsequently developed herpes zoster verified the molecular identity of the two viruses responsible for these different clinical presentations.

VZVis a member of the family Herpesviridae, sharing with other members such structural characteristics as a lipid envelope surrounding a nucleocapsid with icosahedral symmetry, a total diameter of approximately 180 to 200 nm, and centrally located double-stranded DNA that is about 125,000 bp in length.

PATHOGENESIS AND PATHOLOGY

Primary Infection Transmission is most likely to take place by the respiratory route; the subsequent localized replication of the virus at an undefined site (presumably the nasopharynx) leads to seeding of the reticuloendothelial system and ultimately to the development of viremia. Viremia in patients with chickenpox is reflected in the diffuse and scattered nature of the skin lesions and can be verified in selected cases by the recovery ofVZV from the blood. Vesicles involve the corium and dermis, with degenerative changes characterized by ballooning, the presence of multinucleated giant cells, and eosinophilic intranuclear inclusions. Infection may involve localized blood vessels of the skin, resulting in necrosis and epidermal hemorrhage. With the evolution of disease, the vesicular fluid becomes cloudy because of the recruitment of polymorphonuclear leukocytes and the presence of degenerated cells and fibrin. Ultimately, the vesicles either rupture and release their fluid (which includes infectious virus) or are gradually reabsorbed.

Recurrent Infection The mechanism of reactivation ofVZV that results in herpes zoster is unknown. Presumably, the virus infects the dorsal root ganglia during chickenpox, where it remains latent until reactivated. Histopathologic examination of representative dorsal root ganglia during active herpes zoster demonstrates hemorrhage, edema, and lymphocytic infiltration.

Active replication ofVZV in other organs, such as the lung or the brain, can occur during either chickenpox or herpes zoster but is uncommon in the immunocompetent host. Pulmonary involvement is characterized by interstitial pneumonitis, multinucleated giant cell formation, intranuclear inclusions, and pulmonary hemorrhage. Central nervous system (CNS) infection leads to histopathologic evidence of perivascular cuffing similar to that encountered in measles and other viral encephalitides. Focal hemorrhagic necrosis of the brain, characteristic of herpes simplex virus encephalitis, is uncommon in VZV infection.

EPIDEMIOLOGY AND CLINICAL MANIFESTATIONS

Chickenpox Humans are the only known reservoir forVZV. Chickenpox is highly contagious, with an attack rate of at least 90% among susceptible (seronegative) individuals. Persons of both sexes and all races are infected equally often. The virus is endemic in the population at large; however, it becomes epidemic among susceptible individuals during seasonal peaks -- namely, late winter and early spring in the temperate zone. Children between the ages of 5 and 9 are most commonly affected and account for 50% of all cases. Most other cases involve children aged 1 to 4 and those aged 10 to 14. Approximately 10% of the population of the United States over the age of 15 is susceptible to infection.

The incubation period of chickenpox ranges between 10 and 21 days but is usually between 14 and 17 days. Secondary attack rates in susceptible siblings within a household are between 70 and 90%. Patients are infectious approximately 48 h prior to the onset of the vesicular rash, during the period of vesicle formation (which generally lasts 4 to 5 days), and until all vesicles are crusted.

Clinically, chickenpox presents as a rash, low-grade fever, and malaise, although a few patients develop a prodrome 1 to 2 days before onset of the exanthem. In the immunocompetent patient, this is usually a benign illness that is associated with lassitude and with body temperatures of 37.8 to 39.4°C (100 to 103°F) of 3 to 5 days' duration. The skin lesions -- the hallmark of the infection -- include maculopapules, vesicles, and scabs in various stages of evolution (Plate IID-36,Fig. 183-CD1). These lesions, which evolve from maculopapules to vesicles over hours to days, appear on the trunk and face and rapidly spread to involve other areas of the body. Most are small and have an erythematous base with a diameter of 5 to 10 mm. Successive crops appear over a 2- to 4-day period. Lesions also can be found on the mucosa of the pharynx and/or the vagina. Their severity varies from one person to another. Some individuals have very few lesions, while others have as many as 2000. Younger children tend to have fewer vesicles than older individuals. Secondary and tertiary cases within families are associated with a relatively large number of vesicles. Immunocompromised patients -- both children and adults, particularly those with leukemia -- have lesions (often with a hemorrhagic base) that are more numerous and take longer to heal than those of immunocompetent patients. Immunocompromised individuals are also at greater risk for visceral complications, which occur in 30 to 50% of cases and are fatal 15% of the time.

The most common infectious complication of varicella is secondary bacterial superinfection of the skin, which is usually caused by *Streptococcus pyogenes* or

Staphylococcus aureus. This complication may result from excoriation of skin lesions after scratching. Gram's staining of skin lesions should help clarify the etiology of unusually erythematous and pustulated lesions.

The most common extracutaneous site of involvement in children is theCNS. The syndrome of acute cerebellar ataxia and meningeal irritation generally appears around 21 days after the onset of the rash and rarely develops in the preeruptive phase. The cerebrospinal fluid (CSF) contains lymphocytes and elevated levels of protein. CNS involvement is a benign complication ofVZVinfection in children and generally does not require hospitalization. Aseptic meningitis, encephalitis, transverse myelitis, Guillain-Barre syndrome, and Reye's syndrome also can occur. Encephalitis is reported in 0.1 to 0.2% of children with chickenpox. Other than supportive care, no specific therapy is available for patients with CNS involvement.

Varicella pneumonia is the most serious complication following chickenpox, developing more commonly in adults (up to 20% of cases) than in children. It usually has its onset 3 to 5 days into the illness and is associated with tachypnea, cough, dyspnea, and fever. Cyanosis, pleuritic chest pain, and hemoptysis are frequent. Roentgenographic evidence of disease consists of nodular infiltrates and interstitial pneumonitis. Resolution of pneumonitis parallels improvement of the skin rash; however, patients may have persistent fever and compromised pulmonary function for weeks.

Other complications of chickenpox include myocarditis, corneal lesions, nephritis, arthritis, bleeding diatheses, acute glomerulonephritis, and hepatitis. Hepatic involvement, distinct from Reye's syndrome and usually asymptomatic, is common in chickenpox and is usually characterized by elevated levels of liver enzymes, particularly aspartate and alanine aminotransferases.

Perinatal varicella is associated with a high mortality rate when maternal disease develops within 5 days before delivery or within 48 h thereafter. Because the newborn does not receive protective transplacental antibodies and has an immature immune system, the illness may be unusually severe. The reported mortality rate has been as high as 30% in this group. Congenital varicella, with clinical manifestations of limb hypoplasia, cicatricial skin lesions, and microcephaly at birth, is extremely uncommon.

Herpes Zoster Herpes zoster, a sporadic disease, is the consequence of reactivation of latentVZV from the dorsal root ganglia. Most patients have no history of recent exposure to other individuals with VZV infection. Herpes zoster occurs at all ages, but its incidence is highest (5 to 10 cases per 1000 persons) among individuals in the sixth through the eighth decades of life. Recurrent herpes zoster is exceedingly rare except in immunocompromised hosts, especially those with AIDS.

Herpes zoster, also called shingles, is characterized by a unilateral vesicular eruption within a dermatome, often associated with severe pain. The dermatomes from T3 to L3 are most frequently involved. If the ophthalmic branch of the trigeminal nerve is involved, zoster ophthalmicus results. The factors responsible for the reactivation ofVZV are not known. In children reactivation is usually benign, whereas in adults it can be debilitating. The continuum of pain from onset to resolution is known as *zoster-associated pain*. The onset of disease is heralded by pain within the dermatome

that may precede lesions by 48 to 72 h; an erythematous maculopapular rash evolves rapidly into vesicular lesions. In the normal host, these lesions may remain few in number and continue to form only for a period of 3 to 5 days. The total duration of disease is generally between 7 and 10 days; however, it may take as long as 2 to 4 weeks for the skin to return to normal. In a few patients, characteristic localization of pain to a dermatome with serologic evidence of herpes zoster has been reported in the absence of skin lesions. When branches of the trigeminal nerve are involved, lesions may appear on the face, in the mouth, in the eye, or on the tongue. In the Ramsay Hunt syndrome (Plate IID-35), pain and vesicles appear in the external auditory canal, and patients lose their sense of taste in the anterior two-thirds of the tongue while developing ipsilateral facial palsy. The geniculate ganglion of the sensory branch of the facial nerve is involved.

The most debilitating complication of herpes zoster, in both the normal and the immunocompromised host, is pain associated with acute neuritis and postherpetic neuralgia. Postherpetic neuralgia is uncommon in young individuals; however, at least 50% of patients over age 50 with zoster report some degree of pain in the involved dermatome months after the resolution of cutaneous disease. Changes in sensation in the dermatome, resulting in either hypo- or hyperesthesia, are common.

CNSinvolvement may follow localized herpes zoster. Many patients without signs of meningeal irritation haveCSFpleocytosis and moderately elevated levels of CSF protein. Symptomatic meningoencephalitis is characterized by headache, fever, photophobia, meningitis, and vomiting. A rare manifestation of CNS involvement is granulomatous angiitis with contralateral hemiplegia, which can be diagnosed by cerebral arteriography. Other neurologic manifestations include transverse myelitis with or without motor paralysis.

Like chickenpox, herpes zoster is more severe in the immunocompromised host than in the normal individual. Lesions continue to form for over a week, and scabbing is not complete in most cases until 3 weeks into the illness. Patients with Hodgkin's disease and non-Hodgkin's lymphoma are at greatest risk for progressive herpes zoster. Cutaneous dissemination (Plate IID-37,Fig. 183-CD2) develops in about 40% of these patients. Among patients with cutaneous dissemination (Fig. 183-CD3), the risk of pneumonitis, meningoencephalitis, hepatitis, and other serious complications is increased by 5 to 10%. However, even in immunocompromised patients, disseminated zoster is rarely fatal.

Patients who have received a bone marrow transplant are at particularly high risk ofVZVinfection. Thirty percent of cases of posttransplantation VZV infection occur within 1 year (50% of these within 9 months); 45% of the patients involved have cutaneous or visceral dissemination. The mortality rate in this situation is 10%. Postherpetic neuralgia, scarring, and bacterial superinfection are especially frequent in VZV infections occurring within 9 months of transplantation. Among infected patients, concomitant graft-versus-host disease increases the chance of dissemination and/or death.

DIFFERENTIAL DIAGNOSIS

The diagnosis of chickenpox is not difficult. The characteristic rash and a history of recent exposure should lead to a prompt diagnosis. Other viral infections that can mimic chickenpox include disseminated herpes simplex virus infection in patients with atopic dermatitis and the disseminated vesiculopapular lesions sometimes associated with coxsackievirus infection, echovirus infection, or atypical measles. However, these rashes are more commonly morbilliform with a hemorrhagic component rather than vesicular or vesiculopustular. Rickettsialpox can be confused with chickenpox; however, it can be distinguished easily by detection of the "herald spot" at the site of the mite bite and the development of a more pronounced headache. Serologic testing is also useful in differentiating rickettsialpox from varicella.

Unilateral vesicular lesions in a dermatomal pattern should lead rapidly to the diagnosis of herpes zoster, although the occurrence of shingles without a rash has been reported. Both herpes simplex virus infections and coxsackievirus infections can cause dermatomal vesicular lesions. Supportive diagnostic virology and fluorescent staining of skin scrapings with monoclonal antibodies are helpful in ensuring the proper diagnosis. In the prodromal stage of herpes zoster, the diagnosis can be exceedingly difficult and may be made only after lesions have appeared or by retrospective serologic assessment.

LABORATORY FINDINGS

Unequivocal confirmation of the diagnosis is possible only through the isolation ofVZV in susceptible tissue-culture cell lines, the demonstration of either seroconversion or a fourfold or greater rise in antibody titer between convalescent- and acute-phase serum specimens, or the detection of VZV DNA by polymerase chain reaction (PCR). A rapid impression can be obtained by a Tzanck smear, with scraping of the base of the lesions in an attempt to demonstrate multinucleated giant cells, although the sensitivity of this method is low (about 60%). PCR technology for the detection of viral DNA in vesicular fluid is available in a limited number of diagnostic laboratories. Direct immunofluorescent staining of cells from the lesion base or detection of viral antigens by other assays (such as the immunoperoxidase assay) is also useful, although these tests are not commercially available. The most frequently employed serologic tools for assessing host response are the immunofluorescent detection of antibodies to VZV membrane antigens, the fluorescent antibody to membrane antigen (FAMA) test, immune adherence hemagglutination, and enzyme-linked immunosorbent assay (ELISA). The FAMA test and the ELISA appear to be the most sensitive.

PROPHYLAXIS

While chickenpox in the otherwise healthy host is relatively benign, it can cause morbidity and death. Furthermore, the parents of a child with chickenpox often lose a significant amount of time from work. A live attenuated varicella vaccine has been licensed and is recommended for administration to all immunocompetent children and adults at risk of infection.

The immunocompromised individual is at significant risk for developing progressive varicella; modalities of prevention include passive immunization or experimental administration of the same live attenuated vaccine used in the immunocompetent child.

Immune prophylaxis can consist of the administration of specific zoster immune globulin (ZIG) derived from patients with herpes zoster, varicella-zoster immune globulin (VZIG), or the intravenous formulation of zoster immune plasma (ZIP). Both ZIG and VZIG should be given within 96 h (preferably within 72 h) of exposure to ensure efficacy. It is likely that ZIP can be given somewhat later. Indications for the administration of VZIG are summarized inTable 183-1.

TREATMENT

Medical management of chickenpox in the immunologically normal host is directed toward the prevention of avoidable complications. Obviously, good hygiene includes daily bathing and soaks. Secondary bacterial infection of the skin can be avoided by meticulous skin care, particularly with close cropping of fingernails. Pruritus can be decreased with topical dressings or the administration of antipruritic drugs. Tepid water baths and wet compresses are better than drying lotions for the relief of itching. Aluminum acetate soaks for the management of herpes zoster can be both soothing and cleansing. Administration of aspirin to children with chickenpox should be avoided because of the association of aspirin derivatives with the development of Reye's syndrome. Acyclovir therapy (800 mg by mouth five times daily for 5 to 7 days) is recommended for adolescents and adults with chickenpox of£24 h duration. Likewise, acyclovir therapy may be of benefit to children <12 years of age if initiated early in the disease (<24 h) at a dose of 20 mg/kg every 6 h.

Patients with herpes zoster benefit from oral antiviral therapy, as evidenced by accelerated healing of lesions and resolution of zoster-associated pain with acyclovir, valacyclovir, or famciclovir. Acyclovir, now off patent, is administered at a dosage of 800 mg five times daily for 7 to 10 days. Famciclovir, the prodrug of penciclovir, is at least as effective as acyclovir and perhaps more so. One study showed twofold faster resolution of postherpetic neuralgia in famciclovir-treated patients with zoster than in recipients of placebo. The dose is 500 mg by mouth three times daily for 7 days. Valacyclovir, the prodrug of acyclovir, accelerates healing and resolution of zoster-associated pain more promptly than acyclovir. The dose is 1 g by mouth three times daily for 5 to 7 days. Both famciclovir and valacyclovir offer the advantage of a lower dosing frequency than acyclovir.

In the immunocompromised host, both chickenpox and herpes zoster (including disseminated disease) should be treated with intravenous acyclovir, which reduces the occurrence of visceral complications but has no effect on healing of skin lesions or pain. The dose is 10 to 12.5 mg/kg every 8 h for 7 days. Oral acyclovir therapy is not recommended for the treatment ofVZVinfections in immunocompromised patients. Concomitant with the administration of intravenous acyclovir, it is desirable to attempt to wean these patients from immunosuppressive treatment.

Patients with varicella pneumonia may require removal of bronchial secretions and ventilatory support. Persons with zoster ophthalmicus should be referred immediately to an ophthalmologist. Therapy for this condition consists of the administration of analgesics for severe pain and the use of atropine. Acyclovir accelerates healing.

The management of acute neuritis and/or postherpetic neuralgia can be particularly

difficult. In addition to the judicious use of analgesics, ranging from nonnarcotics to narcotic derivatives, drugs such as gabapentin, amitriptyline hydrochloride, and fluphenazine hydrochloride have been reported to be beneficial for pain relief. In one study, glucocorticoid therapy administered early in the course of localized herpes zoster significantly accelerated such quality-of-life improvements as a return to usual activity and termination of analgesia. The dose of prednisone administered orally was 60 mg/d on days 1 through 7, 30 mg/d on days 8 through 14, and 15 mg/d on days 15 through 21. This regimen is appropriate only for relatively healthy elderly persons who have moderate or severe pain at presentation. Patients with osteoporosis, diabetes mellitus, glycosuria, or hypertension may not be appropriate candidates. Glucocorticoids should not be used without concomitant antiviral therapy.

184. EPSTEIN-BARR VIRUS INFECTIONS, INCLUDING INFECTIOUS MONONUCLEOSIS - *Jeffrey I. Cohen*

DEFINITION

Epstein-Barr virus (EBV) is the cause of heterophile-positive infectious mononucleosis (IM), which is characterized by fever, sore throat, lymphadenopathy, and atypical lymphocytosis. EBV is also associated with several human tumors, including nasopharyngeal carcinoma, Burkitt's lymphoma, Hodgkin's disease, and -- in patients with immunodeficiencies (including AIDS) -- B cell lymphoma. The virus, a member of the family Herpesviridae, consists of a linear, double-stranded DNA core surrounded by an icosahedral nucleocapsid and by the viral envelope, which contains glycoproteins. The two types of EBV that are widely prevalent in nature are not distinguishable by conventional serologic tests.

EPIDEMIOLOGY

EBVinfections occur worldwide. These infections are most common in early childhood, with a second peak during late adolescence. By adulthood, more than 90% of individuals have been infected and have antibodies to the virus.IM is usually a disease of young adults. In lower socioeconomic groups and in areas of the world with lower standards of hygiene (e.g., developing countries), EBV tends to infect children at an early age, and symptomatic IM is uncommon. In areas with higher standards of hygiene (e.g., the United States), infection with EBV is often delayed until adulthood, and IM is more prevalent.

EBVis spread by contact with oral secretions. The virus is frequently transmitted from asymptomatic adults to infants and among young adults by transfer of saliva during kissing. Transmission by less intimate contact is rare. EBV has been transmitted by blood transfusion and by bone marrow transplantation. Studies indicate that more than 90% of asymptomatic seropositive individuals shed the virus in oropharyngeal secretions.

PATHOGENESIS

EBVis transmitted by salivary secretions. The virus infects the epithelium of the oropharynx and the salivary glands and is shed from these cells. While B cells may become infected after contact with epithelial cells, studies suggest that lymphocytes in the tonsillar crypts can be infected directly. The virus then spreads through the bloodstream. The proliferation and expansion of EBV-infected B cells along with reactive T cells duringIMresult in enlargement of lymphoid tissue. Polyclonal activation of B cells leads to the production of antibodies to host-cell and viral proteins. During the acute phase of IM, up to 1 in every 100 B cells in the peripheral blood is infected by EBV, while after recovery, about 1 in every million B cells is infected. During IM there is an inverted CD4+/CD8+ T cell ratio. The percentage of CD4+ T cells decreases, while there are large clonal expansions of CD8+ T cells; up to 40% of CD8+ T cells are directed against EBV antigens during acute infection. Data suggest that memory B cells, not epithelial cells, are the reservoir for EBV in the body: Shedding of EBV from the oropharynx stops but the virus persists in B cells when patients are treated with

acyclovir.

TheEBVreceptor (CD21), present on the surface of B cells and epithelial cells, is also the receptor for the C3d component of complement. EBV infection of epithelial cells results in viral replication and production of virions. When B cells are infected by EBV in vitro, they become transformed and can proliferate indefinitely. During latent infection of B cells, only the EBV nuclear antigens (EBNAs), latent membrane proteins (LMPs), and small EBV RNAs are expressed in vitro. EBV-transformed B cells secrete immunoglobulin; only a small fraction of cells produce virus.

Cellular immunity is more important than humoral immunity in controllingEBVinfection. In the initial phase of infection, suppressor T cells, natural killer cells, and nonspecific cytotoxic T cells are important in controlling the proliferation of EBV-infected B cells. Levels of markers of T cell activation and serum interferon g are elevated. Later in infection, HLA-restricted cytotoxic T cells that recognizeEBNAsand LMPsand destroy EBV-infected cells are generated. Studies have shown that one of the late genes expressed during EBV replication, *BCRF1*, is a homologue of interleukin 10 and can inhibit the production of interferong by mononuclear cells in vitro. In addition, EBNA-1 inhibits antigen processing.

If T cell immunity is compromised,EBV-infected B cells may begin to proliferate. When EBV is associated with lymphoma, virus-induced proliferation is but one step in a multistep process of neoplastic transformation. In many EBV-containing tumors, LMP-1 mimics members of the tumor necrosis factor receptor family (e.g., CD40), transmitting growth-proliferating signals.

CLINICAL MANIFESTATIONS

MostEBVinfections in infants and young children either are asymptomatic or present as mild pharyngitis with or without tonsillitis. In contrast, up to 75% of infections in adolescents present asIM.

Signs and Symptoms The incubation period forIM in young adults is about 4 to 6 weeks. A prodrome of fatigue, malaise, and myalgia may last for 1 to 2 weeks before the onset of fever, sore throat, and lymphadenopathy. Fever is usually low-grade and is most common in the first 2 weeks of the illness; however, it may persist for over a month. Common signs and symptoms are listed along with their frequencies inTable 184-1. Lymphadenopathy and pharyngitis are most prominent during the first 2 weeks of the illness, while splenomegaly is more prominent during the second and third weeks. Lymphadenopathy most often affects the posterior cervical nodes but may be generalized. Enlarged lymph nodes are frequently tender and symmetric but are not fixed in place. Pharyngitis, often the most prominent sign, can be accompanied by enlargement of the tonsils with an exudate resembling that of streptococcal pharyngitis. A morbilliform or papular rash, usually on the arms or trunk, develops in about 5% of cases. Most patients treated with ampicillin develop a macular rash (Fig. 186-CD1); this rash is not predictive of future adverse reactions to penicillins. Erythema nodosum and erythema multiforme have also been described (Chap. 57). Most patients have symptoms for 2 to 4 weeks, but malaise and difficulty concentrating can persist for months.

SymptomaticIM is uncommon in infants and young children. IM in the elderly presents relatively often as nonspecific symptoms, including prolonged fever, fatigue, myalgia, and malaise; in contrast, pharyngitis, lymphadenopathy, splenomegaly, and atypical lymphocytes are relatively rare in elderly patients.

Laboratory Findings The white blood cell count is usually elevated and peaks at 10,000 to 20,000/uL during the second or third week of illness. Lymphocytosis is usually demonstrable, with more than 10% atypical lymphocytes. The latter cells are enlarged lymphocytes that have abundant cytoplasm, vacuoles, and indentations of the cell membrane. CD8+ cells predominate among the atypical lymphocytes. Low-grade neutropenia and thrombocytopenia are common during the first month of illness. Liver function is abnormal in more than 90% of cases. Serum levels of aminotransferases and alkaline phosphatase are usually mildly elevated; the serum concentration of bilirubin is elevated in about 40% of cases.

Complications Most cases ofIM are self-limited. Deaths are very rare and most often are due to central nervous system (CNS) complications, splenic rupture, upper airway obstruction, or bacterial superinfection.

WhenCNScomplications develop, they usually do so during the first 2 weeks ofEBVinfection; in some patients, especially children, they are the only clinical manifestations ofIM. Heterophile antibodies and atypical lymphocytes may be absent. Meningitis and encephalitis are the most common neurologic abnormalities, and patients may present with headache, meningismus, or cerebellar ataxia; acute hemiplegia and psychosis have also been described. The cerebrospinal fluid (CSF) contains mainly lymphocytes, with occasional atypical lymphocytes. Most cases resolve without neurologic sequelae. Acute EBV infection has also been associated with cranial nerve palsies (especially ones involving cranial nerve VII), Guillain-Barre syndrome, acute transverse myelitis, and peripheral neuritis.

Autoimmune hemolytic anemia occurs in about 2% of cases during the first 2 weeks. In most cases the anemia is Coombs'-test positive, with cold agglutinins directed against the i red blood cell antigen. Most patients with hemolysis have mild anemia that lasts for 1 or 2 months, but some patients have severe disease with hemoglobinuria and jaundice. Nonspecific antibody responses may also include rheumatoid factor, antinuclear antibodies, anti-smooth muscle antibodies, antiplatelet antibodies, and cryoglobulins.IM has been associated with red-cell aplasia, severe granulocytopenia, thrombocytopenia, pancytopenia, and hemophagocytic syndrome. The spleen ruptures in fewer than 0.5% of cases. Splenic rupture is more common among males than among females and may be manifest as abdominal pain, referred shoulder pain, or hemodynamic compromise.

Hypertrophy of lymphoid tissue in the tonsils or adenoids can result in upper airway obstruction, as can inflammation and edema of the epiglottis, pharynx, or uvula. About 10% of patients withIMdevelop streptococcal pharyngitis after their initial sore throat resolves.

Other rare complications associated with acuteEBVinfection include hepatitis (which can

be fulminant), myocarditis or pericarditis with electrocardiographic changes, pneumonia with pleural effusion, interstitial nephritis, genital ulcerations, and vasculitis.

OTHER DISEASES ASSOCIATED WITH EBV INFECTION

EBV-associated lymphoproliferative disease has been described in patients with congenital or acquired immunodeficiency, including those with severe combined immunodeficiency or AIDS, recipients of bone marrow transplants, and recipients of organ transplants who are receiving immunosuppressive drugs (especially cyclosporine). Proliferating EBV-infected B cells infiltrate lymph nodes and multiple organs, and patients present with fever and lymphadenopathy or gastrointestinal symptoms. Pathologic studies show B cell hyperplasia or poly- or monoclonal lymphoma. The X-linked lymphoproliferative syndrome (Duncan's disease) is a recessive disorder of young boys who have a normal response to childhood infections but develop fatal lymphoproliferative disorders after infection with EBV. The gene mutated in this syndrome, SAP or SH2D1A, has been identified; its product binds to a protein that mediates interactions of B and T cells. Most patients with this syndrome die of acuteIM; others develop hypogammaglobulinemia, malignant B cell lymphomas, aplastic anemia, or agranulocytosis. IM has also proved fatal to some patients with no obvious preexisting immune abnormality.

Oral hairy leukoplakia (Plate IID-42) is an early manifestation of infection with HIV in adults (Chap. 309). Most patients present with raised, white corrugated lesions on the tongue (and occasionally on the buccal mucosa) that containEBV DNA. Children infected with HIV can develop lymphoid interstitial pneumonitis; EBV DNA is often found in lung tissue from these patients.

Patients with the chronic fatigue syndrome may have titers of antibody toEBV that are elevated but are not significantly different from those in healthy EBV-seropositive adults. While some patients have malaise and fatigue that persist for weeks or months afterIM, persistent EBV infection is not a cause of the chronic fatigue syndrome. Chronic active EBV infection is very rare and is distinct from the chronic fatigue syndrome. The affected patients have an illness lasting more than 6 months with markedly elevated titers of antibody to EBV and evidence of organ involvement, including hepatosplenomegaly, lymphadenopathy, and pneumonitis, uveitis, or neurologic disease.

EBVis associated with several malignancies. About 15% of cases of Burkitt's lymphoma in the United States and about 90% of those in Africa are associated with EBV (Chap. 112). African patients with Burkitt's lymphoma have high levels of antibody to EBV, and their tumor tissue usually contains viral DNA. EBV-containing Burkitt's lymphoma also occurs in patients with AIDS. Anaplastic nasopharyngeal carcinoma is uniformly associated with EBV; the affected tissues contain viral DNA and antigens. Patients with nasopharyngeal carcinoma often have elevated titers of antibody to EBV (Chap. 87).

EBVhas been associated with Hodgkin's disease, especially the mixed-cellularity type (Chap. 112). Patients with Hodgkin's disease often have elevated titers of antibody to EBV, and in about half of cases viral DNA and antigens are found in Reed-Sternberg cells. In some cases, EBV DNA has been detected in tonsillar carcinoma,

angioimmunoblastic lymphadenopathy, angiocentric nasal NK/T cell immunoproliferative lesions, T cell lymphoma, thymoma, gastric carcinoma, andCNSlymphoma from patients with no underlying immunodeficiency. Studies have demonstrated viral DNA in leiomyosarcomas from AIDS patients and in smooth-muscle tumors from organ transplant recipients. Virtually all CNS lymphomas in AIDS patients are associated with EBV.

DIAGNOSIS

Serologic Testing The heterophile test is used for the diagnosis ofIM in children and adults (Table 184-2). Heterophile antibody is an IgM antibody that does not bindEBVproteins. In the test for this antibody, human serum is absorbed with guinea pig kidney, and the heterophile titer is defined as the greatest serum dilution that agglutinates sheep, horse, or cow erythrocytes. A titer of 40-fold or greater is diagnostic of acute EBV infection in a patient who has symptoms compatible with IM and atypical lymphocytes. Tests for heterophile antibodies are positive in 40% of patients with IM during the first week of illness and in 80 to 90% during the third week. Therefore, repeated testing may be necessary, especially if the initial test is performed early. Tests usually remain positive for 3 months after the onset of illness, but heterophile antibodies can persist for up to 1 year. These antibodies usually are not detectable in children<5 years of age, in the elderly, or in patients presenting with symptoms not typical of IM. The commercially available monospot test for heterophile antibodies is somewhat more sensitive than the classic heterophile test. False-positive results in the monospot test are more common in children and in patients with other viral infections.

EBV-specific antibody testing is used for patients with suspected acute EBV infection who lack heterophile antibodies and for patients with atypical infections. Serologic tests are particularly useful in young children, who often do not develop heterophile antibodies. Titers of IgM and IgG antibodies to viral capsid antigen (VCA) are elevated in the serum of more than 90% of patients at the onset of disease. IgM antibody to VCA is useful for the diagnosis of acuteIMbecause it is present at elevated titers only during the first 2 months of the disease; in contrast, IgG antibody to VCA is often used to assess exposure to EBV in the past because it persists for life.

Antibodies to early antigens (EAs) are found either in a diffuse pattern in the nucleus and cytoplasm of infected cells (EA-D antibody) or restricted to the cytoplasm (EA-R antibody). These antibodies are detectable 3 to 4 weeks after the onset of symptoms in patients withIM. About 70% of individuals with IM, especially those with relatively severe disease, have EA-D antibodies during the course of their illness. These antibodies usually persist for only 3 to 6 months. Levels of EA-D antibodies are also elevated in patients with nasopharyngeal carcinoma or chronic activeEBVinfection. EA-R antibodies are only occasionally detected in patients with IM but are often found at elevated titers in patients with African Burkitt's lymphoma or chronic active EBV infection.

IgA antibodies toEBVantigens have proved useful for the identification of patients with nasopharyngeal carcinoma and of persons at high risk for the disease. Seroconversion toEBNApositivity is also useful for the diagnosis of acute infection with EBV. Antibodies to EBNA are detectable relatively late (3 to 6 weeks after the onset of symptoms) in nearly all cases of acute EBV infection and persist for the lifetime of the patient. These

antibodies may be lacking in immunodeficient patients and in those with chronic active EBV infection.

Other Studies Detection ofEBV DNA, RNA, or proteins has been valuable in demonstrating the association of the virus with various malignancies. The polymerase chain reaction has been used to detect EBV DNA in theCSF of some AIDS patients with lymphomas and to monitor the amount of EBV DNA in the blood of patients with lymphoproliferative disease. Culture of EBV from throat washings or blood is not helpful in the diagnosis of acute infection, since EBV commonly persists in the oropharynx and in B cells for the lifetime of the infected individual.

Differential Diagnosis The differential diagnosis ofIM and atypical lymphocytosis includes acute infection with cytomegalovirus, *Toxoplasma*, HIV, human herpesvirus 6, and hepatitis viruses as well as drug hypersensitivity reactions. Cytomegalovirus is the most common cause of heterophile-negative mononucleosis, usually involves older patients, and is associated with a lower frequency of sore throat, splenomegaly, and lymphadenopathy than IM due toEBV. Other diseases that share some of the features of IM include rubella, acute infectious lymphocytosis in children, and lymphoma or leukemia.

TREATMENT

Therapy for IMconsists of supportive measures, with rest and analgesia. Excessive physical activity during the first month should be avoided to reduce the possibility of splenic rupture. If splenic rupture occurs, splenectomy is required. Glucocorticoid therapy is not indicated for uncomplicated IM and in fact may predispose to bacterial superinfection. Prednisone (40 to 60 mg/d for 2 to 3 days, with subsequent tapering of the dose over 1 to 2 weeks) has been used for the prevention of airway obstruction in patients with severe tonsillar hypertrophy, for autoimmune hemolytic anemia, and for severe thrombocytopenia. Glucocorticoids have also been used in a few selected patients with severe malaise and fever and in patients with severeCNS or cardiac disease.

Acyclovir has had no significant clinical impact onIM in controlled trials. In one study, the combination of acyclovir and prednisolone had no significant effect on the duration of symptoms of IM. Acyclovir, at a dosage of 400 to 800 mg five times daily, has been effective for the treatment of oral hairy leukoplakia (despite common relapses) and some cases of chronic activeEBVdisease. This agent generally has not been beneficial for patients with lymphoproliferative syndromes. When possible, therapy for EBV lymphoproliferative disease should be directed toward the reduction of immunosuppressive medication. New therapies, including the use of interferona and the infusion of donor T cells or EBV-specific cytotoxic T cells, are being studied.

The isolation of patients withIM is unnecessary. Vaccines directed against the majorEBVglycoprotein have been effective in animal studies and are currently undergoing small-scale clinical trials.

185. CYTOMEGALOVIRUS AND HUMAN HERPESVIRUS TYPES 6, 7, AND 8 - *Martin S. Hirsch*

CYTOMEGALOVIRUS

DEFINITION

Cytomegalovirus (CMV), which was initially isolated from patients with congenital cytomegalic inclusion disease, is now recognized as an important pathogen in all age groups. In addition to inducing severe birth defects, CMV causes a wide spectrum of disorders in older children and adults, ranging from an asymptomatic, subclinical infection to a mononucleosis syndrome in healthy individuals to disseminated disease in immunocompromised patients. Human CMV is one of several related species-specific viruses that cause similar diseases in various animals. All are associated with the production of characteristic enlarged cells -- hence the name *cytomegalovirus*.

CMVis a member of the b-herpesvirus group and has double-stranded DNA, a protein capsid, and a lipoprotein envelope. Like other herpesviruses, CMV demonstrates icosahedral symmetry, replicates in the cell nucleus, and can cause either a lytic and productive or a latent infection. CMV can be distinguished from other herpesviruses by certain biologic properties, such as host range and type of cytopathology induced. Viral replication is associated with the production of large intranuclear inclusions and smaller cytoplasmic inclusions. The virus appears to replicate in a variety of cell types in vivo; in tissue culture it grows preferentially in fibroblasts. Although there is little evidence that CMV is oncogenic in vivo, the virus does transform fibroblasts in rare instances, and genomic transforming fragments have been identified.

EPIDEMIOLOGY

CMVhas a worldwide distribution. Approximately 1% of newborns in the United States are infected with CMV, and the percentage is higher in many less developed countries. Communal living and poor personal hygiene facilitate early spread. Perinatal and early childhood infections are common. Virus may be present in milk, saliva, feces, and urine. Transmission of CMV has been identified among young children in day-care centers and has been traced from infected toddler to pregnant mother to developing fetus. When an infected child introduces CMV into a household, 50% of susceptible family members seroconvert within 6 months.

The virus is not readily spread by casual contact but requires repeated or prolonged intimate exposure for transmission. In late adolescence and young adulthood,CMV is often transmitted sexually, and asymptomatic viral carriage in semen or cervical secretions is common. CMV antibody is present at detectable levels in nearly 100% of female prostitutes and sexually active homosexual men. Sexually active adults may harbor several strains of CMV simultaneously. Transfusion of whole blood or certain blood products containing viable leukocytes may also transmit CMV, with a frequency of 0.14 to 10% per unit transfused.

Once infected, an individual probably carriesCMV for life. The infection usually remains latent. However, CMV reactivation syndromes develop frequently when T

lymphocyte-mediated immunity is compromised -- for example, after organ transplantation or in association with lymphoid neoplasms and certain acquired immunodeficiencies (in particular, infection with HIV;Chap. 309). Most primary CMV infections in organ transplant recipients (Chap. 136) result from transmission of the virus in the graft itself. In CMV-seropositive transplant recipients, infection results from reactivation of latent virus or, less commonly, from reinfection by a new strain of CMV. CMV infection may be associated with coronary artery stenosis following heart transplantation or coronary angioplasty, but this association requires further validation.

PATHOGENESIS

CongenitalCMVinfection can result from either primary or reactivation infection of the mother. However, clinical disease in the fetus or newborn is almost exclusively related to primary maternal infection (Table 185-1). The factors determining the severity of congenital infection are unknown; a deficient capacity to produce precipitating antibodies and to mount T cell responses to CMV is associated with relatively severe disease.

Primary infection in late childhood or adulthood is often associated with a vigorous T lymphocyte response that may contribute to the development of a mononucleosis syndrome similar to that observed following Epstein-Barr virus (EBV) infection (Chap. 184). The hallmark of such infection is the appearance of atypical lymphocytes in the peripheral blood; these cells are predominantly activated CD8+ T lymphocytes. Polyclonal activation of B cells by the virus contributes to the development of rheumatoid factors and other autoantibodies duringCMVmononucleosis.

Once acquired by symptomatic or asymptomatic primary infection,CMVpersists indefinitely in tissues of the host. The sites of persistent or latent infection are unclear but probably include multiple cell types and various organs. Transmission following blood transfusion or organ transplantation is due to silent infections in these tissues. Autopsy studies suggest that salivary glands and bowel may be areas of latent infection.

If the host's T cell responses become compromised by disease or by iatrogenic immunosuppression, latent virus can be reactivated to cause a variety of syndromes. Chronic antigenic stimulation in the presence of immunosuppression (for example, following tissue transplantation) appears to be an ideal setting forCMVactivation and CMV-induced disease. Certain particularly potent suppressants of T cell immunity, such as antithymocyte globulin, are associated with a high rate of clinical CMV syndromes, which may follow either primary or reactivation infection. CMV may itself contribute to further T lymphocyte hyporesponsiveness, which often precedes superinfection with other opportunistic pathogens, such as *Pneumocystis carinii*. CMV and *P. carinii* are frequently found together in immunosuppressed patients with severe interstitial pneumonia. CMV may function as a cofactor to activate latent HIV infection.

PATHOLOGY

Cytomegalic cells in vivo (presumed to be infected epithelial cells) are two to four times larger than surrounding cells and often contain an 8- to 10-um intranuclear inclusion that is eccentrically placed and is surrounded by a clear halo, producing an "owl's eye"

appearance. Smaller granular cytoplasmic inclusions are demonstrated occasionally. Cytomegalic cells are found in a wide variety of organs, including salivary gland, lung, liver, kidney, intestine, pancreas, adrenal gland, and the central nervous system.

The cellular inflammatory response to infection consists of plasma cells, lymphocytes, and monocyte-macrophages. Granulomatous reactions occasionally develop, particularly in the liver. Immunopathologic reactions may contribute toCMVdisease. Immune complexes have been detected in infected infants, sometimes in association with CMV-related glomerulopathies. Immune-complex glomerulopathy has been observed in some CMV-infected patients after renal transplantation.

CLINICAL MANIFESTATIONS

Congenital CMV Infection Fetal infections range from inapparent to severe and disseminated. Cytomegalic inclusion disease develops in approximately 5% of infected fetuses and is seen almost exclusively in infants born to mothers who develop primary infections during pregnancy. Petechiae, hepatosplenomegaly, and jaundice are the most common presenting features (60 to 80% of cases). Microcephaly with or without cerebral calcifications, intrauterine growth retardation, and prematurity are reported in 30 to 50% of cases. Inguinal hernias and chorioretinitis are less common. Laboratory abnormalities include elevated alanine aminotransferase levels, thrombocytopenia, conjugated hyperbilirubinemia, hemolysis, and elevated cerebrospinal fluid protein levels. The prognosis for severely infected infants is poor; the mortality rate is 20 to 30%, and few of the patients who survive escape intellectual or hearing difficulties in later years. The differential diagnosis of cytomegalic inclusion disease in infants includes syphilis, rubella, toxoplasmosis, infection with herpes simplex virus or enterovirus, and bacterial sepsis.

Most congenitalCMVinfections are clinically inapparent at birth. Between 5 and 25% of asymptomatically infected infants develop significant psychomotor, hearing, ocular, or dental abnormalities over the next several years.

Perinatal CMV Infection The newborn may acquireCMV at the time of delivery by passage through an infected birth canal or by postnatal contact with maternal milk or other secretions. Approximately 40 to 60% of infants who are breast-fed for longer than 1 month by seropositive mothers become infected. Iatrogenic transmission also can result from neonatal blood transfusion. Screening of blood products before they are transfused into low-birth-weight seronegative infants or into seronegative pregnant women decreases the risk of infection.

The great majority of infants infected at or after delivery remain asymptomatic. However, protracted interstitial pneumonitis has been associated with perinatally acquiredCMVinfection, particularly in premature infants, and occasionally has been accompanied by infection with *Chlamydia trachomatis*, *P. carinii*, or *Ureaplasma urealyticum*. Poor weight gain, adenopathy, rash, hepatitis, anemia, and atypical lymphocytosis may also be found, and CMV excretion often persists for months or years.

CMV Mononucleosis The most common clinical manifestation ofCMVinfection in

normal hosts beyond the neonatal period is a heterophil antibody-negative mononucleosis syndrome. This manifestation may develop spontaneously or may follow the transfusion of leukocyte-containing blood products. Although the syndrome occurs at all ages, it most often involves sexually active young adults. Incubation periods range from 20 to 60 days, and the illness generally lasts for 2 to 6 weeks. Prolonged high fevers, sometimes accompanied by chills, profound fatigue, and malaise, characterize this disorder. Myalgias, headache, and splenomegaly are frequent, but in CMV mononucleosis (as opposed to infectious mononucleosis caused byEBV), exudative pharyngitis and cervical lymphadenopathy are rare. Occasional patients develop rubelliform rashes, often after exposure to ampicillin. Less commonly observed are interstitial or segmental pneumonia, myocarditis, pleuritis, arthritis, and encephalitis. In rare cases, Guillain-Barre syndrome complicates CMV mononucleosis. The characteristic laboratory abnormality is relative lymphocytosis in peripheral blood, with more than 10% atypical lymphocytes. Total leukocyte counts may be low, normal, or markedly elevated. Although significant jaundice is uncommon, serum aminotransferase and alkaline phosphatase levels are often moderately elevated. Heterophil antibodies are absent; however, transient immunologic abnormalities are common and may include the presence of cryoglobulins, rheumatoid factors, cold agglutinins, and antinuclear antibodies. Hemolytic anemia, thrombocytopenia, and granulocytopenia complicate recovery in rare instances.

Most patients recover without sequelae, although postviral asthenia may persist for months. The excretion ofCMV in urine, genital secretions, and/or saliva often continues for months or years. Rarely, CMV infection is fatal in immunocompetent hosts; even when such patients survive, they can have recurrent episodes of fever and malaise that are sometimes associated with autonomic nervous system dysfunction (e.g., attacks of sweating or flushing).

CMV Infection in the Immunocompromised Host (See alsoTable 185-1) CMV appears to be the most common and important viral pathogen complicating organ transplantation (Chap. 136). In recipients of kidney, heart, lung, and liver transplants, CMV induces a variety of syndromes, including fever and leukopenia, hepatitis, pneumonitis, esophagitis, gastritis, colitis, and retinitis. CMV disease may be an independent risk factor for both graft loss and death. The period of maximal risk is between 1 and 4 months after transplantation, although retinitis may be a later complication. The risk of disease appears to be greater after primary infection than after reactivation. In addition, molecular studies indicate that seropositive transplant recipients are susceptible to reinfection with donor-derived, genotypically variant CMV, and such infection often results in disease. Reactivation infection, although frequent, is less likely than primary infection to be important clinically. Clinical disease is related to various factors, such as the degree of immunosuppression; patients receiving certain immunosuppressive agents, such as antithymocyte globulin, appear to be more likely to have severe infections than those receiving other agents, such as cyclosporine. The transplanted organ is particularly vulnerable as a target for CMV infection; thus, there is a tendency for CMV hepatitis to follow liver transplantation and for CMV pneumonitis to follow lung transplantation.

CMVpneumonia occurs in 15 to 20% of bone marrow transplant recipients, with a case-fatality rate of 84 to 88%. The risk is greatest between 5 and 13 weeks after

transplantation, and the several risk factors identified include certain types of immunosuppressive therapy, acute graft-versus-host disease, older age, viremia, and seropositivity before transplantation.

CMVis recognized as an important pathogen in patients with advanced HIV infection (Chap. 309), in whom it often causes retinitis or disseminated disease, particularly when peripheral-blood CD4+ cell counts fall below 50 to 100/uL. As treatment for underlying HIV infection has improved, the incidence of serious CMV infections (e.g., retinitis) has decreased. However, institution of highly active antiretroviral regimens sometimes leads to acute flare-ups of CMV retinitis during the first few weeks of therapy.

Syndromes produced byCMV in the immunocompromised host often begin with prolonged fever, malaise, anorexia, fatigue, night sweats, and arthralgias or myalgias. Liver function abnormalities, leukopenia, thrombocytopenia, and atypical lymphocytosis may be observed during these episodes. The development of tachypnea, hypoxia, and unproductive cough signals respiratory involvement. Radiologic examination of the lung often demonstrates bilateral interstitial or reticulonodular infiltrates, which begin in the periphery of the lower lobes and spread centrally and superiorly; localized segmental, nodular, or alveolar patterns are less common. The differential diagnosis includes infection with *P. carinii*; infections due to other viral, bacterial, or fungal pathogens; pulmonary hemorrhage; and injury secondary to irradiation or to treatment with cytotoxic drugs.

GastrointestinalCMVinvolvement may be localized or extensive and almost exclusively affects compromised hosts. Ulcers of the esophagus, stomach, small intestine, or colon may result in bleeding or perforation. CMV infection may lead to exacerbations of underlying ulcerative colitis. Hepatitis occurs frequently, particularly following liver transplantation, and CMV-associated acalculous cholecystitis and adrenalitis have been described.

CMVrarely causes meningoencephalitis in otherwise healthy individuals. Two forms of CMV encephalitis are seen in patients with AIDS. One resembles HIV encephalitis and presents as progressive dementia; the other is a ventriculoencephalitis characterized by cranial-nerve deficits, nystagmus, disorientation, lethargy, and ventriculomegaly. In immunocompromised patients, CMV can also cause subacute progressive polyradiculopathy, which is often reversible if recognized and treated promptly.

CMVretinitis is an important cause of blindness in immunocompromised patients, particularly patients with advanced AIDS (Chap. 309). Early lesions consist of small, opaque, white areas of granular retinal necrosis that spread in a centrifugal manner and are later accompanied by hemorrhages, vessel sheathing, and retinal edema (seePlate IV-2). CMV retinopathy must be distinguished from that due to other conditions, including toxoplasmosis, candidiasis, and herpes simplex virus infection.

FatalCMVinfections are often associated with persistent viremia and the involvement of multiple organ systems. Progressive pulmonary infiltrates, pancytopenia, hyperamylasemia, and hypotension are characteristic features that are frequently found in conjunction with a terminal bacterial, fungal, or protozoan superinfection. Extensive adrenal necrosis with CMV inclusions is often documented at autopsy, as is CMV

involvement of many other organs.

DIAGNOSIS

The diagnosis ofCMVinfection usually cannot be made reliably on clinical grounds alone. Isolation of the virus or detection of CMV antigens or DNA from appropriate clinical specimens, together with demonstration of a fourfold or greater rise in antibody titers or persistently elevated antibody titers, is the preferred diagnostic approach. Virus excretion or viremia is readily detected by culture of appropriate specimens on human fibroblast monolayers. If viral titers are high, as is frequently the case in congenital disseminated infection or in patients with AIDS, characteristic cytopathic effects may be detected within a few days. However, in some situations -- such as CMV mononucleosis -- viral titers are low, and cytopathic effects may take several weeks to appear. Many laboratories expedite diagnosis with an overnight tissue-culture method (shell vial assay) involving centrifugation and an immunocytochemical detection technique employing monoclonal antibodies to an immediate-early CMV antigen. Isolation of virus from urine or saliva does not, by itself, constitute proof of acute infection, since excretion from these sites may continue for months or years after illness. Detection of CMV viremia is a better predictor of acute infection.

Detection ofCMVantigens (pp65) in peripheral-blood leukocytes or of CMV DNA in blood or tissues may hasten the diagnosis of CMV disease in certain populations, including organ transplant recipients and persons with AIDS. Such assays may yield a positive result several days earlier than culture methods. The detection of CMV DNA in cerebrospinal fluid by the polymerase chain reaction is useful in the diagnosis of CMV encephalitis or polyradiculopathy.

A variety of serologic assays are available to detect increases in titers of antibody toCMVantigens. An increased antibody level may not be detectable for up to 4 weeks after primary infection, and titers often remain high for years after infection. For this reason, single-sample antibody determinations are of no value in assessing the acuteness of infection. Detection of CMV-specific IgM is sometimes useful in the diagnosis of recent or active infection; circulating rheumatoid factors may result in occasional false-positive IgM tests.

TREATMENT

Several prophylactic measures are useful for the prevention ofCMVinfection in patients at high risk. The use of blood from seronegative donors or of blood that has been frozen, thawed, and deglycerolized greatly decreases the rate of transfusion-associated transmission of CMV. Similarly, matching of organ or bone marrow transplants by CMV serology, using organs only from seronegative donors for seronegative recipients, reduces rates of primary infection following transplantation. Both live attenuated and CMV subunit vaccines have been evaluated, but neither is close to approval for general use.

CMVimmune globulin has been reported to reduce rates of occurrence of CMV-associated syndromes and of fungal or parasitic superinfections among seronegative renal transplant recipients. Studies in bone marrow transplant recipients

have produced conflicting results. Prophylactic acyclovir has been demonstrated to reduce rates of CMV infection and disease in certain seronegative renal transplant recipients; acyclovir is not effective in the treatment of active CMV disease, however.

Ganciclovir is a guanosine derivative that has considerably more activity againstCMV than its congener acyclovir. After intracellular conversion by a viral phosphotransferase encoded by CMV gene region UL97, ganciclovir triphosphate is a selective inhibitor of CMV DNA polymerase. Several clinical studies have indicated response rates of 70 to 90% among patients with AIDS given ganciclovir for the treatment of CMV retinitis or colitis. In bone marrow transplant recipients with CMV pneumonia, ganciclovir is less effective when given alone, but it elicits a favorable clinical response 50 to 70% of the time when it is combined with CMV immune globulin. Prophylactic or suppressive ganciclovir may be useful in high-risk bone marrow or organ transplant recipients (e.g., those who are CMV-seropositive before transplantation or who are CMV culture-positive afterward). In many patients with AIDS, persistently low CD4+ cell counts, and CMV disease, clinical and virologic relapses occur promptly if treatment with ganciclovir is discontinued. Therefore, prolonged maintenance regimens are recommended for such patients. Resistance to ganciclovir is common among patients treated for more than 3 months and is usually related to mutations in the CMV UL97 gene.

Ganciclovir therapy forCMVretinitis consists of a 14- to 21-day induction course (5 mg/kg intravenously twice a day) followed by a prolonged intravenous or oral maintenance regimen. For parenteral maintenance, the dose is 5 mg/kg daily or 6 mg/kg 5 days per week. Peripheral-blood neutropenia develops in 16 to 29% of treated patients but is often ameliorated by granulocyte or granulocyte-macrophage colony-stimulating factor. Oral ganciclovir at a high dose (3 g/d) can also be used for maintenance, although the blood levels achieved are insufficient for acute induction regimens. Although progression (as assessed by funduscopy) is more rapid with oral than with intravenous ganciclovir maintenance (mean time to progression, 68 vs. 96 days; $p = .03$), the ease of administration and reduced toxicity of the oral preparation may make it an acceptable alternative for some patients who do not have sight-threatening central retinitis. The use of oral ganciclovir as prophylaxis in high-risk AIDS patients (i.e., those with CD4+ cell counts of<100/uL) has been studied in two placebo-controlled trials, with somewhat contradictory results.

Foscarnet (sodium phosphonoformate) also acts againstCMVinfection by inhibiting viral DNA polymerase. Because this agent does not require phosphorylation to be active, it is also effective against most ganciclovir-resistant CMV isolates. A comparative trial of foscarnet and ganciclovir in 234 patients with AIDS and CMV retinitis demonstrated equivalent activity against retinitis but longer survival (12.6 vs. 8.5 months) in the foscarnet group. Although the reasons for the latter difference are unclear, the antiretroviral activity of foscarnet and the greater use of zidovudine by foscarnet recipients are strong possibilities. Foscarnet is less well tolerated than ganciclovir and causes considerable toxicity, including renal dysfunction, hypomagnesemia, hypokalemia, hypocalcemia, genital ulcers, dysuria, nausea, and paresthesia. Moreover, foscarnet administration requires the use of an infusion pump and close clinical monitoring. With aggressive hydration and dose adjustments for renal dysfunction, the toxicity of foscarnet can be reduced. The use of foscarnet should be avoided when a saline load cannot be tolerated (e.g., in cardiomyopathy). The approved

induction regimen is 60 mg/kg every 8 h for 2 weeks, although 90 mg/kg every 12 h is equally effective and no more toxic. Maintenance infusions should deliver 90 to 120 mg/kg once daily; no oral preparation is available. Foscarnet-resistant viruses may emerge during extended therapy.

Ganciclovir may also be administered via a slow-release pellet sutured into the eye. Although this intraocular device provides good local protection, contralateral eye disease and disseminated disease are not affected, and early retinal detachment is possible. A combination of intraocular and systemic therapy may be better than the intraocular implant alone.

Cidofovir is a nucleotide analogue with a long intracellular half-life that allows intermittent intravenous administration. Induction regimens of 5 mg/kg weekly for 2 weeks are followed by maintenance regimens of 3 to 5 mg/kg every 2 weeks. Cidofovir can cause severe nephrotoxicity through dose-dependent proximal tubular cell injury; however, this adverse effect can be ameliorated somewhat by saline hydration and probenecid.

HUMAN HERPESVIRUS TYPES 6, 7, AND 8

Human herpesvirus (HHV) type 6 was first isolated in 1986 from peripheral-blood leukocytes of six persons with various lymphoproliferative disorders. The virus has a worldwide distribution, and two genetically distinct variants (HHV-6A and HHV-6B) are now recognized.

Infection withHHV-6 frequently develops during infancy as maternal antibody wanes. Congenital infections have also been described. HHV-6 (mostly variant B) can cause exanthem subitum (Fig. 18-CD2) (roseola infantum), a common illness characterized by fever with subsequent rash. HHV-6 is also a major cause of febrile seizures without rash during infancy. In older age groups, HHV-6 has been associated with mononucleosis syndromes, focal encephalitis, and (in immunocompromised hosts) pneumonitis and disseminated disease. In transplant recipients, HHV-6 infection may be associated with graft dysfunction. As many as 80% of adults are seropositive for HHV-6. The virus may be transmitted by saliva and possibly by genital secretions. There is no established treatment or vaccine.

HHV-7 was isolated in 1990 from T lymphocytes from the peripheral blood of a healthy 26-year-old man. Other isolates have since been obtained. It appears that the virus is frequently acquired during childhood and is frequently present in the saliva of healthy adults. No human disease has yet been definitively linked to HHV-7, although some cases of exanthem subitum (Fig. 18-CD2) and other childhood febrile illnesses have been associated with HHV-7 infection. An association has been made between HHV-7 and pityriasis rosea, but further studies must confirm this relationship.

Unique herpesvirus-like DNA sequences were reported during 1994 and 1995 in tissues derived from Kaposi's sarcoma and body cavity-based lymphoma occurring in patients with AIDS. When subjected to representational-difference analyses, more than 90% of Kaposi's sarcoma tissue samples were found to contain these sequences, whereas appropriate control tissues did not. The same herpesvirus-like DNA sequences have

been reported in Kaposi's sarcoma tissue from non-AIDS patients, in a subgroup of AIDS-related B-cell body cavity-based lymphomas, and in lymph nodes from patients with multicentric Castleman's disease (a condition also known as angiofollicular lymph node hyperplasia, giant lymph node hyperplasia, lymphoid hamartoma, and follicular lymphoreticuloma, which is especially aggressive and frequently fatal). Approximately 15% of non-Kaposi's sarcoma tissue specimens from patients with AIDS contain these herpesvirus-like sequences, which have also been found in semen from both AIDS and non-AIDS patients. The virus has been propagated in cell culture and namedHHV-8; it is also referred to as Kaposi's sarcoma-associated herpesvirus. Several serologic assays suggest a low rate of background positivity (0 to 29%) among HIV-negative blood donors but a high rate of positivity (>80%) among patients with Kaposi's sarcoma. The etiologic role of HHV-8 in Kaposi's sarcoma and other diseases remains to be established, although HHV-8 seroconversion during HIV infection appears to be highly predictive of the development of Kaposi's sarcoma.

186. SMALLPOX, VACCINIA, AND OTHER POXVIRUSES - *Fred Wang*

Two poxviruses, smallpox virus and molluscum contagiosum virus, cause natural disease in humans, and other poxviruses are associated with zoonotic infections. Monkeypox virus and smallpox virus typically cause systemic disease with rash, whereas the other poxviruses cause localized skin lesions. Poxviruses are the only DNA viruses that replicate in the cytoplasm, where accumulated viral particles form eosinophilic inclusions, or Guarnieri bodies, visible by light microscopy. Many poxvirus genes interfere with different aspects of the host immune response and provide important insights into the pathogenesis and virulence of viral infection. Genetically engineered vaccinia and avipoxviruses offer great promise as potential vectors for vaccination against other diseases.

SMALLPOX

The last case of endemic smallpox was reported in 1977 from Somalia. In 1980 the World Health Organization officially declared that smallpox had been eliminated worldwide as a result of a global vaccination and eradication program. Important features that contributed to the unique success of this vaccine program included (1) universal interest in eliminating this costly disease with high morbidity and mortality, (2) the infection's long incubation period and low level of communicability, (3) the ease of diagnosis of skin lesions by characteristic histology or antigen detection, (4) the fact that humans were the sole reservoir of the infection, (5) the absence of a carrier state, and (6) the availability of an effective live-virus vaccine that could readily be delivered to less developed countries because of its resistance to chemicals, temperature changes, and drying. The only known remaining repositories of smallpox virus reside in two research laboratories (located in the United States and Russia), and the issue of whether these last samples should be maintained or destroyed remains controversial.

Before the eradication of smallpox, variola virus existed as two related strains: *variola major* (smallpox), with a case-mortality rate of 20 to 50%, and *variola minor* (alastrim), which caused a clinically milder form of smallpox with a mortality of <1%. The clinical presentation of smallpox is now primarily of historic note. However, the threat of biologic terrorism means that smallpox remains a remote possibility in the differential diagnosis of a vesicular exanthem. Fever and macular rash appear after an average incubation period of 12 days, with a progression to typical vesicular and pustular lesions over 1 to 2 weeks. Rash generally appears first on the face, oral mucosa, and arms, with relative sparing of the trunk. Smallpox lesions may be confused with common chickenpox (varicella-zoster) infection but tend to be more diffuse, peripheral, and uniform in their stage of development. Polymerase chain reaction promises to be more useful than traditional electron microscopy or virus isolation for confirming variola or other poxvirus infections.

VACCINIA

The origin of vaccinia virus -- the virus used for vaccination against smallpox -- is uncertain, but it was probably derived from cowpox virus, variola virus, or a hybrid of the two. It is now a laboratory virus with no natural host. Experience has proven the effectiveness of live vaccinia virus vaccine, although its efficacy and safety were not

established in controlled studies. Percutaneous administration of vaccinia virus vaccine results in protective cellular and humoral immune responses in >95% of primary vaccinees. Formation of a pustule and scab at the site of inoculation is indicative of immunity; because immunity wanes after 10 to 20 years, revaccination every 10 years is recommended for continued protection. Routine smallpox vaccination was discontinued in 1971 and has not been required for international travel since 1982. However, the development of recombinant vaccinia viruses for potential use in vaccines against other infectious agents or as immunotherapy against malignant diseases has led to the recommendation that laboratory and health care employees working directly with vaccinia virus vectors be considered for vaccination. Selected groups that may be exposed to poxviruses (e.g., some military personnel and individuals who work with animals) are also vaccinated.

The most frequent adverse complication of vaccination is inadvertent inoculation (usually autoinoculation) at other sites. More serious complications, which are more common among primary vaccinees and infants than among revaccinees and adults, include (1) generalized vaccinia in otherwise healthy individuals, which is generally self-limited; (2) eczema vaccinatum, which consists of disseminated cutaneous lesions in highly susceptible patients with eczema or other chronic skin diseases and is occasionally severe or even fatal; (3) progressive vaccinia (vaccinia necrosum), which is a severe, potentially fatal illness occurring in patients with immunodeficiency, whether congenital, acquired (e.g., via leukemia or lymphoma), iatrogenic (e.g., via chemotherapy or glucocorticoid treatment), or HIV induced; and (4) postinfectious encephalitis, which is rare (3 cases per million primary vaccinees) but can be fatal in 15 to 25% of cases and can leave 25% of patients with permanent neurologic sequelae. Since vaccinees can transmit vaccinia virus to susceptible individuals, vaccination is contraindicated if the proposed recipient or his or her household contacts have eczema, are immunocompromised, or are pregnant. Vaccinia immune globulin (0.6 mL/kg) derived from the plasma of vaccinated persons may be useful for the treatment of severe generalized vaccinia, eczema vaccinatum, progressive vaccinia, and ocular vaccinia resulting from inadvertent inoculation but is of no value for the treatment of postinfectious encephalitis.

MOLLUSCUM CONTAGIOSUM

Molluscum contagiosum is generally a benign disease characterized by pearly, flesh-colored, umbilicated skin lesions 2 to 5 mm in diameter (Plate IID-41,Fig. 186-CD1). A relative lack of inflammation and necrosis distinguishes these proliferative lesions from other poxvirus lesions. The infection can be transmitted by close contact, including sexual intercourse. Swimming pools are a common vector for transmission. Atopy and compromise of skin integrity can increase the risk of infection. Lesions can be found anywhere on the body except the palms and soles and may be associated with an eczematous rash. In most cases the disease is self-limited and has no systemic complications. Molluscum contagiosum develops especially often in association with the advanced stages of HIV infection, with a prevalence of 5 to 18% among HIV-infected patients (Chap. 309). The disease is often more generalized, severe, and persistent in AIDS patients than in other groups, frequently involving the face and upper body. Extensive molluscum contagiosum has also been reported in conjunction with other types of immunodeficiency.

The diagnosis of molluscum contagiosum can be made by histologic demonstration of cytoplasmic eosinophilic inclusions characteristic of poxvirus replication. This virus cannot be propagated in vitro, but electron microscopy and molecular studies can be used for its identification.

There is no specific systemic treatment for molluscum contagiosum, but a variety of techniques for physical ablation have been used. Molluscum contagiosum may respond to effective control of HIV infection with highly active antiretroviral therapy. Cidofovir is also being investigated for potential clinical use against molluscum contagiosum.

MONKEYPOX VIRUS AND OTHER POXVIRUSES

Monkeypox virus naturally infects nonhuman primates in the tropical rain forests of western and central Africa and can infect humans who come into direct contact with infected animals. Human disease is rare and is characterized by a systemic illness and vesicular rash similar to those of variola. A large outbreak of monkeypox occurred between February 1996 and October 1997 in central Africa, with a case-fatality ratio of 3%; a prolonged period of active cases, suggesting a potential for sustained person-to-person transmission; and a high proportion of younger patients, suggesting the possible consequences of discontinued smallpox vaccination. Clinical presentations were occasionally confused with the more common varicella-zoster virus infection.

Other poxviruses can cause localized vesicular lesions when humans come into direct contact with infected animals. These viruses include cowpox virus (rodents, cats); milkers' node virus (cows; Fig. 186-CD2); buffalopox virus (buffaloes); bovine papular stomatitis virus (cows); and orf virus (Fig. 186-CD3), which is also known as contagious pustular dermatitis virus (sheep, goats).

187. PARVOVIRUS - *Neil R. Blacklow*

DEFINITION

The parvovirus group includes several species-specific viruses of animals. One parvovirus, designated B19, is known to be a human pathogen. B19 is a small (diameter, 20 to 25 nm), icosahedral, nonenveloped, single-stranded DNA virus with an outer capsid formed by two structural proteins. Individual virus particles contain DNA strands of positive or negative polarity. The virus is stable and retains infectivity after incubation at 60°C for 16 h. It has failed to grow in conventional cell culture lines and animal model systems but does replicate in vitro in erythroid progenitor cells derived from human bone marrow, umbilical cord, peripheral blood, or fetal liver sources.

During the 1980s, it was discovered that B19 causes a variety of disorders ranging from erythema infectiosum and acute arthropathy in otherwise healthy hosts to transient aplastic crisis and chronic anemia in compromised patients to fetal infection manifested by death or hydrops fetalis. Many of the severe manifestations of B19 viremia relate to the propensity of the virus to infect and lyse erythroid precursor cells in the bone marrow. The name B19 is derived from the code number of the human serum in which the virus was discovered.

PATHOGENESIS

Two studies of adult volunteers have provided a basis for understanding the pathogenesis of B19 infection, which has two phases. The first phase is characterized by viremia that develops approximately 6 days after intranasal inoculation of B19 into susceptible individuals who lack serum antibodies to the virus. The viremia lasts about 1 week; its clearance is correlated with the development of IgM antibodies to B19, which remain detectable for up to a few months. IgG antibodies develop several days later and persist indefinitely. Nonspecific systemic symptoms lasting 2 or 3 days occur early during the viremic phase; these symptoms include headache, malaise, myalgia, fever, chills, and pruritus and are accompanied by reticulocytopenia and excretion of the virus from the respiratory tract. Several days after the onset of symptoms, a clinically insignificant decline in hemoglobin concentration is noted; the decreased level is maintained for 7 to 10 days, during which time examination of bone marrow samples reveals a marked depletion of erythroid precursor cells. Transient mild lymphopenia, neutropenia, and a drop in platelet count also may be found. A second phase of illness begins around 17 or 18 days after virus inoculation (after the clearance of viremia, the cessation of viral shedding in throat secretions, and the resolution of reticulocytopenia). This illness mimics erythema infectiosum in adults, with 2 or 3 days of fine maculopapular rash accompanied by arthralgias and arthritis that last another 1 or 2 days. This phase occurs in the presence of rising serum titers of antibody to B19.

The studies just described indicate that B19 disease in the otherwise *healthy host*, manifested by self-limited erythema infectiosum and/or arthropathy, is almost certainly an immune-complex disorder. This concept is supported by the induction of erythema infectiosum through the infusion of immunoglobulins into chronically viremic patients. In contrast, B19 disease in the *compromised host* (chronic hemolytic disease or immunodeficiency syndromes) is often serious, resulting from the destruction by B19 of

erythroid precursor cells. Normal hosts can tolerate 7 to 10 days of shutoff of erythropoiesis; however, patients with hemolytic disease who require increased production of erythrocytes do not tolerate erythroid cell destruction and thus usually develop severe transient aplastic crisis. Patients who are immunodeficient may fail to clear B19 viremia, the results being persistent infection of red blood cells and chronic severe anemia. The fetus requires a higher level of red cell production than do adults and has an immature immune system; both these factors could explain B19-induced hydrops fetalis.

B19 binds specifically to a cellular receptor, erythrocyte P antigen; this specific binding explains the tropism of B19 for erythroid progenitor cells, particularly pronormoblasts and normoblasts. The few persons who lack P antigen cannot be infected with B19.

EPIDEMIOLOGY

Although B19 infections occur year-round, they appear most commonly as outbreaks of erythema infectiosum in schools during winter and spring months. Between 20 and 60% of children in outbreaks are symptomatic, and many are asymptomatically infected. Seroepidemiologic studies indicate that approximately half of adults possess serum antibodies to B19. Antibody prevalence (reflecting prior exposure and probable immunity to the virus) rises rapidly between the ages of 5 and 18 years and continues to increase with age -- a pattern probably indicating ongoing exposure during adulthood. B19 can be detected in throat swabbings, respiratory tract secretions, and serum, and its detection at these sites probably correlates with infectiousness. Thus, patients with transient aplastic crisis are highly infectious. Their infectivity has been firmly documented as the source of one well-defined nosocomial outbreak of erythema infectiosum among nurses. In contrast, individuals with erythema infectiosum are much less infectious. The usual route of viral transmission under natural conditions is unknown but may be respiratory or through direct contact. B19 can be transmitted during therapy with clotting factor concentrate, even after exposure to detergent, steam, or dry heat.

CLINICAL MANIFESTATIONS

Erythema Infectiosum (Fig. 187-CD1) Erythema infectiosum is the most common manifestation of B19 infection and occurs predominantly in children. This entity is also called *fifth disease* because it was classified in the late nineteenth century as the fifth in a series of six exanthems of childhood. Normally a mild illness, erythema infectiosum typically presents as a facial rash with a "slapped-cheek" appearance that is sometimes preceded by low-grade fever. The rash may develop quickly on the arms and legs and usually has a lacy, reticular, erythematous appearance (Plate IID-40). The trunk, palms, and soles are less commonly involved. Occasionally, the rash appears with maculopapular, morbilliform, vesicular, purpuric, or pruritic characteristics. The typical rash resolves in about a week but can recur intermittently for several weeks, particularly after stress, exercise, exposure to sunlight, bathing, or change in environmental temperature. Arthralgia and arthritis are uncommon among children but are frequent among adults, in whom the rash is often absent or nonspecific, with a lack of the characteristic facial erythema.

Arthropathy B19 infection in adults most commonly presents as acute arthralgias and arthritis, sometimes accompanied by rash. The arthritis is characteristically symmetric and peripheral, involving the wrists, hands, and knees most frequently. It normally resolves in about 3 weeks and is nondestructive. However, a small percentage of patients have arthritis persisting for months or even (in rare cases) for years. It is not known whether these individuals have persistent infection or an abnormal immune response to the virus.

Transient Aplastic Crisis B19 infection is the cause in most instances of transient aplastic crisis developing suddenly in patients with chronic hemolytic disease. Nearly all hemolytic conditions can be affected by B19 infection, including sickle cell disease, erythrocyte enzyme deficiencies, hereditary spherocytosis, thalassemias, paroxysmal nocturnal hemoglobinuria, and autoimmune hemolysis. B19-induced aplastic crisis also can occur in the setting of acute blood loss. Patients present with weakness, lethargy, pallor, and severe anemia, a syndrome often preceded by a few days of nonspecific symptoms. These patients have intense reticulocytopenia lasting 7 to 10 days, and their bone marrow contains no erythroid precursor cells despite a normal myeloid series. Transient aplastic crisis can produce life-threatening anemia and may require urgent transfusion therapy. Unlike patients with erythema infectiosum or arthropathy, those with transient aplastic crisis are viremic and can readily transmit B19 infection to other people.

Chronic Anemia in Immunodeficient Patients Immunodeficient patients may be unable to eliminate B19 infection, probably because they cannot produce adequate levels of virus-specific IgG antibodies. The result is persistent infection with destruction of erythroid precursor cells in the bone marrow and chronic transfusion-dependent anemia. This condition has been described occasionally in patients with immunodeficiency related to infection with HIV, congenital immunodeficiencies, and acute lymphoblastic leukemia during maintenance chemotherapy as well as in recipients of bone marrow, heart, liver, and renal transplants. In addition, some cases of idiopathic pure red-cell aplasia probably are caused by persistent B19 infection. B19-induced chronic anemia may be the presenting finding of an otherwise unrecognized immunodeficiency. Chronic anemia may fluctuate in intensity over time and may be cured or controlled by immunoglobulin therapy. Both the spectrum of immunodeficiencies associated with B19-induced chronic anemia and the frequency of the association remain to be determined.

Fetal and Congenital Infection Maternal B19 infections usually do not adversely affect the fetus. More often than not, in fact, the fetus remains uninfected. Therefore, couples in which the pregnant woman is infected should be counseled as to the relatively low risk of fetal infection. It is estimated that fewer than 10% of maternal B19 infections in the first 20 weeks of pregnancy lead to fetal death; when fetal death does occur, it is usually attributable to the development of nonimmune hydrops fetalis, wherein the fetus succumbs to severe anemia and congestive heart failure. In these instances, B19 can be detected in fetal tissues, with predominant infection of erythroblasts. Pregnant women with known exposure to B19 should have their serum monitored for IgM antibodies to the virus and for elevated levels of a-fetoprotein and human chorionic gonadotropin; ultrasonic examinations of the fetus for hydrops should also be conducted. Some hydropic fetuses survive B19 infection and appear normal at delivery.

Rarely, fetal infection with hydrops results in congenital anemia and hypogammaglobulinemia that is unresponsive to immunoglobulin therapy.

Possible Clinical Associations Case studies suggest a link -- as yet inconclusive -- between B19 and several rheumatic diseases, most notably rheumatoid arthritis but also vasculitis (including polyarteritis, Wegener's granulomatosis, and giant cell arteritis), lupus erythematosus, dermatomyositis, and juvenile rheumatoid arthritis. Other unproven associations include those involving multiple systems: cardiac (myocarditis), hematologic (hemophagocytic syndrome, idiopathic thrombocytopenic purpura), hepatic (fulminant hepatitis), neurologic (meningoencephalitis), and respiratory (pneumonia).

DIAGNOSIS

Diagnosis most commonly relies on measurements of B19-specific IgM and IgG antibodies, which can be detected with commercially available immunoassay kits. The virus, its DNA, or its antigens are also detected in the serum or infected tissues of some patients. Acute infection can be proven by B19-compatible symptoms and the presence of IgM antibodies or virus itself, whereas past infection is documented by IgG antibodies. Individuals with erythema infectiosum and acute arthropathy usually have IgM antibodies without detectable virus in serum. Those with transient aplastic crisis may have IgM antibodies but typically possess high titers of virus and its DNA in serum; the bone marrow of these patients shows characteristic giant pronormoblasts and hypoplasia. Immunodeficient patients with anemia often lack readily detectable antibodies but have viral particles and DNA in serum. Fetal infection may be recognized by hydrops fetalis and the presence of B19 DNA in amniotic fluid or fetal blood in association with maternal IgM antibodies to B19.

TREATMENT

Erythema infectiosum usually requires no treatment; the same is true for many cases of arthropathy. More severe cases of arthritis, particularly those involving chronic symptoms, can be treated with nonsteroidal anti-inflammatory agents. Transient aplastic crisis is usually treated with erythrocyte transfusions. In immunodeficient anemic patients, B19 infection should be treated with commercial intravenous immunoglobulin, which is known to contain IgG antibodies to B19. This therapy controls and may cure B19 infection.

PROPHYLAXIS

Prophylaxis of B19 infection with immunoglobulin should be considered for patients with chronic hemolysis or immunodeficiency and for pregnant women. The risk of infection for these persons may be reduced by hand washing before eating or after contact with respiratory or other secretions when B19 is known to be present in a community. Patients with transient aplastic crisis or chronic B19 infection (but not those with erythema infectiosum or arthropathy) pose a serious risk for nosocomial transmission of infection. They should be hospitalized in a private room with contact and respiratory isolation precautions. It is not known whether pre- or postexposure administration of immunoglobulin prevents infection. No vaccine for B19 is currently available; however, a baculovirus-infected insect cell line that expresses noninfectious immunogenic B19

capsid proteins is being evaluated to determine an optimal regimen for use as a vaccine.

188. HUMAN PAPILLOMAVIRUSES - *Richard C. Reichman*

DEFINITION

Human papillomaviruses (HPVs) selectively infect the epithelium of the skin and mucous membranes. These infections may be asymptomatic, produce warts, or be associated with a variety of benign and malignant neoplasias.

ETIOLOGIC AGENT

Papillomaviruses are members of the *Papillomavirus* genus of the family Papovaviridae. They are nonenveloped, measure 50 to 55 nm in diameter, have icosahedral capsids composed of 72 capsomeres, and contain a double-stranded circular DNA genome of about 7900 base pairs. The genomic organization of all papillomaviruses is similar and consists of an early (E) region, a late (L) region, and a noncoding upstream regulatory region. OncogenicHPVtypes can immortalize human keratinocytes, and this activity has been mapped to products of early genes E6 and E7. E6 protein facilitates the degradation of the p53 tumor suppressor protein, and E7 protein binds the retinoblastoma gene product and related proteins. The E1 and E2 proteins modulate viral DNA replication and regulate gene expression. The L1 gene codes for the major capsid protein, which makes up 80% of the virion mass. L2 codes for a minor capsid protein. Type-specific conformational antigenic determinants are located on the virion surface. Papillomavirus types are distinguished from one another by the degree of nucleic acid sequence homology. Distinct types share fewer than 90% of their DNA sequences in L1. More than 80 types of HPV are recognized, and individual types are associated with specific clinical manifestations (Table 188-1). HPVs are species-specific and have not been propagated in tissue culture or in common experimental animals. However, HPV types 1, 6, 11, 16, 40, and 83 have been produced in human tissues implanted in immunodeficient mice.

EPIDEMIOLOGY

There are few good studies of the incidence or prevalence of warts in well-defined human populations. Common warts (verruca vulgaris) are found in as many as 25% of some groups and are most prevalent among young children. Plantar warts (verruca plantaris) are also widely prevalent; they occur most often among adolescents and young adults. Condyloma acuminatum (anogenital warts) is one of the most common sexually transmitted diseases in the United States.HPVinfection of the uterine cervix produces the squamous cell abnormalities most frequently detected on Papanicolaou smears.

Most genitalHPVinfections are transmitted through direct contact with infectious lesions. Close personal contact is also assumed to play a role in the transmission of most cutaneous warts; the importance of fomites in this setting is not clear. Minor trauma at the site of inoculation may facilitate transmission. Recurrent respiratory papillomatosis in young children is an uncommon disease that is acquired from maternal genital tract infection; in adults, the disease may be transmitted through orogenital sexual contact.

HPVinfection has been strongly associated with the development of dysplasia and

cancer of the uterine cervix. More than 95% of cervical cancers contain DNA of oncogenic (high-risk) HPV types, such as 16, 18, and 31. HPV DNA is also present in the precursor lesions of cervical cancer, known as cervical intraepithelial neoplasias. Such lesions containing DNA of oncogenic HPV types are more likely to progress than those associated with low-risk types, such as 6 and 11. HPV DNA is transcribed in tumor tissues; many epidemiologic studies have confirmed a relation between HPV infection (with or without cofactors) and the development of cervical cancer, although most cervical HPV infections are self-limited. Infection with specific HPV types has also been associated with squamous cell carcinomas and dysplasias of the penis, anus, vagina, and vulva. In patients with epidermodysplasia verruciformis, squamous cell cancers develop frequently at sites infected with specific HPV types, including 5 and 8.

Serologic studies with virus-like particles as antigens have demonstrated type-specific antibodies in most patients withHPVgenital tract infections.

CLINICAL MANIFESTATIONS

The clinical manifestations of HPVinfection depend on the location of the lesions and the type of virus. Common warts (Fig. 128-CD6) usually occur on the hands as flesh-colored to brown, exophytic, hyperkeratotic papules. Plantar warts (Fig. 188-CD1) may be quite painful; they can be differentiated from calluses by paring of the surface to reveal thrombosed capillaries. Flat warts (verruca plana;Fig. 188-CD2) are most common among children and occur on the face, neck, chest, and flexor surfaces of the forearms and legs.

Anogenital warts develop on the skin and mucosal surfaces of the external genitalia and perianal areas (Plate IID-55). Among circumcised men, warts are most commonly found on the penile shaft. Lesions commonly occur at the urethral meatus and may extend proximally. Perianal warts are common among homosexual men but develop in heterosexual men as well. In women, warts appear first at the posterior introitus and adjacent labia. They then spread to other parts of the vulva and commonly involve the vagina and cervix. These lesions may be present without external warts. The differential diagnosis of anogenital warts includes condylomata lata of secondary syphilis, molluscum contagiosum, hirsutoid papillomatosis (pearly penile papules), fibroepitheliomas, and a variety of benign and malignant mucocutaneous neoplasms. Respiratory papillomatosis in young children may be life-threatening and presents as hoarseness, stridor, or respiratory distress. The disease in adults is usually milder.

Immunosuppressed patients, particularly those undergoing organ transplantation, often develop pityriasis versicolor-like lesions, from which DNA of severalHPVtypes has been extracted. Occasionally, such lesions appear to undergo malignant transformation. Patients infected with HIV frequently have severe clinical manifestations of HPV infection and appear to be at unusually high risk for cervical and anal malignancies. HPV disease in patients with HIV infection is difficult to treat and often recurs.

Epidermodysplasia verruciformis is a rare autosomal recessive disease characterized by the inability to controlHPVinfection. Patients are often infected with unusual HPV types and frequently develop cutaneous squamous cell malignancies, particularly in sun-exposed areas. The lesions resemble flat warts or macules similar to those of

pityriasis versicolor.

The complications of warts include itching and occasionally bleeding. In rare cases warts become secondarily infected with bacteria or fungi. Large masses of warts may cause mechanical problems, such as obstruction of the birth canal. Dysplasias of the uterine cervix are generally asymptomatic until frank carcinoma develops. Patients with anogenitalHPVdisease may develop serious psychological symptoms due to anxiety or depression over this condition.

PATHOGENESIS

The incubation period ofHPVdisease is usually 3 to 4 months, with a range of 1 month to 2 years. All types of squamous epithelium can be infected by HPV, and the gross and histologic appearances of individual lesions vary with the site of infection and the type of virus. The replication of HPV begins with the infection of basal cells. As cellular differentiation proceeds, HPV DNA replicates and is transcribed. Ultimately, virions are assembled in the nucleus and released when keratinocytes are shed. This process is associated with proliferation of all epidermal layers except the basal layer and produces acanthosis, parakeratosis, and hyperkeratosis. Koilocytes, large round cells with pyknotic nuclei, appear in the granular layer. Histologically normal epithelium may contain HPV DNA, and residual DNA after treatment can be associated with recurrent disease.

EpisomalHPV DNA is present in the nuclei of infected cells in benign lesions caused by the virus. However, in severe dysplasias and cancers, HPV DNA is generally integrated, with disruption of the E1/E2 open reading frames. This disruption leads to upregulation of E6 and E7 and subsequent interference with cellular tumor suppressor proteins.

Host defense responses toHPVinfection are incompletely understood, and immune correlates of protection from infection and resolution of disease have not been established. Because patients with defects in cell-mediated immune responses, including transplant recipients and patients with HIV infection, frequently develop severe HPV disease, such responses are probably important for the control of virus replication. Histologic studies demonstrating an epidermal lymphomonocytic infiltrate in resolving warts suggest that local immunity may be of particular importance in the resolution of disease. HPV infection can also elicit a serologic response, and antibodies to the viral capsid have been found in sera from patients with anogenital warts, cutaneous warts, and respiratory papillomatosis. Antibodies to E-region proteins, most notably E7, have been detected among patients with cervical carcinoma. Vaccine studies in animals have shown that production of neutralizing antibodies can be associated with protection from papillomavirus infection.

DIAGNOSIS

Most warts that are visible to the naked eye can be diagnosed correctly by history and physical examination alone. The use of a colposcope is invaluable in assessing vaginal and cervical lesions and is helpful in the diagnosis of oral and cutaneousHPVdisease as well. Papanicolaou smears prepared from cervical scrapings often show cytologic evidence of HPV infection. Persistent or atypical lesions should be biopsied and

examined by routine histologic methods. The most sensitive and specific methods of virologic diagnosis entail the use of techniques such as the polymerase chain reaction or the hybrid capture assay to detect HPV nucleic acids and to identify specific virus types. Serologic techniques to diagnose HPV infection are not helpful in individual cases and are not widely available.

TREATMENT

Decisions regarding the initiation of therapy should be made with the knowledge that currently available modes of treatment are not completely effective and some have significant side effects. In addition, treatment may be expensive, and manyHPVlesions resolve spontaneously. Frequently used therapies include cryosurgery, application of caustic agents, electrodesiccation, surgical excision, and ablation with a laser. Topical antimetabolites such as 5-fluorouracil also have been used. Both failure and recurrence have been well documented with all of these methods of treatment. Cryosurgery is the initial treatment of choice for condyloma acuminatum. Topically applied podophyllum preparations as well as podofilox may also be used. Various interferon preparations have been used with modest success in the treatment of respiratory papillomatosis and condyloma acuminatum. A topically applied interferon inducer, imiquimod, is also of benefit in the treatment of condyloma acuminatum. The diagnosis and management of anogenital dysplasias and of internal anogenital warts require special skills and resources, and patients with such lesions should be referred to a qualified specialist.

No effective methods for the prevention ofHPVinfections are available at present other than the avoidance of contact with infectious lesions. Barrier methods of contraception may be helpful in preventing the transmission of condyloma acuminatum and other HPV-associated diseases of the genital tract. Vaccines consisting of virus-like particles can prevent papillomavirus disease in some animal models and have been shown to induce neutralizing antibodies in phase 1 studies in humans. More extensive clinical trials of these preparations are under way.

(Bibliography omitted in Palm version)

SECTION 13 -DNA AND RNA RESPIRATORY VIRUSES

189. COMMON VIRAL RESPIRATORY INFECTIONS - *Raphael Dolin*

GENERAL CONSIDERATIONS

Acute viral respiratory illnesses are among the most common of human diseases, accounting for one-half or more of all acute illnesses. The incidence of acute respiratory disease in the United States is from 3 to 5.6 cases per person per year. The rates are highest among children under 1 year old (6.1 to 8.3 cases per year) and remain high until age 6, when a progressive decrease begins. Adults have 3 to 4 cases per person per year. Morbidity from acute respiratory illnesses accounts for 30 to 50% of time lost from work by adults and for 60 to 80% of time lost from school by children. The use of antibacterial agents to treat viral respiratory infections represents a major source of abuse of that category of drugs.

It has been estimated that two-thirds to three-fourths of cases of acute respiratory illnesses are caused by viruses. More than 200 antigenically distinct viruses from 8 different genera have been reported to cause acute respiratory illness, and it is likely that additional agents will be described in the future. The vast majority of these viral infections involve the upper respiratory tract, but lower respiratory tract disease can also develop, particularly in younger age groups and in certain epidemiologic settings.

The illnesses caused by respiratory viruses traditionally have been divided into multiple distinct syndromes, such as the "common cold," pharyngitis, croup (laryngotracheobronchitis), tracheitis, bronchiolitis, bronchitis, and pneumonia. Each of these general categories of illnesses has a certain epidemiologic and clinical profile; for example, croup occurs exclusively in very young children and has a characteristic clinical course. Some types of respiratory illnesses are more likely to be associated with certain viruses (e.g., the common cold with rhinoviruses), while others occupy characteristic epidemiologic niches (e.g., adenovirus infections in military recruits). The syndromes most commonly associated with infections with the major respiratory virus groups are summarized in Table 189-1. Most respiratory viruses clearly have the potential to cause more than one type of respiratory illness, and frequently features of several types of illness are found in the same patient. Moreover, the clinical illnesses induced by these viruses are rarely sufficiently distinctive to permit an etiologic diagnosis on clinical grounds alone, although the epidemiologic setting increases the likelihood that one group of viruses rather than another is involved. In general, laboratory methods must be relied on to establish a specific viral diagnosis.

This chapter reviews viral infections caused by five of the major groups of respiratory viruses: rhinoviruses, coronaviruses, respiratory syncytial viruses, parainfluenza viruses, and adenoviruses. Influenza viruses, which are a major cause of mortality as well as morbidity, are reviewed inChap. 190. Herpesviruses, which occasionally cause pharyngitis and which also cause lower respiratory tract disease in immunosuppressed patients, are reviewed inChap. 182. Enteroviruses, which account for occasional respiratory illnesses during the summer months, are reviewed inChap. 193.

RHINOVIRUS INFECTIONS

ETIOLOGIC AGENT

Rhinoviruses are members of the Picornaviridae family, small (15 to 30 nm) nonenveloped viruses that contain a single-stranded RNA genome. In contrast to other members of the picornavirus family, such as enteroviruses, rhinoviruses are acid-labile and are almost completely inactivated at pH £3. Rhinoviruses grow preferentially at 33° to 34°C -- the temperature of the human nasal passages -- rather than at the higher temperature (37°C) of the lower respiratory tract. One hundred distinct serotypes and one subtype of rhinovirus are recognized.

EPIDEMIOLOGY

Rhinoviruses are a major cause of the common cold and have been isolated from 15 to 40% of adults with common cold-like illnesses. Overall rates of infection with rhinoviruses are higher among infants and young children and decrease with increasing age. Rhinovirus infections occur throughout the year, with seasonal peaks in early fall and spring in temperate climates. Rhinovirus infections are most often introduced into families by preschool or grade-school children younger than 6 years old. Between 25 and 70% of initial illnesses in family settings are followed by secondary cases, with the highest attack rates among the youngest siblings at home. Attack rates also increase with family size.

Rhinoviruses appear to spread through direct contact with infected secretions, usually respiratory droplets. In some studies of volunteers, transmission was most efficient by hand-to-hand contact, with subsequent self-inoculation of the conjunctival or nasal mucosa. In other studies, transmission by large- or small-particle aerosol was demonstrated. Virus also can be recovered from plastic surfaces inoculated 1 to 3 h previously; this observation suggests that environmental surfaces contribute to transmission. In studies of married couples in which neither partner had detectable serum antibody, transmission was associated with prolonged contact (122 h or more) during a 7-day period. Transmission was infrequent unless virus was recoverable from the donor's hands and nasal mucosa, at least 1000 $TCID_{50}$ of virus was present in nasal washes from the donor, and the donor was at least moderately symptomatic with the "cold." Despite anecdotal observations, exposure to cold temperatures, fatigue, or sleep deprivation has not been associated with increased rates of rhinovirus-induced illness in volunteers.

Infection with rhinoviruses is worldwide in distribution. By the time they reach adulthood, nearly all individuals have neutralizing antibodies to multiple serotypes, although the prevalence of antibody to any one serotype varies widely. Multiple serotypes circulate simultaneously, and generally no single serotype or group of serotypes has been more prevalent than the others.

PATHOGENESIS

Rhinoviruses infect cells through attachment to specific cellular receptors; most serotypes attach to intercellular adhesion molecule 1, while a few use low-density lipoprotein as the cellular receptor. Relatively limited information is available on the

histopathology and pathogenesis of acute rhinovirus infections in humans. Examination of biopsy specimens obtained during experimentally induced and naturally occurring illness indicates that the nasal mucosa is edematous, is often hyperemic, and -- during acute illness -- is covered by a mucoid discharge. There is a mild infiltrate with inflammatory cells, including neutrophils, lymphocytes, plasma cells, and eosinophils. Mucus-secreting glands in the submucosa appear hyperactive; the nasal turbinates are engorged, a condition that may lead to obstruction of nearby openings of sinus cavities. Several mediators, such as bradykinin, lysylbradykinin, prostaglandins, histamine, and interleukins 1, 6, and 8, have been linked to the development of signs and symptoms in rhinovirus-induced colds.

The incubation period for rhinovirus illness is short, generally 1 or 2 days. Virus shedding coincides with the onset of illness or may begin shortly before symptoms develop. The mechanisms of immunity to rhinovirus are not well worked out. In some studies, the presence of homotypic antibody has been associated with significantly reduced rates of subsequent infection and illness, but data conflict regarding the relative importance of serum and local antibody in protection from rhinovirus infection.

CLINICAL MANIFESTATIONS

The most common clinical manifestations of rhinovirus infections are those of the common cold. Illness usually begins with rhinorrhea and sneezing accompanied by nasal congestion. The throat is frequently sore, and in some cases sore throat is the initial complaint. Systemic signs and symptoms, such as malaise and headache, are mild or absent, and fever is unusual. Illness generally lasts for 4 to 9 days and resolves spontaneously without sequelae. In children, bronchitis, bronchiolitis, and bronchopneumonia have been reported; nevertheless, it appears that rhinoviruses are not major causes of lower respiratory tract disease in children. Rhinoviruses may cause exacerbations of asthma and chronic pulmonary disease in adults. The vast majority of rhinovirus infections resolve without sequelae, but complications related to obstruction of the eustachian tubes or sinus ostia, including otitis media or acute sinusitis, can develop.

DIAGNOSIS

Although rhinoviruses are the most frequently recognized cause of the common cold, similar illnesses are caused by a variety of other viruses, and the etiologic diagnosis cannot be made on clinical grounds alone. Rather, rhinovirus infection is diagnosed by isolation of the virus from nasal washes or nasal secretions in tissue culture. In practice, this procedure is rarely undertaken because of the benign, self-limited nature of the illness. Given the many serotypes of rhinovirus, diagnosis by serum antibody tests is currently impractical. Likewise, common laboratory tests, such as white cell count and sedimentation rate, are not helpful.

TREATMENT

Rhinovirus infections are generally mild and self-limited, so treatment is not usually necessary. Therapy in the form of antihistamines and nonsteroidal anti-inflammatory drugs may be beneficial in patients with particularly pronounced symptoms, and

reduction of activity is prudent in instances of significant discomfort or fatigability. Antibacterial agents should be used only if bacterial complications such as otitis media or sinusitis develop. Specific antiviral therapy is not available. Application of interferon sprays intranasally has been effective in the prophylaxis of rhinovirus infections but is also associated with local irritation of the nasal mucosa. Prevention of rhinovirus infection by antibodies directed against rhinovirus receptors or by the soluble purified receptors themselves is under study. Experimental vaccines to certain rhinovirus serotypes have been prepared, but their usefulness is questionable because of the myriad serotypes and the uncertainty about mechanisms of immunity. Thorough hand washing, environmental decontamination, and protection against autoinoculation may help to reduce rates of transmission of infection.

CORONAVIRUS INFECTIONS

ETIOLOGIC AGENT

Coronaviruses are pleomorphic, single-stranded RNA viruses that measure 80 to 160 nm in diameter. The name derives from the crownlike appearance produced by the club-shaped projections that stud the viral envelope. Coronaviruses that infect humans fall into two distinct antigenic groups (I and II), which are represented by prototype isolates 229E and OC43. Coronaviruses are fastidious and are difficult to culture in vitro. Some strains will grow only in human tracheal organ cultures rather than in tissue culture.

EPIDEMIOLOGY

Only limited seroepidemiologic studies of coronavirus infections have been conducted. Seroprevalence studies of strains 229E and OC43 have demonstrated the presence of serum antibodies at rates ranging from 12% to>80% in various populations. Overall, coronaviruses account for 10 to 20% of common colds. Coronavirus infections appear to be particularly prevalent in late fall, winter, and early spring -- times when rhinovirus infections are less common. A cyclical pattern has been suggested for outbreaks of infection with strains OC43 and 229E, with outbreaks occurring every 2 to 4 years.

CLINICAL MANIFESTATIONS

The clinical features of illness caused by coronaviruses are similar to those of illness caused by rhinoviruses. In studies of volunteers, the mean incubation period of illness induced by coronaviruses (3 days) is somewhat longer than that of illness caused by rhinoviruses, and the duration of illness is somewhat shorter (mean, 6 to 7 days). In some studies, the amount of nasal discharge was somewhat greater in colds induced by coronaviruses than in those induced by rhinoviruses. Coronaviruses have been recovered from infants with pneumonia and from military recruits with lower respiratory tract disease and have been associated with worsening of chronic bronchitis. However, the overall significance of coronaviruses in lower respiratory tract disease in humans remains unclear.

TREATMENT

The approach to the treatment of common colds caused by coronaviruses is similar to that discussed above for rhinovirus-induced illnesses. Because of uncertainty regarding the number and relative importance of coronavirus subgroups and the mechanisms of immunity, vaccines against coronaviruses have not been developed.

RESPIRATORY SYNCYTIAL VIRUS INFECTIONS

ETIOLOGIC AGENT

Respiratory syncytial virus (RSV) is a member of the Paramyxoviridae family and comprises the genus *Pneumovirus*. RSV, an enveloped virus approximately 150 to 300 nm in diameter, is so named because its replication in vitro leads to the fusion of neighboring cells into large multinucleated syncytia. The single-stranded RNA genome codes for 10 virus-specific proteins. Viral RNA is contained in a helical nucleocapsid surrounded by a lipid envelope bearing two glycoproteins: the G protein, by which the virus attaches to cells, and the F (fusion) protein, which facilitates entry of the virus into the cell by fusing host and viral membranes. RSV was once considered to be of a single antigenic type, but two distinct groups (A and B) and multiple subtypes within each group have now been described. Antigenic diversity is reflected by differences in the G protein, while the F protein is highly conserved. The epidemiologic significance of the antigenic diversity is under investigation. Both antigenic groups can circulate simultaneously in outbreaks, although the relative proportions of each vary.

EPIDEMIOLOGY

RSVis the major respiratory pathogen of young children and the foremost cause of lower respiratory disease in infants. Infection with RSV is seen throughout the world in annual epidemics that occur in late fall, winter, or spring and last up to 5 months. The virus is rarely encountered during the summer. Rates of illness are highest among infants between 1 and 6 months of age, peaking between 2 and 3 months of age. The attack rates among susceptible infants and children are extraordinarily high, approaching 100% in settings such as day-care centers where large numbers of susceptible infants are present. RSV accounts for 20 to 25% of hospital admissions of young infants and children for pneumonia and for up to 75% of cases of bronchiolitis in this age group. It has been estimated that more than half of infants who are at risk will become infected during an RSV epidemic.

In older children and adults, reinfection withRSV is frequent but disease is milder than in infancy. A common cold-like syndrome is the illness most commonly associated with RSV infection in adults. Severe lower respiratory tract disease with pneumonitis can occur in elderly (often institutionalized) adults and in patients with immunocompromising disorders or treatment, including recipients of bone-marrow and solid-organ transplants. RSV is also an important nosocomial pathogen; during an outbreak, it can infect pediatric patients and up to 25 to 50% of the staff on pediatric wards. The spread of virus among families is efficient: up to 40% of siblings may become infected when RSV is introduced into the family setting.

RSVis transmitted primarily by close contact with contaminated fingers or fomites and by self-inoculation of the conjunctiva or anterior nares. Virus also may be spread by

coarse aerosols produced by coughing or sneezing, but it is inefficiently spread by fine-particle aerosols. The incubation period is ~4 to 6 days, and virus shedding may last for ³2 weeks in children and for shorter periods in adults.

PATHOGENESIS

Little is known about the histopathology of minorRSVinfection. Severe bronchiolitis or pneumonia is characterized by necrosis of the bronchiolar epithelium and a peribronchiolar infiltrate of lymphocytes and mononuclear cells. Interalveolar thickening and filling of alveolar spaces with fluid can also be found. The characteristics of the immune response to RSV are not well elucidated. Because reinfection occurs frequently and is often associated with illness, the immunity that develops after single episodes of infection clearly is not complete or long-lasting. However, the cumulative effect of multiple reinfections is to temper subsequent disease and to provide some temporary measure of protection against infection. Studies of experimentally induced disease in healthy volunteers indicate that the presence of nasal IgA neutralizing antibody correlates more closely with protection than does the presence of serum antibody. Studies in infants, however, suggest that maternally acquired antibody provides some protection from lower respiratory tract disease, although illness can be severe even in infants who have moderate levels of maternally derived serum antibody. The relatively severe disease observed in immunosuppressed patients and experimental animal models indicates that cell-mediated immunity is an important mechanism of host defense against RSV. Evidence suggests that class I MHC-restricted cytotoxic T cells may be particularly important in this regard.

CLINICAL MANIFESTATIONS

RSVinfection leads to a wide spectrum of respiratory illnesses. In infants, 25 to 40% of infections result in lower respiratory tract involvement, including pneumonia, bronchiolitis, and tracheobronchitis. In this age group, illness begins most frequently with rhinorrhea, low-grade fever, and mild systemic symptoms, often accompanied by cough and wheezing. Most patients recover gradually over 1 to 2 weeks. In more severe illness, tachypnea and dyspnea develop, and eventually frank hypoxia, cyanosis, and apnea can ensue. Physical examination may reveal diffuse wheezing, rhonchi, and rales. Chest radiography shows hyperexpansion, peribronchial thickening, and variable infiltrates ranging from diffuse interstitial infiltrates to segmental or lobar consolidation. Illness may be particularly severe in children born prematurely and in those with congenital cardiac disease, bronchopulmonary dysplasia, nephrotic syndrome, or immunosuppression. One study documented a 37% mortality rate for infants with RSV pneumonia and congenital cardiac disease.

In adults, the most common symptoms ofRSVinfection are those of the common cold, with rhinorrhea, sore throat, and cough. Illness is occasionally associated with moderate systemic symptoms such as malaise, headache, and fever. RSV also has been reported to cause lower respiratory tract disease with fever in adults, including severe pneumonia in the elderly. RSV pneumonia can be a significant cause of morbidity and mortality in patients (particularly children) undergoing bone-marrow and solid-organ transplantation.

LABORATORY FINDINGS AND DIAGNOSIS

The diagnosis ofRSVinfection can be suspected on the basis of a suggestive epidemiologic setting -- that is, severe illness among infants during an outbreak of RSV in the community. Infections in older children and adults cannot be differentiated with certainty from those caused by other respiratory viruses. The specific diagnosis is established by isolation of RSV from respiratory secretions, including sputum, throat swabs, or nasopharyngeal washes. Virus is detected in tissue culture and is identified specifically through immunologic reactions detected by immunofluorescence, enzyme-linked immunosorbent assay (ELISA), or other techniques. Immunofluorescence microscopy of nasal scrapings or washings provides a rapid diagnosis. Serologic tests that depend on fourfold or greater rises in complement-fixing or neutralizing antibody titers are useful for diagnosis in older children and adults but are less sensitive in children under 4 months of age. ELISA is more sensitive than complement-fixation or neutralization tests in the detection of serum antibody. Serologic diagnosis requires comparison of acute- and convalescent-phase serum specimens and is therefore not useful during acute illness.

TREATMENT

Treatment of upper respiratory tractRSVinfection is aimed primarily at the alleviation of symptoms and is similar to that for other viral infections of the upper respiratory tract. For lower respiratory tract infections, respiratory therapy, including hydration, suctioning of secretions, and administration of humidified oxygen and antibronchospastic agents, is given as needed. In severe hypoxia, intubation and ventilatory assistance may be required. Studies of infants with RSV infection who were given aerosolized ribavirin, a nucleoside analogue active in vitro against RSV, have demonstrated a beneficial effect on the resolution of lower respiratory tract illness, including alleviation of blood-gas abnormalities. Treatment with ribavirin is recommended for infants who are severely ill or who are at high risk for complications of RSV infection; included are premature infants and those with bronchopulmonary dysplasia, congenital heart disease, or immunosuppression. The effects of ribavirin in adults with RSV pneumonia have not been established. The monthly administration of human immunoglobulin with high titers of antibody to RSV (RSVIG) or of a chimeric mouse-human IgG antibody to RSV (palivizumab) has been approved as prophylaxis against RSV for children younger than 2 years of age who have bronchopulmonary dysplasia or were born prematurely.

Considerable interest exists in the development of vaccines againstRSV. Inactivated whole-virus vaccines have been ineffective; in one study, they actually potentiated the disease in infants. Other approaches include immunization with purified F and G surface glycoproteins of RSV or generation of stable, live attenuated virus vaccines. In settings such as pediatric wards where rates of transmission are high, barrier methods for the protection of hands and conjunctivae may be useful in reducing the spread of virus.

PARAINFLUENZA VIRUS INFECTIONS

ETIOLOGIC AGENT

Parainfluenza viruses belong to the Paramyxoviridae family, are 150 to 250 nm in diameter, are enveloped, and contain a single-stranded RNA genome. The envelope is

studded with two glycoproteins: one possesses both hemagglutinin and neuraminidase activity and the other contains fusion activity. The viral RNA genome is enclosed in a helical nucleocapsid and codes for seven or eight virus-specific proteins. All four distinct serotypes of parainfluenza viruses share certain antigens with other members of the Paramyxoviridae family, including mumps and Newcastle disease viruses.

EPIDEMIOLOGY

Parainfluenza viruses are distributed throughout the world; infection with type 4 (subtypes 4A and 4B) has been reported less widely, probably because type 4 is more difficult to grow in tissue culture. Infection is acquired in early childhood, so that by 8 years of age most children have antibodies to serotypes 1, 2, and 3. Types 1 and 2 cause epidemics during the fall, primarily in odd-numbered years. Type 3 infection has been detected during all seasons of the year, but epidemics have occurred annually in the spring.

The contribution of parainfluenza infections to respiratory disease varies with both the location and the year. In studies conducted in the United States, parainfluenza virus infections have accounted for 4.3 to 22% of respiratory illnesses in children. In adults, parainfluenza infections are generally mild and account for fewer than 5% of respiratory illnesses. The major importance of parainfluenza viruses is as a cause of respiratory illness in young children, in whom they rank second only toRSV as causes of lower respiratory tract illness. Parainfluenza virus type 1 is the most frequent cause of croup (laryngotracheobronchitis) in children, while serotype 2 causes similar, although generally less severe, disease. Type 3 is an important cause of bronchiolitis and pneumonia in infants, while illnesses associated with type 4 have generally been mild. Unlike types 1 and 2, type 3 frequently causes illness during the first month of life, when passively acquired maternal antibody is still present. Parainfluenza viruses are spread through infected respiratory secretions, primarily by person-to-person contact and/or by large droplets. The incubation period has varied from 3 to 6 days in experimental infections but may be somewhat shorter for naturally occurring disease in children.

PATHOGENESIS

Immunity to parainfluenza viruses is incompletely understood, but evidence suggests that immunity to infections with serotypes 1 and 2 is mediated by local IgA antibodies in the respiratory tract. Passively acquired serum neutralizing antibodies also confer some protection against infection with types 1, 2, and -- to a lesser degree -- 3. Studies in experimental animal models and in immunosuppressed patients suggest that cell-mediated immunity may also be important in parainfluenza virus infections.

CLINICAL MANIFESTATIONS

Parainfluenza virus infections occur most frequently among children, in whom initial infection with serotype 1, 2, or 3 is associated with an acute febrile illness 50 to 80% of the time. Children may present with coryza, sore throat, hoarseness, and cough that may or may not be croupy. In severe croup, fever persists, with worsening coryza and sore throat. A brassy or barking cough may progress to frank stridor. Most children recover over the next 1 or 2 days, although progressive airway obstruction and hypoxia

ensue occasionally. If bronchiolitis or pneumonia develops, progressive cough accompanied by wheezing, tachypnea, and intercostal retractions may occur. In this setting, sputum production increases modestly. Physical examination shows nasopharyngeal discharge and oropharyngeal injection, along with rhonchi, wheezes, or coarse breath sounds. Chest x-rays can show air trapping and occasionally interstitial infiltrates.

In older children and adults, parainfluenza infections tend to be milder, presenting most frequently as a common cold or as hoarseness, with or without cough. Lower respiratory tract involvement in older children and adults is uncommon, but tracheobronchitis in adults has been reported. Severe, prolonged, and even fatal parainfluenza infection has been reported in children and adults with severe immunosuppression, including bone-marrow and solid-organ transplant recipients.

LABORATORY FINDINGS AND DIAGNOSIS

The clinical syndromes caused by parainfluenza viruses (with the possible exception of croup in young children) are not sufficiently distinctive to be diagnosed on clinical grounds alone. A specific diagnosis is established by detection of virus in respiratory tract secretions, throat swabs, or nasopharyngeal washings. Virus is detected by growth in tissue culture (either by hemagglutination or by a cytopathic effect), by immunofluorescence of viral antigens in exfoliated cells from the respiratory tract, or by ELISA. Polymerase chain reaction assays have also been developed. Serologic diagnosis is based on a fourfold or greater rise in antibody titer, as detected by hemagglutination inhibition or by complement-fixation or neutralization tests in acute- and convalescent-phase specimens. However, as frequent heterotypic responses occur among the parainfluenza serotypes, the serotype causing illness often cannot be identified by serologic techniques alone.

Acute epiglottitis caused by *Haemophilus influenzae* type b must be differentiated from viral croup. Influenza A virus also is a common cause of croup during epidemic periods.

TREATMENT

For upper respiratory tract illness, symptoms can be treated as discussed for other viral respiratory tract illnesses. If complications such as sinusitis, otitis, or superimposed bacterial bronchitis develop, appropriate antibiotics should be administered. Mild cases of croup should be treated with bed rest and moist air generated by vaporizers. More severe cases require hospitalization and close observation for the development of respiratory distress. If acute respiratory distress develops, humidified oxygen and intermittent racemic epinephrine are usually administered. Aerosolized or systemically administered glucocorticoids are beneficial; the latter have a more profound effect. No specific antiviral therapy is available, although ribavirin is active against parainfluenza viruses in vitro and anecdotal reports describe its use clinically. Effective vaccines against parainfluenza viruses have not been developed.

ADENOVIRUS INFECTIONS

ETIOLOGIC AGENT

Adenoviruses are complex DNA viruses that measure 70 to 80 nm in diameter. Human adenoviruses belong to the genus *Mastadenovirus*, which includes at least 47 serotypes. Adenoviruses have a characteristic morphology consisting of an icosahedral shell composed of 20 equilateral triangular faces and 12 vertices. The protein coat (capsid) consists of hexon subunits with group-specific and type-specific antigenic determinants and penton subunits at each vertex primarily containing group-specific antigens. A fiber with a knob at the end projects from each penton; this fiber contains type-specific and some group-specific antigens. Human adenoviruses have been divided into six subgenera (A through F) on the basis of the homology of DNA genomes and other properties. The adenovirus genome is a linear double-stranded DNA that codes for structural and nonstructural polypeptides. The replicative cycle of adenovirus may result either in lytic infection of cells or in the establishment of a latent infection (primarily involving lymphoid cells). Some adenovirus types can induce oncogenic transformation, and tumor formation has been observed in rodents; however, despite intensive investigation, adenoviruses have not been associated with tumors in humans.

EPIDEMIOLOGY

Adenovirus infections most frequently affect infants and children. Infections occur throughout the year but are most common from fall to spring. Adenoviruses account for 3 to 5% of acute respiratory infections in children but for fewer than 2% of respiratory illnesses in civilian adults. Nearly 100% of adults have serum antibody to multiple serotypes -- a finding indicating that infection is common in childhood. Types 1, 2, 3, and 5 are the most frequent isolates from children. Certain adenovirus serotypes -- particularly 4 and 7 but also 3, 14, and 21 -- are associated with outbreaks of acute respiratory disease in military recruits in winter and spring. Adenovirus infection can be transmitted by inhalation of aerosolized virus, by inoculation of virus into conjunctival sacs, and probably by the fecal-oral route as well. Type-specific antibody generally develops after infection and is associated with protection against infection with the same serotype.

CLINICAL MANIFESTATIONS

In children, adenoviruses cause a variety of clinical syndromes. The most common is an acute upper respiratory tract infection, with prominent rhinitis. On occasion, lower respiratory tract disease, including bronchiolitis and pneumonia, also develops. Adenoviruses, particularly types 3 and 7, cause pharyngoconjunctival fever, a characteristic acute febrile illness of children that occurs in outbreaks, most often in summer camps. The syndrome is marked by bilateral conjunctivitis in which the bulbar and palpebral conjunctivae have a granular appearance. Low-grade fever is frequently present for the first 3 to 5 days, and rhinitis, sore throat, and cervical adenopathy develop. The illness generally lasts for 1 to 2 weeks and resolves spontaneously. Febrile pharyngitis without conjunctivitis also has been associated with adenovirus infection. Adenoviruses have been isolated from cases of whooping cough with or without *Bordetella pertussis;* the significance of adenovirus in that disease is unknown.

In adults, the most frequently reported illness has been acute respiratory disease caused by adenovirus types 4 and 7 in military recruits. This illness is marked by a

prominent sore throat and the gradual onset of fever, which often reaches 39°C (102.2°F) on the second or third day of illness. Cough is almost always present, and coryza and regional lymphadenopathy are frequently seen. Physical examination may show pharyngeal edema, injection, and tonsillar enlargement with little or no exudate. If pneumonia has developed, auscultation and x-ray of the chest may indicate areas of patchy infiltration.

Adenoviruses have been associated with a number of non-respiratory tract diseases, including acute diarrheal illness caused by types 40 and 41 in young children and hemorrhagic cystitis caused by types 11 and 21. Epidemic keratoconjunctivitis, caused most frequently by types 8, 19, and 37, has been associated with contaminated common sources such as ophthalmic solutions and roller towels. Adenoviruses also have been implicated in disseminated disease and pneumonia in immunosuppressed patients, including recipients of solid-organ or bone-marrow transplants and patients with AIDS. In the latter group, high-numbered and intermediate serotypes have been isolated, usually in the setting of low CD4+ counts, but their isolation frequently has not been clearly linked to disease manifestations. Adenovirus nucleic acids have been detected in myocardial cells from patients with "idiopathic" myocardiopathies, and adenoviruses have been suggested as causative agents in some cases.

LABORATORY FINDINGS AND DIAGNOSIS

Adenovirus infection should be suspected in the epidemiologic setting of acute respiratory disease in military recruits and in certain of the clinical syndromes (such as pharyngoconjunctival fever or epidemic keratoconjunctivitis) in which outbreaks of characteristic illnesses occur. In most cases, however, illnesses caused by adenovirus infection cannot be differentiated from those caused by a number of other viral respiratory agents and *Mycoplasma pneumoniae*. A definitive diagnosis of adenovirus infection is established by culture or detection of the virus by means of ELISA or nucleic acid hybridization from sites such as the conjunctiva and oropharynx or from sputum, urine, or stool. Virus may be detected in tissue culture by cytopathic changes and specifically identified by immunofluorescence or other immunologic techniques. Adenovirus types 40 and 41, which have been associated with diarrheal disease in children, require special tissue-culture cells for isolation, and these serotypes are most commonly detected by direct ELISA of stool. Serum antibody rises can be demonstrated by complement-fixation or neutralization tests, ELISA, radioimmunoassay, or (for those adenoviruses that hemagglutinate red cells) hemagglutination inhibition tests.

TREATMENT

Only symptom-based treatment and supportive therapy are available for adenovirus infections, and no clinically useful antiviral compounds have been identified. Live vaccines have been developed against adenovirus types 4 and 7 and have been used to control illness in military recruits. These vaccines consist of live, unattenuated virus administered in enteric-coated capsules. Infection of the gastrointestinal tract with types 4 and 7 does not cause disease but stimulates local and systemic antibodies that are protective against subsequent acute respiratory disease due to those serotypes. Vaccines prepared from purified subunits of adenovirus are being investigated. Adenoviruses are also being studied as live-virus vectors for the delivery of vaccine

antigens and for gene therapy.

(Bibliography omitted in Palm version)

190. INFLUENZA - *Raphael Dolin*

DEFINITION

Influenza is an acute respiratory illness caused by infection with influenza viruses. The illness affects the upper and/or lower respiratory tract and is often accompanied by systemic signs and symptoms such as fever, headache, myalgia, and weakness. Outbreaks of illness of variable extent and severity occur nearly every winter. Such outbreaks result in significant morbidity in the general population and in increased mortality rates among certain high-risk patients, mainly as a result of pulmonary complications.

ETIOLOGIC AGENT

Influenza viruses are members of the Orthomyxoviridae family. Influenza A and B viruses constitute one genus, and influenza C viruses make up the other. The designation of influenza viruses as type A, B, or C is based on antigenic characteristics of the nucleoprotein (NP) and matrix (M) protein antigens. Influenza A viruses are further subdivided (subtyped) on the basis of the surface hemagglutinin (H) and neuraminidase (N) antigens (see below); individual strains are designated according to the site of origin, isolate number, year of isolation, and subtype -- for example, influenza A/Sydney/5/97 (H3N2). Influenza B and C viruses are similarly designated, but H and N antigens from these viruses do not receive subtype designations, since intratypic variations in influenza B antigens are less extensive than those in influenza A viruses and may not occur with influenza C virus.

Most of the information on the molecular biology of influenza viruses has come from studies of influenza A viruses; less is known about the replicative cycle of influenza B and C viruses. Morphologically, influenza viruses A, B, and C are similar. The virions are irregularly shaped spherical particles, 80 to 120 nm in diameter, and have a lipid envelope from the surface of which the H and N glycoproteins project (Fig. 190-1). The hemagglutinin is the site by which virus binds to cell receptors, whereas the neuraminidase degrades the receptor and probably plays a role in the release of virus from infected cells after replication has taken place. Influenza viruses enter cells by receptor-mediated endocytosis, forming a virus-containing endosome. The viral hemagglutinin mediates fusion of the endosomal membrane with the virus envelope, and viral nucleocapsids are subsequently released into the cytoplasm. Antibodies to the H antigen are the major determinants of immunity to influenza virus, while those to the N antigen limit viral spread and contribute to reduction of the infection. The inner surface of the lipid envelope contains the M proteins M1 and M2, the functions of which are incompletely understood but which may be involved in virus assembly and in stabilization of the lipid envelope. The virion also contains theNPantigen, which is associated with the viral genome, as well as three polymerase (P) proteins that are essential for transcription and synthesis of viral RNA. Two nonstructural (NS) proteins of unknown function are also present in infected cells.

The genomes of influenza A and B viruses consist of eight single-stranded RNA segments, which code for the structural and nonstructural proteins. Because the genome is segmented, the opportunity for reassortment of genes during infection is

high, and reassortment occurs frequently during infection of cells with more than one influenza A virus.

EPIDEMIOLOGY

Influenza outbreaks are recorded virtually every year, although their extent and severity vary widely. Localized outbreaks take place at variable intervals, usually every 1 to 3 years. Except for the past two decades, global epidemics or pandemics have occurred approximately every 10 to 15 years since the 1918-1919 pandemic (Table 190-1).

The most extensive and severe outbreaks are caused by influenza A viruses. In part, this predominance is a result of the remarkable propensity of the H and N antigens of influenza A virus to undergo periodic antigenic variation. Major antigenic variations are referred to as *antigenic shifts*, which may be associated with pandemics and are restricted to influenza A viruses. Minor variations are called *antigenic drifts*. These antigenic changes may involve the hemagglutinin alone or both the hemagglutinin and the neuraminidase. In human infections, three major antigenic subtypes of hemagglutinins (H1, H2, and H3) and two of neuraminidases (N1 and N2) have been recognized. The hemagglutinins formerly designated as H0 and Hsw are now classified as variants of H1. An example of an antigenic shift involving both the hemagglutinin and the neuraminidase is that of 1957, when the predominant influenza A virus subtype shifted from H1N1 to H2N2; this shift resulted in a severe pandemic, with an estimated 70,000 excess deaths (i.e., deaths in excess of the number expected without an influenza epidemic) in the United States alone. In 1968, an antigenic shift involving only the hemagglutinin occurred (H2N2 to H3N2); the subsequent pandemic was less severe than that of 1957. In 1977, an H1N1 virus emerged and caused a pandemic that primarily affected younger individuals (i.e., those born after 1957). As can be seen in Table 190-1, H1N1 viruses circulated from 1918 to 1956; thus, individuals born prior to 1957 would be expected to have some degree of immunity to H1N1 viruses. During most outbreaks of influenza A, a single subtype has circulated at a time. However, since 1977, H1N1 and H3N2 viruses have circulated simultaneously, resulting in outbreaks of varying severity. In some outbreaks, influenza B viruses have also circulated simultaneously with influenza A viruses.

The origin of pandemic strains is unknown. Given the marked differences between the primary structures of the hemagglutinins of different subtypes of influenza A viruses (H1, H2, and H3), it seems unlikely that antigenic shifts result from spontaneous mutations in the hemagglutinin gene. Because the segmented genome of influenza viruses may result in high rates of reassortment, it has been suggested that pandemic strains may emerge by reassortment of genes between human and animal viruses. There was concern that such reassortment might have occurred in 1997 in Hong Kong, where cases of infection caused by influenza virus A/H5N1 were detected in humans during an extensive outbreak of avian influenza A/H5N1 in poultry. However, only a few cases of A/H5N1 influenza in humans were documented, and the infection did not spread into the community. Influenza B viruses do not have an animal reservoir and do not undergo antigenic shifts, although they do undergo antigenic drift.

Pandemics provide the most dramatic evidence of the impact of influenza. However, illnesses that occur between pandemics account for greater total mortality and

morbidity, albeit over a longer period. From 1972 through the present, influenza has been associated with at least 20,000 excess deaths during more than half of the interpandemic epidemics in the United States; more than 40,000 influenza-associated deaths occurred in each of three of these epidemics. Influenza A viruses that circulate between pandemics demonstrate antigenic drifts in the H antigen. These antigenic drifts apparently result from point mutations involving the RNA segment that codes for the hemagglutinin. Epidemiologically significant strains -- that is, those with the potential to cause widespread outbreaks -- exhibit changes in amino acids in at least two of the major antigenic sites in the hemagglutinin molecule. Since two point mutations are unlikely to occur simultaneously, it is believed that antigenic drifts result from point mutations occurring sequentially during the spread of virus from person to person. Antigenic drifts have been reported nearly annually since 1977 for H1N1 viruses and since 1968 for H3N2 viruses.

Influenza A epidemics begin abruptly, peak over a 2- to 3-week period, generally last for 2 to 3 months, and often subside almost as rapidly as they began. The first indication of influenza activity in a community is an increase in the number of children with febrile respiratory illnesses who present for medical attention. This increase is followed by increases in rates of influenza-like illnesses among adults and eventually by an increase in hospital admissions for patients with pneumonia, worsening of congestive heart failure, and exacerbations of chronic pulmonary disease. Rates of absence from work and school also rise at this time. An increase in the number of deaths caused by pneumonia and influenza is generally a late observation in an outbreak. Attack rates have been highly variable from outbreak to outbreak but most commonly are in the range of 10 to 20% of the general population. During the pandemic of 1957, it was estimated that the attack rate of clinical influenza exceeded 50% in urban populations and that an additional 25% or more of individuals in these populations may have been subclinically infected with influenza A virus. Among institutionalized populations and in semiclosed settings with a large number of susceptible individuals, even higher attack rates have been reported.

Epidemics of influenza occur almost exclusively during the winter months in the temperate zones of the northern and southern hemispheres. In those locations, it is highly unusual to detect influenza A virus at other times, although serologic rises or even outbreaks have been noted rarely during warm-weather months. In contrast, influenza virus infections occur throughout the year in the tropics. Where or how influenza A virus persists between outbreaks in temperate zones is unknown. It is possible that influenza A viruses are maintained in the human population on a worldwide basis by person-to-person transmission and that large population clusters support a low level of interepidemic transmission. Alternatively, human strains may persist in animal reservoirs. Convincing evidence to support either explanation is not available. In the modern era, rapid transportation may contribute to the transmission of viruses among widespread geographic locales.

The factors that result in the inception and termination of outbreaks of influenza are incompletely understood. A major determinant of the extent and severity of an outbreak is the level of immunity in the population at risk. With the emergence of an antigenically novel influenza virus to which little or no antibody is present in a community, extensive outbreaks may occur. When the absence of antibody is worldwide, epidemic disease

may spread around the globe, resulting in a pandemic. Such pandemic waves can continue for several years, until immunity in the population reaches a high level. In the years following pandemic influenza, antigenic drifts among influenza viruses result in outbreaks of variable severity in populations with high levels of immunity to the pandemic strain that circulated earlier. This situation persists until another antigenically novel pandemic strain emerges. On the other hand, outbreaks sometimes end despite the persistence of a large pool of susceptible individuals in the population.

Occasionally, the emergence of a significantly different antigenic variant will result only in a localized outbreak. The swine influenza outbreak of 1976 in the United States, caused by an A/H1N1 virus antigenically similar to the virus that circulated in 1918-1919, may be an example, although this outbreak may have represented simply the introduction of a swine influenza virus into a crowded human population without spread beyond that setting. The cluster of human infections with influenza A/H5N1 in Hong Kong in 1997 may also be an example of this phenomenon. It has been suggested that certain viruses, such as recently circulating A/H1N1 strains, may be intrinsically less virulent and cause less severe disease than other variants, even in immunologically virgin subjects. If so, then other (undefined) factors besides the level of preexisting immunity must play a role in the epidemiology of influenza.

Influenza B virus causes outbreaks that are generally less extensive and are associated with less severe disease than those caused by influenza A virus. The hemagglutinin and neuraminidase of influenza B virus undergo less frequent and less extensive variation than those of influenza A viruses; this characteristic may account, in part, for the lesser extent of disease. Influenza B outbreaks are seen most frequently in schools and military camps, although outbreaks in institutions in which elderly individuals reside have also been noted on occasion. The most serious complication of influenza B virus infection is Reye's syndrome (Chap. 300). Influenza C virus has only infrequently been associated with human disease, although the wide prevalence of serum antibody to this virus indicates that asymptomatic infection may be common.

The morbidity and mortality caused by influenza outbreaks continue to be substantial. Most individuals who die in this setting have underlying diseases that place them at high risk for complications of influenza. Excess hospitalizations for adults with high-risk medical conditions have ranged from 20 to 1000 per 100,000 during recent outbreaks of influenza. The most prominent high-risk conditions are chronic cardiac and pulmonary diseases as well as old age. Mortality among individuals with chronic metabolic, renal, and certain immunosuppressive diseases has also been elevated, although lower than that among patients with chronic cardiopulmonary diseases. The morbidity attributable to influenza in the general population is considerable. For each of three outbreaks in the United States that were studied during the 1960s, estimated direct and indirect economic costs ranged from $1.5 to $3.5 billion; today such costs would obviously be much greater.

PATHOGENESIS

The initial event in influenza is infection of the respiratory epithelium with influenza virus acquired from respiratory secretions of acutely infected individuals. In all likelihood, transmission occurs via aerosols generated by coughs and sneezes, although

hand-to-hand contact, other personal contact, and even fomite transmission may take place. Experimental evidence suggests that infection by a small-particle aerosol (particle diameter,<10 um) is more efficient than that by larger droplets. Initially, viral infection involves the ciliated columnar epithelial cells, but it also may involve other respiratory tract cells, including alveolar cells, mucous gland cells, and macrophages. In infected cells, virus replicates within 4 to 6 h, after which infectious virus is released to infect adjacent or nearby cells. In this way, infection spreads from a few foci to a large number of respiratory cells over several hours. In experimentally induced infection, the incubation period of illness has ranged from 18 to 72 h, depending on the size of the virus inoculum. Histopathologic study reveals degenerative changes, including granulation, vacuolization, swelling, and pyknotic nuclei, in infected ciliated cells. The cells eventually become necrotic and desquamate; in some areas, previously columnar epithelium is replaced by flattened and metaplastic epithelial cells. The severity of illness is correlated with the quantity of virus shed in secretions; thus, the degree of viral replication itself may be an important factor in pathogenesis. Despite the frequent development of systemic signs and symptoms such as fever, headache, and myalgias, influenza virus has only rarely been detected in extrapulmonary sites (including the bloodstream). Evidence suggests that the pathogenesis of systemic symptoms in influenza may be related to the induction of certain cytokines, particularly tumor necrosis factor a and interleukin 6.

The host response to influenza infections involves a complex interplay of humoral antibody, local antibody, cell-mediated immunity, interferon, and other host defenses. Serum antibody responses, which can be detected by the second week after primary infection, are measured by a variety of techniques: hemagglutination inhibition (HI), complement fixation (CF), neutralization, enzyme-linked immunosorbent assay (ELISA), and antineuraminidase antibody assay. Antibodies directed against the hemagglutinin appear to be the most important mediators of immunity; in several studies, HI titers of $^{3}40$ have been associated with protection from infection. Secretory antibodies produced in the respiratory tract are predominantly of the IgA class and also play a major role in protection against infection. Secretory antibody neutralization titers of$^{3}4$ have also been associated with protection. A variety of cell-mediated immune responses, both antigen-specific and antigen-nonspecific, can be detected early after infection and depend on the prior immune status of the host. These responses include T-cell proliferative, T-cell cytotoxic, and natural killer cell activity. Interferons have been detected in respiratory secretions shortly after the shedding of virus has begun, and rises in interferon titers coincide with decreases in virus shedding.

The host defense factors responsible for cessation of virus shedding and resolution of illness have not been defined specifically. Virus shedding generally stops within 2 to 5 days after symptoms first appear, at a time when serum and local antibody responses often are not detectable by conventional techniques (although antibody rises may be detected earlier by use of highly sensitive techniques, particularly in individuals with previous immunity to the virus). It has been suggested that interferon, cell-mediated immune responses, and/or nonspecific inflammatory responses are important in the resolution of illness.

MANIFESTATIONS

Influenza has most frequently been described as an illness characterized by the abrupt onset of systemic symptoms, such as headache, feverishness, chills, myalgia, or malaise, and accompanying respiratory tract signs, particularly cough and sore throat. In many cases, the onset is so abrupt that patients can recall the precise time they became ill. A typical case of naturally occurring influenza is depicted in Fig. 190-2. However, the spectrum of clinical presentations is wide, ranging from a mild, afebrile respiratory illness similar to the common cold (with either a gradual or an abrupt onset) to severe prostration with relatively few respiratory signs and symptoms. In most of the cases that come to a physician's attention, the patient has a fever, with temperatures of 38° to 41°C (100.4° to 105.8°F). A rapid temperature rise within the first 24 h of illness is generally followed by a gradual defervescence over a 2- to 3-day period, although, on occasion, fever may last for as long as a week. Patients report a feverish feeling and chilliness, but true rigors are rare. Headache, either generalized or frontal, is often particularly troublesome. Myalgias may involve any part of the body but are most common in the legs and lumbosacral area. Arthralgias may also develop.

Respiratory complaints often become more prominent as systemic symptoms subside. Many patients have a sore throat or persistent cough, which may last for a week or more and which is often accompanied by substernal discomfort. Ocular signs and symptoms include pain on motion of the eyes, photophobia, and burning of the eyes.

Physical findings are usually minimal in cases of uncomplicated influenza. Early in the illness, the patient appears flushed and the skin is hot and dry, although diaphoresis and mottled extremities are sometimes evident, particularly in older patients. Examination of the pharynx may yield surprisingly unremarkable results despite a severe sore throat, but injection of the mucous membranes and postnasal discharge are apparent in some cases. Mild cervical lymphadenopathy may be noted, especially in younger individuals. The results of chest examination are largely negative in uncomplicated influenza, although rhonchi, wheezes, and scattered rales have been reported with variable frequency in different outbreaks. Frank dyspnea, hyperpnea, cyanosis, diffuse rales, and signs of consolidation are indicative of pulmonary complications. Patients with apparently uncomplicated influenza have been reported to have a variety of mild ventilatory defects and increased alveolar-capillary diffusion gradients; thus, subclinical pulmonary involvement may be more frequent than is appreciated.

In uncomplicated influenza, the acute illness generally resolves over a 2- to 5-day period, and most patients have largely recovered in 1 week. In a significant minority (particularly the elderly), however, symptoms of weakness or lassitude (postinfluenzal asthenia) may persist for several weeks and may prove troublesome for persons who wish to resume their full level of activity promptly. The pathogenetic basis for this asthenia is unknown, although pulmonary function abnormalities may persist for several weeks after uncomplicated influenza.

COMPLICATIONS

The most common complication of influenza is pneumonia: "primary" influenza viral pneumonia, secondary bacterial pneumonia, or mixed viral and bacterial pneumonia. Primary influenza viral pneumonia is the least common but most severe of the

pneumonic complications. It presents as acute influenza that does not resolve but instead progresses relentlessly, with persistent fever, dyspnea, and eventual cyanosis. Sputum production is generally scanty, but the sputum can contain blood. Few physical signs may be evident early in the illness. In more advanced cases, diffuse rales may be noted, and chest x-ray findings consistent with diffuse interstitial infiltrates and/or acute respiratory distress syndrome may be present. In such cases, arterial blood-gas determinations show marked hypoxia. Viral cultures of respiratory secretions and lung parenchyma, especially if samples are taken early in illness, yield high titers of virus. In fatal cases of primary viral pneumonia, histopathologic examination reveals a marked inflammatory reaction in the alveolar septa, with edema and infiltration by lymphocytes, macrophages, occasional plasma cells, and variable numbers of neutrophils. Fibrin thrombi in alveolar capillaries, along with necrosis and hemorrhage, have also been noted. Eosinophilic hyaline membranes can be found lining alveoli and alveolar ducts.

Primary influenza viral pneumonia has a predilection for individuals with cardiac disease, particularly those with mitral stenosis (Fig. 190-CD1), but has also been reported in otherwise healthy young adults as well as in older individuals with chronic pulmonary disorders. In some epidemics of influenza (notably those of 1918 and 1957), pregnancy increased the risk of primary influenza pneumonia.

Secondary bacterial pneumonia follows acute influenza. Improvement of the patient's condition over 2 to 3 days is followed by a reappearance of fever along with clinical signs and symptoms of bacterial pneumonia, including cough, production of purulent sputum, and physical and x-ray signs of consolidation. The most common bacterial pathogens in this setting are *Streptococcus pneumoniae*, *Staphylococcus aureus*, and *Haemophilus influenzae* -- organisms that can colonize the nasopharynx and that cause infection in the wake of changes in bronchopulmonary defenses. The etiology can often be determined by Gram's staining and culture of an appropriately obtained sputum specimen. Secondary bacterial pneumonia occurs most frequently in high-risk individuals with chronic pulmonary and cardiac disease and in elderly individuals. Patients with secondary bacterial pneumonia often respond to antibiotic therapy when it is instituted promptly.

Perhaps the most common pneumonic complications during outbreaks of influenza have mixed features of viral and bacterial pneumonia. Patients may experience a gradual progression of their acute illness or may show transient improvement followed by clinical exacerbation, with eventual manifestation of the clinical features of bacterial pneumonia. Sputum cultures may contain both influenza A virus and one of the bacterial pathogens described above. Patchy infiltrates or areas of consolidation may be detected by physical examination and chest x-ray. Patients with mixed viral and bacterial pneumonia generally have less widespread involvement of the lung than those with primary viral pneumonia, and their bacterial infections may respond to appropriate antibiotics. Mixed viral and bacterial pneumonia occurs primarily in patients with chronic cardiovascular and pulmonary diseases.

Other pulmonary complications associated with influenza include worsening of chronic obstructive pulmonary disease and exacerbation of chronic bronchitis and asthma. In children, influenza infection may present as croup.

In addition to the pulmonary complications of influenza, a number of extrapulmonary complications may occur. These include *Reye's syndrome*, a serious complication in children that is associated with influenza B and to a lesser extent with influenza A virus infection as well as with varicella-zoster virus infection. An epidemiologic association between Reye's syndrome and aspirin therapy for the antecedent viral infection has been noted, and the incidence of Reye's syndrome has decreased markedly with widespread warnings regarding the use of aspirin by children with acute viral respiratory infections. A detailed description of Reye's syndrome is found in Chap. 300.

Myositis, rhabdomyolysis, and myoglobinuria are occasional complications of influenza infection. Although myalgias are exceedingly common in influenza, true myositis is rare. Patients with acute myositis have exquisite tenderness of the affected muscles, most commonly in the legs, and may not be able to tolerate even the slightest pressure, such as the touch of bedsheets. In the most severe cases, there is frank swelling and bogginess of muscles. Serum levels of creatine phosphokinase and aldolase are markedly elevated, and an occasional patient has developed renal failure from myoglobinuria. The pathogenesis of influenza-associated myositis is also unclear, although the presence of influenza virus in affected muscles has been reported.

Myocarditis and pericarditis were reported in association with influenza virus infection during the 1918-1919 pandemic; these reports were based largely on histopathologic findings, and these complications have been reported only infrequently since that time. Electrocardiographic changes during acute influenza are common among patients who have cardiac disease but have been ascribed most often to exacerbations of the underlying cardiac disease rather than to direct involvement of the myocardium with influenza virus.

Central nervous system (CNS) diseases, including encephalitis, transverse myelitis, and Guillain-Barre syndrome, have been reported during influenza. The etiologic relationship of influenza virus to such CNS illnesses remains unestablished. Toxic shock syndrome caused by *S. aureus* infection following acute influenza infection has also been reported (Chap. 139).

In addition to complications involving the specific organ systems described above, influenza outbreaks include a number of cases in which elderly and other high-risk individuals develop influenza and subsequently experience a gradual deterioration of underlying cardiovascular, pulmonary, or renal function -- changes that occasionally are irreversible and lead to death. These fatalities contribute to the overall excess mortality associated with influenza A outbreaks.

LABORATORY FINDINGS AND DIAGNOSIS

Laboratory diagnosis is accomplished during acute influenza by isolation of the virus from throat swabs, nasopharyngeal washes, or sputum. Virus is usually detected in tissue culture or less commonly is found in the amniotic cavity of chick embryos within 48 to 72 h after inoculation. The rapid viral diagnostic tests now available detect viral nucleoprotein or neuraminidase with high specificity and sensitivities of 57 to 81% compared with tissue culture. Viral nucleic acids have been detected in clinical samples by reverse transcriptase polymerase chain reaction. The type of influenza virus (A or B)

may be determined by either immunofluorescence orHItechniques, and the hemagglutinin subtype of influenza A virus (H1, H2, or H3) may be identified by HI with use of subtype-specific antisera. Serologic methods for diagnosis require comparison of antibody titers in sera obtained during the acute illness with those in sera obtained 10 to 14 days after the onset of illness and are useful primarily in retrospect. Fourfold or greater titer rises as detected by HI orCF or significant rises as measured byELISAare diagnostic of acute infection. CF tests are generally less sensitive than other serologic techniques, but, as they detect type-specific antigens, they may be particularly useful when subtype-specific reagents are not available.

Other laboratory tests are generally not helpful in making a specific diagnosis of influenza virus infection. Leukocyte counts are variable, frequently being low early in illness and normal or slightly elevated later. Severe leukopenia has been described in overwhelming viral or bacterial infection, while leukocytosis with more than 15,000 cells/uL raises the suspicion of secondary bacterial infection.

DIFFERENTIAL DIAGNOSIS

On clinical grounds alone, an individual case of influenza may be difficult to differentiate from an acute respiratory illness caused by any of a variety of respiratory viruses or by *Mycoplasma pneumoniae*. Severe streptococcal pharyngitis or early bacterial pneumonia may mimic acute influenza, although bacterial pneumonias generally do not run a self-limited course. Purulent sputum in which a bacterial pathogen can be detected by Gram's staining is an important diagnostic feature in bacterial pneumonia. The fact that influenza occurs in characteristic outbreaks during the winter months may facilitate a clinical diagnosis. When local health authorities indicate that influenza is present in the community, an acute febrile respiratory illness can be attributed to influenza with a high degree of certainty, particularly if the typical features of abrupt onset and systemic symptoms are present.

TREATMENT

In uncomplicated cases of influenza, symptom-based therapy with acetaminophen for the relief of headache, myalgia, and fever may be considered, but the use of salicylates should be avoided in children below 18 years of age because of the possible association of salicylates with Reye's syndrome. Since cough is ordinarily self-limited, treatment with cough suppressants generally is not indicated, although codeine-containing compounds may be employed if the cough is particularly troublesome. Patients should be advised to rest and maintain hydration during acute illness and should return to full activity only gradually after the illness has resolved, especially if the illness has been severe.

Specific antiviral therapy is available for influenza: amantadine and rimantadine for influenza A and the neuraminidase inhibitors zanamivir and oseltamivir for both influenza A and influenza B. If begun within 48 h of the onset of illness, treatment with amantadine or rimantadine has reduced the duration of systemic and respiratory symptoms of influenza by ~50%. From 5 to 10% of individuals who receive amantadine experience mildCNS side effects, primarily jitteriness, anxiety, insomnia, or difficulty in concentrating. These side effects disappear promptly upon cessation of the drug.

Rimantadine appears to be equally efficacious and is associated with less frequent CNS side effects than is amantadine. In adults, the usual dose of amantadine or rimantadine is 200 mg/d for 3 to 7 days. Since both drugs are excreted via the kidney, the dose should be reduced to£100 mg/d in elderly patients and patients with renal insufficiency. Zanamivir, inhaled orally at a dose of 10 mg twice a day for 5 days, or oseltamivir, ingested orally at a dose of 75 mg twice a day for 5 days, has reduced the duration of signs and symptoms of influenza by 1 to 1.5 days if treatment is started within 2 days of the onset of illness. Zanamivir may exacerbate bronchospasm in asthmatic patients, and oseltamivir has been associated with nausea and vomiting, whose frequency can be reduced by drug administration with food. Currently, only amantadine and zanamivir are approved in the United States for treatment of children (the latter for use in children³7 years old). Ribavirin, a nucleoside analogue with activity against a variety of viral agents, has been reported to be effective against both influenza A and influenza B virus infections when administered as an aerosol, although it is relatively ineffective when administered orally.

Studies demonstrating the therapeutic efficacy of antiviral compounds in influenza have primarily involved young adults with uncomplicated disease; it is not known whether such compounds are effective in the treatment of complications such as influenza pneumonia. Therapy for primary influenza pneumonia is directed at maintaining oxygenation and is most appropriately undertaken in an intensive care unit, with aggressive respiratory and hemodynamic support as needed. Bypass membrane oxygenators have been employed in this setting with variable results. When an acute respiratory distress syndrome develops, fluids must be administered cautiously, with close monitoring of blood gases and hemodynamic function.

Antibacterial drugs should be reserved for the therapy of bacterial complications of acute influenza, such as secondary bacterial pneumonia. The choice of antibiotics should be guided by Gram's staining and culture of appropriate specimens of respiratory secretions, such as sputum or transtracheal aspirates. If the etiology of a case of bacterial pneumonia is unclear from an examination of respiratory secretions, empirical antibiotics effective against the most common bacterial pathogens in this setting (*S. pneumoniae*, *S. aureus*, and *H. influenzae*) should be selected (Chaps. 138,139, and149).

PROPHYLAXIS

The major public health measure for prevention of influenza has been the use of inactivated influenza vaccines derived from influenza A and B viruses that circulated during the previous influenza season. If the vaccine virus and the currently circulating viruses are closely related, 50 to 80% protection against influenza would be expected. Presently available vaccines have been highly purified and are associated with few reactions. Up to 5% of individuals experience low-grade fever and mild systemic symptoms 8 to 24 h after vaccination, and up to one-third develop mild redness or tenderness at the vaccination site. Since the vaccine is produced in eggs, individuals with true hypersensitivity to egg products either should be desensitized or should not be vaccinated. Although the 1976 swine influenza vaccine appears to have been associated with an increased frequency of Guillain-Barre syndrome, influenza vaccines administered since 1976 generally have not been. Possible exceptions were noted

during the 1992-1993 and 1993-1994 influenza seasons, when there may have been an excess risk of Guillain-Barre syndrome of slightly more than one case per million among vaccine recipients. However, the overall health risk following influenza outweighs the potential risk associated with vaccination. Investigational live attenuated ("cold-adapted") influenza A and B vaccines also have been developed and have been highly effective in preventing influenza in studies in adults and children. Such vaccines are administered intranasally and stimulate local antibody production more efficiently than conventional inactivated vaccines.

The U.S. Public Health Service recommends influenza vaccination for any individual>6 months of age who is at an increased risk for complications of influenza. Included are individuals with chronic cardiovascular or pulmonary disorders (including asthma) and residents of nursing homes and other chronic-care facilities. Other populations for whom the vaccine is recommended include healthy individuals >65 years of age and individuals who have required regular medical attention for diabetes mellitus, renal disease, hemoglobinopathies, or immunosuppression. Individuals who provide care for high-risk patients or who come into frequent contact with such patients, including household members, should also receive vaccine to reduce the likelihood of transmission of infection. Vaccination is recommended for women who will be in the second or third trimester of pregnancy during the influenza season and for individuals 6 months to 18 years of age who are receiving long-term aspirin therapy and may be at risk for Reye's syndrome. Since commercially available vaccines are inactivated ("killed"), they may be administered safely to immunocompromised patients. Influenza vaccination is not associated with exacerbations of chronic nervous-system diseases such as multiple sclerosis. Vaccine should be administered early in the autumn before influenza outbreaks occur and should be repeated annually to maintain immunity against the most current influenza virus strains.

Of the vaccines currently available (inactivated whole-virus vaccine, subvirion vaccine, and purified surface-antigen vaccine), only the "split-virus" preparations (i.e., the subvirion and purified surface-antigen vaccines) should be given to children<13 years old, since the whole-virus preparations have been associated with higher rates of adverse reactions in this age group.

Studies have shown amantadine and rimantadine to be 70 to 100% effective in the prophylaxis of illness associated with influenza A virus infection. Such prophylaxis is most likely to be used for high-risk individuals who have not received influenza vaccine or in a situation where the vaccines previously administered are relatively ineffective because of antigenic changes in the circulating virus. During an outbreak, amantadine or rimantadine can be administered simultaneously with inactivated vaccine, since neither drug interferes with an immune response to the vaccine. In fact, there is evidence that the protective effects of amantadine and vaccine may be additive. Amantadine has also been employed to control nosocomial outbreaks of influenza A. For prophylaxis, administration of amantadine or rimantadine should be instituted promptly when influenza A activity is detected and must be continued daily for the duration of the outbreak. The dosage most frequently employed has been 200 mg/d for adults, but the dose should be reduced for patients with renal insufficiency and for the elderly. Viruses resistant to both amantadine and rimantadine can emerge quickly after therapy with these drugs, and the possible transmission of these resistant viruses has

been reported. The neuraminidase inhibitors zanamivir and oseltamivir have also been reported to be highly effective in the prophylaxis of influenza A and offer the advantage of efficacy against influenza B as well. They are currently under review for use as prophylaxis. As with amantadine and rimantadine, the neuraminidase inhibitors must be administered daily to maintain prophylaxis.

SECTION 14 -RNA VIRUSES

191. THE HUMAN RETROVIRUSES - *Anthony S. Fauci*, *Dan L. Longo*

The retroviruses, which make up a large family (Retroviridae), infect mainly vertebrates. They have a unique replication cycle whereby their genetic information is encoded by RNA rather than DNA. Retroviruses contain an RNA-dependent DNA polymerase (a reverse transcriptase) that directs the synthesis of a DNA form of the viral genome after infection of a host cell. The designation *retrovirus* denotes that information in the form of RNA is transcribed into DNA in the host cell -- a sequence that overturned a central dogma of molecular biology: that information passes unidirectionally from DNA to RNA to protein. The observation that RNA was the source of genetic information in the causative agents of certain animal tumors led to a number of paradigm-shifting biologic insights regarding not only the direction of genetic-information passage but also the viral etiology of certain cancers and the concept of oncogenes as normal host genes scavenged and altered by a viral vector.

The family Retroviridae includes three subfamilies (Table 191-1): Oncovirinae, of which human T-cell lymphotropic virus (HTLV) type I is the most important in humans; Lentivirinae, of which HIV is the most important in humans; and Spumavirinae, the "foamy" viruses, named for the pathologic appearance of infected cells. A number of spumaviruses have been isolated from humans; however, they are not associated with any known disease and therefore are not discussed further in this chapter.

The wide variety of interactions of a retrovirus with its host range from completely benign events (e.g., silent carriage of endogenous retroviral sequences in the germ-line genome of many animal species) to rapidly fatal infections (e.g., exogenous infection with an oncogenic virus such as Rous sarcoma virus in chickens). The ability of retroviruses to acquire and alter the structure and function of host cell sequences has revolutionized our understanding of molecular carcinogenesis. The viruses can insert into the germ-line genome of the host cell and behave as a transposable or movable genetic element. They can activate or inactivate genes near the site of integration into the genome. They can rapidly alter their own genome by recombination and mutation under selective environmental stimuli.

Most human viral diseases occur as a consequence of either tissue destruction by the virus itself or the host's response to the virus. Although these mechanisms are operative in retroviral infections, retroviruses have additional mechanisms of inducing disease, including the malignant transformation of an infected cell and the induction of an immunodeficiency state that leads to opportunistic diseases (infections and neoplasms; Chap. 309).

STRUCTURE AND LIFE CYCLE

Despite the wide range of biologic consequences of retroviral infection, all retroviruses are similar in structure, genome organization, and mode of replication. Retroviruses are 70 to 130 nm in diameter and have a lipid-containing envelope surrounding an icosahedral capsid with a dense inner core. The core contains two identical copies of the single-stranded RNA genome. The RNA molecules are 8 to 10 kb long and are

complexed with reverse transcriptase and tRNA. Other viral proteins, such as integrase, are also components of the virion particle. The RNA has features usually found in mRNA: a cap site at the 5¢ end of the molecule, which is important in the initiation of mRNA translation, and a polyadenylation site at the 3¢ end, which influences mRNA turnover (i.e., messages with shorter polyA tails turn over faster than messages with longer polyA tails). However, the retroviral RNA is not translated; instead it is transcribed into DNA. The DNA form of the retroviral genome is called a *provirus*.

The replication cycle of retroviruses proceeds in two phases (Fig. 191-1). In the first phase, the virus enters the cytoplasm after binding to a specific cell-surface receptor (with HIV, a cell-surface coreceptor is also utilized for binding and entry); the viral RNA and reverse transcriptase synthesize a double-stranded DNA version of the RNA template; and the provirus moves into the nucleus and integrates into the host cell genome. This proviral integration is permanent. Although some animal retroviruses integrate into a single specific site of the host genome in every infected cell, the four known pathogenic human retroviruses (HTLV-I, HTLV-II, HIV-1, and HIV-2) integrate randomly. This first phase of replication depends entirely on gene products in the virus. The second phase includes the synthesis and processing of viral genomes, mRNAs, and proteins using host cell machinery, often under the influence of viral gene products. Virions are assembled and released from the cell by budding from the membrane; host cell membrane proteins are frequently incorporated into the envelope of the virus. Proviral integration occurs during the S phase of the cell cycle; thus, in general, nondividing cells are resistant to retroviral infection. Only the lentiviruses are able to infect nondividing cells. Once a host is infected, it is infected for life.

Retroviral genomes include both coding and noncoding sequences (Fig. 191-2). In general, noncoding sequences are important recognition signals for DNA or RNA synthesis or processing events and are located in the 5¢ and 3¢ terminal regions of the genome. All retroviral genomes are terminally redundant, containing identical sequences called *long terminal repeats* (LTRs). The ends of the retroviral RNA genome differ slightly in sequence from the integrated retroviral DNA. In the latter, the LTR sequences are repeated in both the 5¢ and the 3¢ terminus of the virus. The LTRs contain sequences involved in initiating the expression of the viral proteins, the integration of the provirus, and the polyadenylation of viral RNAs. The primer binding site, which is critical for the initiation of reverse transcription, and the viral packaging sequences are located outside the LTR sequences. The coding regions include the *gag* (group-specific antigen, core protein), *pol* (RNA-dependent DNA polymerase), and *env* (envelope) genes. The *gag* gene encodes a precursor polyprotein that is cleaved to form three to five capsid proteins; a fraction of the Gag precursor proteins also contain a protease responsible for cleaving the Gag and Pol polyproteins. A Gag-Pol polyprotein gives rise to the protease that is responsible for cleaving the Gag-Pol polyprotein. The *pol* gene encodes three proteins: the reverse transcriptase, the integrase, and the protease. The reverse transcriptase functions to copy the viral RNA into the double-stranded DNA provirus, which can attach to the host cell DNA via the action of integrase. The protease functions to cleave the Gag-Pol polyprotein into smaller protein products. The *env* gene encodes the envelope glycoproteins: one protein that binds to specific surface receptors and determines what cell types can be infected and a smaller transmembrane protein that anchors the complex to the envelope. The cartoon in Fig. 191-3 shows how the retroviral gene products make up the virus structure.

HTLVs have a region between *env* and the 3¢LTR that encodes at least two proteins in overlapping reading frames; Tax, a 40-kD protein that does not bind to DNA but induces the expression of host cell transcription factors that alter host cell gene expression; and Rex, a 27-kD protein that regulates the expression of viral mRNAs. These two proteins are produced from messages that are similar but that are spliced differently from overlapping but distinct exons.

The lentiviruses in general, and HIV-1 and -2 in particular, contain a larger genome than other pathogenic retroviruses. They contain an untranslated region between *pol* and *env* that encodes portions of several proteins, varying with the reading frame into which the mRNA is spliced. Tat is a 14-kD protein that augments the expression of virus from theLTR. The Rev protein of HIV-1, similar to the Rex protein ofHTLV, regulates RNA splicing and/or RNA transport. The Nef protein downregulates CD4, the cellular receptor for HIV; alters host T cell activation pathways; and enhances viral infectivity. The Vif protein is necessary for the proper assembly of the HIV nucleoprotein core in many types of cells; without Vif, proviral DNA is not efficiently produced in these infected cells. Vpr, Vpu (HIV-1 only), and Vpx (HIV-2 only) are viral proteins encoded by translation of the same message in different reading frames. As noted above, oncogenic retroviruses depend on cell proliferation for their replication; lentiviruses can infect nondividing cells, largely owing to effects mediated by Vpr. Vpr facilitates transport of the provirus into the nucleus and can induce other cellular changes, such as G2 growth arrest and differentiation of some target cells. Vpx is structurally related to Vpr, but its functions are not fully defined. Vpu promotes the degradation of CD4 in the endoplasmic reticulum and stimulates the release of virions from infected cells.

Retroviruses can be either exogenously acquired by infection with a virion capable of replication or transmitted in the germ line as endogenous virus. Endogenous retroviruses are often replication-defective. The human genome contains endogenous retroviral sequences, but there are no known replication-competent endogenous retroviruses in humans.

In general, viruses that contain only the *gag*, *pol*, and *env* genes either are not pathogenic or take a long time to induce disease because the pathogenesis of neoplastic transformation relies on the chance integration of the provirus at a spot in the genome that will result in the expression of a cellular gene (proto-oncogene) that becomes transforming by virtue of its unregulated expression. For example, avian leukosis virus causes B cell leukemia by inducing the expression of *myc*. Some retroviruses possess captured and altered cellular genes near their integration site, and these viral oncogenes are capable of transforming the infected host cell. Viruses that have oncogenes often have lost a portion of their genome that is required for replication. Such viruses need helper viruses to reproduce, a feature that may explain why these acute transforming retroviruses are rare in nature. All human retroviruses identified to date are exogenous and are not acutely transforming (that is, they lack a transforming oncogene).

These remarkable properties of retroviruses have led to experimental efforts to use them as vectors to insert specific genes into particular cell types, a process known as *gene therapy* or *gene transfer*. The process could be used to repair a genetic defect or

to introduce a new property that could be used therapeutically; for example, a gene (e.g., thymidine kinase) that would make a tumor cell susceptible to killing by a drug (e.g., ganciclovir) could be inserted. One source of concern about the use of retroviral vectors in humans is that replication-competent viruses might rescue endogenous retroviral replication, with unpredictable results. This concern is not merely hypothetical: The detection of proteins encoded by endogenous retroviral sequences on the surface of cancer cells implies that the genetic events leading to the cancer were able to activate the synthesis of these usually silent genes.

HUMAN T-CELL LYMPHOTROPIC VIRUS

HTLV-I was isolated in 1980 from a T-cell lymphoma cell line from a patient originally thought to have cutaneous T cell lymphoma. Later it became clear that the patient had a distinct form of lymphoma (originally reported in Japan) called *adult T cell leukemia/lymphoma* (ATL). Serologic data have determined that HTLV-I is the cause of at least two important diseases: ATL and tropical spastic paraparesis, also called *HTLV-I-associated myelopathy* (HAM). HTLV-I may also play a role in infective dermatitis and uveitis syndromes.

Two years after the isolation ofHTLV-I, HTLV-II was isolated from a patient with an unusual form of hairy cell leukemia that affected T cells. Although early epidemiologic studies of HTLV-II failed to reveal a consistent disease association, more recent studies suggest an association of HTLV-II with human disease (see "Associated Diseases" under "Features of HTLV-II Infection," below), particularly among injection drug users.

BIOLOGY AND MOLECULAR BIOLOGY

Because the biology ofHTLV-I and that of HTLV-II are similar, the following discussion will focus on HTLV-I.

The cellular receptor forHTLV-I has not yet been identified, but it maps to chromosome 17. Generally, only T cells are productively infected, but infection of B cells and other cell types is occasionally detected. The most common outcome of HTLV-I infection is latent carriage of randomly integrated provirus in CD4+ T cells. HTLV-I does not contain an oncogene and does not insert into a unique site in the genome. Indeed, most infected cells express no viral gene products. The only viral gene product that is routinely expressed in tumor cells transformed by HTLV-I in vivo is *tax*, and even *tax* is not expressed in the tumor cells of manyATLpatients. Cells transformed in vitro, by contrast, actively transcribe HTLV-I RNA and produce infectious virions. Most HTLV-I-transformed cell lines are the result of the infection of a normal host T cell in vitro. It is difficult to establish cell lines derived from authentic ATL cells.

Although *tax* does not itself bind to DNA, it does induce the expression of a wide range of host-cell gene products, including transcription factors (especially *c-rel*, *ets*-1 and -2, and members of the *fos/jun* family), cytokines [e.g., interleukin (IL) 2, granulocyte-macrophage colony-stimulating factor, and tumor necrosis factor (TNF)], and membrane proteins and receptors [major histocompatibility (MHC) molecules and IL-2 receptor a]. The genes activated by *tax* are generally controlled by transcription factors of the *c-rel* and cyclic AMP response element binding (CREB) protein families. It

is unclear how this induction of host gene expression leads to neoplastic transformation. Induction of a cytokine-autocrine loop has been proposed; however, IL-2 is not the crucial cytokine. The involvement of IL-4, IL-7, and IL-15 has been proposed.

In light of the irregular expression of *tax* inATLcells, it has been suggested that *tax* is important in the early phases of transformation but is not essential for the maintenance of the transformed state. As is clear from the epidemiology ofHTLV-I infection, transformation of an infected cell is a rare event and may depend on heterogeneous second, third, or fourth genetic hits. No consistent chromosomal abnormalities have been described inATL; however, individual cases with *p53* mutations and translocations involving the T cell receptor genes on chromosome 14 have been reported. *Tax* may repress certain DNA repair enzymes, permitting the accumulation of genetic damage that would normally be repaired. However, the molecular pathogenesis of HTLV-I-induced neoplasia is not fully understood.

FEATURES OF HTLV-I INFECTION

Epidemiology HTLV-I infection is transmitted in at least three ways: from mother to child, especially in breast milk; through sexual activity, more commonly from men to women; and through the blood -- via contaminated transfusions or contaminated needles. The virus is most commonly transmitted perinatally. Compared with HIV, which can be transmitted in cell-free form, HTLV-I is less infectious, and its transmission usually requires cell-to-cell contact.

HTLV-I is endemic in southwestern Japan and Okinawa, where more than 1 million persons are infected. Antibodies to HTLV-I are present in the serum of up to 35% of Okinawans, 10% of residents of the Japanese island of Kyushu, and<1% of persons in nonendemic regions of Japan. Despite this high prevalence of infection, only about 500 cases ofATL are diagnosed in this area each year. Clusters of infection have been noted in other areas of the Orient, such as Taiwan; in the Caribbean basin, including northeastern South America; in central Africa; in Italy; in Israel; in the Arctic; and in the southeastern part of the United States.

A progressive spastic or ataxic myelopathy that develops in an individual who isHTLV-I positive (i.e., who has serum antibodies to HTLV-I) is likely to be due to direct nervous system infection with the virus; a similar disorder may result from infection with HIV or HTLV-II. In rare instances, patients withHAM are seronegative but have detectable antibody to HTLV-I in the cerebrospinal fluid (CSF).

The cumulative lifetime risk of developingATL is 2% amongHTLV-I-infected patients; a similar risk is projected forHAM. The distribution of the two diseases overlaps the distribution of HTLV-I, with>95% of affected patients showing serologic evidence of HTLV-I infection. The latent period between infection and the emergence of disease is 20 to 30 years for ATL. For HAM, the median latency period is about 3.3 years (range, 4 months to 30 years). The development of ATL is rare among persons infected by blood products; however, ~20% of patients with HAM acquire HTLV-I from contaminated blood.

Associated Diseases

ATL Four clinical types ofHTLV-I-induced neoplasia have been described: acute, lymphomatous, chronic, and smoldering. All of these tumors are monoclonal proliferations of CD4+post-thymic T cells with clonal proviral integrations and clonal T-cell receptor gene rearrangements.

About 60% of patients who develop malignancy have classic *acute*ATL, which is characterized by a short clinical prodrome (~2 weeks between the first symptoms and the diagnosis) and an aggressive natural history (median survival period, 6 months). The clinical picture is dominated by rapidly progressive skin lesions, pulmonary involvement, hypercalcemia, and lymphocytosis with cells containing lobulated or "flower-shaped" nuclei (seePlate V-40). The malignant cells have monoclonal proviral integrations and express CD4, CD3, and CD25 (low-affinityIL-2 receptors) on their surface. Serum levels of CD25 can be used as a tumor marker. Anemia and thrombocytopenia are rare. The skin lesions may be difficult to distinguish from those in mycosis fungoides. Lytic bone lesions, which are common, do not contain tumor cells but rather are composed of osteolytic cells, usually without osteoblastic activity. Despite the leukemic picture, bone marrow involvement is patchy in most cases.

The hypercalcemia ofATL is multifactorial; the tumor cells produce osteoclast-activating factors (TNF-a,IL-1, lymphotoxin) and can also produce a parathyroid hormone-like molecule. The affected patients have an underlying immunodeficiency that makes them susceptible to opportunistic infections similar to those seen in patients with AIDS (Chap. 309). The pathogenesis of the immunodeficiency is unclear. Pulmonary infiltrates in ATL patients reflect leukemic infiltration half the time and opportunistic infections with organisms such as *Pneumocystis carinii* and other fungi the other half. Gastrointestinal symptoms are nearly always related to opportunistic infection. Serum concentrations of lactate dehydrogenase (LDH) and alkaline phosphatase are often elevated. About 10% of patients have leptomeningeal involvement leading to weakness, altered mental status, paresthesia, and/or headache. Unlike other forms of central nervous system (CNS) lymphoma, ATL may be accompanied by normalCSFprotein levels. The diagnosis depends on finding ATL cells in the CSF (Chap. 112).

The *lymphomatous* type ofATLoccurs in ~20% of patients and is similar to the acute form in its natural history and clinical course, except that circulating abnormal cells are rare and lymphadenopathy is evident. The histology of the lymphoma is variable but does not influence the natural history. In general, the diagnosis is suspected on the basis of the patient's birthplace and the presence of skin lesions and hypercalcemia. The diagnosis is confirmed by the detection of antibodies toHTLV-I in serum.

Patients with the *chronic* form of ATLgenerally have normal serum levels of calcium andLDH and no involvement of theCNS, bone, or gastrointestinal tract. The median duration of survival for these patients is 2 years. In some cases, chronic ATL progresses to the acute form of the disease.

Fewer than 5% of patients have the *smoldering* form ofATL. In this form, the malignant cells have monoclonal proviral integration;<5% of peripheral-blood cells exhibit typical morphologic abnormalities; hypercalcemia, adenopathy, and hepatosplenomegaly do not develop; theCNS, the bones, and the gastrointestinal tract are not involved; and skin

and pulmonary lesions may be present. The median survival period of this small subset of patients appears to be ³5 years.

HAM (Tropical Spastic Paraparesis) In contrast toATL, in which there is a slight predominance of male patients,HAMaffects females disproportionately.HAMresembles multiple sclerosis in certain ways (Chap. 371). The onset is insidious. Symptoms include weakness or stiffness in one or both legs, back pain, and urinary incontinence. Sensory changes are usually mild, but peripheral neuropathy may develop. The disease generally takes the form of slowly progressive and unremitting thoracic myelopathy; one-third of patients are bedridden within 10 years of diagnosis, and one-half are unable to walk unassisted by this point. Patients display spastic paraparesis or paraplegia with hyperreflexia, ankle clonus, and extensor plantar responses. Cognitive function is usually spared; cranial nerve abnormalities are unusual.

Magnetic resonance imaging (MRI) reveals lesions in both the white matter and the paraventricular regions of the brain as well as in the spinal cord. Pathologic examination of the spinal cord shows symmetric degeneration of the lateral columns, including the corticospinal tracts; some cases involve the posterior columns as well. The spinal meninges and cord parenchyma contain an inflammatory infiltrate with myelin destruction.

HTLV-I is not usually found in cells of theCNS but may be detected in a small population of lymphocytes present in theCSF. In general, HTLV-I replication is greater inHAM than in ATL, and patients with HAM have a stronger immune response to the virus. Antibodies to HTLV-I are present in the serum and appear to be produced in the CSF ofHAMpatients, where titers are often higher than in the serum. The pathophysiology of HAM may involve the induction of autoimmune destruction of neural cells by T cells with specificity for viral components such as Tax or Env proteins. One theory is that susceptibility to HAM may be related to the presence of human leukocyte antigen (HLA) alleles capable of presenting viral antigens in a fashion that leads to autoimmunity. Insufficient data are available to confirm an HLA association.

Other putative HTLV-I-related diseases In areas whereHTLV-I is endemic, diverse inflammatory and autoimmune diseases have been attributed to the virus, including uveitis, dermatitis, pneumonitis, rheumatoid arthritis, and polymyositis. However, a causal relationship between HTLV-I and these illnesses has not been rigorously established.

Prevention Women in endemic areas should not breast-feed their children, and blood donors should be screened for serum antibodies toHTLV-I. As in the prevention of HIV infection, the practice of safe sex and the avoidance of needle sharing are important.

TREATMENT

For the small number of patients who developHTLV-I-related disease, therapies are not curative. In patients with the acute and lymphomatous types ofATL, the disease progresses rapidly. Hypercalcemia is generally controlled by glucocorticoid administration and cytotoxic therapy directed against the neoplasm. The tumor is highly responsive to combination chemotherapy that is employed against other forms of

lymphoma; however, patients are susceptible to overwhelming bacterial and opportunistic infections, and ATL relapses within 4 to 10 months after remission in most patients. The combination of interferona and zidovudine may extend survival. Because viral replication is not clearly associated with ATL progression, zidovudine is probably effective through its cytotoxic effects (as a chain-terminating thymidine analogue) rather than its antiviral effects. An experimental approach using an yttrium 90-labeled antibody to theIL-2 receptor appears promising but is not widely available. Patients with the chronic or smoldering form of ATL may be managed with an expectant approach: Treat any infections, and watch and wait for signs of progression to acute disease.

Patients withHAM may obtain some benefit from the use of glucocorticoids to reduce inflammation. Antiretroviral regimens have not been effective. In one study, danazol (200 mg tid) produced significant neurologic improvement in five of six treated patients, with resolution of urinary incontinence in two cases, decreased spasticity in three, and the restoration of the ability to walk after confinement to a wheelchair in two. Physical therapy and rehabilitation are important components of management.

FEATURES OF HTLV-II INFECTION

Epidemiology HTLV-II is endemic in certain Native American tribes. It is generally considered to be a New World virus that was brought from Asia to the Americas 10,000 to 40,000 years ago during the migration of infected populations across the Bering land bridge.

The mode of transmission ofHTLV-II is probably the same as that of HTLV-I (see above). HTLV-II may be less readily transmitted sexually than HTLV-I.

Studies of large cohorts of injection drug users with serologic assays that reliably distinguishHTLV-I from HTLV-II indicate that the vast majority of HTLV-positive subjects are infected with HTLV-II. The seroprevalence of HTLV in a cohort of 7841 injection drug users from drug treatment centers in Baltimore, Chicago, Los Angeles, New Jersey (Asbury Park and Trenton), New York City (Brooklyn and Harlem), Philadelphia, and San Antonio was 20.9%, with>97% of cases due to HTLV-II. The seroprevalence of HTLV-II was higher in the Southwest and the Midwest than in the Northeast. In contrast, the seroprevalence of HIV-1 was higher in the Northeast than in the Southwest or the Midwest. Approximately 3% of the cohort members were infected with both HTLV-II and HIV-1. The seroprevalence of HTLV-II increased linearly with age. Women were significantly more likely to be infected with HTLV-II than were men; the virus is thought to be more efficiently transmitted from male to female than from female to male.

Associated Diseases AlthoughHTLV-II was isolated from a patient with a T cell variant of hairy cell leukemia, this virus has not been consistently associated with a particular disease and in fact has been thought of as "a virus searching for a disease." However, evidence is accumulating that HTLV-II may play a role in certain neurologic, hematologic, and dermatologic diseases. These data require confirmation, particularly in light of the previous confusion regarding the relative prevalences of HTLV-I and HTLV-II among injection drug users.

Prevention Avoidance of needle sharing, safe-sex practices, screening of blood (by

assays forHTLV-I, which also detect HTLV-II), and avoidance of breast-feeding by infected women are important principles in the prevention of spread of HTLV-II.

HUMAN IMMUNODEFICIENCY VIRUS

HIV-1 and HIV-2 are members of the lentivirus subfamily of Retroviridae and are the only lentiviruses known to infect humans. The lentiviruses are slow-acting by comparison with viruses that cause acute infection (e.g., influenza virus) but not by comparison with other retroviruses. The features of acute primary infection with HIV resemble those of more classic acute infections. The characteristic chronicity of HIV disease is consistent with the designation *lentivirus*.**For a detailed discussion of HIV, see Chap. 309.*

192. VIRAL GASTROENTERITIS - *Harry B. Greenberg*

In less developed countries, acute infectious diarrheal disease is a leading cause of morbidity in all age groups and of mortality in infants and young children. In developed countries, acute diarrheal illness remains an important cause of morbidity among both children and adults. Two distinct groups of viruses -- the rotaviruses and the enteric caliciviruses, such as Norwalk virus -- as well as a variety of bacterial pathogens (Chap. 131) have emerged as important etiologic agents of gastroenteritis. The rotaviruses are primarily pathogens of young children. The Norwalk and related enteric caliciviruses affect adults as well as children. Several important gastrointestinal viruses are characterized inTable 192-1 and depicted inFig. 192-1.

ROTAVIRUS

Classification and Characterization Rotaviruses are members of the Reoviridae family. The rotavirus virion consists of a 100-nm triple-shelled icosahedral capsid surrounding a genome composed of 11 segments of double-stranded RNA. Several genetically distinct groups of rotaviruses (groups A, B, C, etc.) have been identified, but group A strains account for the great majority of illnesses in humans. With only one exception, the rotavirus gene segments are monocistronic. The virus has two surface proteins (VP4 and VP7), both of which are involved in viral neutralization. The major internal capsid protein (VP6) is the target of cross-reactive antibody to different virus strains. This protein also appears to induce protective immunity, although the mechanism is not clear. Because rotaviruses have a segmented genome, they are capable of undergoing gene reassortment at high frequency. The role of gene reassortment in generating rotavirus antigenic diversity is not known. In immunocompetent humans and animals, rotavirus infection is characterized by replication that is localized almost exclusively in the epithelial cells of the small intestine.

Epidemiology Rotavirus infection occurs worldwide. By the age of 3 years, virtually every individual has been infected by rotaviruses at least once. Most rotavirus infections are subclinical or cause mild gastrointestinal illnesses that do not require hospitalization. The first infection is the most likely to be symptomatic; subsequent infections are often mild or asymptomatic. In areas with a temperate climate, rotavirus infection is seasonal, occurring in the colder winter months. In the United States, the annual seasonal rotavirus epidemic tends to spread from west to east, starting in California and ending in New England. In tropical areas, rotavirus infection tends to occur throughout the year, with some increase in incidence during the cooler rainy season.

Rotaviruses are the single most important cause of severe dehydrating diarrhea in infants and children<3 years old in both developed and less developed countries; they account for 25 to 50% of all cases of diarrhea requiring hospitalization or intensive rehydration therapy. During a rotavirus outbreak in a temperate climate, this percentage can be as high as 80%. In the United States, between 5 and 10% of all diarrheal episodes among children under the age of 5 years are caused by rotavirus. Infection due to rotavirus accounts for ~500,000 physician visits per year in the United States. Although severe rotavirus infections are confined primarily to infants and young children, these agents are frequently associated with mild diarrhea in adults, particularly family members of affected infants, geriatric patients, and immunocompromised hosts. They

are responsible for up to 10% of cases of traveler's diarrhea (Chap. 131). Rotaviruses also may cause occasional cases of acute and chronic diarrhea in patients with AIDS.

Rotavirus serotypes have been defined by the antigenicity of both VP4 (P serotype) and VP7 (G serotype). At least 14 distinct G serotypes of rotavirus have been described, but only four types are commonly encountered in the United States. At least 20 P serotypes have been identified to date, of which only two are common among children in this country. The relationship of the frequency of infection with these multiple serotypes to host immune status is unclear. It does appear, however, that infection with one or two serotypes induces some degree of heterotypic immunity to severe disease.

A large variety of mammalian and avian species can be infected by rotavirus, but these animal rotavirus strains do not frequently cause disease in humans. Rotaviruses are shed in very large numbers in the stool (up to 10_{10}particles per gram of feces). Although transmission presumably takes place via the fecal-oral route, rotavirus infection spreads with great efficacy in developed as well as less developed countries.

Pathophysiology Rotavirus infects and kills the mature villus tip cells of the small intestine. The mature epithelial cells are replaced by immature absorptive cells that cannot absorb carbohydrates or other nutrients efficiently. Rotavirus infection thus leads to osmotic diarrhea due to nutrient malabsorption. Changes in intracellular cyclic adenosine monophosphate or guanosine monophosphate are not involved in the etiology of rotavirus diarrhea. Rotavirus also encodes a nonstructural protein (NSP4) that appears to function as an enterotoxin during infection. It is not known whether immunity to NSP4 plays a role in protection or disease resolution.

Manifestations The manifestations of rotavirus infection range from subclinical infection through mild diarrhea to severe, occasionally fatal dehydrating illness. Most information concerning the signs and symptoms of rotavirus infection has been derived from studies of hospitalized young children. The onset of illness is usually abrupt. More than 80% of affected children develop vomiting followed by diarrhea. About one-third of hospitalized children have a temperature of>39°C (>102.2°F). Mucus is commonly found in the stool, but white and red blood cells are present in the stool in fewer than 15% of cases.

Rotavirus infection frequently occurs in conjunction with respiratory tract symptoms, but there is little evidence to indicate that rotavirus replicates in the respiratory tract. Rotavirus infection has been observed in association with a wide variety of other clinical syndromes, including sudden infant death syndrome, Reye's syndrome, encephalitis, aseptic meningitis, pneumonia, exanthema subitum, Kawasaki's syndrome, necrotizing enterocolitis, intussusception, Schonlein-Henoch purpura, hemolytic-uremic syndrome, disseminated intravascular coagulation, and Crohn's disease. The etiologic relationship between these clinical syndromes and rotavirus infection is probably coincidental rather than causal. Rotavirus infection may be especially severe or even fatal in immunocompromised children.

Clinical Immunity Relative immunity to rotavirus illness is acquired early in childhood, after one or two natural infections. Subclinical infections in neonates have been shown to protect these children against severe rotavirus gastroenteritis for up to 3 years. Immunity is not complete, and adults with low levels of antibody can be symptomatically

infected. Local humoral immunity appears to be the critical determinant in protection, and cellular immune mechanisms seem to be involved as well.

Diagnosis Because rotavirus is shed in large amounts in the stool, detection is relatively easy. Various specific and highly sensitive commercial immunoassays are available to detect rotavirus antigen in fecal specimens. DNA probe diagnosis appears to be sensitive and specific, as do polymerase chain reaction (PCR)-based assays, but these detection methods have been used primarily for research purposes. No particular signs or symptoms are pathognomonic for rotavirus infection, but this infection is more frequently associated with severe dehydration than are infections caused by other enteric bacterial or viral pathogens.

TREATMENT

Although rotavirus diarrhea appears to be caused primarily by intestinal epithelial-cell lysis and death, it can be adequately managed with standard oral rehydration therapy. Only rarely is intravenous rehydration required. Since rotavirus infections have persisted in developed countries with advanced sanitation facilities and widely available clean water, it is unlikely that these infections will prove to be preventable by hygienic measures alone. Progress with a number of candidate live attenuated vaccines suggests that prevention through vaccination may be feasible. In 1998, a multivalent rotavirus vaccine was licensed for use in children under the age of 6 months in the United States. The vaccine virus was a live attenuated animal rotavirus containing genes encoding the four human G serotypes most common in the United States. The licensed vaccine was administered orally as three doses and was highly effective in preventing severe rotavirus illness. Reports of intussusception associated with the administration of rotavirus vaccine have been published; further studies are required to define the relative risk. However, because of the apparent association with intussusception, this first rotavirus vaccine has been withdrawn from use.

NORWALK AND RELATED ENTERIC CALICIVIRUSES

Classification and Characterization Various round 27- to 32-nm particles, some with clearly defined ultrastructure, have been identified in the stools of individuals with acute nonbacterial gastroenteritis. In the past, these agents have been difficult to classify because they are shed in the stool in small amounts for only a few days and have not been adapted to cell culture or to animal models. The Norwalk virus is the most extensively studied and best-characterized member of this group of enteric caliciviruses, which also includes such serologically or genetically distinct viruses as Hawaii virus, Snow Mountain virus, Southampton virus, Lordsdale virus, Mexico virus, Sapporo virus, and a number of agents described as calicivirus-like. Molecular biologic studies have shown that all these viruses have a protein structure similar to that of typical caliciviruses, with a single structural protein of ~60 kDa. The genomes of Norwalk virus and numerous related viruses have been cloned and sequenced. The genomes are plus-stranded RNA molecules of ~7.5 kb. On the basis of these molecular biologic studies, the human enteric caliciviruses can be divided into two groups: the Norwalk-like viruses (NLVs) and the Sapporo-like viruses (SLVs). The SLVs have a more typical calicivirus-like ultrastructure and cause diarrhea in young children. Unlike the NLVs, the SLVs may not cause frequent epidemics in adults.

Epidemiology Infection withNLVs is common year-round, with a clear winter peak. The seasonality ofSLVs has not yet been widely studied. More than 80% of adults in both developed and less developed countries have antibodies to these viruses. Antibody is acquired at a younger age among children in less developed countries than among those in developed areas; this observation is consistent with the assumption that NLVs are spread by the fecal-oral route. In the United States, the NLVs are responsible for ~90% of all epidemics of nonbacterial gastroenteritis. These agents have been incriminated in a variety of food-borne epidemics, and transmission vehicles have included oysters, green salad, and chocolate icing. The NLVs are common causes of waterborne epidemics of gastroenteritis and have been shown to be etiologic agents in nursing home, cruise ship, and institutional (summer camp and school) outbreaks. NLVs are also responsible for a small proportion of cases of traveler's diarrhea. NLV infection is a common cause of mild to moderate childhood diarrhea.

In less developed countries, the role of NLVinfection in the etiology of diarrhea in adults has not been thoroughly investigated. Preliminary studies indicate that NLVs can cause mild diarrhea in young children, but they do not appear to cause severe illness in infants in either developed or less developed countries.

Pathophysiology Information concerning the pathologic changes induced by the enteric caliciviruses is based almost entirely on a few studies of volunteers during the 1970s and 1980s. After infection with Norwalk or Hawaii virus, the architecture of the proximal small intestine is altered, with villus shortening, crypt hyperplasia, and infiltration of the lamina propria by polymorphonuclear and mononuclear cells. No changes are observed in the stomach or colon. The cells in which viral replication takes place have not been identified. The histologic alterations are accompanied by mild steatorrhea, carbohydrate malabsorption, and decreased levels of some brush border enzymes. No changes in adenylate cyclase activity have been observed.

Manifestations Norwalk illness has an incubation period of 18 to 72 h. The disease is characterized by the abrupt onset of nausea and abdominal cramps followed by vomiting and/or diarrhea. Vomiting is reported more frequently for children than for adults. Low-grade fever [>37.5° C (>99.5° F)] develops in about half of affected individuals. Headache, myalgias, and abdominal pain are common. The white blood cell count is normal; rarely, there is leukocytosis with relative lymphopenia. Red and white blood cells are not found in the stool. The illness is usually mild and self-limited, lasting 24 to 48 h.

Clinical Immunity Most people in developed countries do not have long-term resistance (i.e., that lasting³2 years) to Norwalk reinfection. Short-term (several-month) immunity -- at least to homotypic challenge -- does appear to develop. In volunteers challenged with Norwalk agent, there is a paradoxical relationship between the level of antibody toNLVs and susceptibility to illness: Low levels of Norwalk antibody in the serum and intestine are associated with clinical resistance to illness. It appears, therefore, that immune mechanisms are not the primary determinants of long-term protection from NLVs. Immunity to theSLVs may be more durable.

Diagnosis, Treatment, and Prevention Enzyme-linked immunosorbent assays

andPCR-based assays have been developed forNLVs and several other 27- to 32-nm gastroenteritis agents. However, these assays are not yet widely available, and their utility for general diagnosis has not been tested. Because Norwalk illness is acute and self-limited, treatment is not usually required. In the rare case of severe vomiting or diarrhea, oral or intravenous rehydration is indicated. Because long-term immunity to the NLVs does not usually follow natural infection, the role of vaccination may be limited to specific settings (e.g., the military). Recombinant NLV particles have been produced and are capable of inducing an immune response when administered orally to volunteers.

MISCELLANEOUS ENTERIC VIRAL PATHOGENS

Enteric adenoviruses are a minor cause of diarrheal illness in infants and children, accounting for 10% of cases. These viruses differ from other adenovirus strains in a variety of ways, including neutralization serotype, restriction endonuclease digestion pattern, and ability to grow in tissue culture. The role of enteric adenovirus illness in adults or in persons in less developed countries is not known.

Several strains of antigenically distinct rotaviruses, presently called *atypical rotaviruses* or *groups B and C rotaviruses*, have been identified as the cause of occasional episodes of diarrhea in humans and animals.

Preliminary epidemiologic studies have indicated that *astroviruses* are a fairly frequent cause of mild to moderate diarrhea in young children in developed and less developed countries, accounting for about one-quarter to one-half as much illness as group A rotaviruses. Moreover, preliminary data indicate that astroviruses are a common cause of diarrhea in immunocompromised hosts, such as bone marrow transplant recipients and patients with AIDS. Astroviruses are 27 to 32 nm in diameter, have a characteristic icosahedral ultrastructure, and contain a plus-stranded RNA genome with a size of ~7.0 kb and a unique genomic organization. At least seven distinct serotypes have been identified. The current availability of sensitive and specific diagnostic assays should allow more complete assessment of the importance of these agents.

Coronaviruses are frequent causes of diarrheal disease in a variety of animals. Using electron microscopy, several investigators have identified putative coronavirus-like particles in the stools of patients with diarrhea. In most cases, however, these particles do not have the typical morphologic features of coronaviruses and may represent bacterial breakdown products or cellular fragments.

193. ENTEROVIRUSES AND REOVIRUSES - *Jeffrey I. Cohen*

ENTEROVIRUSES

CLASSIFICATION AND CHARACTERIZATION

Enteroviruses are so named because of their ability to multiply in the gastrointestinal tract. Despite their name, these viruses are not a prominent cause of gastroenteritis. Enteroviruses encompass 64 human serotypes: 3 serotypes of poliovirus, 23 serotypes of coxsackievirus A, 6 serotypes of coxsackievirus B, 28 serotypes of echovirus, and enteroviruses 68 through 71.

Human enteroviruses contain a single-stranded RNA genome surrounded by an icosahedral capsid comprising four viral proteins. These viruses have no lipid envelope and are stable in acidic environments, including the stomach. They are resistant to inactivation by standard disinfectants (e.g., alcohol, detergents) and can persist for days at room temperature.

PATHOGENESIS AND IMMUNITY

Much of what is known about the pathogenesis of enteroviruses has been derived from studies of poliovirus infection. After ingestion, poliovirus is thought to infect epithelial cells in the mucosa of the gastrointestinal tract and then to spread to and replicate in the submucosal lymphoid tissue of the tonsils and Peyer's patches. The virus next spreads to the regional lymph nodes, a viremic phase ensues, and the virus replicates in organs of the reticuloendothelial system. In some cases, a second viremia occurs and the virus replicates further in various tissues, sometimes causing symptomatic disease.

It is uncertain whether poliovirus reaches the central nervous system (CNS) during viremia or whether it also spreads via peripheral nerves. Since viremia precedes the onset of neurologic disease in humans and in experimentally infected chimpanzees, it has been assumed that the virus enters the CNS via the bloodstream. The poliovirus receptor is a member of the immunoglobulin superfamily. Poliovirus infection is limited to primates, largely because of the ability of their cells to express the viral receptor. Studies demonstrating the poliovirus receptor in the end-plate region of muscle at the neuromuscular junction suggest that if the virus enters the muscle during viremia, it could travel across the neuromuscular junction up the axon to the anterior horn cells. Studies of monkeys or transgenic mice expressing the poliovirus receptor show that, after intramuscular injection, poliovirus does not reach the spinal cord if the sciatic nerve is cut. Taken together, these findings suggest that poliovirus can spread directly from muscle to the CNS by neural pathways. The receptor for echovirus types 1 and 8 is VLA-2 integrin, that for echovirus 7 is CD55, and that for coxsackievirus B is CAR (also used by adenovirus).

Poliovirus can usually be cultured from the blood 3 to 5 days after infection, before the development of neutralizing antibodies. While viral replication at secondary sites begins to slow 1 week after infection, it continues in the gastrointestinal tract. Poliovirus is shed from the oropharynx for up to 3 weeks after infection and from the gastrointestinal tract for as long as 12 weeks; immunodeficient patients can shed poliovirus for more than 1

year. During replication in the gastrointestinal tract, attenuated oral poliovirus can mutate, reverting to a more neurovirulent phenotype within a few days. The clinical significance of this increased neurovirulence is unknown.

Humoral and secretory immunity in the gastrointestinal tract is important for the control of enterovirus infections. Enteroviruses induce specific IgM, which usually persists for< 6 months, and specific IgG, which persists for life. Capsid protein VP1 is the predominant target of neutralizing antibody, which generally confers lifelong protection against subsequent disease caused by the same serotype but does not prevent infection or virus shedding. Enteroviruses also induce cellular immunity, but the importance of this mechanism in limiting infection is uncertain. Patients with impaired cellular immunity are not known to develop unusually severe disease when infected with enteroviruses. In contrast, the severe infections in patients with agammaglobulinemia emphasize the importance of humoral immunity in controlling enterovirus infections. IgA antibodies are important in reducing poliovirus replication in and shedding from the gastrointestinal tract. Breast milk contains IgA specific for enteroviruses and can protect humans from infection.

EPIDEMIOLOGY

Enteroviruses have a worldwide distribution. More than 50% of nonpoliovirus enterovirus infections and more than 90% of poliovirus infections are subclinical. When symptoms do develop, they are usually nonspecific and occur in conjunction with fever; only a minority of infections are associated with specific clinical syndromes. The incubation period for most enterovirus infections ranges from 2 to 14 days but usually is less than a week.

Enterovirus infection is more common in socioeconomically disadvantaged areas, especially in those where conditions are crowded and in tropical areas where hygiene is poor. Infection is most common among infants and young children; serious illness develops most often during the first few days of life and in older children and adults. In developing countries, where children are infected at an early age, poliovirus infection has less often been associated with paralysis; in countries with better hygiene, older children and adults are more likely to be seronegative, become infected, and develop paralysis. Passively acquired maternal antibody reduces the risk of symptomatic infection in neonates. Young children are the most frequent shedders of enteroviruses and are usually the index cases in family outbreaks. In temperate climates, enterovirus infections occur most often in the summer and fall; no seasonal pattern is apparent in the tropics.

Most enteroviruses are transmitted primarily by the fecal-oral route from fecally contaminated fingers or inanimate objects. Patients are most infectious shortly before and after the onset of symptomatic disease, when virus is present in the stool and throat. The ingestion of virus-contaminated food or water can also cause disease. Certain enteroviruses (such as enterovirus 70, which causes acute hemorrhagic conjunctivitis) can be transmitted by direct inoculation from the fingers to the eye. Airborne transmission is important for some viruses that cause respiratory tract disease, such as coxsackievirus A21. Enteroviruses can be transmitted across the placenta from mother to fetus, causing severe disease in the newborn. The transmission of

enteroviruses through blood transfusions or insect bites has not been documented. Nosocomial spread of coxsackievirus and echovirus has taken place in hospital nurseries.

DIAGNOSIS

Isolation of enterovirus in cell culture is the most common procedure for the diagnosis of infection. While cultures of stool, nasopharyngeal, or throat samples from patients with enterovirus diseases are often positive, isolation of the virus from these sites does not prove that it is directly associated with disease because these sites are frequently colonized for weeks in patients with subclinical infections. Isolation of virus from the throat is more likely to be associated with disease than isolation from the stool since virus is shed for shorter periods from the throat. Cultures of cerebrospinal fluid (CSF), serum, fluid from body cavities, or tissues are positive less frequently, but a positive result is indicative of disease caused by enterovirus. In some cases the virus can be isolated only from the blood or only from the CSF; therefore, it is important to culture multiple sites. Cultures are more likely to be positive earlier than later in the course of infection. Most human enteroviruses can be detected within a week after inoculation of cell cultures. Cultures may be negative because of the presence of neutralizing antibody, lack of susceptibility of the cells used, or inappropriate handling of the specimen. Coxsackievirus A may require inoculation into special cell-culture lines or into suckling mice.

Identification of the serotype of an enterovirus is useful primarily for epidemiologic studies and, with a few exceptions, has little clinical utility. It is important to identify serious infections with enterovirus during epidemics and to distinguish the vaccine strain of poliovirus from the other enteroviruses in the throat or in the feces. Stool and throat samples for culture as well as acute- and convalescent-phase serum specimens should be obtained from all patients with suspected poliomyelitis. In the absence of a positiveCSFculture, a positive culture of stool obtained within the first 2 weeks after the onset of symptoms is most often used to confirm the diagnosis of poliomyelitis. If poliovirus is isolated, it should be sent to the Centers for Disease Control and Prevention (CDC) in Atlanta for identification as either a wild-type or a vaccine virus.

The polymerase chain reaction (PCR) has been used to amplify viral nucleic acid fromCSF, serum, urine, throat swabs, and tissues. A single pair of PCR primers can detect more than 92% of the serotypes that infect humans. With the proper controls, PCR of the CSF is highly sensitive (³95%) and specific (>80%) and is more rapid than culture. PCR of serum is also highly sensitive and specific in the diagnosis of disseminated disease. PCR may be particularly helpful for the diagnosis and follow-up of enterovirus disease in immunodeficient patients receiving immunoglobulin therapy, whose viral cultures may be negative. Antigen detection and hybridization of enterovirus sequences in human tissues with a specific probe are additional options, but these techniques are generally less sensitive than PCR.

Serologic diagnosis of enterovirus infection is limited by the large number of serotypes and the lack of a common antigen. Demonstration of seroconversion may be useful in rare cases for confirmation of culture results, but serologic testing is usually limited to epidemiologic studies. Serum should be collected and frozen soon after the onset of

disease and again about 4 weeks later. Measurement of neutralizing titers is the most accurate method for antibody determination; measurement of complement-fixation titers is usually less sensitive. Titers of virus-specific IgM are elevated in both acute and chronic infection.

TREATMENT

Most enterovirus infections are mild and resolve spontaneously; however, intensive supportive care may be needed for cardiac, hepatic, orCNSdisease. Intravenous, intrathecal, or intraventricular immunoglobulin has been used with apparent success for the treatment of chronic enterovirus meningoencephalitis and dermatomyositis in patients with hypo- or agammaglobulinemia. The disease may stabilize or resolve during therapy; however, some patients decline inexorably despite therapy. Intravenous administration of immunoglobulin with high titers of antibody to the infecting virus has been successful in the treatment of some cases of life-threatening infection in neonates, who may not have maternally acquired antibody. In one trial involving neonates with enterovirus infections, immunoglobulin containing very high titers of antibody to the infecting virus reduced rates of viremia; however, the study was too small to show a substantial clinical benefit. Oral pleconaril, a capsid-binding antiviral agent, reduced symptoms in a placebo-controlled trial of enteroviral aseptic meningitis and in a challenge study with coxsackievirus. This drug is available for compassionate use in patients with certain severe enterovirus infections. Glucocorticoids are contraindicated.

Good hand-washing practices and the use of gowns and gloves are important in limiting nosocomial transmission of enteroviruses during epidemics. Enteric precautions are indicated for 7 days after the onset of enterovirus infections.

POLIOVIRUS

Manifestations Most infections with poliovirus are asymptomatic. After an incubation period of 3 to 6 days, about 5% of patients present with a minor illness (abortive poliomyelitis) manifested by fever, malaise, sore throat, anorexia, myalgias, and headache. This condition usually resolves in 3 days. About 1% of patients present with aseptic meningitis (nonparalytic poliomyelitis). Examination ofCSFreveals lymphocytic pleocytosis, a normal glucose level, and a normal or slightly elevated protein level; CSF polymorphonuclear leukocytes may be present early. In some patients, especially children, malaise and fever precede the onset of aseptic meningitis.

The least common presentation is that of paralytic disease. After one or several days, signs of aseptic meningitis are followed by severe back, neck, and muscle pain and by the rapid or gradual development of motor weakness. In some cases the disease appears to be biphasic, with aseptic meningitis followed first by apparent recovery but then (1 or 2 days later) by the return of fever and the development of paralysis; this form is more common among children than among adults. Weakness is generally asymmetric, is proximal more than distal, and may involve the legs (most commonly); the arms; or the abdominal, thoracic, or bulbar muscles. Paralysis develops during the febrile phase of the illness and usually does not progress after defervescence. Urinary retention may also occur. Examination reveals weakness, fasciculations, decreased muscle tone, and reduced or absent reflexes in affected areas. Transient hyperreflexia

sometimes precedes the loss of reflexes. Patients frequently report sensory symptoms, but objective sensory testing usually yields normal results. Bulbar paralysis may lead to dysphagia, difficulty in handling secretions, or dysphonia. Respiratory insufficiency due to aspiration, involvement of the respiratory center in the medulla, or paralysis of the phrenic or intercostal nerves may develop, and severe medullary involvement may lead to circulatory collapse. Most patients with paralysis recover some function weeks to months after infection. About two-thirds of patients have residual neurologic sequelae.

Paralytic disease is more common among older individuals, pregnant women, and persons exercising strenuously or undergoing trauma at the time ofCNSsymptoms. Tonsillectomy predisposes to bulbar poliomyelitis, and intramuscular injections increase the risk of paralysis in the involved limb(s).

At present, the only cases of poliomyelitis in the United States are due to live poliovirus vaccine; of the four cases reported in the United States in 1997 and 1998, three occurred in recipients of the first or second dose of oral poliovirus vaccine (OPV), and one occurred in an adult contact of a recipient of OPV. The median interval from vaccination to the onset of symptoms is usually 3 weeks. About 5% of the cases of poliomyelitis associated with vaccine occur in members of the community who have had no known direct contact with vaccinees. About 15% of all cases of vaccine-associated poliomyelitis involve immunodeficient children or adults, most of whom have hypo- or agammaglobulinemia. In these patients the median interval between vaccination and the onset of symptoms is 6 weeks, but disease can develop up to 6 months after vaccination. The risk of developing poliomyelitis after oral vaccination is estimated at 1 case per 2.5 million doses administered. The risk of developing paralytic disease after oral vaccination is about 2000 times higher among immunodeficient patients than among immunocompetent children.

The *postpolio syndrome* presents as a new onset of weakness, fatigue, fasciculations, and pain with additional atrophy of the muscle group involved during the initial paralytic disease 20 to 40 years earlier. The syndrome is more common among women and with increasing time after acute disease. The onset is insidious, and weakness occasionally extends to muscles that were not involved during the initial illness. The prognosis is generally good; progression to further weakness is usually slow, with plateau periods that range from 1 to 10 years. The postpolio syndrome is thought to be due to progressive dysfunction and loss of motor neurons that compensated for the neurons lost during the original infection and not to persistent or reactivated poliovirus infection.

Prevention and Eradication (See also Chap. 122) After a peak of 57,879 cases of poliomyelitis in the United States in 1952, the introduction of inactivated vaccine in 1955 and of oral vaccine in 1961 ultimately eradicated disease due to wild-type poliovirus in the western hemisphere. Such disease has not been documented in the United States since 1979, when cases occurred among religious groups who had declined immunization. In the western hemisphere, paralysis due to wild-type poliovirus was last documented in 1991.

In 1988, the World Health Organization adopted a resolution to eradicate poliomyelitis by the year 2000. From 1988 to 1997, the number of cases worldwide decreased by 89%, with about 6227 cases reported from 46 countries in 1998. More than 80% of the

world's cases of confirmed polio in 1998 occurred in India, Pakistan, Bangladesh, and Nigeria. Polio is a source of concern for unimmunized or partially immunized travelers to these regions. Outbreaks of polio in Europe and North America have been traced to cases imported from the Indian subcontinent. Clearly, global eradication of polio is necessary to eliminate the risk of importation of wild-type virus. Outbreaks are thought to have been facilitated by suboptimal rates of vaccination, isolated pockets of unvaccinated children, poor sanitation and crowding, improper vaccine-storage conditions, and a reduced level of response to one of the serotypes in the vaccine.

For the development of liveOPVcontaining all three poliovirus serotypes, wild-type virus was attenuated by passage in monkey kidney cell cultures. OPV strains differ from the wild-type strains in a limited number of nucleotide changes (i.e., fewer than 60). Multiple doses are required to ensure infection and development of immunity to all three serotypes. While intramuscular injections of other vaccines (live or attenuated) can be given concurrently with OPV, unnecessary intramuscular injections should be avoided during the first month after vaccination because they increase the risk of vaccine-associated paralysis. Inactivated poliovirus vaccine is generated by formalin inactivation of the three serotypes of live poliovirus. Since 1988 an enhanced-potency inactivated poliovirus vaccine (IPV) has been available in the United States.

OPVand IPVinduce antibodies that persist for at least 5 years. Both vaccines induce IgG and IgA antibodies. Compared with recipients of IPV, recipients of OPV shed less virus and less frequently develop reinfection with wild-type virus after exposure to poliovirus. Although IPV is safe and efficacious, OPV offers the advantages of ease of administration, lower cost, and induction of intestinal immunity resulting in a reduction in the risk of community transmission of wild-type virus. Because of progress toward global eradication of polio (with a reduced risk of imported cases) and the continued occurrence of cases of vaccine-associated polio, theCDCrecommended in 1997 that children receive a sequential schedule of two doses of IPV followed by two doses of OPV or a four-dose schedule of IPV alone. To further reduce the risk of vaccine-associated polio, the Advisory Committee for Immunization Practices recommended (in June 1999) an all-IPV regimen for childhood poliovirus vaccination. Beginning in January 2000, children should receive IPV at 2, 4, and 6 to 18 months and 4 to 6 years of age. OPV will be used only in special circumstances: (1) for mass immunization campaigns to control outbreaks of polio; (2) for vaccination of unimmunized children who will be traveling to a polio-endemic area within 4 weeks; and (3) for children whose parents do not accept an all-IPV regimen. The latter children should receive at least two doses of IPV before receiving OPV. The risk of vaccine-associated polio should be discussed before administering OPV. Recommendations for vaccination of adults are listed inTable 193-1.

COXSACKIEVIRUS, ECHOVIRUS, AND OTHER ENTEROVIRUSES

An estimated 5 to 10 million cases of symptomatic enterovirus disease occur in the United States each year. Enteroviruses are the most common cause of aseptic meningitis and nonspecific febrile illnesses of neonates. Certain clinical syndromes are more likely to be caused by certain serotypes (Table 193-2), but there is much overlap. From 1970 to 1983, 70% of enterovirus infections were caused by only 10 of the 64 human serotypes. Echoviruses 9 and 11 alone accounted for 24% of recognized

enterovirus infections; echoviruses 4, 6, and 30 and coxsackieviruses A9 and B2 through B5 accounted for 46%.

Nonspecific Febrile Illness (Summer Grippe) The most common clinical manifestation of enterovirus infection is a nonspecific febrile illness. After an incubation period of 3 to 6 days, patients present with an acute onset of fever, malaise, and headache. Occasional cases are associated with upper respiratory symptoms, and some cases include nausea and vomiting. Symptoms often last for 3 to 4 days, and most cases resolve in a week. While infections with other respiratory viruses occur more often from late fall to early spring, enterovirus febrile illness frequently occurs in the summer and early fall.

Generalized Disease of the Newborn Most serious enterovirus infections in infants develop during the first week of life, although severe disease can occur up to 3 months of age. Neonates often present with an illness resembling bacterial sepsis, with fever, irritability, and lethargy. Laboratory abnormalities include leukocytosis with a left shift, thrombocytopenia, elevated values in liver function tests, andCSFpleocytosis. The illness can be complicated by myocarditis and hypotension, fulminant hepatitis and disseminated intravascular coagulation, meningitis or meningoencephalitis, or pneumonia. It may be difficult to distinguish enterovirus infection from bacterial sepsis, although a history of a recent virus-like illness in the mother provides a clue.

Aseptic Meningitis and Encephalitis Enteroviruses are the cause of up to 90% of cases of aseptic meningitis in children and young adults in which an etiologic agent can be identified. Patients with aseptic meningitis typically present with an acute onset of fever, chills, headache, photophobia, and pain on eye movement. Nausea and vomiting are also common. Examination reveals meningismus without localizing neurologic signs; drowsiness or irritability may also be apparent. In some cases, a febrile illness may be reported that remits but returns several days later in conjunction with signs of meningitis. Other systemic manifestations may provide clues to an enteroviral cause, including diarrhea, myalgias, rash, pleurodynia, myocarditis, and herpangina. Examination of theCSFinvariably reveals pleocytosis; early in the course, polymorphonuclear leukocytes may be present or even predominant, raising the possibility of bacterial or other nonviral causes of meningitis. Partially treated bacterial meningitis may be particularly difficult to exclude in some instances. A useful rule is that the CSF cell count in enteroviral meningitis shows a shift to lymphocytic predominance within 24 h of presentation, and the total count generally does not exceed 1000 cells/uL. Additional CSF findings consist of a normal glucose content and a normal or only slightly elevated (by£100 mg/mL) level of protein. Enteroviruses and mumps virus may produce a similar picture of meningitis; a low CSF glucose level suggests mumps, whereas a normal CSF glucose level and transient CSF polymorphonuclear pleocytosis suggest enterovirus infection. Symptoms ordinarily resolve within a week, although CSF abnormalities can persist for several weeks. Enteroviral meningitis is often more severe in adults than in children. Neurologic sequelae are rare, and most patients have an excellent prognosis.

Enteroviral encephalitis is much less common than enteroviral aseptic meningitis. Occasional highly inflammatory cases of enteroviral meningitis may be complicated by a mild form of encephalitis that is recognized on the basis of progressive lethargy,

disorientation, and sometimes seizures. Less commonly, severe primary encephalitis may develop. It is estimated that 10 to 20% of cases of viral encephalitis are due to enteroviruses. Immunocompetent patients generally have a good prognosis.

Patients with hypo- or agammaglobulinemia or severe combined immunodeficiency may develop chronic meningitis or encephalitis; about half of these patients have a dermatomyositis-like syndrome, with peripheral edema, rash, and myositis. They may also have chronic hepatitis. Patients may develop neurologic disease while receiving gamma globulin replacement therapy. Echoviruses (especially echovirus 11) are the most common pathogens in this situation.

Paralytic disease due to enteroviruses other than poliovirus occurs sporadically and is usually less severe than poliomyelitis. Most cases are due to enterovirus 70 or 71 or to coxsackievirus A7 or A9. Guillain-Barre syndrome is also associated with enterovirus infection. While some studies have suggested a link between enteroviruses and the chronic fatigue syndrome, most recent studies have not demonstrated such an association.

Pleurodynia (Bornholm Disease) Patients with pleurodynia present with an acute onset of fever and spasms of pleuritic chest or upper abdominal pain. Chest pain is more frequent in adults, and abdominal pain is more common in children. Paroxysms of severe, knifelike pain usually last 15 to 30 min and are associated with diaphoresis and tachypnea. Fever peaks within an hour after the onset of paroxysms and subsides when pain resolves. The involved muscles are tender to palpation, and a pleural rub may be detected. The white blood cell count and chest x-ray are usually normal. Most cases are due to coxsackievirus B and occur during epidemics. Symptoms resolve in a few days, and recurrences are rare. Treatment includes the administration of nonsteroidal anti-inflammatory agents or the application of heat to the affected muscles.

Myocarditis and Pericarditis Enteroviruses are estimated to cause up to one-third of cases of acute myocarditis. Coxsackievirus B and its RNA have been detected in pericardial fluid and myocardial tissue in some cases of acute myocarditis and pericarditis. Most cases of enteroviral myocarditis or pericarditis occur in newborns, adolescents, or young adults. More than two-thirds of patients are male. Patients often present with an upper respiratory tract infection that is followed by fever, chest pain, dyspnea, arrhythmias, and occasionally heart failure. A pericardial friction rub is documented in half of cases, and the electrocardiogram shows ST segment elevations or ST- and T-wave abnormalities. Serum levels of myocardial enzymes are often elevated. Neonates commonly have severe disease, while most older children and adults recover completely. Up to 10% of cases progress to chronic dilated cardiomyopathy. Chronic constrictive pericarditis may also be a sequela.

Exanthems Enterovirus infection is the leading cause of exanthems in children in the summer and fall. While exanthems are associated with many enteroviruses, certain types have been linked to specific syndromes. Echoviruses 9 and 16 have frequently been associated with exanthem and fever. Rashes may be discrete (rubelliform) or confluent (morbilliform), beginning on the face and spreading to the trunk and extremities. Echovirus 9 is the most common cause of rubelliform rash. Unlike the rash of rubella, the enteroviral rash occurs in the summer and is not associated with

lymphadenopathy. Roseola-like rashes develop after defervescence, with macules and papules on the face and trunk. The Boston exanthem, caused by echovirus 16, is a roseola-like rash that often affects multiple members of a family. A variety of other rashes have been associated with enteroviruses, including erythema multiforme and vesicular, urticarial, petechial, or purpuric lesions. Enanthems also occur, including lesions that resemble the Koplik's spots seen with measles.

Hand-Foot-and-Mouth Disease (Fig. 193-CD1) After an incubation period of 4 to 6 days, patients with hand-foot-and-mouth disease present with fever, anorexia, and malaise; these manifestations are followed by the development of sore throat and vesicles (Plate IID-39) on the buccal mucosa and often on the tongue and then by the appearance of tender vesicular lesions on the dorsum of the hands, sometimes with involvement of the palms. The vesicles may form bullae and quickly ulcerate. About one-third of patients also have lesions on the palate, uvula, or tonsillar pillars, and one-third have a rash on the feet (including the soles) or on the buttocks. The disease is highly infectious, with attack rates of close to 100% among young children. The lesions usually resolve in 1 week. Most cases are due to coxsackievirus A16 or enterovirus 71.

An epidemic of enterovirus 71 infection in Taiwan in 1998 resulted in thousands of cases of hand-foot-and-mouth disease or herpangina. Severe complications included CNS disease, myocarditis, and pulmonary hemorrhage. About 90% of those who died were children£5 years old, and these deaths were associated with pulmonary edema or pulmonary hemorrhage. CNS disease included aseptic meningitis, flaccid paralysis (similar to poliomyelitis), or rhombencephalitis with myoclonus and tremor or ataxia. The mean age of patients with CNS complications was 2.5 years, and magnetic resonance imaging in cases with encephalitis usually showed brain-stem lesions.

Herpangina Herpangina (Fig. 193-CD2) is usually caused by coxsackievirus A and presents as acute-onset fever, sore throat, dysphagia, and grayish-white papulovesicular lesions on an erythematous base that ulcerate. The lesions can persist for weeks; are present on the soft palate, anterior pillars of the tonsils, and uvula; and are concentrated in the posterior portion of the mouth. In contrast to herpes stomatitis, enteroviral herpangina is not associated with gingivitis. Acute lymphonodular pharyngitis associated with coxsackievirus A10 presents as white or yellow nodules surrounded by erythema in the posterior oropharynx. The lesions do not ulcerate.

Acute Hemorrhagic Conjunctivitis Patients with acute hemorrhagic conjunctivitis present with an acute onset of severe eye pain, blurred vision, photophobia, and watery discharge from the eye. Examination reveals edema, chemosis, and subconjunctival hemorrhage and often shows punctate keratitis and conjunctival follicles as well. Preauricular adenopathy is often found. Epidemics and nosocomial spread have been associated with enterovirus 70 and coxsackievirus A24. Systemic symptoms, including headache and fever, develop in 20% of cases, and recovery is usually complete in 10 days. The sudden onset and short duration of the illness help to distinguish acute hemorrhagic conjunctivitis from other ocular infections such as those due to adenovirus and *Chlamydia*. Paralysis has been associated with some cases of acute hemorrhagic conjunctivitis due to enterovirus 70 during epidemics.

Other Manifestations Enteroviruses are an infrequent cause of childhood pneumonia

and the common cold. Coxsackievirus B has been isolated at autopsy from the pancreas of a few children presenting with insulin-dependent diabetes mellitus; however, most attempts to isolate the virus have been unsuccessful. Other diseases that have been associated with enterovirus infection include bronchitis, bronchiolitis, croup, infectious lymphocytosis, polymyositis, acute arthritis, and acute nephritis.

REOVIRUSES

Reoviruses are double-stranded RNA viruses encompassing three serotypes. Serologic studies indicate that most humans are infected with reoviruses during childhood; however, it has been difficult to establish a definite link of reovirus infection with a particular disease. It is likely that most infections either are asymptomatic or cause very mild disease. One outbreak of reovirus infection in children resulted in minor upper respiratory tract symptoms. Reovirus is considered a rare cause of mild gastroenteritis in infants and children. Speculation regarding an association of reovirus type 3 with idiopathic neonatal hepatitis and extrahepatic biliary atresia is based on an elevated prevalence of antibody to reovirus among some of these patients, detection of viral RNA by PCR in hepatobiliary tissues in some studies, and detection of virus in the porta hepatis in one case.

(Bibliography omitted in Palm version)

194. MEASLES (RUBEOLA) - *Anne Gershon*

DEFINITION

Measles (rubeola) is a highly contagious, acute, exanthematous respiratory disease with a characteristic clinical picture and pathognomonic enanthem. A successful live attenuated measles vaccine became available in 1963 in the United States and elsewhere, and measles is now an unusual disease in most developed countries where this vaccine is widely used. However, measles continues to occur sporadically in mini-epidemics in the United States, and major epidemics in developing nations make this disease a persistent cause of childhood morbidity and mortality.

ETIOLOGIC AGENT

Measles virus is a member of the genus *Morbillivirus* and the family Paramyxoviridae. It is closely related to the viruses causing canine and porcine distemper, rinderpest of cattle, and *peste des petits ruminants* of goats and sheep. There is only one antigenic type. Measles virions are pleomorphic spherical structures having a diameter of 100 to 250 nm and consisting of six proteins. The inner capsid is composed of a coiled helix of RNA and three proteins, and the outer envelope consists of a matrix protein bearing two types of short surface-glycoprotein projections or peplomers. One peplomer is a conical hemagglutinin (H) and the other a dumbbell-shaped fusion (F) protein. The genome has been sequenced, and it is thereby possible to distinguish vaccine-type measles virus from the wild type. In addition, genetic variability of wild-type measles virus occurs; eight genotypes have been identified.

EPIDEMIOLOGY

Measles has a worldwide distribution; humans are the only natural hosts, although other primates can be experimentally infected. During the prevaccination era in the United States, measles epidemics occurred every 2 to 5 years in the winter and spring. In an epidemic year, roughly half a million measles cases were reported; 99% of adults had serologic evidence of previous measles infection. After the live attenuated vaccine became available, the number of cases reported to the Centers for Disease Control and Prevention (CDC) fell, with a nadir of 1497 cases in 1983. After an upsurge to more than 27,000 cases (with 89 deaths) in 1990, the disease was once more brought under control (with only 312 cases reported to the CDC in 1993), in part through the routine administration of two doses of vaccine. The foremost reason for the resurgence of measles was failure to immunize infants and young children, especially in inner-city areas. Primary vaccine failure (documented in about 5% of individuals) and secondary vaccine failure or waning immunity accounted for some cases.

In recent years the majority of cases of measles have involved preschool children. Between 1993 and 1996, fewer than 1000 cases were reported annually in the United States; in 1995 there were 309 reported cases, and in 1996 there were 508. Molecular studies indicated interruption of transmission of indigenous measles in 1993. Most cases have since resulted from international importations of the virus. Mortality is highest among children under 2 years of age and among adults. Patients with impaired cell-mediated immunity are at especially high risk for severe or even fatal measles. The

measles-associated mortality rate in the United States is about 0.3%; in developing countries, mortality frequently exceeds 1% and sometimes approaches 10%.

Measles virus is transmitted by respiratory secretions, predominantly through exposure to aerosols but also through direct contact with larger droplets. Patients are contagious from 1 or 2 days before the onset of symptoms until 4 days after the appearance of the rash. Infectivity peaks during the prodromal phase. The mean intervals from infection to onset of symptoms and to appearance of rash are 10 and 14 days, respectively.

PATHOGENESIS AND PATHOLOGY

Measles virus invades the respiratory epithelium and spreads via the bloodstream to the reticuloendothelial system, from which it infects all types of white blood cells, thereby establishing infection of the skin, respiratory tract, and other organs. Both viremia and viruria develop. Multinucleated giant cells with inclusion bodies in the nucleus and cytoplasm (Warthin-Finkeldey cells) are found in respiratory and lymphoid tissues and are pathognomonic for measles. Direct invasion of T lymphocytes and increased levels of suppressive cytokines, such as interleukin 4, may play a role in the temporary depression of cellular immunity that accompanies and transiently follows measles. The major infected cell in the blood is the monocyte. Infection of the entire respiratory tract accounts for the characteristic cough and coryza of measles and for the less frequent manifestations of croup, bronchiolitis, and pneumonia. Generalized damage to the respiratory tract, with resultant loss of cilia, predisposes to secondary bacterial infections such as pneumonia and otitis media.

Specific antibodies are not detectable before the onset of rash. Cellular immunity (consisting of cytotoxic T cells and possibly natural killer cells) plays a prominent role in host defense, and patients who are deficient in cellular immunity are at high risk for severe measles. Children with isolated agammaglobulinemia are not at increased risk. Immune reactions to the virus in the endothelial cells of dermal capillaries play a substantial role in the development of Koplik's spots (the pathognomonic enanthem) as well as in that of rash; in immunodeficient hosts, measles may be severe despite the absence of these manifestations. Measles antigens have been demonstrated in involved skin during early stages of the illness.

Pathologic changes in measles encephalitis include focal hemorrhage, congestion, and perivascular demyelination. Measles virus is rarely isolated from cerebrospinal fluid (CSF) in cases of encephalitis, which are thought to be due to the interaction of virus-infected cells with local cellular immune factors.

CLINICAL MANIFESTATIONS

Measles begins with a 2- to 4-day respiratory prodrome of malaise, cough, coryza, conjunctivitis with lacrimation, nasal discharge, and increasing fever [with temperatures as high as 40.6°C (105°F), probably reflecting secondary viremia]. At this stage of the illness, in which the rash has not yet developed, influenza may be suspected. Just before the onset of the rash, Koplik's spots appear as 1- to 2-mm blue-white spots on a bright red background. Without adequate illumination for examination, they may be overlooked. Koplik's spots are typically located on the buccal mucosa alongside the

second molars and may be extensive; they are not associated with any other infectious disease. The spots wane after the onset of rash and soon disappear. The entire buccal and inner labial mucosa may be inflamed, and the lips may be reddened.

The characteristic erythematous, nonpruritic, maculopapular rash of measles (Fig. 194-CD1) begins at the hairline and behind the ears, spreads down the trunk and limbs to include the palms and soles, and often becomes confluent. At this time, the patient is at the most severe point of the illness. By the fourth day, the rash begins to fade in the order in which it appeared. Brownish discoloration of the skin and desquamation may occur later. Fever usually resolves by the fourth or fifth day after the onset of rash; prolonged fever suggests a complication of measles. Lymphadenopathy, diarrhea, vomiting, and splenomegaly are common features. The chest x-ray may be abnormal, even in uncomplicated measles, because of the propensity of this virus to invade the respiratory tract. The entire illness usually lasts about 10 days. The disease tends to be more severe in adults than in children, with higher fever, more prominent rash, and a higher incidence of complications.

Milder forms of the illness with less intense symptoms and a milder rash, termed *modified measles*, may occur in individuals with preexisting partial immunity induced by active or passive vaccination. These patients include infants under 1 year of age who retain some proportion of passively acquired maternal antibodies. On occasion, individuals with a history of immunization may develop modified measles.

COMPLICATIONS

The complications of measles can conveniently be divided into three groups, according to the site involved: the respiratory tract, the central nervous system (CNS), and the gastrointestinal tract. Respiratory tract involvement, manifested as laryngitis, croup, or bronchitis, occurs in the majority of cases of uncomplicated measles. In young children, otitis media is the most common complication. Pneumonia is a frequent reason for hospitalization, especially of adults. The pneumonia is of viral origin in the majority of cases, but secondary bacterial infection (most commonly caused by streptococci, pneumococci, or staphylococci) also takes place with some frequency. Primary giant cell (Hecht's) pneumonia is most often documented in immunocompromised and/or malnourished patients.

Encephalographic abnormalities in the absence of symptoms ofCNSdisease are extremely frequent in measles. Symptomatic CNS disease, with fever, headache, drowsiness, coma, and/or seizures, occurs in about 1 case in 1000. Symptoms usually begin within days after the onset of rash but occasionally appear for the first time several weeks later. About 10% of patients do not survive acute measles encephalitis; a significant percentage of surviving patients develop permanent sequelae, such as mental retardation or epilepsy. Most cases appear to result from an immune-mediated response to myelin proteins (postinfectious encephalomyelitis) and not directly from viral infection of the CNS (Chap. 371). Rarely, transverse myelitis follows measles. Immunocompromised patients are at risk for progressive fatal encephalitis 1 to 6 months after measles; in some cases, even though prior measles has not been recognized, the virus is identified at autopsy. Subacute sclerosing panencephalitis (SSPE) -- a protracted, chronic, extremely rare form of measles encephalitis -- sometimes follows

measles and is particularly common among children who have measles before the age of 2 years (Chap. 373). SSPE has virtually disappeared in the United States as a result of widespread vaccination. Typically, progressive dementia evolves over several months. SSPE is thought to be due to a complex interaction of the host with defective measles virus. It is associated with extremely high levels of antibodies to measles virus in the blood andCSF.

Gastrointestinal complications of measles include gastroenteritis, hepatitis, appendicitis, ileocolitis, and mesenteric adenitis. It is not uncommon to detect high levels of alanine and aspartate aminotransferases in the absence of gastrointestinal signs such as jaundice.

Other, rare complications include myocarditis, glomerulonephritis, and postinfectious thrombocytopenic purpura. Measles can exacerbate preexisting tuberculosis, presumably through depression of cellular immunity induced by the virus. Natural measles and immunization against measles can result in tuberculin skin-test anergy lasting for about 1 month.

ATYPICAL MEASLES

An atypical form of measles has been reported in individuals who received formalin-inactivated measles vaccine (used in the United States from 1963 through 1967 and in Canada until 1970) and subsequently were exposed to measles virus. After a several-day prodrome of fever, myalgia, and headache, the rash appears. Unlike the rash of typical measles, that of atypical measles begins peripherally and moves centrally; it can be urticarial, maculopapular, hemorrhagic, and/or vesicular. Fever is usually high and is accompanied by edema of the extremities, interstitial pulmonary infiltrates, hepatitis, and (on occasion) pleural effusion. The differential diagnosis often includes Rocky Mountain spotted fever, Henoch-Schonlein purpura, meningococcemia, drug allergy, toxic shock syndrome, and varicella. Despite the severity of atypical measles, patients invariably recover after a convalescence that may be prolonged. Measles virus is not isolated from these patients, and they do not spread the virus to others. This disease is believed to be due to hypersensitivity to measles virus induced by the inactivated vaccine. Formalin inactivation destroys the antigenicity of the F protein, antibodies to which are important in preventing spread of the virus from one cell to another. The role of cellular immunity in this process is unknown. Extremely high convalescent titers of antibody to measles virus (e.g., 1:1,000,000) are diagnostic of atypical measles. To prevent this syndrome, adults who received formalin-inactivated measles vaccine should be reimmunized with at least one dose of live attenuated measles vaccine. Since inactivated measles vaccine has not been available for more than 25 years, atypical measles has now virtually disappeared.

MEASLES IN THE IMMUNOCOMPROMISED HOST

Patients with defects in cell-mediated immunity are at risk for severe protracted and fatal measles. Included in this category are patients with congenital cellular immune defects or malignancy, recipients of immunosuppressive therapy, or persons infected with HIV. In these patients, measles may not be accompanied by a rash. Complications are primary measles (giant cell) pneumonia, progressive encephalitis beginning weeks to

months after initial infection, and (in HIV-infected patients) progression to AIDS.

MEASLES IN ADULTS

Measles is naturally a disease of childhood and, like many other viral infections, is more severe in adults than in children. About 3% of young adults with measles develop primary viral pneumonia and require hospitalization. Hepatitis and bronchospasm are more common among adults with measles than among children, and the rash is more severe and more confluent in adults. Bacterial superinfection is more common among adults, more than one-third of whom develop respiratory complications such as otitis media, sinusitis, and pneumonia. Adults may develop measles because they were never immunized or (more rarely) because their vaccine-induced immunity has waned. Very low titers of antibody to measles virus have been associated with lack of protection.

LABORATORY FINDINGS

Lymphopenia and neutropenia are common in measles and may be due to invasion of leukocytes by the virus, with subsequent cell death. Leukocytosis may herald a bacterial superinfection. Patients with measles encephalitis usually have an elevated protein concentration inCSF as well as lymphocytosis. A specific diagnosis of measles can be made quickly by immunofluorescent staining of a smear of respiratory secretions for measles antigen; monoclonal antibodies conjugated to fluorescein are commercially available for this purpose. Secretions can also be examined microscopically for multinucleated giant cells. Measles virus can be isolated from respiratory secretions or urine and rapidly identified in tissue culture with fluorescein-labeled monoclonal antibodies. Measles virus RNA has been demonstrated by diagnostic reverse-transcription polymerase chain reaction. A number of serologic tests are available for the diagnosis of measles; however, a serologic diagnosis cannot necessarily be made quickly since both acute- and convalescent-phase sera are usually tested, ideally at the same time. The older hemagglutination inhibition test has been replaced by enzyme immunoassay (EIA), which is more sensitive and simpler to perform. EIA can be used to measure specific IgM and thus to diagnose measles on the basis of an acute-phase serum sample alone. Specific IgM antibodies are detectable within 1 to 2 days after the appearance of rash, and the IgG titer rises significantly after 10 days. As already mentioned, atypical measles andSSPE are associated with extremely high titers of antibody.

DIFFERENTIAL DIAGNOSIS

Classic measles -- with Koplik's spots, cough, coryza, conjunctivitis, and a rash beginning on the head -- is easily diagnosed on clinical grounds. Modified measles is more difficult to diagnose clinically since one or more characteristic signs may be lacking. The differential diagnosis of measles includes Kawasaki's syndrome, scarlet fever, infectious mononucleosis, toxoplasmosis, drug eruption, and *Mycoplasma pneumoniae* infection. Most of these conditions can be identified by either culture or serologic assay. In the differential diagnosis of measles, attention should be paid to the current epidemiology of the disease in the community and to the patient's history of measles vaccination and foreign travel.

PREVENTION

The development of live attenuated measles vaccine by Enders and his colleagues was a milestone in American medicine. This vaccine, used in the United States for the routine immunization of children since 1963, induces seroconversion in about 95% of recipients and probably confers lifelong protection. Waning immunity to measles after immunization has been documented only on rare occasions. For the past 25 years, measles vaccine has been available as the combination vaccine measles-mumps-rubella (MMR); MMR vaccine should be administered to children between the ages of 12 and 15 months. (Vaccination at 12 months is preferred for infants whose mothers were immunized against measles in childhood. These mothers have lower antibody titers than women who have had natural measles, and their infants correspondingly have transplacental antibodies of lower titer and shorter duration.) A second dose of MMR vaccine is recommended for school-aged children at 4 to 12 years of age. This two-dose policy was developed in the late 1980s in response to measles outbreaks in the United States. Since the institution of the two-dose regimen and the increased effort to immunize all children, measles has again become an unusual disease in the United States. Regional guidelines that reflect the current local epidemiology of measles should be followed.

Older susceptible persons should also be immunized. Individuals should be considered susceptible to measles unless they have documentation of physician-diagnosed measles or of the receipt of two doses of vaccine, have laboratory evidence of measles immunity, or were born before 1957. Rarely, individuals born before 1957 develop measles, and those who are at risk of exposure to measles (e.g., health workers, teachers, and international travelers) should be tested for measles antibody and immunized if necessary. Approximately 10% of healthy vaccinees develop a fever, with temperatures up to 39.4°C (103°F), 5 to 7 days after vaccination; this fever lasts 1 to 5 days and is accompanied by a transient rash. Individuals previously immunized only with killed vaccine are considered susceptible and should receive at least one dose -- and preferably two doses -- ofMMRvaccine. Transient adverse reactions in these individuals include fever, malaise, and redness and swelling at the injection site.

Because of the severity of measles in this group and the lack of reported problems following vaccination, children with asymptomatic HIV infection should receiveMMRvaccine; those with severe immunosuppression (<15% CD4 lymphocytes) should not. A case of fatal measles due to vaccine-type virus was reported in a college student with AIDS. Measles vaccine is contraindicated for persons with impaired cell-mediated immunity, for pregnant women, and for persons with a history of anaphylaxis due to egg protein or neomycin. Minor illnesses, with or without fever and a history of convulsions, are not contraindications to vaccination. Vaccination should be deferred for 6 to 11 months after the receipt of immune globulin or of blood products containing antibodies and for at least 3 months after the discontinuation of immunosuppressive treatment. Vaccine failures have been ascribed to faulty storage of the preparation used, immunization of infants with preexisting (maternally derived) antibodies, and simultaneous administration of measles vaccine and immune globulin.

Children and adults who are susceptible to measles and are exposed to the disease should receive postexposure prophylaxis. Standard immune globulin, given

intramuscularly within 6 days of exposure, can exert a protective or modifying effect; the earlier it is given, the better the outcome. The dose is 0.25 mL/kg for healthy persons and 0.5 mL/kg for immunocompromised persons, with a maximum dose of 15 mL. Immune globulin is particularly strongly indicated for susceptible household contacts, especially those less than 1 year of age, and for immunocompromised persons. HIV-infected persons, particularly those with severe immunosuppression, should be given immune globulin after exposure, regardless of their measles immune status and whether or not they are receiving intravenous immunoglobulin. Vaccination within 72 h of exposure may also provide protection against clinical measles, but this strategy is contraindicated as postexposure prophylaxis for immunocompromised individuals. Vaccine and immune globulin should not be given concurrently.

TREATMENT

Therapy for measles is largely supportive and symptom-based. Patients with otitis media and pneumonia should be given standard antibiotics. Patients with encephalitis need supportive care, including observation for increased intracranial pressure. Controlled trials suggest clinical benefit from high doses of vitamin A in severe or potentially severe measles, especially in children under the age of 2 years. A dose of 50,000 IU is used for infants age 1 to 6 months, 100,000 IU for infants age 7 to 12 months, and 200,000 IU for children over 1 year. A single dose is administered on two consecutive days. Transient vomiting and headache may be associated with the administration of vitamin A. Ribavirin is effective against measles virus in vitro and may be considered for use in immunocompromised individuals.

195. RUBELLA (GERMAN MEASLES) - *Anne Gershon*

DEFINITION

Rubella is an acute viral infection of children and adults that characteristically includes rash, fever, and lymphadenopathy and has a broad spectrum of other possible manifestations. However, a high percentage of rubella infections in both children and adults are subclinical. In addition, the illness can resemble a mild attack of measles (rubeola) and can cause arthritis, especially in adults. Rubella during pregnancy can lead to fetal infection, with the production of a significant constellation of malformations (*congenital rubella syndrome*) in a high proportion of infected fetuses.

ETIOLOGIC AGENT

Rubella virus, a togavirus, is the only member of the *Rubivirus* genus and is closely related to the alphaviruses. Unlike these agents, however, it does not require a vector for transmission. Moreover, there is no RNA sequence homology between rubella virus and the alphaviruses.

The rubella virion is composed of an inner icosahedral capsid of RNA and protein that is surrounded by a lipid-containing envelope with a diameter of about 60 nm. The structural proteins associated with rubella virus are E1 and E2 (transmembrane envelope glycoproteins) and C (the capsid protein that surrounds the viral RNA). Only one serotype has been identified.

EPIDEMIOLOGY

In the United States during the prevaccine era, rubella was most common in the spring and most often affected school-age children; only 80 to 90% of adults were immune; and major epidemics occurred every 6 to 9 years. The most recent epidemic in the United States occurred in 1964 to 1965, when there were more than 12 million reported cases of postnatal rubella and more than 20,000 cases of the congenital rubella syndrome. Since the introduction of live attenuated rubella vaccine in 1969, there have been no epidemics; limited outbreaks have been reported in settings where susceptible individuals come into close contact with one another (e.g., schools and workplaces). In 1996, only 213 cases of postnatally acquired rubella -- most of them in young adults -- and 2 confirmed cases of congenital rubella syndrome were reported to the Centers for Disease Control and Prevention (CDC).

Whether symptomatic or subclinical, rubella is contagious, albeit less so than measles. Its incubation period is 18 days on average, with a range of 12 to 23 days. The virus, which is spread in droplets shed in respiratory secretions, infects the respiratory tract and then the bloodstream. In postnatally acquired infections, rubella virus is shed during the prodromal phase of the illness, and shedding from the pharynx can continue for about a week after onset. Despite high titers of specific neutralizing antibodies, infants with congenital rubella may excrete rubella virus from the respiratory tract and in the urine until the age of 2 years. This excretion raises important issues related to infection control in hospital and day-care settings. Persons recently immunized with live attenuated rubella vaccine do not transmit the vaccine virus to others, although low

titers of rubella virus may be detected transiently in the pharynx.

After an attack of rubella, specific antibodies and cell-mediated immunity develop and probably play a significant role in protection against future disease. Asymptomatic reinfection at the level of the respiratory tract is common upon reexposure to the virus but is rarely if ever associated with viremia.

Rubella virus has been cultured from respiratory secretions during reinfection. Fetal infection may occur during maternal reinfection but is acknowledged to be extremely rare because of the absence of maternal viremia under these circumstances. Viremia following reinfection of individuals immunized against rubella is also rare. Thus the current level of congenital rubella in the United States is exceedingly low.

PATHOGENESIS AND PATHOLOGY

Little is known about the microscopic pathology of postnatally acquired rubella since the disease is invariably self-limited. Like that of measles, the rash of rubella is immunologically mediated; its onset coincides with the development of specific antibodies. Viremia can be demonstrated for about a week before and ends within a few days after the onset of rash.

The cause of the damage to cells and organs in congenital rubella is not well understood. Proposed mechanisms of fetal damage include mitotic arrest of cells, tissue necrosis without inflammation, and chromosomal damage. The growth of the fetus may be retarded. Other findings may include decreased numbers of megakaryocytes in the bone marrow, extramedullary hematopoiesis, and interstitial pneumonia.

CLINICAL MANIFESTATIONS

Postnatally Acquired Rubella Infection acquired after birth usually results in an extremely mild or subclinical illness. A prodromal phase is uncommon in children; adults may have more severe disease, with a brief prodrome of malaise, fever, and anorexia. The foremost symptoms of postnatally acquired rubella include posterior auricular, cervical, and suboccipital lymphadenopathy; fever; and rash. The rash often begins on the face and spreads down the body (Fig. 195-CD1). It is maculopapular but not confluent, is sometimes accompanied by mild coryza and conjunctivitis, and generally lasts for 3 to 5 days. A petechial enanthem on the soft palate, designated *Forschheimer spots*, may occur but is not specific for rubella. Fever may be absent entirely or may be present for only several days in the early phase of the illness.

Complications of postnatally acquired rubella are uncommon; bacterial superinfection is rare. One particularly troublesome complication is seen almost exclusively in women: arthritis, most frequently involving the fingers, wrists, and/or knees, develops as the rash is appearing and may take several weeks to resolve. Chronic arthritis resulting from rubella is extremely rare. Rubella virus has been isolated from joint fluid during acute rubella arthritis and from peripheral blood in chronic rubella arthritis.

Another complication of postnatally acquired rubella is hemorrhage due to both thrombocytopenia and vascular damage, which occurs in 1 of every 3000 patients.

Thrombocytopenia may last for weeks or months; it can have long-term consequences if there is bleeding into organs such as the eye or the brain.

Both children and adults may develop encephalitis after rubella; the incidence is about five times lower than that of encephalitis following measles. Adults are more likely than children to develop encephalitis; the mortality rate from this complication is 20 to 50%. Mild hepatitis is an unusual complication. Immunosuppressed patients are not at increased risk for rubella as they are for measles.

Congenital Rubella Maternal infection in early pregnancy can lead to fetal infection, with resultant congenital rubella. The classic signs of congenital rubella are cataract, heart disease, and deafness, but a myriad of other defects have been reported. These abnormalities include signs and symptoms that are transient, such as low birth weight, thrombocytopenia, hepatosplenomegaly, jaundice, and pneumonia; those that are permanent, such as deafness, pulmonic stenosis, patent ductus arteriosus, glaucoma, and cataract; and those that are developmental, such as mental retardation, diabetes mellitus, and behavioral disorders.

The most important factor in the pathogenicity of rubella virus for the fetus is gestational age at the time of infection. Maternal infection during the first trimester leads to fetal infection in about 50% of cases; maternal infection early in the second trimester leads to fetal infection in about one-third of cases. Fetal malformations not only are more common after maternal infection in the first trimester but also tend to be more severe and to involve more organ systems. While a fetus infected in the fourth week of gestation may develop many problems, one infected later (e.g., in the 20th week) may have isolated deafness as the only symptom.

DIAGNOSIS

Since postnatally acquired rubella is such a mild disease and since many cases are subclinical, diagnosis on clinical grounds can be difficult. Other diseases that may mimic rubella include toxoplasmosis, scarlet fever, modified measles, roseola, fifth disease (erythema infectiosum due to parvovirus B19), and enteroviral infection. Routine laboratory tests usually reveal leukopenia and atypical lymphocytes.

The isolation of rubella virus in cell cultures of throat samples, urine, or other secretions is difficult and expensive but is sometimes undertaken. This technique is most useful when congenital rubella is suspected. A laboratory diagnosis is more often made serologically. The most commonly used test is an enzyme-linked immunosorbent assay (ELISA) for IgG and IgM antibodies. Acute rubella is diagnosed by the documentation of a fourfold or greater rise in the titer of IgG antibodies in paired acute- and convalescent-phase serum specimens or by the detection of rubella-specific IgM antibodies in one serum specimen. However, false-negative and -positive IgM reactions are sometimes obtained. Moreover, true-positive IgM reactions can be obtained in both primary infection and reinfection. Congenital rubella is diagnosed by the isolation of rubella virus, the detection of IgM antibodies in a single serum sample, and/or the documentation of either the persistence of rubella antibodies in serum beyond 1 year of age or a rising antibody titer anytime during infancy in an unvaccinated child. Biopsied tissues and/or blood and cerebrospinal fluid have also been used for the demonstration

of rubella antigens with monoclonal antibodies and for the detection of rubella RNA by in situ hybridization and polymerase chain reaction.

PREVENTION

Live attenuated rubella vaccine was licensed in 1969, 7 years after the virus was first isolated in culture. This vaccine was developed as a strategy to prevent congenital rubella by ensuring that very few pregnant women would be susceptible and that there would be little circulating wild-type virus. Rubella vaccine induces seroconversion in more than 95% of recipients. Since its licensure, there have been no major epidemics in the United States, and the number of cases has declined by 98%. The vaccine currently licensed in the United States, RA 27/3, is propagated in human diploid cells and is more immunogenic (particularly with regard to the stimulation of secretory immunity) than previously licensed vaccines. The present vaccination strategy, developed in part when measles was not being adequately controlled, is to immunize all infants at 12 to 15 months of age with measles-mumps-rubella (MMR) vaccine and to administer a second dose at 4 to 12 years of age. Rubella vaccine may also be administered to anyone who is thought to be susceptible to the infection and is not pregnant; it is particularly important that hospital workers of either sex be immune to rubella so that nosocomial transmission is avoided. While there has been little change in the prevalence of immunity to rubella among women of childbearing age (about 80%), the incidence of congenital rubella is extremely low -- about 10 cases annually. It is likely that, although antibody may be undetectable years after immunization, protection against infection -- possibly due to cell-mediated immunity -- is the rule. At present, there is little if any evidence of significant waning of clinically important immunity to rubella with time.

On occasion, rubella vaccine may cause arthralgia or arthritis, especially in young women. Very rarely, rubella vaccination results in chronic arthritis; however, even cases of frank arthritis in vaccinees are self-limited, lasting only about 1 week.

After investigation of a series of more than 400 women who were inadvertently immunized during pregnancy and who carried their infants to term, theCDC has concluded that vaccine-type rubella virus either does not cause the congenital rubella syndrome at all or does so at an incidence too low to be detected. Nonetheless, rubella vaccine is contraindicated for use in pregnant women, and it is recommended that pregnancy be avoided for at least 3 months after rubella vaccination. It is acceptable for rubella-susceptible children whose mothers are also susceptible to be immunized, since vaccinated individuals do not shed rubella virus or transmit it to susceptible individuals. Although it is recommended that rubella vaccine not be given to immunosuppressed persons, the vaccine is given to children infected with HIV. No adverse effects of rubella vaccine have been reported in immunocompromised patients.

TREATMENT

There is no specific therapy for rubella. At one time, immune globulin was used in an effort to prevent congenital rubella when pregnant women became infected. However, since administration of immune globulin did not prevent maternal viremia, this approach was discarded. Treatment is given for symptoms such as fever, arthralgia, and arthritis.

196. MUMPS - *Anne Gershon*

DEFINITION

Mumps is an acute, systemic, communicable viral infection whose most distinctive feature is swelling of one or both parotid glands. Involvement of other salivary glands, the meninges, the pancreas, and the gonads is also common.

ETIOLOGIC AGENT

Mumps virus, a paramyxovirus, is pleomorphic and has a diameter ranging from 100 to 600 nm. The virion is composed of RNA and five proteins. The RNA is surrounded by an envelope with glycoprotein projections. There are two envelope glycoproteins -- a hemagglutinin-neuraminidase (HN) and a hemolysis cell fusion antigen (F) -- as well as a matrix envelope protein (M). There are two internal components: a nucleocapsid protein (NP) and an RNA polymerase protein. There is only one antigenic type of mumps virus.

EPIDEMIOLOGY

After the introduction of mumps vaccine in 1967, the incidence of clinical mumps declined significantly in the United States. In 1968 (before widespread immunization), 185,691 cases of mumps were reported in this country. The 906 cases reported in 1995 represent a reduction in the number of cases by>99% from prevaccine levels; this is the lowest number of cases ever reported in a year. Before widespread vaccination, the incidence of mumps was highest in the winter and spring, with epidemics every 2 to 5 years. At that time, mumps was principally a disease of childhood, although today more than 50% of cases occur in young adults. Epidemics tended to occur in confined populations, such as those in schools and the military services.

The incubation period of mumps generally ranges from 14 to 18 days, with extremes of 7 and 23 days. However, because a contact may be shedding virus before the onset of clinical disease or (like one-third of patients) may have subclinical infection, the incubation period in individual cases is often uncertain. One attack of mumps usually confers lifelong immunity. Long-term immunity is also associated with immunization.

PATHOGENESIS

Mumps virus is transmitted by droplet nuclei, saliva, and fomites. Replication of the virus in the epithelium of the upper respiratory tract leads to viremia, which is followed by infection of glandular tissues and/or the central nervous system (CNS).

Little is known of the pathology of mumps since the disease is rarely fatal. The affected glands contain perivascular and interstitial mononuclear cell infiltrates with prominent edema. Necrosis of acinar and epithelial duct cells is evident in the salivary glands and in the germinal epithelium of the seminiferous tubules.

CLINICAL MANIFESTATIONS

The prodrome of mumps consists of fever, malaise, myalgia, and anorexia. Parotitis, if it develops, usually does so within the next 24 h but may be delayed for as long as a week; it is generally bilateral, although the onset on the two sides may not be synchronous and at times only one side is affected. The submaxillary and sublingual glands are involved less often than the parotid and are almost never involved alone. Swelling of the parotid is accompanied by tenderness and obliteration of the space between the ear lobe and the angle of the mandible. The patient frequently reports an earache and finds it difficult to eat, swallow, or talk. Glandular swelling increases for a few days and then gradually subsides, disappearing within a week. The orifice of Stensen's duct is commonly red and swollen. Presternal pitting edema has been described in about 5% of mumps cases, often in association with submandibular adenitis.

Other than parotitis, orchitis is the most common manifestation of mumps among postpubertal males, developing in about 20% of cases. The testis is painful and tender and is enlarged to several times its normal size; accompanying fever is common. Later, testicular atrophy develops in half of the affected men. Since orchitis is bilateral in fewer than 15% of cases, sterility after mumps is rare. Oophoritis in women -- far less common than orchitis in men -- may cause lower abdominal pain but does not lead to sterility.

Aseptic meningitis, which may develop before, during, after, or in the absence of parotitis, is a common manifestation of mumps in both children and adults. Symptoms include stiff neck, headache, and drowsiness. Pleocytosis of the cerebrospinal fluid (CSF), with up to 1000 cells/uL, may develop in up to 50% of cases of clinical mumps, but clinical signs of meningeal irritation are documented in only 5 to 25% of cases. Within the first 24 h, polymorphonuclear leukocytes may predominate in CSF, but by the second day nearly all the cells are lymphocytes. The glucose level in CSF may be abnormally low, and this finding may arouse suspicion of bacterial meningitis. Aseptic meningitis due to mumps without parotitis is indistinguishable clinically from that caused by other viruses. Mumps meningitis is almost invariably self-limited, although cranial nerve palsies have occasionally led to permanent sequelae, particularly deafness. More rarely, mumps virus may cause encephalitis, which presents as high fever with marked changes in the level of consciousness and frequently results in permanent sequelae in survivors. OtherCNSproblems occasionally associated with mumps include cerebellar ataxia, facial palsy, transverse myelitis, Guillain-Barre syndrome, and aqueductal stenosis leading to hydrocephalus.

Mumps pancreatitis, which may present as abdominal pain, is difficult to diagnose because an elevated serum amylase level can be associated with either parotitis or pancreatitis. Other unusual complications of mumps include myocarditis, mastitis, thyroiditis, nephritis, arthritis, and thrombocytopenic purpura. An excessive number of spontaneous abortions are associated with gestational mumps when the disease occurs during the first trimester. Mumps in pregnancy does not lead to premature birth or fetal malformations.

DIFFERENTIAL DIAGNOSIS

The diagnosis of mumps is made easily in patients with acute bilateral parotitis and a

history of recent exposure. When parotitis is unilateral or absent or when sites other than the parotid gland are involved, laboratory diagnosis is required (see below).

The myriad causes of bilateral parotid swelling other than mumps virus include infection with other viruses, such as parainfluenza virus type 3, coxsackieviruses, and influenza A virus; metabolic diseases, such as diabetes mellitus and uremia; and drugs, such as phenylbutazone and thiouracil. Unilateral parotid swelling can result from a tumor, a cyst, or a ductal obstruction due to stones or strictures. Other conditions associated with chronic parotid swelling include sarcoidosis, Sjogren's syndrome, and infection with HIV. Suppurative parotitis, usually caused by *Staphylococcus aureus*, is most often unilateral.

Other entities should be considered when manifestations consistent with mumps appear in organs other than the parotid. Testicular torsion may produce a painful scrotal mass resembling that seen in mumps orchitis. Other viruses (e.g., enteroviruses) may cause aseptic meningitis that is clinically indistinguishable from that due to mumps virus.

LABORATORY DIAGNOSIS

Mumps virus is readily isolated after inoculation of appropriate clinical specimens into a variety of host systems, such as rhesus monkey kidney cells and human embryonic lung fibroblasts. The virus can be rapidly identified by the use of cells grown in shell vials and of fluorescein-labeled monoclonal antibodies. Mumps virus may be recovered from saliva, throat, and urine during the first few days of illness and from the CSF of patients with mumps meningitis. Shedding of virus in the urine may persist for as long as 2 weeks. No particular peripheral blood cell count is characteristic of mumps.

Highly sensitive enzyme-linked immunosorbent assays are useful for diagnosis of mumps and for determination of susceptibility to the disease. Acute mumps can be diagnosed either by the examination of acute- and convalescent-phase sera for a significant increase in IgG antibody titer or by the demonstration of specific IgM in one serum specimen. Use of a skin-test antigen to assess immunity to mumps has been replaced by serologic testing.

PREVENTION

Live attenuated mumps vaccine (Jeryl Lynn strain) induces antibodies that protect against infection in more than 95% of cases. The subcutaneously administered vaccine may be given to children older than 1 year but is not recommended for younger infants because of the potential for interference by passive maternal antibodies. Mumps vaccine is usually administered as part of the measles-mumps-rubella (MMR) vaccine at the age of 12 to 15 months and again at 4 to 12 years of age. This MMR vaccine is also recommended for susceptible older children, adolescents, and adults, particularly adolescent males who have not had mumps. For these patients, either MMR or monovalent mumps vaccine may be given; two doses are preferred. Inadvertent immunization of individuals who are already immune is not associated with significant adverse reactions. Mumps vaccine is not recommended for pregnant women, for patients receiving glucocorticoids, or for other immunocompromised hosts. However, children with HIV infection who are not severely immunocompromised can safely be

immunized against mumps; MMR vaccine is usually used for this purpose (Chap. 194).

TREATMENT

Therapy for parotitis and other manifestations of mumps is symptom-based. The administration of analgesics and the application of warm or cold compresses to the parotid area may be helpful. Mumps immune globulin is of no value in the prophylaxis or treatment of established disease. Testicular pain may be minimized by the local application of cold compresses and gentle support for the scrotum. Anesthetic blocks may also be used. Neither the administration of glucocorticoids nor incision of the tunica albuginea is of proven value for the treatment of severe orchitis. Anecdotal information on a small number of patients with orchitis suggests that administration of interferona may be helpful.

197. RABIES VIRUS AND OTHER RHABDOVIRUSES - *Lawrence Corey*

RABIES VIRUS

DEFINITION

Rabies is an acute viral disease of the central nervous system (CNS) that affects all mammals and that is transmitted by infected secretions, usually saliva. Most exposures to rabies are through the bite of an infected animal, but on occasion contact with a virus-containing aerosol or the ingestion or transplantation of infected tissues may initiate the disease process.

ETIOLOGY

The rabies virus is a bullet-shaped, enveloped, single-stranded RNA virus that is 75 to 80 nm in diameter and belongs to the genus *Lyssavirus* within the rhabdovirus family. The envelope glycoproteins of rabies viruses are arranged in knoblike structures that cover the surface of the virion. Genetic and phenotypic analyses of the envelope have been used to detail the molecular epidemiology and spread of unique variants within animal species. The viral glycoproteins bind to acetylcholine receptors, contribute to the neurovirulence of rabies virus, elicit neutralizing and hemagglutination-inhibiting antibodies, and stimulate cytotoxic T cell immunity. The nucleocapsid antigen induces a complement-fixing antibody as well as T helper cell reactivity. Neutralizing antibodies to the surface glycoproteins appear to be protective and are directed at conformational epitopes of the viral envelope glycoprotein. The antibodies to rabies virus used in diagnostic immunofluorescence assays are generally directed against the nucleocapsid antigens. Isolates of rabies virus from different animal species and locales differ in their antigenic and biologic properties. These variations may account for differences in virulence between isolates. Interferon is induced by rabies virus, particularly in those tissues with high virus concentrations, and may play some role in retarding progressive infection.

EPIDEMIOLOGY

Rabies is found in animals in all regions of the world except Australasia and Antarctica. Rabies exists in two epidemiologic forms: *urban rabies*, propagated chiefly by unimmunized domestic dogs and cats, and *sylvatic rabies*, propagated by skunks, foxes, raccoons, mongooses, wolves, and bats. Infection in domestic animals usually represents a "spillover" from sylvatic reservoirs of infection. Human infection occurs through contact with unimmunized domestic animals or from exposure to wild animals in locales where rabies is enzootic or epizootic. The worldwide incidence of rabies is estimated at more than 30,000 cases per year. Southeast Asia, the Philippines, Africa, the Indian subcontinent, and tropical South America are areas where the disease is especially common. In some endemic areas, 1 to 2% of autopsies yield evidence of rabies. Increased spread of terrestrial rabies (i.e., rabies in animals that walk on the ground rather than rabies in animals that fly) and increased travel to countries where urban rabies exists have made the recognition of clinical rabies and its prevention of increasing importance. While focal epidemics of terrestrial rabies have occurred in the United States and Europe, human rabies is uncommon, largely because of successful

domestic-animal vaccination programs. Since 1980, 36 human cases of rabies have been diagnosed in the United States; 58% of these cases were associated with exposure to bats, while one-third were acquired through dog bites sustained outside the United States. Most persons with proven clinical rabies in this country report no history of an animal bite. More than one-third of recent cases have been diagnosed post-mortem.

In most areas of the world, the dog is the most important vector of rabies virus for humans. However, the wolf (in eastern Europe and Arctic regions), the mongoose (in South Africa and the Caribbean), the fox (in western Europe), and the vampire bat (in Latin America) may also be prominent vectors. Although rabies in wildlife is common throughout both the developed and the undeveloped world, most cases of postexposure prophylaxis are associated with domesticated animals such as dogs and cats. In the United States, local governments are charged with initiating and maintaining programs for rabies vaccination of all dogs, cats, and ferrets. Rodents and lagomorphs are rarely infected with rabies virus. Several cases of human-to-human transmission of rabies through corneal transplantation have also been documented. Bite and nonbite exposures to infected humans could theoretically transmit rabies. Because of delayed diagnosis, postexposure prophylaxis of health care workers and close contacts of cases is common.

PATHOGENESIS

The first event in rabies is the introduction of live virus through the epidermis or onto a mucous membrane. Initial viral replication appears to occur within striated muscle cells at the site of inoculation. The peripheral nervous system is exposed at the neuromuscular and/or neurotendinous spindles of unmyelinated sensory nerve cell endings. The virus then spreads centripetally up the nerve to the CNS, probably via peripheral nerve axoplasm, at a rate of ~3 mm/h. Viremia has been documented in experimental conditions but is thought not to play a role in naturally acquired disease. Once the virus reaches the CNS, it replicates almost exclusively within the gray matter and then passes centrifugally along autonomic nerves to other tissues -- the salivary glands, adrenal medulla, kidneys, lungs, liver, skeletal muscles, skin, and heart. Passage of the virus into the salivary glands and viral replication in mucinogenic acinar cells facilitate further transmission via infected saliva. The incubation period of rabies is exceedingly variable, ranging from 7 days to>1 year (mean, 1 to 2 months) and apparently depending on the amount of virus introduced, the amount of tissue involved, host defense mechanisms, and the actual distance that the virus has to travel from the site of inoculation to the CNS. Rates of infection and mortality are highest from bites on the face, intermediate from bites on the hands and arms, and lowest from bites on the legs. Cases of human rabies with an extended incubation period (2 to 7 years) have been reported, but they are rare. Host immune responses and viral strains also influence disease expression.

The neuropathology of rabies resembles that of other viral diseases of theCNS: hyperemia, varying degrees of chromatolysis, nuclear pyknosis, and neuronophagia of the nerve cells; infiltration by lymphocytes and plasma cells of the Virchow-Robin space; microglial infiltration; and parenchymal areas of nerve cell destruction. In experimental animal models, adenohypophyseal infection with rabies virus, with reduction in growth

hormone and vasopressin release, is common. The most characteristic pathologic finding of rabies in the CNS is the formation of cytoplasmic inclusions called *Negri bodies* within neurons. Each eosinophilic mass measures ~10 nm and is made up of a finely fibrillar matrix and rabies virus particles. Negri bodies are distributed throughout the brain, particularly in Ammon's horn, the cerebral cortex, the brainstem, the hypothalamus, the Purkinje cells of the cerebellum, and the dorsal spinal ganglia. Negri bodies are not demonstrated in at least 20% of cases of rabies, and their absence from brain material does not rule out the diagnosis.

CLINICAL MANIFESTATIONS

The clinical manifestations of rabies can be divided into four stages: (1) a nonspecific prodrome, (2) an acute encephalitis similar to other viral encephalitides, (3) a profound dysfunction of brainstem centers that produces the classic features of rabies encephalitis, and (4) death or, in rare cases, recovery.

The prodromal period usually lasts 1 to 4 days and is marked by fever, headache, malaise, myalgias, increased fatigability, anorexia, nausea and vomiting, sore throat, and a nonproductive cough. The prodromal symptom suggestive of rabies is the complaint of paresthesia and/or fasciculations at or around the site of inoculation of virus. These sensations, which may be related to the multiplication of virus in the dorsal root ganglion of the sensory nerve supplying the area of the bite, are reported by 50 to 80% of patients.

The encephalitic phase is usually ushered in by periods of excessive motor activity, excitation, and agitation. Confusion, hallucinations, combativeness, bizarre aberrations of thought, muscle spasms, meningismus, opisthotonic posturing, seizures, and focal paralysis soon appear. Characteristically, the periods of mental aberration are interspersed with completely lucid periods, but as the disease progresses the lucid periods get shorter until the patient lapses into coma. Hyperesthesia, with excessive sensitivity to bright light, loud noise, touch, and even gentle breezes, is very common. On physical examination, the temperature may be found to be as high as 40.6°C (105°F). Abnormalities of the autonomic nervous system include dilated irregular pupils; increased lacrimation, salivation, and perspiration; and postural hypotension. Evidence of upper motor neuron paralysis, with weakness, increased deep tendon reflexes, and extensor plantar responses, is the rule. Paralysis of the vocal cords is common. Unfortunately, the presenting signs and symptoms of rabies are indistinguishable from those of other viral and neurologic diseases. Thus delays in diagnosis are frequent. The presence of hydrophobia or aerophobia (seen in about two-thirds of recent cases) increases the likelihood of antemortem diagnosis.

The manifestations of brainstem dysfunction begin shortly after the onset of the encephalitic phase. Cranial nerve involvement causes diplopia, facial palsies, optic neuritis, and the characteristic difficulty with deglutition. The combination of excessive salivation and difficulty in swallowing produces the traditional picture of "foaming at the mouth." Hydrophobia, the painful, violent, involuntary contraction of the diaphragmatic, accessory respiratory, pharyngeal, and laryngeal muscles initiated by swallowing liquids, is seen in ~50% of cases. Involvement of the amygdaloid nucleus may result in priapism and spontaneous ejaculation. The patient lapses into coma, and involvement

of the respiratory center produces an apneic death. The prominence of early brainstem dysfunction distinguishes rabies from other viral encephalitides and accounts for the rapid downhill course. The median period of survival after the onset of symptoms is 4 days, with a maximum of 20 days, unless artificial supportive measures are instituted.

If intensive respiratory support is used, a number of late complications may appear. These include inappropriate secretion of antidiuretic hormone, diabetes insipidus, cardiac arrhythmias, vascular instability, adult respiratory distress syndrome, gastrointestinal bleeding, thrombocytopenia, and paralytic ileus. Recovery is very rare and, when it occurs, gradual.

Rabies may also present as an ascending paralysis resembling the Landry/Guillain-Barre syndrome (dumb rabies, *rage tranquille*). Initially, this clinical pattern was reported most frequently among persons given postexposure rabies prophylaxis after being bitten by vampire bats. Paralytic rabies also occurs in Southeast Asia among persons with canine exposures.

The difficulty of diagnosing rabies associated with ascending paralysis is illustrated by cases of person-to-person transmission of the virus by tissue transplantation. Corneal transplants from donors who died of presumed Landry/Guillain-Barre syndrome produced clinical rabies in and caused the deaths of the recipients. Retrospective pathologic examinations of the brains of recipients demonstrated Negri bodies, and rabies virus was subsequently isolated from each donor's frozen eye.

LABORATORY FINDINGS

Early in the disease, hemoglobin values and routine blood chemistry results are normal; abnormalities develop as hypothalamic dysfunction, gastrointestinal bleeding, and other complications ensue. The peripheral white blood cell count is usually slightly elevated (12,000 to 17,000/uL) but may be normal or as high as 30,000/uL.

The specific diagnosis of rabies depends on (1) the isolation of virus from infected secretions [saliva or, rarely, cerebrospinal fluid (CSF)] or tissue (brain), (2) the serologic demonstration of acute infection, (3) the detection of viral antigen in infected tissue (e.g., corneal impression smears, skin biopsies, or brain), or (4) the detection of viral nucleic acid (RNA) by polymerase chain reaction (PCR). A reference laboratory evaluating antemortem samples can confirm rabies with high sensitivity and specificity. Isolation of virus from saliva, demonstration of viral nucleic acid in saliva, or detection of viral antigen in a nuchal skin biopsy specimen is most sensitive. Examination of corneal epithelium specimens appears less sensitive. In the unvaccinated person, demonstration of rabies antibodies in serum or CSF may be useful, although such antibodies may not appear until late in the course of disease. Samples of brain obtained at postmortem examination or brain biopsy should be subjected to (1) mouse inoculation studies for virus isolation, (2) fluorescent antibody (FA) staining for viral antigen, and (3) histologic and/or electron microscopic examination for Negri bodies or reverse transcription PCR for rabies virus RNA.

Postexposure rabies prophylaxis rarely elicitsCSFneutralizing antibody to rabies virus. If present after prophylaxis, such antibody is usually found at a low titer (<1:64), whereas

CSF titers in human rabies may vary from 1:200 to 1:160,000.

DIFFERENTIAL DIAGNOSIS

There is little to distinguish rabies from other viral encephalitides. The most helpful clue to the diagnosis is a history of a bite or other salivary exposure to a potentially infected animal. As bite exposures are infrequent among U.S. cases, a history of relatively recent travel to a rabies-endemic area should be sought. Other problems to be considered in the differential diagnosis include hysterical reactions to animal bites (pseudohydrophobia), Landry/Guillain-Barre syndrome, poliomyelitis, and allergic encephalomyelitis developing in response to rabies vaccine; this last problem is usually associated with receipt of nerve tissue-derived vaccine and usually begins 1 to 4 weeks after vaccination.

TREATMENT

Postexposure Prophylaxis (See Fig. 197-1) Although rabies among humans is rare in the United States, each year ~35,000 persons receive postexposure prophylaxis. The decision to initiate postexposure prophylaxis should include the following considerations: (1) whether the individual came into physical contact with saliva or another substance likely to contain rabies virus, (2) whether rabies is known or suspected in the species and area associated with the exposure (e.g., all persons within the continental United States bitten by a bat that escapes should receive postexposure prophylaxis), and (3) the circumstances surrounding the exposure (e.g., whether the bite was provoked or unprovoked). Bites associated with the feeding of an animal are considered to have been provoked.

If rabies is known or suspected to be present in the animal species involved in a human exposure, the implicated animal should be captured if possible. Any wild animal involved in a rabies exposure; any ill, unvaccinated, or stray domestic animal involved in a rabies exposure; and any animal inflicting an unprovoked bite, exhibiting abnormal behavior, or suspected of being rabid should be humanely killed. The animal's head should be sent immediately to an appropriate laboratory for rabiesFAexamination. If examination of the brain by the FA technique gives negative results, it can be assumed that the saliva contains no virus, and the exposed person need not be treated. Persons exposed to wild animals that subsequently escape, that are capable of carrying rabies (bats, skunks, coyotes, foxes, raccoons, etc.), and that inhabit an area where rabies is known or suspected to be present should undergo both passive and active immunization against rabies (see below) as soon as possible after exposure.

In an area in which feline or canine rabies is not prevalent, a healthy biting dog, cat, or ferret can be confined and observed for 10 days. Persons in such an area should not begin a course of prophylaxis unless the animal develops clinical signs of rabies. If the animal becomes ill or behaves abnormally during the observation period, it should be killed forFAexamination. Experimental and epidemiologic evidence suggests that animals that remain healthy for 10 days after a bite will not have transmitted rabies virus at the time of the bite. In areas of high endemicity for canine rabies, immediate examination of the animal's brain, especially in the case of a severe bite, may be warranted. Bites of rodents, rabbits, and hares almost never require antirabies

postexposure prophylaxis. Unless the exposed person can rule out a bite, scratch, or mucous membrane exposure, postexposure prophylaxis should be considered after direct contact between a human and a bat.

Postexposure prophylaxis of rabies includes rigorous cleansing and treatment of the wound and the administration of rabies vaccine together with antirabies immunoglobulin. Postexposure prophylaxis should be initiated as soon as possible after exposure. As the incubation period of rabies is quite variable, postexposure prophylaxis should be begun as long as clinical signs of rabies are not present.

1. *Wound cleansing and treatment*. Thorough cleansing and treatment of the bite wound constitute an important component of rabies prevention. The wound should be scrubbed with soap and then flushed with water. Both mechanical cleansing and chemical cleansing are important. Quaternary ammonium compounds such as 1 to 4% benzalkonium chloride, 1% cetrimonium bromide, or povidone-iodine solutions should be utilized. Tetanus toxoid and antibiotic prophylaxis should be administered as needed.

2. *Passive immunization with antirabies antiserum of either equine or human origin*. Postexposure antirabies vaccination should include the administration of both passive antibody and vaccine, except when the individual has previously received preexposure prophylaxis. Human rabies immune globulin (RIG) is preferred because equine antiserum may cause serum sickness. RIG is administered only once, at the beginning of the postexposure prophylaxis regimen. The recommended dose of RIG is 20 IU/kg. The dose of equine antiserum is 40 units/kg. The full dose should be thoroughly infiltrated into the area around the wound and into the wound itself. Any remaining portion of the dose is injected intramuscularly at a site distant from the vaccine.

3. *Active immunization with antirabies vaccine*. Three rabies vaccines are available in the United States: (1) human diploid cell vaccine (HDCV), which can be given either intramuscularly or intradermally; (2) rabies vaccine absorbed (RVA); and (3) purified chick embryo cell vaccine. The latter two vaccines are administered intramuscularly. Each vaccine is derived from a different strain of rabies virus and prepared in a slightly different formulation. The three vaccines are considered equally efficacious and safe, and any of the three can be administered in conjunction withRIG. Five 1-mL doses of HDCV are given intramuscularly, preferably in the deltoid or anterolateral thigh area: the gluteal area should not be utilized. The five doses of HDCV should be administered within 28 days on the following schedule: days 0, 3, 7, 14, and 28. The World Health Organization also recommends 21- and 90-day injections. Severe reactions to these vaccines are uncommon. Immediate hypersensitivity responses, such as urticaria, have been reported in ~1 of every 650 recipients. Systemic reactions, such as fever, headache, and nausea, are generally mild and are reported in 1 to 4% of recipients. Local reactions, such as swelling, erythema, and induration at the injection site, occur in 15 to 20% of vaccinees. Guillain-Barre syndrome has been reported but appears to be quite rare.

In the developing world, several other effective rabies vaccines have been licensed and used extensively. They include vaccines made in chick embryonic cells, primary hamster cells, Vero cells, and duck embryonic cells. As some of these preparations are somewhat less immunogenic than the vaccines approved by the U.S. Food and Drug

Administration (FDA), evaluation of serum antibodies after immunization is suggested by some authorities.

The combination ofRIG andHDCVelicits high titers of neutralizing antibodies in almost all recipients. Only rarely has this regimen proved unsuccessful in preventing the development of rabies. None of the patients in whom rabies was diagnosed in the United States between 1980 and 1996 had received postexposure prophylaxis. Administration of vaccine alone appears to be associated with a higher failure rate than use of the combination, especially in severe bite exposures. Because of cost, postexposure prophylaxis consisting of intradermal injections of rabies vaccine is being used increasingly in the developing world. The combination of RIG plus 0.1-mL intradermal doses of HDCV at eight sites on day 0, four sites on day 7, and one site on days 28 and 91 produces good antibody responses and has had excellent clinical results. Alternatively, the World Health Organization has approved a regimen of two 0.1-mL doses at two intradermal sites on days 0, 3, and 7 and a 0.1-mL intradermal injection at a single site on days 21 and 90. TheFDA has not approved the intradermal route for postexposure prophylaxis.

Preexposure Prophylaxis Individuals at high risk of contact with rabies virus, including veterinarians, cave explorers, laboratory workers, and animal handlers, should receive preexposure prophylaxis with rabies vaccine. Three 1-mL intramuscular or three 0.1-mL intradermal injections ofHDCV on days 0, 7, and 21 or 28 should be administered. Concomitant chloroquine administration interferes with the antibody response to rabies vaccine. Depending on the level of risk, serologic testing should be done at 6-month to 2-year intervals.

An immune complex reaction consisting of urticaria, arthralgia, arthritis, angioedema, and systemic symptoms has been reported in up to 6% of persons receiving intramuscular booster doses ofHDCV. This reaction is self-limited and appears to be associated with the presence ofb-propiolactone-altered human serum albumin in the vaccine and the development of IgE antibodies to this antigen.

Persons who work in high-risk areas should undergo periodic measurement of antibodies. When neutralizing titers fall below 1:5, booster doses should be given. Booster doses may be administered as a single 1-mL intramuscular or 0.1-mL intradermal injection. Postexposure prophylaxis in individuals previously given preexposure prophylaxis consists of two intramuscular doses ofHDCV on days 0 and 3.RIG is not given in these situations.

MOKOLA VIRUS

Mokola virus was first isolated from wild shrews captured in Nigeria and was shown to be related morphologically and serologically to rabies virus. The subsequent isolation of the virus from cats in South Africa suggested a wider prevalence of the agent than had previously been expected. Only two cases of clinical infection have been reported; both were in children. One patient had a nonfatal illness characterized by fever, pharyngitis, and convulsions; Mokola virus was recovered fromCSF. In the second patient, fever with cough and vomiting was followed within several days by drowsiness, confusion, and generalized flaccid weakness. The CSF was normal. The patient progressed to

deep coma and died within 10 days of onset. Mokola virus was isolated from the brain, and examination of histopathologic sections revealed finely granular cytoplasmic inclusions that were distinguishable from Negri bodies in many neurons.

VESICULAR STOMATITIS VIRUS

Vesicular stomatitis is a viral illness of animals that occasionally affects humans. It presents as an acute, self-limited, influenza-like disease. The disease in animals is found in the United States and South America and affects chiefly domestic cattle, horses, swine, wild deer, raccoons, skunks, and bobcats.

In animals, vesicular stomatitis is characterized by the development of vesicles on the oral mucosa, particularly the tongue; the udders; and the heels. The mode of spread is probably by direct contact; however, epidemics tend to occur in warm weather, and isolation of the virus from *Phlebotomus* sandflies in Panama and *Aedes* species in New Mexico suggests that these insects may be vectors. Two distinct serotypes, New Jersey and Indiana, have been recognized, and most outbreaks in North America have been attributed to the New Jersey strain.

In humans, vesicular stomatitis is most common among laboratory workers. In one report, three-fourths of laboratory personnel handling experimentally infected animals or manipulating the virus developed neutralizing antibodies. The disease is also transmissible, however, under natural conditions among workers having direct contact with infected animals, especially cattle. An incubation period ranging from 1 to 6 days is followed by the sudden onset of fever [with temperatures of up to 40°C (104°F)], chills, profuse sweating, myalgias, malaise, headache, and pain on ocular movement. One-third to one-half of patients have a sore throat and cervical and/or submandibular adenopathy. Small raised vesicular lesions may appear on the buccal mucosa. Conjunctivitis and coryza are evident in ~20% of cases. Occasionally, small subcorneal, intraepithelial vesicles appear on the fingers, usually in association with direct inoculation of the virus. Symptoms generally last 3 to 4 days, but occasionally the course is diphasic. Inapparent infection is common: among laboratory workers with serologic evidence of infection, only about one-half report symptoms. In some areas of Panama, 17 to 35% of the population have neutralizing antibodies to vesicular stomatitis virus.

The differential diagnosis includes hand-foot-and-mouth disease, herpangina, primary herpetic pharyngitis and other mucocutaneous syndromes, and influenza. The virus is not commonly isolated from patients. However, a rise in titer of complement-fixation and/or neutralizing antibody to vesicular stomatitis virus between acute- and convalescent-phase sera helps to confirm the diagnosis. Treatment is nonspecific.

198. INFECTIONS CAUSED BY ARTHROPOD- AND RODENT-BORNE VIRUSES - *C. J. Peters*

Most viral infections that come to medical attention in office or hospital practice in the developed countries are caused by viruses that can be latent in the human host, such as the herpesviruses, or by viruses that are continuously transmitted among humans, such as measles virus, influenza virus, and HIV. However, some other viruses are transmitted in nature without regard to humans and only incidentally infect and produce disease in humans; in addition, a few agents are regularly spread among humans by arthropods. Most of these viruses either are maintained by arthropods or chronically infect rodents. Obviously, the mode of transmission is not a rational basis for taxonomic classification. Indeed, zoonotic viruses from at least seven virus families act as significant human pathogens (Table 198-1). The virus families differ fundamentally from one another in terms of morphology, replication mechanisms, and genetics. Information on a virus's membership in a family or genus is enlightening with regard to maintenance strategies, sensitivity to antivirals, and some aspects of pathogenesis but does not necessarily predict which clinical syndromes -- if any -- the virus will cause in humans.

FAMILIES OF ARTHROPOD- AND RODENT-BORNE VIRUSES

The Arenaviridae The Arenaviridae are spherical, 110- to 130-nm particles that bud from the cell's plasma membrane and utilize ambisense RNA genomes with two segments for replication. There are two main phylogenetic branches of Arenaviridae: the Old World viruses, such as Lassa fever and lymphocytic choriomeningitis (LCM) viruses, and the New World viruses, including those causing the South American hemorrhagic fevers (HFs). Arenaviruses persist in nature by chronically infecting rodents with a striking one-virus-one-rodent species relationship. These rodent infections result in long-term virus excretion and perhaps in lifelong viremia; vertical infection is common with some arenaviruses. Humans become infected through the inhalation of aerosols containing arenaviruses, which are then deposited in the terminal air passages, and probably also through close contact with rodents and their excreta, which results in the contamination of mucous membranes or breaks in the skin.

The Bunyaviridae The family Bunyaviridae includes four medically significant genera. All of these spherical viruses have three negative-sense RNA segments maturing into 90- to 120-nm particles in the Golgi complex and exiting the cell by exocytosis. Viruses of the genus *Bunyavirus* are largely mosquito-borne and have a viremic vertebrate intermediate host; many are also transovarially transmitted in their specific mosquito host. One serologic group also uses biting midges as vectors. Sandflies or mosquitoes are the vectors for the genus *Phlebovirus* (named after phlebotomus fever or sandfly fever, the best-known disease associated with the genus), while ticks serve as vectors for the genus *Nairovirus*. Viruses of both of these genera are also associated with vertical transmission in the arthropod host and with horizontal spread through viremic vertebrate hosts. The genus *Hantavirus* is unique among the Bunyaviridae in that it is not transmitted by arthropods but is maintained in nature by rodent hosts that chronically shed virus. Like the arenaviruses, the hantaviruses usually display striking virus-rodent species specificity. Hantaviruses do not cause chronic viremia in their rodent host and are transmitted only horizontally from rodent to rodent.

Other Families The Flaviviridae are positive-sense, single-stranded RNA viruses that form particles of 40 to 50 nm in the endoplasmic reticulum. The flaviviruses discussed here are from the genus *Flavivirus* and make up two phylogenetically and antigenically distinct divisions transmitted among vertebrates by mosquitoes and ticks, respectively. The mosquito-borne viruses fall into phylogenetic groups that include yellow fever virus, the four dengue viruses, and encephalitis viruses, while the tick-borne group encompasses a geographically varied spectrum of species, some of which are responsible for encephalitis or for hemorrhagic disease with encephalitis. The Reoviridae are double-stranded RNA viruses with multisegmented genomes. These 80-nm particles are the only viruses discussed in this chapter that do not have a lipid envelope and thus are insensitive to detergents. The Togaviridae have a single positive strand RNA genome and bud particles of ~60 to 70 nm from the plasma membrane. The togaviruses discussed here are all members of the genus *Alphavirus* and are transmitted among vertebrates by mosquitoes in their natural cycle.**The Filoviridae and the Rhabdoviridae are discussed in Chaps. 199 and 197, respectively.*

PROMINENT FEATURES OF ARTHROPOD- AND RODENT-BORNE VIRUSES

Although this chapter discusses the major features of selected arthropod- and rodent-borne viruses, it does not deal with more than 500 other distinct recognized zoonotic viruses, about one-fourth of which infect humans. Zoonotic viruses are undergoing genetic evolution, "new" zoonotic viruses are being discovered, and the epidemiology of zoonotic viruses is continuing to evolve through environmental changes affecting vectors, reservoirs, and humans. These zoonotic viruses are most numerous in the tropics but are also found in temperate and frigid climates. Their distribution and seasonal activity may be variable and often depend largely on ecologic conditions such as rainfall and temperature, which in turn affect the density of vectors and reservoirs and the development of infection therein.

Maintenance and Transmission Arthropod-borne viruses infect their vectors after the ingestion of a blood meal from a viremic vertebrate. The vectors then develop chronic, systemic infection as the viruses penetrate the gut and spread throughout the body. The viruses eventually reach the salivary glands during a period that is referred to as *extrinsic incubation* and that typically lasts 1 to 3 weeks in mosquitoes. At this point an arthropod is competent to continue the chain of transmission by infecting another vertebrate when a subsequent blood meal is taken. The arthropod generally is unharmed by the infection, and the natural vertebrate partner usually has only transient viremia with no overt disease. An alternative mechanism for virus maintenance in its arthropod host is transovarial transmission, which is common among members of the family Bunyaviridae.

Rodent-borne viruses such as the hantaviruses and arenaviruses are maintained in nature by chronic infection transmitted between rodents. As in arthropod-borne virus cycles, there is usually a high degree of rodent-virus specificity, and there is no overt disease in the reservoir/vector.

Epidemiology The distribution of arthropod- and rodent-borne viruses is restricted by the areas inhabited by their reservoir/vectors and provides an important clue in the differential diagnosis. Table 198-2 shows the approximate geographic distribution of the

most important of these viruses. Members of each family, each genus, and even each serologically related group usually occur in each area but may not be pathogenic in all areas or may not be a commonly recognized cause of disease in all areas and so may not be included in the table. Although there is generally no overt disease in the vertebrate reservoirs, disease in nonhuman target species may be a useful diagnostic clue, and serologic testing of selected animals may be a useful way to monitor virus circulation.

Most of these diseases are acquired in a rural setting; a few have urban vectors. Seoul, sandfly fever, and Oropouche viruses are examples of urban viruses, but the most notable are yellow fever, dengue, and chikungunya viruses, which are transmitted between humans with the mosquito *Aedes aegypti* as a principal or alternate vector. A history of mosquito bite has little diagnostic significance in the individual; a history of tick bite is more diagnostically specific. Rodent exposure is often reported by persons infected with an arenavirus or a hantavirus but again has little specificity. Indeed, aerosols may infect persons who have no recollection of having even seen rodents.

Syndromes Human disease caused by arthropod- and rodent-borne viruses is often subclinical. The spectrum of possible responses to infection is wide, and our knowledge of the outcome of most of these infections is limited. The usual disease syndromes associated with these viruses have been grouped into four categories: fever and myalgia, arthritis and rash, encephalitis, and hemorrhagic fever. Although for the purposes of this discussion most viruses have been placed in a single group, the categories often overlap. For example, West Nile and Venezuelan equine encephalitis viruses are discussed as encephalitis viruses, but during epidemics they may cause many cases of milder febrile syndromes and relatively uncommon cases of encephalitis. Similarly, Rift Valley fever virus is best known as a cause ofHF, but the attack rates for febrile disease are far higher, and encephalitis is occasionally seen as well.LCMvirus is classified as a cause of fever and myalgia because this syndrome is its most common disease manifestation and, even when central nervous system (CNS) disease occurs, it is usually mild and is preceded by fever and myalgia. Dengue virus infection is considered as a cause of fever and myalgia (dengue fever) because this is by far the most common manifestation worldwide and is the syndrome most likely to be seen in the United States; however, dengue HF is also discussed in the HF section because of its complicated pathogenesis and importance in pediatric practice in certain areas of the world.

Diagnosis Laboratory diagnosis is required in any given case, although epidemics occasionally provide clinical and epidemiologic clues on which an educated guess as to etiology can be based. For most arthropod- and rodent-borne viruses, acute-phase serum samples (collected within 3 or 4 days of onset) have yielded isolates, and paired sera have been used to demonstrate rising antibody titers by a variety of tests. Intensive efforts to develop rapid tests forHF have resulted in an antigen-detection enzyme-linked immunosorbent assay (ELISA) and an IgM-capture ELISA that can provide a diagnosis based on a single serum sample within a few hours and are particularly useful in severe cases. More sensitive reverse transcription polymerase chain reaction (RT-PCR) tests may yield diagnoses based on samples without detectable antigen and may also provide useful genetic information about the virus. Preliminary data suggest that similar tests applied to some fever-myalgia syndromes would give positive results if developed

further. Hantavirus infections differ from others discussed here in that severe acute disease is immunopathologic; patients present with serum IgM that serves as the basis for a sensitive and specific test. Every ELISA must include a control incorporating a negative antigen with each serum sample tested; the frequent failure to include such a control has resulted in numerous false-positive results in diagnostic tests.

At the time of diagnosis, patients with encephalitis are generally no longer viremic or antigenemic and usually do not have virus in cerebrospinal fluid (CSF). In this situation, the value of serologic methods andRT-PCRis being validated. IgM capture is increasingly being used for the simultaneous testing of serum and CSF. IgGELISA or classic serology is useful in the evaluation of past exposure to the viruses, many of which circulate in areas with a minimal medical infrastructure and sometimes cause mild or subclinical infection.

The remainder of this chapter offers general descriptions of the broad syndromes caused by arthropod- and rodent-borne viruses and then addresses specific differences between diseases. It is important to remember that most of the diseases under consideration have not been studied in detail with modern medical approaches and thus available data may be incomplete or biased.

FEVER AND MYALGIA

Fever and myalgia constitute the syndrome most commonly associated with zoonotic virus infection. Many of the numerous viruses belonging to the families listed inTable 198-1 probably cause this syndrome, but several viruses have been selected for inclusion in the table because of their prominent associations with the syndrome and their biomedical importance.

The syndrome typically begins with the abrupt onset of fever, chills, intense myalgia, and malaise. Patients may also report joint pains, but no true arthritis is detectable. Anorexia is characteristic and may be accompanied by nausea or even vomiting. Headache is common and may be severe, with photophobia and retroorbital pain. Physical findings are minimal and are usually confined to conjunctival injection with pain on palpation of muscles or the epigastrium. The duration of symptoms is quite variable but generally is 2 to 5 days, with a biphasic course in some instances. The spectrum of disease varies from subclinical to temporarily incapacitating.

Less constant findings include a maculopapular rash. Epistaxis may occur but does not necessarily indicate a bleeding diathesis. A minority of the cases caused by some viruses are known or suspected to include aseptic meningitis, but this diagnosis is difficult in remote areas, given the patients' photophobia and myalgia as well as the lack of opportunity to examine theCSF. Although pharyngitis may be noted or radiographic evidence of pulmonary infiltrates found in some cases, these viruses are not primary respiratory pathogens. The differential diagnosis includes anicteric leptospirosis, rickettsial diseases, and the early stages of other syndromes discussed in this chapter. These diseases are often described as "flulike," but the usual absence of cough and coryza makes influenza an unlikely confounder except at the earliest stages.

Complete recovery is generally the outcome in this syndrome, although prolonged

asthenia and nonspecific symptoms have been described in some cases, particularly after infection withLCM or dengue virus. Treatment is supportive, with aspirin avoided because of the potential for exacerbated bleeding and Reye's syndrome. Efforts at prevention are best based on vector control, which, however, may be expensive or impossible. For mosquito control, destruction of breeding sites is generally the most economically and environmentally sound approach; spraying to kill adult mosquitoes and thus to reduce their numbers transiently may have a preventive role in selected settings but has not been notably effective in the past. Measures taken by the individual to avoid the vector can be valuable. Avoiding the vector's habitat and times of peak activity, preventing the vector from entering dwellings by using screens or other barriers, judiciously applying arthropod repellents such as diethyltoluamide (DEET) to the skin, and wearing permethrin-impregnated clothing are all possible approaches, depending on the vector and its habits.

LYMPHOCYTIC CHORIOMENINGITIS

LCMis transmitted from the common house mouse (*Mus musculus*) to humans by aerosols of excreta and secreta. LCM virus, an arenavirus, is maintained in the mouse mainly by vertical transmission from infected dams. The vertically infected mouse remains viremic for life, with high concentrations of virus in all tissues. Infected colonies of pet hamsters have also served as a link to humans. LCM virus is widely used in immunology laboratories as a model of T cell function and can silently infect cell cultures and passaged tumor lines, resulting in infections among scientists and animal caretakers. Patients with LCM may have a history of residence in rodent-infested housing or other exposure to rodents. An antibody prevalence of ~5 to 10% has been reported in adults from the United States, Argentina, and endemic areas of Germany.

LCMdiffers from the general syndrome of fever and myalgia in that its onset is gradual. Among the conditions occasionally associated with LCM are orchitis, transient alopecia, arthritis, pharyngitis, cough, and maculopapular rash. An estimated one-fourth of patients or fewer suffer a febrile phase of 3 to 6 days and then, after a brief remission, develop renewed fever accompanied by severe headache, nausea and vomiting, and meningeal signs lasting for about a week. These patients virtually always recover fully, as do the uncommon patients with clear-cut signs of encephalitis. Recovery may be delayed by transient hydrocephalus.

During the initial febrile phase, leukopenia and thrombocytopenia are common and virus can usually be isolated from blood. During theCNSphase of the illness, virus may be found in theCSF, but antibodies are present in blood. The pathogenesis ofLCM is thought to resemble that following direct intracranial inoculation of the virus into adult mice; the onset of the immune response leads to T cell-mediated immunopathologic meningitis. During the meningeal phase, CSF mononuclear-cell counts range from the hundreds to the low thousands per microliter, and hypoglycorrhachia is found in one-third of cases. The IgM-captureELISA of serum and CSF is usually positive;RT-PCRassays have been developed for application to CSF.

Infection withLCMvirus should be suspected in acutely ill febrile patients with marked leukopenia and thrombocytopenia. In cases of aseptic meningitis, any of the following should suggest LCM: well-marked febrile prodrome, adult age, autumn seasonality, low

CSFglucose levels, or CSF mononuclear cell counts>1000/uL.

In pregnant women,LCMvirus infection may lead to fetal invasion with consequent congenital hydrocephalus and chorioretinitis. Since the maternal infection may be mild, consisting of only a short febrile illness, antibodies to the virus should be sought in both the mother and the fetus in suspicious circumstances, particularly TORCH-negative neonatal hydrocephalus. [TORCH is a battery of tests encompassing *t*oxoplasmosis, *o*ther conditions (congenital syphilis and viruses), *r*ubella, *c*ytomegalovirus, and *h*erpes simplex virus.]

BUNYAMWERA VIRUS INFECTION

The mosquito-transmitted Bunyamwera serogroup viruses are found on every continent except Australia and Antarctica. Bunyamwera virus and its close relative Ilesha virus commonly cause febrile disease in Africa. Other related viruses are implicated in such disease in Southeast Asia (Batai virus), Europe (Calovo virus), and South America (Wyeomyia virus). In North America, Cache Valley virus has been implicated in febrile human disease and in rare instances of more serious systemic illness; the presence of serum antibodies to this virus may be associated with congenital malformations. In Central America, the closely related Fort Sherman virus causes the fever-myalgia syndrome.

GROUP C VIRUS INFECTION

The group C viruses include at least 11 agents transmitted by mosquitoes in neotropical forests. These agents are among the most common causes of arboviral infection in humans entering American jungles and cause acute febrile disease.

TAHYNA VIRUS INFECTION

This California serogroup virus (see discussion of California encephalitis, below) occurs in central and western Europe, and related viruses are emerging in Russia. The significance of Tahyna virus in human health has been well studied only in the Czech and Slovak Republics; there, the virus was found to be a prominent cause of febrile disease, in some cases causing pharyngitis, pulmonary syndromes, and aseptic meningitis. The potential for arboviruses to be unexpectedly involved in such cases in areas of high mosquito prevalence needs to be kept in mind.

OROPOUCHE FEVER

Oropouche virus is transmitted in Central and South America by a biting midge, *Culicoides paraensis*, which often breeds to high density in cacao husks and other vegetable detritus found in towns and cities. Explosive epidemics involving thousands of cases have been reported from several towns in Brazil and Peru. Rash and aseptic meningitis have been detected in a number of cases.

SANDFLY FEVER

The sandfly *Phlebotomus papatasi* transmits sandfly fever. Female sandflies may be

infected by the oral route as they take a blood meal and may transmit the virus to offspring when they lay their eggs after a second blood meal. This prominent transovarial pattern was the first to be recognized among dipterans and complicates virus control. A previous designation for sandfly fever, "3-day fever," instructively describes the brief, debilitating course associated with this essentially benign infection. There is neither a rash norCNSinvolvement, and complete recovery is the rule.

Sandfly fever is found in the circum-Mediterranean area, extending to the east through the Balkans into China as well as into the Middle East and southwestern Asia. The vector is found in both rural and urban settings and is known for its small size, which enables it to penetrate standard mosquito screens and netting, and for its short flight range. Epidemics have been described in the wake of natural disasters and wars. In parts of Europe, sandfly populations and virus transmission were greatly reduced by the extensive residual spraying conducted after World War II to control malaria, and the incidence continues to be low. A common pattern of disease in endemic areas consists of high attack rates among travelers and military personnel with little or no disease in the local population, who are protected after childhood infection. In addition to the two well-characterized, non-cross-protective Sicilian and Naples virus species, more than 30 related phleboviruses are transmitted by sandflies and mosquitoes, but most are of unknown significance in terms of human health.

TOSCANA VIRUS DISEASE

Toscana virus is a *Phlebovirus* (family Bunyaviridae) transmitted primarily by the circum-Mediterranean sandfly *P. perniciosus*. The vertebrate amplifying host, if one exists, is unknown. Toscana virus infection is common during the summer among rural residents and vacationers; a number of cases have been identified in travelers returning to Germany and Scandinavia. The disease may manifest as an uncomplicated febrile illness but is often associated with aseptic meningitis, with virus isolated from theCSF.

PUNTA TORO VIRUS DISEASE

Of the several phleboviruses that are associated with New World sandflies and infect humans, Punta Toro virus is the best known. The disease caused by this virus is clinically similar to but epidemiologically different from that caused by the Naples or Sicilian sandfly fever viruses. Punta Toro virus infections are sporadic and are acquired in the tropical forest, where the vectors rest on tree buttresses. Epidemics have not been reported, but antibody prevalences among inhabitants of villages in the endemic areas indicate a cumulative lifetime exposure rate of>50%.

DENGUE FEVER

All four distinct dengue viruses (dengue 1-4) have *A. aegypti* as their principal vector, and all cause a similar clinical syndrome. In rare cases, second infection with a serotype of dengue virus different from that involved in the primary infection leads to dengueHF with severe shock (see below). Sporadic cases are seen in the settings of endemic transmission and epidemic disease. Year-round transmission between latitudes 25°N and 25°S has been established, and seasonal forays of the viruses to points as far north as Philadelphia are thought to have taken place in the United States. With increasing

spread of the vector mosquito throughout the tropics and subtropics, large areas of the world have become vulnerable to the introduction of dengue viruses, particularly through air travel by infected humans, and both dengue fever and the related dengue HF are becoming increasingly common. Conditions favorable to dengue transmission exist in the southern United States, and bursts of dengue fever activity are to be expected in this region, particularly along the Mexican border, where water may be stored in containers and *A. aegypti* numbers may therefore be greatest: this mosquito, which is also an efficient vector of the yellow fever and chikungunya viruses, typically breeds near human habitation, using relatively fresh water from sources such as water jars, vases, discarded containers, coconut husks, and old tires. *A. aegypti* usually inhabits dwellings and bites during the day.

After an incubation period of 2 to 7 days, the typical patient experiences the sudden onset of fever, headache, retroorbital pain, and back pain along with the severe myalgia that gave rise to the colloquial designation "break-bone fever." There is often a macular rash on the first day as well as adenopathy, palatal vesicles, and scleral injection. The illness may last a week, with additional symptoms usually including anorexia, nausea or vomiting, marked cutaneous hypersensitivity, and -- near the time of defervescence -- a maculopapular rash beginning on the trunk and spreading to the extremities and the face. Epistaxis and scattered petechiae are often noted in uncomplicated dengue, and preexisting gastrointestinal lesions may bleed during the acute illness.

Laboratory findings include leukopenia, thrombocytopenia, and, in many cases, serum aminotransferase elevations. The diagnosis is made by IgMELISA or paired serology during recovery or by antigen-detection ELISA orRT-PCRduring the acute phase. Virus is readily isolated from blood in the acute phase if mosquito inoculation or mosquito cell culture is used.

COLORADO TICK FEVER

Several hundred cases of Colorado tick fever are reported annually in the United States. The infection is acquired between March and November through the bite of an infected *Dermacentor andersoni* tick in mountainous western regions at altitudes of 1200 to 3000 m (4000 to 10,000 ft). Small mammals serve as the amplifying host. The most common presentation consists of fever and myalgia; meningoencephalitis is not uncommon, and hemorrhagic disease, pericarditis, myocarditis, orchitis, and pulmonary presentations are also reported. Rash develops in a substantial minority of cases. The disease usually lasts 7 to 10 days and is often biphasic. The most important differential diagnostic considerations since the beginning of the twentieth century have been Rocky Mountain spotted fever and tularemia.

Infection of erythroblasts and other marrow cells by Colorado tick fever virus results in the appearance and persistence (for several weeks) of erythrocytes containing the virus. This feature, detected in smears stained by immunofluorescence, can be diagnostically helpful. The clinical laboratory detects leukopenia and thrombocytopenia.

ORBIVIRUS INFECTION

The orbiviruses encompass many human and veterinary pathogens. For example,

Orungo virus is widely transmitted by mosquitoes in tropical Africa and causes febrile disease in humans. The Kemerova complex includes the Kemerova, Lipovnik, and Tribec viruses of Russia and central Europe; these viruses are transmitted by ticks and are associated with febrile and neurologic disease.

VESICULAR STOMATITIS

SeeChap. 197.

ENCEPHALITIS

Arboviral encephalitis is a seasonal disease, commonly occurring in the warmer months. Its incidence varies markedly with time and place, depending on ecologic factors. The causative viruses differ substantially in terms of case-infection ratio (i.e., the ratio of clinical to subclinical infection), mortality, and residua (Table 198-3). Humans are not an important amplifier of these viruses.

All the viral encephalitides discussed in this section have a similar pathogenesis as far as is known. An infected arthropod ingests a blood meal from a human and infects the host. The initial period of viremia is thought to originate most commonly from the lymphoid system. Viremia leads toCNSinvasion, presumably through infection of olfactory neuroepithelium with passage through the cribiform plate or through infection of brain capillaries and multifocal entry into the CNS. During the viremic phase, there may be little or no recognized disease except in the case of tick-borne flaviviral encephalitis, in which there may be a clearly delineated phase of fever and systemic illness. The disease process in the CNS arises partly from direct neuronal infection and subsequent damage and partly from edema, inflammation, and other indirect effects. The usual pathologic picture is one of focal necrosis of neurons, inflammatory glial nodules, and perivascular lymphoid cuffing; the severity and distribution of these abnormalities vary with the infecting virus. Involved areas display the "luxury perfusion" phenomenon, with normal or increased total blood flow and low oxygen extraction.

The typical patient presents with a prodrome of nonspecific constitutional symptoms, including fever, abdominal pain, vertigo, sore throat, and respiratory symptoms. Headache, meningeal signs, photophobia, and vomiting follow quickly. Involvement of deeper structures may be signaled by lethargy, somnolence, and intellectual deficit (as disclosed by the mental status examination or failure at serial 7 subtraction); more severely affected patients will be obviously disoriented and may be comatose. Tremors, loss of abdominal reflexes, cranial nerve palsies, hemiparesis, monoparesis, difficulty in swallowing, and frontal lobe signs are all common. Convulsions and focal signs may be evident early or may appear during the course of the disease. Some patients present with an abrupt onset of fever, convulsions, and other signs ofCNSinvolvement. The results of human infection range from no significant symptoms through febrile headache to aseptic meningitis and finally to full-blown encephalitis; the proportions and severity of these manifestations vary with the infecting virus.

The acute encephalitis usually lasts from a few days to as long as 2 to 3 weeks, but recovery may be slow, with weeks or months required for the return of maximal recoupable function. Common complaints during recovery include difficulty

concentrating, fatigability, tremors, and personality changes. The acute illness requires management of a comatose patient who may have intracranial pressure elevations, inappropriate secretion of antidiuretic hormone, respiratory failure, and convulsions. There is no specific therapy for these viral encephalitides. The only practical preventive measures are vector management and personal protection against the arthropod transmitting the virus; for Japanese encephalitis or tick-borne encephalitis, vaccination should be considered in certain circumstances (see relevant sections below).

The diagnosis of arboviral encephalitis depends on the careful evaluation of a febrile patient with CNSdisease, with rapid identification of treatable herpes simplex encephalitis, ruling out of brain abscess, exclusion of bacterial meningitis by serialCSFexamination, and performance of laboratory studies to define the viral etiology. Leptospirosis, neurosyphilis, Lyme disease, cat-scratch fever, and newer viral encephalitides such as Nipah virus infection from Malaysia should be considered. The CSF examination usually shows a modest cell count -- in the tens or hundreds or perhaps a few thousand. Early in the process, a significant proportion of these cells may be polymorphonuclear leukocytes, but usually there is a mononuclear cell predominance. CSF glucose levels are usually normal. There are exceptions to this pattern of findings. In eastern equine encephalitis, for example, polymorphonuclear leukocytes may predominate during the first 72 h of disease and hypoglycorrhachia may be detected. InLCM, lymphocyte counts may be in the thousands, and the glucose concentration may be diminished. Experience with imaging studies is still evolving; clearly, however, both computed tomography (CT) and magnetic resonance imaging (MRI) may be normal except for evidence of preexisting conditions or sometimes may suggest diffuse edema. Several patients with eastern equine encephalitis have had focal abnormalities, and individuals with severe Japanese encephalitis have presented with bilateral thalamic lesions that have often been hemorrhagic. Electroencephalography usually shows diffuse abnormalities and is not directly helpful.

A humoral immune response is usually detectable at or near the onset of disease. Both serum andCSFshould be examined for IgM antibodies. Virus generally cannot be isolated from blood or CSF, although Japanese encephalitis virus has been recovered from CSF in severe cases. Virus can be obtained from and viral antigen is present in brain tissue, although its distribution may be focal.

CALIFORNIA, LA CROSSE, AND JAMESTOWN CANYON VIRUS ENCEPHALITIS

The isolation of California encephalitis virus established the California serogroup of viruses as a cause of encephalitis, and its use as a diagnostic antigen led to the description of many cases of "California encephalitis." In fact, however, this virus has been implicated in only a few cases of encephalitis, and the serologically related La Crosse virus is the major cause of encephalitis among viruses in the California serogroup. "California encephalitis" due to La Crosse virus infection is most commonly reported from the upper Midwest but is also found in other areas of the central and eastern United States, most often in West Virginia, Tennessee, North Carolina, and Georgia. The serogroup includes 13 other viruses, some of which may also be involved in human disease that is misattributed because of the complexity of the group's serology; these viruses include the Jamestown Canyon, snowshoe hare, Inkoo, and Trivittatus viruses, all of which have *Aedes* mosquitoes as their vector and all of which

have a strong element of transovarial transmission in their natural cycles.

The mosquito vector of La Crosse virus is *A. triseriatus*. In addition to a prominent transovarial component of transmission, a mosquito can also become infected through feeding on viremic chipmunks and other mammals as well as through venereal transmission from another mosquito. The mosquito breeds in sites such as tree holes and abandoned tires and bites during daylight hours; these findings correlate with the risk factors for cases: recreation in forested areas, residence at the forest's edge, and the presence of abandoned tires around the home. Intensive environmental modification based on these findings has reduced the incidence of disease in a highly endemic area in the Midwest. Most cases occur from July through September. The Asian tiger mosquito, *A. albopictus*, efficiently transmits the virus to mice and also transmits the agent transovarially in the laboratory; this aggressive anthropophilic mosquito has the capacity to urbanize, and its possible impact on transmission to humans is of concern.

An antibody prevalence of³20% in endemic areas indicates that infection is common, butCNSdisease has been recognized primarily in children<15 years of age. The illness varies from a picture of aseptic meningitis accompanied by confusion to severe and occasionally fatal encephalitis. Although there may be prodromal symptoms, the onset of CNS disease is sudden, with fever, headache, and lethargy often joined by nausea and vomiting, convulsions (in one-half of patients), and coma (in one-third of patients). Focal seizures, hemiparesis, tremor, aphasia, chorea, Babinski's sign, and other evidence of significant neurologic dysfunction are common, but residua are not. Perhaps 10% of patients have recurrent seizures in the succeeding months. Other serious sequelae are rare, although a decrease in scholastic standing has been reported and mild personality change has occasionally been suggested. Treatment is supportive over a 1- to 2-week acute phase during which status epilepticus, cerebral edema, and inappropriate secretion of antidiuretic hormone are important concerns. Ribavirin has been used in severe cases, and a clinical trial of this drug is under way.

The blood leukocyte count is commonly elevated, sometimes reaching levels of 20,000/uL, and there is usually a left shift.CSF cell counts are typically 30 to 500/uL with a mononuclear cell predominance (although 25 to 90% of cells are polymorphonuclear in some cases). The protein level is normal or slightly increased, and the glucose level is normal. Specific virologic diagnosis based on IgM-capture assays of serum and CSF is efficient. The only human anatomic site from which virus has been isolated is the brain.

Jamestown Canyon virus has been implicated in several cases of encephalitis in adults; in these cases the disease was usually associated with a significant respiratory illness at onset. Human infection with this virus has been documented in New York, Wisconsin, Ohio, Michigan, Ontario, and other areas of North America where the vector mosquito, *A. stimulans*, feeds on its main host, the white-tailed deer.

ST. LOUIS ENCEPHALITIS

St. Louis encephalitis virus is transmitted between *Culex* mosquitoes and birds. This virus causes low-level endemic infection among rural residents of the western and central United States, where *C. tarsalis* is the vector (see "Western Equine

Encephalitis," below), but the more urbanized mosquito species *C. pipiens* and *C. quinquefasciatus* have been responsible for epidemics resulting in hundreds or even thousands of cases in cities of the central and eastern United States. Most cases occur in June through October. The urban mosquitoes breed in accumulations of stagnant water and sewage with high organic content and readily bite humans in and around houses at dusk. The elimination of open sewers and trash-filled drainage systems is expensive and may not be possible, but screening of houses and implementation of personal protective measures may be an effective approach for individuals. The rural vector is most active at dusk and outdoors; its bites can be avoided by modification of activities and use of repellents.

Disease severity increases with age: infections that result in aseptic meningitis or mild encephalitis are concentrated in children and young adults, while severe and fatal cases primarily affect the elderly. Infection rates are similar in all age groups; thus the greater susceptibility of older persons to disease is a biologic consequence of aging. The disease has an abrupt onset, sometimes following a prodrome, and begins with fever, lethargy, confusion, and headache. In addition, nuchal rigidity, hypotonia, hyperreflexia, myoclonus, and tremor are common. Severe cases can include cranial nerve palsies, hemiparesis, and convulsions. Patients often complain of dysuria and may have viral antigen in urine as well as pyuria. The overall mortality is generally ~7% but may reach 20% among patients over the age of 60. Recovery is slow. Emotional lability, difficulties in concentration and memory, asthenia, and tremor are commonly prolonged in older patients.

TheCSF of patients with St. Louis encephalitis usually contains tens to hundreds of cells, with a lymphocytic predominance and a normal glucose level. Leukocytosis with a left shift is often documented.

JAPANESE ENCEPHALITIS

Japanese encephalitis virus is found throughout Asia, including far eastern Russia, Japan, China, India, Pakistan, and Southeast Asia, and causes occasional epidemics on western Pacific islands. The virus has been detected in the Torres Strait islands, and a human encephalitis case has been identified on the nearby Australian mainland. This flavivirus is particularly common in areas where irrigated rice fields attract the natural avian vertebrate hosts and provide abundant breeding sites for mosquitoes such as *C. tritaeniorhyncus*, which transmit the virus to humans. Additional amplification by pigs, which suffer abortion, and horses, which develop encephalitis, may be significant as well. Vaccination of these additional amplifying hosts may reduce the transmission of the virus. An effective, formalin-inactivated vaccine purified from mouse brain is produced in Japan and licensed for human use in the United States. It is given on days 0, 7, and 30 or -- with some sacrifice in serum neutralizing titer -- on days 0, 7, and 14. Vaccination is indicated for summer travelers to rural Asia, where the risk of clinical disease may be 0.05 to 2.1/10,000 per week. The severe and often fatal disease reported in expatriates must be balanced against the 0.1 to 1% chance of a late systemic or cutaneous allergic reaction. These reactions are rarely fatal but may be severe and have been known to begin 1 to 9 days after vaccination, with associated pruritus, urticaria, and angioedema. Live attenuated vaccines are being used in China but are not recommended in the United States at this time.

WEST NILE VIRUS INFECTION

West Nile virus is transmitted among wild birds by *Culex* mosquitoes in Africa, the Middle East, southern Europe, and Asia. It is a frequent cause of febrile disease withoutCNSinvolvement, but it occasionally causes aseptic meningitis and severe encephalitis; these serious infections are particularly common among children and the elderly. The febrile-myalgic syndrome caused by West Nile virus differs from many others by the frequent appearance of a maculopapular rash concentrated on the trunk and lymphadenopathy. Headache, ocular pain, sore throat, nausea and vomiting, and arthralgia (but not arthritis) are common accompaniments. In addition, the virus has been implicated in severe and fatal hepatic necrosis in Africa.

In 1996 West Nile virus caused more than 300 cases ofCNSdisease, with 10% mortality, in the Danube flood plain, including Bucharest. In 1999 the virus appeared in New York City and other areas of the northeastern United States, causing more than 60 cases of aseptic meningitis or encephalitis among humans as well as die-offs among crows, exotic zoo birds, and other avians. The encephalitis was most severe among the elderly and was often associated with notable muscle weakness and even with flaccid paralysis. The virus, thought to have been transmitted in New York City by the ubiquitous *C. pipiens* mosquito, returned to larger areas of the northeastern United States in the summer of 2000 and threatens to spread farther in the Americas via bird migration.

West Nile virus falls into the same phylogenetic group of flaviviruses as St. Louis and Japanese encephalitis viruses, as do Murray Valley and Rocio viruses. The latter two viruses are both maintained in mosquitoes and birds and produce a clinical picture resembling that of Japanese encephalitis. Murray Valley virus has caused occasional epidemics and sporadic cases in Australia. Rocio virus caused recurrent epidemics in a focal area of Brazil in 1975 to 1977 and then virtually disappeared.

CENTRAL EUROPEAN TICK-BORNE ENCEPHALITIS AND RUSSIAN SPRING-SUMMER ENCEPHALITIS

A spectrum of tick-borne flaviviruses has been identified across the Eurasian land mass. Many are known mainly as agricultural pathogens (e.g., louping ill virus in the United Kingdom). From Scandinavia to the Urals, central European tick-borne encephalitis is transmitted by *Ixodes ricinus.* Human cases occur between April and October, with a peak in June and July. A related and more virulent virus is that of Russian spring-summer encephalitis, which is associated with *I. persulcatus* and is distributed from Europe across the Urals to the Pacific Ocean. The ticks transmit the disease primarily in the spring and early summer, with a lower rate of transmission later in summer. Small mammals are the vertebrate amplifiers for both viruses. The risk varies by geographic area and can be highly localized within a given area; human cases usually follow outdoor activities or consumption of raw milk from infected goats or other infected animals.

After an incubation period of 7 to 14 days or perhaps longer, the central European viruses classically result in a febrile-myalgic phase that lasts for 2 to 4 days and is

thought to correlate with viremia. A subsequent remission for several days is followed by the recurrence of fever and the onset of meningeal signs. TheCNSphase varies from mild aseptic meningitis, which is more common among younger patients, to severe encephalitis with coma, convulsions, tremors, and motor signs lasting for 7 to 10 days before improvement begins. Spinal and medullary involvement can lead to typical limb-girdle paralysis and to respiratory paralysis. Most patients recover, only a minority with significant deficits. Infections with the far eastern viruses generally run a more abrupt course. The encephalitic syndrome caused by these viruses sometimes begins without a remission and has more severe manifestations than the European syndrome. Mortality is high, and major sequelae -- most notably, lower motor neuron paralyses of the proximal muscles of the extremities, trunk, and neck -- are common.

In the early stage of the illness, virus may be isolated from the blood. In theCNSphase, IgM antibodies are detectable in serum and/orCSF. Thrombocytopenia sometimes develops during the initial febrile illness, which resembles the early hemorrhagic phase of some other tick-borne flaviviral infections, such as Kyasanur Forest disease. Other tick-borne flaviviruses are less common causes of encephalitis, including louping ill virus in the United Kingdom and Powassan virus.

There is no specific therapy for infection with these viruses. However, effective alum-adjuvanted, formalin-inactivated vaccines are produced in Austria, Germany, and Russia. Two doses of the Austrian vaccine separated by an interval of 1 to 3 months appear to be effective in the field, and antibody responses are similar when vaccine is given on days 0 and 14. Other vaccines have elicited similar neutralizing antibody titers. Since rare cases of postvaccination Guillain-Barre syndrome have been reported, vaccination should be reserved for persons likely to experience rural exposure in an endemic area during the season of transmission. Cross-neutralization for the central European and far eastern strains has been established, but there are no published field studies on cross-protection of formalin-inactivated vaccines. Because 0.2 to 4% of ticks in endemic areas may be infected, tick bites raise the issue of immunoglobulin prophylaxis. Prompt administration of high-titered specific preparations should probably be undertaken, although no controlled data are available to prove the efficacy of this measure. Immunoglobulin should not be administered late because of the risk of antibody-mediated enhancement.

POWASSAN ENCEPHALITIS

Powassan virus is a member of the tick-borne encephalitis virus complex and is transmitted by *I. cookei* among small mammals in eastern Canada and the United States, where it has been responsible for 20 recognized cases of human disease. Other ticks may transmit the virus in a wider geographic area, and there is some concern that *I. scapularis* (also called *I. dammini*), a competent vector in the laboratory, may become involved as it becomes more prominent in the United States. Patients with Powassan encephalitis -- often children -- present in May through December after outdoor exposure and an incubation period thought to be about 1 week. Powassan encephalitis is severe, and sequelae are common.

EASTERN EQUINE ENCEPHALITIS

Eastern equine encephalitis is found primarily within endemic swampy foci along the eastern coast of the United States, with a few inland foci as far removed as Michigan. Human cases present from June through October, when the bird-*Culiseta* mosquito cycle spills over into other mosquito species such as *A. sollicitans* or *A. vexans*, which are more likely to bite mammals. There is concern over the potential role of the introduced anthropophilic mosquito species *A. albopictus*, which has been found to be naturally infected and is an effective vector in the laboratory. Horses are a common target for the virus; if not vaccinated, they serve as a harbinger of human disease but probably do not play a significant role in amplification of the virus.

Eastern equine encephalitis is one of the most destructive of the arboviral conditions, with a brusque onset, rapid progression, high mortality, and frequent residua. This severity is reflected in the extensive necrotic lesions and polymorphonuclear infiltrates found at postmortem examination of the brain and the acute polymorphonuclearCSFpleocytosis often occurring during the first 1 to 3 days of disease. In addition, leukocytosis with a left shift is a common feature. A formalin-inactivated vaccine has been used to protect laboratory workers but is not generally available or applicable.

WESTERN EQUINE ENCEPHALITIS

The primary maintenance cycle for western equine encephalitis virus in the United States is between *C. tarsalis* and birds, principally sparrows and finches. Equines and humans become infected, and both species suffer encephalitis without amplifying the virus in nature. St. Louis encephalitis is transmitted in a similar cycle in the same region but causes human disease about a month earlier than the period (July through October) in which western equine encephalitis virus is active. Large epidemics of western equine encephalitis took place in the western and central United States and Canada during the 1930s to 1950s, but in recent years the disease has been uncommon. There were 41 reported cases in the United States in 1987 but only 4 reported cases from 1988 to 1995. This decline in incidence may reflect in part the integrated approach to mosquito management that has been employed in irrigation projects and the increasing use of agricultural pesticides; it almost certainly reflects the increased tendency for humans to be indoors behind closed windows at dusk, the peak period of biting by the major vector.

Western equine encephalitis virus causes a typical diffuse viral encephalitis with an increased attack rate and increased morbidity in the young, particularly children<2 years old. In addition, mortality is high among the young and the very elderly. One-third of individuals who have convulsions during the acute illness have subsequent seizure activity. Infants<1 year old -- particularly those in the first months of life -- are at serious risk of motor and intellectual damage. Twice as many males as females develop clinical encephalitis after 5 to 9 years of age; this difference may be related to greater outdoor exposure of boys to the vector but is also likely due in part to biologic differences. A formalin-inactivated vaccine has been used to protect laboratory workers but is not generally available or applicable.

VENEZUELAN EQUINE ENCEPHALITIS

There are six known types of virus in the Venezuelan equine encephalitis complex. An

important distinction is between the "epizootic" viruses (subtypes IAB and IC) and the "enzootic" viruses (subtypes ID to IF and types II to VI). The epizootic viruses have an unknown natural cycle but periodically cause extensive epidemics in equines and humans in the Americas. These epidemics rely on the high-level viremia in horses and mules that results in the infection of several species of mosquitoes, which in turn infect humans and perpetuate virus transmission. Humans also have high-level viremia but probably are not important in virus transmission. Enzootic viruses are found primarily in humid tropical forest habitats and are maintained between *Culex* mosquitoes and rodents; these viruses cause human disease but are not pathogenic for horses and do not cause epizootics.

Epizootics of Venezuelan equine encephalitis occurred repeatedly in Venezuela, Colombia, Ecuador, Peru, and other South American countries at intervals of£10 years from the 1930s until 1969, when a massive epizootic spread throughout Central America and Mexico, reaching southern Texas in 1972. Genetic sequencing of the virus from the 1969 to 1972 outbreak suggested that it originated from residual "un-inactivated" virus in veterinary vaccines. The outbreak was terminated in Texas with the use of a live attenuated vaccine (TC-83) originally developed for human use by the U.S. Army; this virus was then used for further production of inactivated veterinary vaccines. No further epizootic disease was identified until 1995 and subsequently, when additional epizootics took place in Colombia, Venezuela, and Mexico. The viruses involved in these epizootics as well as previously epizootic subtype IC viruses have been shown to be close phylogenetic relatives of known enzootic subtype ID viruses. This finding suggests that active evolution and selection of epizootic viruses are under way in northern South America.

During epizootics, extensive human infection is the rule, with clinical disease in 10 to 60% of infected individuals. Most infections result in notable acute febrile disease, while relatively few result in encephalitis. A low rate ofCNSinvasion is supported by the absence of encephalitis among the many infections resulting from exposure to aerosols in the laboratory or from vaccine accidents. The most recent large epizootic of Venezuelan equine encephalitis occurred in Colombia and Venezuela in 1995; of the more than 85,000 clinical cases, 4% (with a higher proportion among children than adults) included neurologic symptoms and 300 ended in death.

Enzootic strains of Venezuelan equine encephalitis virus are common causes of acute febrile disease, particularly in areas such as the Florida Everglades and the humid Atlantic coast of Central America. Encephalitis has been documented only in the Florida infections; the three cases were caused by type II enzootic virus, also called *Everglades virus*. All three patients had preexisting cerebral disease. Extrapolation from the rate of genetic change suggests that Everglades virus may have been introduced into Florida <200 years ago and that it is most closely related to the ID subtypes that appear to have given evolutionary rise to the epizootic strains active in South America.

The prevention of epizootic Venezuelan equine encephalitis depends on vaccination of horses with the attenuated TC-83 vaccine or with an inactivated vaccine prepared from that strain. Humans can be protected with similar vaccines, but the use of such products is restricted to laboratory personnel because of reactogenicity and limited availability. In addition, wild-type virus and perhaps TC-83 vaccine may have some degree of fetal

pathogenicity. Enzootic viruses are genetically and antigenically different from epizootic viruses, and protection against the former with vaccines prepared from the latter is relatively ineffective.

ARTHRITIS AND RASH

True arthritis is a common accompaniment of several viral diseases, such as rubella (caused by a non-alphavirus togavirus), parvovirus B19 infection, and hepatitis B; it is an occasional accompaniment of infection due to mumps virus, enteroviruses, herpesviruses, and adenoviruses. It is not generally appreciated that the alphaviruses are also common causes of arthritis. In fact, the alphaviruses discussed below all cause acute febrile diseases accompanied by the development of true arthritis and a maculopapular rash. Rheumatic involvement includes arthralgia alone, periarticular swelling, and (less commonly) joint effusions. Most of these diseases are less severe and have fewer articular manifestations in children than in adults. In temperate climates, these are summer diseases. No specific therapy or licensed vaccines exist.

SINDBIS VIRUS INFECTION

Sindbis virus is transmitted among birds by mosquitoes. Infections with the northern European strains of this virus (which cause, for example, Pogosta disease in Finland, Karelian fever in the independent states of the former Soviet Union, and Okelbo disease in Sweden) and with the genetically related southern African strains are particularly likely to result in the arthritis-rash syndrome. Exposure to a rural environment is commonly associated with this infection, which has an incubation period of<1 week.

The disease begins with rash and arthralgia. Constitutional symptoms are not marked, and fever is modest or lacking altogether. The rash, which lasts about a week, begins on the trunk, spreads to the extremities, and evolves from macules to papules that often vesiculate. The arthritis of this condition is multiarticular, migratory, and incapacitating, with resolution of the acute phase in a few days. Wrists, ankles, phalangeal joints, knees, elbows, and -- to a much lesser extent -- proximal and axial joints are involved. Persistence of joint pains and occasionally of arthritis is a major problem and may go on for months or even years despite a lack of deformity.

CHIKUNGUNYA VIRUS INFECTION

It is likely that chikungunya virus ("that which bends up") is of African origin and is maintained among nonhuman primates on that continent by *Aedes* mosquitoes of the subgenus *Stegomyia* in a fashion similar to yellow fever virus. Like yellow fever virus, chikungunya virus is readily transmitted among humans in urban areas by *A. aegypti*. The *A. aegypti*-chikungunya virus transmission cycle has also been introduced into Asia, where it poses a prominent health problem. The disease is endemic in rural areas of Africa, and intermittent epidemics take place in towns and cities of Africa and Asia. Chikungunya is one more reason (in addition to dengue and yellow fever) that *A. aegypti* must be controlled.

Full-blown disease is most common among adults, in whom the clinical picture may be dramatic. The brusque onset follows an incubation period of 2 to 3 days. Fever and

severe arthralgia are accompanied by chills and constitutional symptoms such as headache, photophobia, conjunctival injection, anorexia, nausea, and abdominal pain. Migratory polyarthritis mainly affects the small joints of the hands, wrists, ankles, and feet, with lesser involvement of the larger joints. Rash may appear at the outset or several days into the illness; its development often coincides with defervescence, which takes place around day 2 or day 3 of disease. The rash is most intense on the trunk and limbs and may desquamate. Petechiae are occasionally seen, and epistaxis is not uncommon, but this virus is not a regular cause of theHFsyndrome, even in children. A few patients develop leukopenia. Elevated levels of aspartate aminotransferase (AST) and C-reactive protein have been described, as have mildly decreased platelet counts. Recovery may require weeks. Some older patients continue to suffer from stiffness, joint pain, and recurrent effusions for several years; this persistence may be especially common in HLA-B27 patients. An investigational live attenuated vaccine has been developed but requires further testing.

A related virus, O'nyong-nyong, caused a major epidemic of arthritis and rash involving at least 2 million people as it moved across eastern and central Africa in the 1960s. After its mysterious emergence, the virus virtually disappeared, leaving only occasional evidence of its persistence in Kenya until a transient resurgence of epidemic activity in 1997.

MAYARO FEVER

Mayaro virus is maintained in the forests of the Americas by *Haemagogus* mosquitoes and nonhuman primates. It causes a frequently endemic and sometimes epidemic infection of humans and appears to produce a syndrome resembling chikungunya.

EPIDEMIC POLYARTHRITIS (ROSS RIVER VIRUS INFECTION)

Ross River virus has caused epidemics of distinctive clinical disease in Australia since the beginning of the twentieth century and continues to be responsible for thousands of cases in rural and suburban areas annually. The virus is transmitted by *A. vigilax* and other mosquitoes, and its persistence is thought to involve transovarial transmission. No definitive vertebrate host has been identified, but several mammalian species, including wallabies, have been suggested. Endemic transmission has also been documented in New Guinea, and in 1979 the virus swept through the eastern Pacific Islands, causing hundreds of thousands of illnesses. The virus was carried from island to island by infected humans and was believed to have been transmitted among humans by *A. polynesiensis* and *A. aegypti*.

The incubation period is 7 to 11 days long, and the onset of illness is sudden, with joint pain usually ushering in the disease. The rash generally develops coincidentally or follows shortly but in some cases precedes joint pains by several days. Constitutional symptoms such as low-grade fever, asthenia, myalgia, headache, and nausea are not prominent and indeed are absent in many cases. Most patients are incapacitated for considerable periods by joint involvement, which interferes with sleeping, walking, and grasping. Wrist, ankle, metacarpophalangeal, interphalangeal, and knee joints are the most commonly involved, although toes, shoulders, and elbows may be affected with some frequency. Periarticular swelling and tenosynovitis are common, and one-third of

patients have true arthritis. Only half of all arthritis patients can resume normal activities within 4 weeks, and 10% still must limit their activity at 3 months. Occasional patients are symptomatic for 1 to 3 years but without progressive arthropathy. Aspirin and nonsteroidal anti-inflammatory drugs are effective for the treatment of symptoms.

Clinical laboratory values are normal or variable in Ross River virus infection. Tests for rheumatoid factor and antinuclear antibodies are negative, and the erythrocyte sedimentation rate is acutely elevated. Joint fluid contains 1000 to 60,000 mononuclear cells per microliter, and Ross River virus antigen is demonstrable in macrophages. IgM antibodies are valuable in the diagnosis of this infection, although they occasionally persist for years. The isolation of the virus from blood by mosquito inoculation or mosquito cell culture is possible early in the illness. Because of the great economic impact of annual epidemics in Australia, an inactivated vaccine is being developed and has been found to be protective in mice.

Perhaps because of the local interest in arboviruses in general and in Ross River virus in particular, other arthritogenic arboviruses have been identified in Australia, including Gan Gan virus, a member of the family Bunyaviridae; Kokobera virus, a flavivirus; and Barmah Forest virus, an alphavirus. The last virus is a common cause of infection and must be differentiated from Ross River virus by specific testing.

HEMORRHAGIC FEVERS

The viralHFsyndrome is a constellation of findings based on vascular instability and decreased vascular integrity. An assault, direct or indirect, on the microvasculature leads to increased permeability and (particularly when platelet function is decreased) to actual disruption and local hemorrhage. Blood pressure is decreased, and in severe cases shock supervenes. Cutaneous flushing and conjunctival suffusion are examples of common, observable abnormalities in the control of local circulation. The hemorrhage is inconstant and is in most cases an indication of widespread vascular damage rather than a life-threatening loss of blood volume. Disseminated intravascular coagulation is occasionally found in any severely ill patient with HF but is thought to occur regularly only in the early phases of HF with renal syndrome, Crimean Congo HF, and perhaps some cases of filovirus HF. In some viral HF syndromes, specific organs may be particularly impaired, such as the kidney in HF with renal syndrome, the lung in hantavirus pulmonary syndrome, or the liver in yellow fever, but in all these diseases the generalized circulatory disturbance is critically important.

The pathogenesis ofHF is poorly understood and varies among the viruses regularly implicated in the syndrome, which number more than a dozen. In some cases direct damage to the vascular system or even to parenchymal cells of target organs is important, whereas in others soluble mediators are thought to play the major role. The acute phase in most cases of HF is associated with ongoing virus replication and viremia. Exceptions are the hantavirus diseases and dengue HF/dengue shock syndrome (DHF/DSS), in which the immune response plays a major pathogenic role.

TheHFsyndromes all begin with fever and myalgia, usually of abrupt onset. Within a few days the patient presents for medical attention because of increasing prostration that is often accompanied by severe headache, dizziness, photophobia, hyperesthesia,

abdominal or chest pain, anorexia, nausea or vomiting, and other gastrointestinal disturbances. Initial examination often reveals only an acutely ill patient with conjunctival suffusion, tenderness to palpation of muscles or abdomen, and borderline hypotension or postural hypotension, perhaps with tachycardia. Petechiae (often best visualized in the axillae), flushing of the head and thorax, periorbital edema, and proteinuria are common. Levels ofAST are usually elevated at presentation or within a day or two thereafter. Hemoconcentration from vascular leakage, which is usually evident, is most marked in hantavirus diseases and inDHF/DSS. The seriously ill patient progresses to more severe symptoms and develops shock and other findings typical of the causative virus. Shock, multifocal bleeding, and CNSinvolvement (encephalopathy, coma, convulsions) are all poor prognostic signs.

One of the major diagnostic clues is travel to an endemic area within the incubation period for a given syndrome (Table 198-4). Except for Seoul, dengue, and yellow fever virus infections, which have urban vectors, travel to a rural setting is especially suggestive of a diagnosis ofHF.

Early recognition is important because of the need for virus-specific therapy and supportive measures, including prompt, atraumatic hospitalization; judicious fluid therapy that takes into account the patient's increased capillary permeability; administration of cardiotonic drugs; use of pressors to maintain blood pressure at levels that will support renal perfusion; treatment of the relatively common secondary bacterial infections; replacement of clotting factors and platelets as indicated; and the usual precautionary measures used in the treatment of patients with hemorrhagic diatheses. Disseminated intravascular coagulation should be treated only if clear laboratory evidence of its existence is found and if laboratory monitoring of therapy is feasible; there is no proven benefit of such therapy. The available evidence suggests thatHFpatients have a decreased cardiac output and will respond poorly to fluid loading as it is often practiced in the treatment of shock associated with bacterial sepsis. Specific therapy is available for several of the HF syndromes. In addition, several diseases considered in the differential diagnosis -- malaria, shigellosis, typhoid, leptospirosis, relapsing fever, and rickettsial disease -- are treatable and potentially lethal. Strict barrier nursing and other precautions against infection of medical staff and visitors are indicated in HF except that due to hantaviruses, yellow fever, Rift Valley fever, and dengue.

LASSA FEVER

Lassa virus is known to cause endemic and epidemic disease in Nigeria, Sierra Leone, Guinea, and Liberia, although it is probably more widely distributed in West Africa. This virus and its relatives exist elsewhere in Africa, but their health significance is unknown. Like other arenaviruses, Lassa virus is spread to humans by small-particle aerosols from chronically infected rodents and may also be acquired during the capture or eating of these animals. It can be transmitted by close person-to-person contact. The virus is often present in urine during convalescence and is suspected to be present in seminal fluid early in recovery. Nosocomial spread has occurred but is uncommon if proper sterile parenteral techniques are used. People of all ages and both sexes are affected; the incidence of disease is highest in the dry season, but transmission takes place year-round. In countries where Lassa virus is endemic, Lassa fever can be a prominent

cause of febrile disease. For example, in one hospital in Sierra Leone, laboratory-confirmed Lassa fever is consistently responsible for one-fifth of admissions to the medical wards. There are probably tens of thousands of Lassa fever cases annually in West Africa alone.

The average case has a gradual onset (among theHFagents, only the arenaviruses are typically associated with a gradual onset) that gives way to more severe constitutional symptoms and prostration. Bleeding is seen in only ~15 to 30% of cases. A maculopapular rash is often noted in light-skinned Lassa patients. Effusions are common, and male-dominant pericarditis may develop late. The fetal death rate is 92% in the last trimester, when maternal mortality is also increased from the usual 15% to 30%; these figures suggest that interruption of the pregnancy of infected women should be considered. White blood cell counts are normal or slightly elevated, and platelet counts are normal or somewhat low. Deafness coincides with clinical improvement in ~20% of cases and is permanent and bilateral in some. Reinfection may occur but has not been associated with severe disease.

High-level viremia or a high serum concentration ofASTstatistically predicts a fatal outcome. Thus patients with an AST level of>150 IU/mL should be treated with intravenous ribavirin. This antiviral nucleoside analogue appears to be effective in reducing mortality from rates among retrospective controls, and its only major side effect is reversible anemia that usually does not require transfusion. The drug should be given by slow intravenous infusion in a dose of 32 mg/kg; this dose should be followed by 16 mg/kg q6h for 4 days and then by 8 mg/kg q8h for 6 days.

SOUTH AMERICANHFSYNDROMES (ARGENTINE, BOLIVIAN, VENEZUELAN, AND BRAZILIAN)

These diseases are similar to one another clinically, but their epidemiology differs with the habits of their rodent reservoirs and the interactions of these animals with humans (Table 198-4). Person-to-person or nosocomial transmission is rare but has occurred.

The basic disease resembles Lassa fever with two marked differences. First, thrombocytopenia -- often marked -- is the rule, and bleeding is quite common. Second,CNSdysfunction is much more common than in Lassa fever and is often manifest by marked confusion, tremors of the upper extremities and tongue, and cerebellar signs. Some cases follow a predominantly neurologic course, with a poor prognosis. The clinical laboratory is helpful in diagnosis since thrombocytopenia, leukopenia, and proteinuria are typical findings.

ArgentineHF is readily treated with convalescent-phase plasma given within the first 8 days of illness. In the absence of passive antibody therapy, intravenous ribavirin in the dose recommended for Lassa fever is likely to be effective in all the South American HF syndromes. The transmission of the disease from men convalescing from Argentine HF to their wives suggests the need for counseling of arenavirus HF patients concerning the avoidance of intimate contacts for several weeks after recovery. A safe, effective, live attenuated vaccine exists for Argentine HF. In experimental animals, this vaccine is cross-protective against the Bolivian HF virus.

RIFT VALLEY FEVER

This mosquito-borne virus is also a pathogen of domestic animals such as sheep, cattle, and goats. It is maintained in nature by transovarial transmission in floodwater *Aedes* mosquitoes and presumably also has a vertebrate amplifier. Epizootics and epidemics occur when sheep or cattle become infected during particularly heavy rains; developing high-level viremia, these animals infect many different species of mosquitoes. Remote sensing via satellite can detect the ecologic changes associated with high rainfall that predict the likelihood of Rift Valley fever transmission; it can also detect the special depressions from which the floodwater *Aedes* mosquito vectors emerge. In addition, the virus is infectious when transmitted by contact with blood or aerosols from domestic animals or their abortuses. The slaughtered meat is not infectious; anaerobic glycolysis in postmortem tissues results in an acidic environment that rapidly inactivates Bunyaviridae such as Rift Valley fever virus and Crimean-Congo HF virus. The natural range of Rift Valley fever virus is confined to sub-Saharan Africa, where its circulation is markedly enhanced by substantial rainfall such as that which occurred during the El Nino phenomenon of 1997. The virus has also been found in Madagascar and has been introduced into Egypt, where it caused major epidemics in 1977 to 1979, 1993, and subsequently. Neither person-to-person nor nosocomial transmission has been documented.

Rift Valley fever virus is unusual in that it causes at least four different clinical syndromes. Most infections are manifested as the febrile-myalgic syndrome. A small proportion result inHF with especially prominent liver involvement. Perhaps 10% of otherwise mild infections lead to retinal vasculitis; funduscopic examination reveals edema, hemorrhages, and infarction, and some patients have permanently impaired vision. A small proportion of cases (<1 in 200) are followed by typical viral encephalitis. One of the complicated syndromes does not appear to predispose to another.

There is no proven therapy for any of the syndromes described above. The sensitivity of animal models of Rift Valley fever to antibody or ribavirin therapy suggests that either could be given intravenously to persons withHF. Both retinal disease and encephalitis occur after the acute febrile syndrome has ended and serum neutralizing antibody has developed -- events suggesting that only supportive care need be given. Epidemic disease is best prevented by vaccination of livestock. The established ability of this virus to propagate after an introduction into Egypt suggests that other potentially receptive areas, including the United States, should have a response ready for such an eventuality. It seems likely that this disease, like Venezuelan equine encephalitis, can be controlled only with adequate stocks of an effective live attenuated vaccine, and there are no such global stocks. A formalin-inactivated vaccine confers immunity to humans, but quantities are limited and three injections are required; this vaccine is recommended for exposed laboratory workers and for veterinarians working in sub-Saharan Africa.

CRIMEAN CONGO HF

This severe HF syndrome has a wide geographic distribution, potentially being found wherever ticks of the genus *Hyalomma* occur (Table 198-4). The propensity of these ticks to feed on domestic livestock and certain wild mammals means that veterinary

serosurveys are the most effective mechanism for the surveillance of virus circulation in a region. Human infection is acquired via a tick bite or during the crushing of infected ticks. Domestic animals do not become ill but do develop viremia; thus there is danger of infection at the time of slaughter and for a brief interval thereafter (through contact with hides or carcasses). Cases have followed sheep shearing. An epidemic in South Africa was associated with slaughter of tick-infested ostriches. Nosocomial epidemics are common and are usually related to extensive blood exposure or needle sticks.

Although generally similar to otherHFsyndromes, Crimean Congo HF causes extensive liver damage, resulting in jaundice in some cases. Clinical laboratory values indicate disseminated intravascular coagulation and show elevations inAST, creatine phosphokinase, and bilirubin. Patients with fatal cases generally have more marked changes, even in the early days of illness, and also develop leukocytosis rather than leukopenia. Thrombocytopenia is also more marked and develops earlier in cases with a fatal outcome.

No controlled trials have been performed with intravenous ribavirin, but clinical experience and retrospective comparison of patients with ominous clinical laboratory values suggest that ribavirin is efficacious and should be given. No human or veterinary vaccines are recommended.

HFWITH RENAL SYNDROME

This disease, the first to be identified as an HF, is widely distributed over Europe and Asia; the major causative viruses and their rodent reservoirs on these two continents are Puumala virus (bank vole, *Clethrionomys glareolus*) and Hantaan virus (striped field mouse, *Apodemus agrarius*), respectively. Other potential causative viruses exist, including Dobrava virus (yellow-necked field mouse, *A. flavicollus*), which causes severe HF with renal syndrome in the Balkans. Seoul virus is associated with the Norway or sewer rat, *Rattus norvegicus*, and has a worldwide distribution through the migration of the rodent; it is associated with mild or moderate HF with renal syndrome in Asia, but in many areas of the world the human disease has been difficult to identify. Most cases occur in rural residents or vacationers; the exception is Seoul virus disease, which may be acquired in an urban or rural setting or from contaminated laboratory rat colonies. Classic Hantaan disease in Korea (Korean HF) and in rural China (epidemic HF) is most common in spring and fall and is related to rodent density and agricultural practices. Human infection is acquired primarily through aerosols of rodent urine, although virus is also present in saliva and feces. Patients with hantavirus diseases are not infectious. HF with renal syndrome is the most important form of HF today, with more than 100,000 cases of severe disease in Asia annually and milder Puumala infections numbering in the thousands as well.

Severe cases ofHF with renal syndrome caused by Hantaan virus evolve in identifiable stages: the febrile stage with myalgia, lasting 3 to 4 days; the hypotensive stage, often associated with shock and lasting from a few hours to 48 h; the oliguric stage with renal failure, lasting 3 to 10 days; and the polyuric stage with diuresis and hyposthenuria.

The *febrile period* is initiated by the abrupt onset of fever, headache, severe myalgia, thirst, anorexia, and often nausea and vomiting. Photophobia, retroorbital pain, and pain

on ocular movement are common, and the vision may become blurred with ciliary body inflammation. Flushing over the face, the V area of the neck, and the back are characteristic, as are pharyngeal injection, periorbital edema, and conjunctival suffusion. Petechiae often develop in areas of pressure, the conjunctivae, and the axillae. Back pain and tenderness to percussion at the costovertebral angle reflect massive retroperitoneal edema. Laboratory evidence of mild to moderate disseminated intravascular coagulation is present. Other laboratory findings include proteinuria and an active urinary sediment.

The *hypotensive phase* is ushered in by falling blood pressure and sometimes by shock. The relative bradycardia typical of the febrile phase is replaced by tachycardia. Kinin activation is marked. The rising hematocrit reflects increasing vascular leakage. Leukocytosis with a left shift develops, and thrombocytopenia continues. Atypical lymphocytes -- which in fact are activated CD8+ and to a lesser extent CD4+ T cells -- circulate. Proteinuria is marked, and the urine's specific gravity falls to 1.010. The renal circulation is congested and compromised from local and systemic circulatory changes resulting in necrosis of tubules, particularly at the corticomedullary junction, and oliguria.

During the *oliguric phase*, hemorrhagic tendencies continue, probably in large part because of uremic bleeding defects. The oliguria persists for 3 to 10 days before renal function returns and marks the onset of the *polyuric stage*, which carries the danger of dehydration and electrolyte abnormalities.

Mild cases ofHF with renal syndrome may be much less stereotypical. The presentation may include only fever, gastrointestinal abnormalities, and transient oliguria followed by hyposthenuria.

HFwith renal syndrome should be suspected in patients with rural exposure in an endemic area. Prompt recognition of the disease will permit rapid hospitalization and expectant management of shock and renal failure. Useful clinical laboratory parameters include leukocytosis, which may be leukemoid and is associated with a left shift; thrombocytopenia; and proteinuria. Mainstays of therapy are the management of shock, reliance on pressors, modest crystalloid infusion, intravenous use of human serum albumin, and treatment of renal failure with prompt dialysis for the usual indications. Hydration may result in pulmonary edema, and hypertension should be avoided because of the possibility of intracranial hemorrhage. Use of intravenous ribavirin has reduced mortality and morbidity in severe cases provided treatment is begun within the first 4 days of illness. The case-fatality ratio may be as high as 15% but with proper therapy should be <5%. Sequelae have not been definitely established, but there is a correlation in the United States between chronic hypertensive renal failure and the presence of antibodies to Seoul virus.

Infections with Puumala virus, the most common cause ofHF with renal syndrome in Europe, result in a much attenuated picture but the same general presentation. The syndrome may be referred to by its former name, *nephropathia epidemica*. Bleeding manifestations are found in only 10% of cases, hypotension rather than shock is usually seen, and oliguria is present in only about half of patients. The dominant features may be fever, abdominal pain, proteinuria, mild oliguria, and sometimes blurred vision or glaucoma followed by polyuria and hyposthenuria in recovery. Mortality is<1%.

The diagnosis is readily made by IgM-captureELISA, which should be positive at admission or within 24 to 48 h thereafter. The isolation of virus is difficult, butRT-PCRof a blood clot collected early in the clinical course or of tissues obtained postmortem will give positive results. Such testing is usually undertaken only if definitive identification of the infecting viral species is required or if molecular epidemiologic questions exist.

HANTAVIRUS PULMONARY SYNDROME

Hantavirus pulmonary syndrome was discovered in 1993, but retrospective identification of cases by immunohistochemistry (1978) and serology (1959) support the idea that it is a recently discovered rather than a truly new disease. The causative viruses are hantaviruses of a distinct phylogenetic lineage that is associated with the rodent subfamily Sigmodontinae. Sin Nombre virus chronically infects the deer mouse (*Peromyscus maniculatus*) and is the most important virus causing hantavirus pulmonary syndrome in the United States. The disease is also caused by a Sin Nombre virus variant from the white-footed mouse (*P. leucopus*), by Black Creek Canal virus (*Sigmodon hispidus*, the cotton rat), and by Bayou virus (*Oryzomys palustris*, the rice rat). Several other related viruses cause the disease in South America, but Andes virus is unusual in that it, alone among hantaviruses, has been implicated in human-to-human transmission. The disease is linked to rodent exposure and particularly affects rural residents living in dwellings permeable to rodent entry or working at occupations that pose a risk of rodent exposure. Each rodent species has its own particular habits; in the case of the deer mouse, these behaviors include living in and around human habitation.

The disease begins with a prodrome of about 3 to 4 days (range, 1 to 11 days) comprising fever, myalgia, malaise, and often gastrointestinal disturbances such as nausea, vomiting, and abdominal pain. Dizziness is common and vertigo occasional. Severe prodromal symptoms bring some individuals to medical attention, but patients are usually recognized as the cardiopulmonary phase begins. Typically, there is slightly lowered blood pressure, tachycardia, tachypnea, mild hypoxemia, and early radiographic signs of pulmonary edema. Physical findings in the chest are often surprisingly scant. The conjunctival and cutaneous signs of vascular involvement seen in other types ofHF are absent. During the next few hours, decompensation may progress rapidly to severe hypoxemia and respiratory failure. Most patients surviving the first 48 h of hospitalization are extubated and discharged within a few days, with no apparent residua.

Management during the first few hours after presentation is critical. The goal is to prevent severe hypoxemia by oxygen therapy and, if needed, intubation and intensive respiratory management. During this period, hypotension and shock with increasing hematocrit invite aggressive fluid administration, but this intervention should be undertaken with great caution. Because of low cardiac output with myocardial depression and increased pulmonary vascular permeability, shock should be managed expectantly with pressors and modest infusion of fluid guided by the pulmonary capillary wedge pressure. Mild cases can be managed by frequent monitoring and oxygen administration without intubation. Many patients require intubation to manage hypoxemia and also develop shock. Mortality remains at ~30 to 40% with good management. The antiviral drug ribavirin inhibits the virus in vitro but did not have a

marked effect on patients treated in an open-label study.

During the prodrome, the differential diagnosis of hantavirus pulmonary syndrome is difficult, but by the time of presentation or within 24 h thereafter, a number of diagnostically helpful clinical features become apparent. Cough is not usually present at the outset but may develop later. Interstitial edema is evident on the chest x-ray. Later, bilateral alveolar edema with a central distribution develops in the setting of a normal-sized heart; occasionally, the edema is initially unilateral. Pleural effusions are often visualized. Thrombocytopenia, circulating atypical lymphocytes, and a left shift (often with leukocytosis) are almost always evident; thrombocytopenia has been a particularly important early clue. Hemoconcentration, proteinuria, and hypoalbuminemia should also be sought. Although thrombocytopenia virtually always develops and prolongation of the partial thromboplastin time is the rule, clinical evidence for coagulopathy or laboratory indications of disseminated intravascular coagulation are found in only a minority of cases, usually in severely ill patients. Severely ill patients also have acidosis and elevated serum levels of lactate. Mildly increased values in renal function tests are common, but patients with severe cases often have markedly elevated concentrations of serum creatinine; some of the viruses other than Sin Nombre virus have been associated with more kidney involvement, but few such cases have been studied. The differential diagnosis includes abdominal surgical conditions and pyelonephritis as well as rickettsial disease, sepsis, meningococcemia, plague, tularemia, influenza, and relapsing fever.

A specific diagnosis is best made by IgM testing of acute-phase serum, which has yielded positive results even in the prodrome. Tests using a Sin Nombre virus antigen detect the related hantaviruses causing the pulmonary syndrome in the Americas. Occasionally, heterologous viruses will react only in the IgGELISA, but this finding is highly suspicious given the very low seroprevalence of these viruses in normal populations.RT-PCRis usually positive when used to test blood clots obtained in the first 7 to 9 days of illness as well as tissues; this test is useful in identifying the infecting virus in areas outside the home range of the deer mouse and in atypical cases.

YELLOW FEVER

Yellow fever virus caused major epidemics in the Americas, Africa, and Europe before the discovery of mosquito transmission in 1900 led to its control through attacks on its urban vector, *A. aegypti*. Only then was it found that a jungle cycle also existed in Africa, involving other *Aedes* mosquitoes and monkeys, and that colonization of the New World with *A. aegypti*, originally an African species, had established urban yellow fever as well as an independent sylvatic yellow fever cycle in American jungles involving *Haemagogus* mosquitoes and New World monkeys. Today, urban yellow fever transmission occurs only in some African cities, but the threat exists in the great cities of South America, where reinfestation by *A. aegypti* has taken place and dengue transmission by the same mosquito is common. As late as 1905, New Orleans suffered more than 3000 cases with 452 deaths from "yellow jack." Despite the existence of a highly effective and safe vaccine, several hundred jungle yellow fever cases occur annually in South America, and thousands of jungle and urban cases occur each year in Africa.

Yellow fever is a typicalHFaccompanied by prominent hepatic necrosis. A period of viremia, typically lasting 3 or 4 days, is followed by a period of "intoxication." During the latter phase in severe cases, the characteristic jaundice, hemorrhages, black vomit, anuria, and terminal delirium occur, perhaps related in part to extensive hepatic involvement. Blood leukocyte counts may be normal or reduced and are often high in terminal stages. Albuminuria is usually noted and may be marked; as renal function fails in terminal or severe cases, the level of blood urea nitrogen rises proportionately. Abnormalities detected in liver function tests range from modest elevations ofASTlevels in mild cases to severe derangement.

Urban yellow fever can be prevented by the control of *A. aegypti*. The continuing sylvatic cycle requires vaccination of all visitors to areas of potential transmission. With few exceptions (in the very young and the elderly), reactions to vaccine are minimal; immunity is provided within 10 days and lasts for at least 10 years. An egg allergy dictates caution in vaccine administration. Although there are no documented harmful effects of the vaccine on the fetus, pregnant women should be immunized only if they are definitely at risk of yellow fever exposure. Since vaccination has been associated with several cases of encephalitis in children under 6 months of age, it should be delayed until after 12 months of age unless the risk of exposure is very high. Timely information on changes in yellow fever distribution and yellow fever vaccine requirements can be obtained from Health Information for Travelers, Centers for Disease Control and Prevention, Atlanta, GA 30333; by fax request (404-332-4565; document number 220022#); by phone (404-332-4559); or on the World-Wide Web athttp://www.cdc.gov.

DENGUE HEMORRHAGIC FEVER/DENGUE SHOCK SYNDROME

A syndrome ofHF noted in the 1950s among children in the Philippines and Southeast Asia was soon associated with dengue virus infections, particularly those occurring against a background of previous exposure to another serotype. The transient heterotypic protection after dengue virus infection is replaced within several weeks by the potential for heterotypic infection resulting in typical dengue fever (see above) or -- uncommonly -- for enhanced disease (secondaryDHF/DSS). In rare instances, primary dengue infections lead to an HF syndrome, but much less is known about pathogenesis in this situation. In the past 20 years, *A. aegypti* has progressively reinvaded Latin America and other areas, and frequent travel by infected individuals has introduced multiple strains of dengue virus from many geographic areas. Thus the pattern of hyperendemic transmission of multiple dengue serotypes has now been established in the Americas and the Caribbean and has led to the emergence of DHF/DSS as a major problem there as well. Millions of dengue infections, including many thousands of cases of DHF/DSS, occur annually. The severe syndrome is unlikely to be seen in U.S. citizens since few children have the dengue antibodies that can trigger the pathogenetic cascade when a second infection is acquired.

Macrophage/monocyte infection is central to the pathogenesis of dengue fever and to the origin ofDHF/DSS. Previous infection with a heterologous dengue-virus serotype may result in the production of nonprotective antiviral antibodies that nevertheless bind to the virion's surface and through interaction with the Fc receptor focus secondary dengue viruses on the target cell, the result being enhanced infection. The host is also

primed for a secondary antibody response when viral antigens are released and immune complexes lead to activation of the classic complement pathway, with consequent phlogistic effects. Cross-reactivity at the T cell level results in the release of physiologically active cytokines, including interferon g and tumor necrosis factora. The induction of vascular permeability and shock depends on multiple factors, including the following:

1. *Presence of enhancing and nonneutralizing antibodies* -- Transplacental maternal antibody may be present in infants <9 months old, or antibody elicited by previous heterologous dengue infection may be present in older individuals. T cell reactivity is also intimately involved.

2. *Age* -- Susceptibility toDHF/DSSdrops considerably after 12 years of age.

3. *Sex* -- Females are more often affected than males.

4. *Race* -- Caucasians are more often affected than blacks.

5. *Nutritional status* -- Malnutrition is protective.

6. *Sequence of infection* -- For example, serotype 1 followed by serotype 2 seems to be more dangerous than serotype 4 followed by serotype 2.

7. *Infecting serotype* -- Type 2 is apparently more dangerous than other serotypes.

In addition, there is considerable variation among strains of a given serotype, with Southeast Asian serotype 2 strains having more potential to causeDHF/DSSthan others.

DengueHF is identified by the detection of bleeding tendencies (tourniquet test, petechiae) or overt bleeding in the absence of underlying causes such as preexisting gastrointestinal lesions. Dengue shock syndrome, usually accompanied by hemorrhagic signs, is much more serious and results from increased vascular permeability leading to shock. In mildDHF/DSS, restlessness, lethargy, thrombocytopenia (<100,000/uL), and hemoconcentration are detected 2 to 5 days after the onset of typical dengue fever, usually at the time of defervescence. The maculopapular rash that often develops in dengue fever may also appear in DHF/DSS. In more severe cases, frank shock is apparent, with low pulse pressure, cyanosis, hepatomegaly, pleural effusions, ascites, and in some cases severe ecchymoses and gastrointestinal bleeding. The period of shock lasts only 1 or 2 days, and most patients respond promptly to close monitoring, oxygen administration, and infusion of crystalloid or -- in severe cases -- colloid. The case-fatality rates reported vary greatly with case ascertainment and the quality of treatment; however, most DHF/DSS patients respond well to supportive therapy, and overall mortality in an experienced center in the tropics is probably as low as 1%.

A virologic diagnosis can be made by the usual means, although multiple flavivirus infections lead to a broad immune response to several members of the group, and this situation may result in a lack of virus specificity of the IgM and IgG immune responses. A secondary antibody response can be sought with tests against several flavivirus antigens to demonstrate the characteristic wide spectrum of reactivity.

The key to control of both dengue fever andDHF/DSSis the control of *A. aegypti*, which also reduces the risk of urban yellow fever and chikungunya virus circulation. Control efforts have been handicapped by the presence of nondegradable tires and long-lived plastic containers in trash repositories, insecticide resistance, urban poverty, and an inability of the public health community to mobilize the populace to respond to the need to eliminate mosquito breeding sites. Live attenuated dengue vaccines are in the late stages of development and have produced promising results in early tests. Whether vaccines can provide safe, durable immunity to an immunopathologic disease such as DHF/DSS in endemic areas is an issue that will have to be tested, but it is hoped that vaccination will reduce transmission to negligible levels.

KYASANUR FOREST DISEASE AND OMSK HEMORRHAGIC FEVER

Kyasanur Forest virus and Omsk HFvirus are geographically restricted, tick-borne flaviviruses that cause a syndrome of viral HF during a wave of viremia and that may also enter theCNS to cause subsequent viral encephalitis (see discussion of tick-borne encephalitis above). There is no therapy for these infections, but an inactivated vaccine has been used in India against Kyasanur Forest disease. A new and related virus isolate has been obtained from butchers with HF in the Middle East; the implication is that there are more agents in this group.

FILOVIRUS HEMORRHAGIC FEVER

199. FILOVIRIDAE (MARBURG AND EBOLA VIRUSES) - *C. J. Peters*

DEFINITION

Both Marburg virus and Ebola virus cause an acute febrile illness associated with high mortality. This illness is characterized by multisystem involvement that begins with the abrupt onset of headache, myalgias, and fever and proceeds to prostration, rash, shock, and often bleeding manifestations. Epidemics usually begin with a single case acquired from an unknown reservoir in nature and spread mainly through close contact with sick persons or their body fluids, either in the home or at the hospital.

ETIOLOGY

The family Filoviridae comprises two antigenically and genetically distinct viruses: Marburg virus and Ebola virus. Ebola virus has four readily distinguishable subtypes named for their original site of recognition (Zaire, Sudan, Cote d'Ivoire, and Reston). Except for Ebola virus subtype Reston, all the Filoviridae are African viruses that cause severe and often fatal disease in humans. The Reston virus, which has been exported from the Philippines on several occasions, has caused fatal infections in monkeys but only subclinical infections in humans. Different isolates of the four Ebola subtypes made over time and space exhibit remarkable sequence conservation, indicating marked genetic stability in their selective niche. Typical filovirus particles contain a single linear, negative-sense, single-stranded RNA arranged in a helical nucleocapsid. The virions are 790 to 970 nm in length; they may also appear in elongated, contorted forms. The lipid envelope confers sensitivity to lipid solvents and common detergents. The viruses are largely destroyed by heat (60°C, 30 min) and by acidity but may persist for weeks in blood at room temperature. The surface glycoprotein self-associates to form the virion surface spikes, which presumably mediate attachment to cells and fusion. The glycoprotein's high sugar content may contribute to its low capacity to elicit neutralizing antibodies. A smaller form of the glycoprotein, bearing many of its antigenic determinants, is produced by in vitro-infected cells and is found in the circulation in human disease; it has been speculated that this circulating soluble protein may suppress the immune response to the virion surface protein or block antiviral effector mechanisms. Both Marburg virus and Ebola virus are biosafety level 4 pathogens because of their high associated mortality rate and aerosol infectivity.

EPIDEMIOLOGY

Marburg virus was first identified in Germany in 1967, when infected African green monkeys (*Cercopithecus aethiops*) imported from Uganda transmitted the agent to vaccine-laboratory workers. Of the 25 human cases acquired from monkeys, 7 ended in death. The six secondary cases were associated with close contact or parenteral exposure. Secondary spread to the wife of one patient was documented, and virus was isolated from the husband's semen despite the presence of circulating antibodies. Subsequently, isolated cases of Marburg virus infection have been reported from eastern and southern Africa, with limited spread.

In 1999, repeated transmission of Marburg virus to workers in a gold mine in eastern Democratic Republic of Congo was documented. The secondary spread of the virus

among patients' families was more extensive than previously noted, resembling that of Ebola virus and emphasizing the importance of hygiene and proper barrier nursing in the epidemiology of these viruses in Africa.

In 1976, epidemics of severe hemorrhagic fever (550 human cases) occurred simultaneously in Zaire and Sudan, and Ebola virus was found to be the etiologic agent. Later, it was shown that different subtypes of virus -- associated with 90% and 50% mortality, respectively -- caused the two epidemics. Both epidemics were associated with interhuman spread (particularly in the hospital setting) and the use of unsterilized needles and syringes, a common practice in developing-country hospitals. The epidemics dwindled as the clinics were closed and people in the endemic area increasingly shunned affected persons and avoided traditional burial practices.

The Zaire subtype of Ebola virus recurred in a major epidemic (317 cases, 88% mortality) in Democratic Republic of Congo in 1995 and in smaller epidemics in Gabon in 1994-1996. Mortality was high, transmission to caregivers and others who had direct contact with body fluids was common, and poor hygiene in hospitals exacerbated spread. In the Congo epidemic, an index case was infected in Kikwit in January 1995. The epidemic smoldered until April, when intense nosocomial transmission forced closure of the hospitals; samples were finally sent to the laboratory for Ebola testing, which yielded positive results within a few hours. International assistance, with barrier nursing instruction and materials, was provided; nosocomial transmission ceased, hospitals reopened, and patients were segregated to prevent intrafamilial spread. The last case was reported in June 1995.

Three separate emergences of Ebola virus (subtype Zaire) were detected in Gabon from 1994 through 1996, all associated with deep forest exposure and subsequent familial and nosocomial transmission. In the 1996 episode, a physician exposed to Ebola-infected patients traveled to South Africa with a fever; a nurse who assisted in a cutdown on the physician developed Ebola hemorrhagic fever and died in spite of intensive care. The index patient was identified retrospectively on the basis of serum antibodies and virus isolation from semen. Thus, distant transport of Ebola virus is an established risk, and limited nosocomial spread is possible even under hygienic conditions.

The Reston subtype of Ebola virus was first seen in the United States in 1989, when it caused a fatal, highly transmissible disease among cynomolgus macaques imported from the Philippines and quarantined in Reston, VA, pending distribution to biomedical researchers. This and other appearances of the Reston virus have been traced to a single export facility in the Philippines, but no source in nature has been established.

Epidemiologic studies (including a specific search in the Kikwit epidemic) have failed to yield evidence for an important role of airborne particles in human disease. This lack of epidemiologic evidence is surprising and seems to conflict with the viruses' classification as biosafety level 4 pathogens based in part on their aerosol infectivity and with formal laboratory assessments showing a high degree of aerosol infectivity for monkeys. Sick humans apparently do not usually generate sufficient amounts of infectious aerosols to pose a significant hazard to those around them.

Available evidence points to a nonprimate reservoir for these viruses, but an intensive search has failed to elucidate what this reservoir might be. Speculation has centered on a possible role for bats, but that hypothesis has arisen in part merely because of the ubiquity of bats when sought in affected areas and the frustration of researchers in identifying a source of virus.

PATHOLOGY AND PATHOGENESIS

In humans and in animal models, Ebola and Marburg viruses replicate well in virtually all cell types, including endothelial cells, macrophages, and parenchymal cells of multiple organs. Viral replication is associated with cellular necrosis both in vivo and in vitro. Significant findings at the light-microscopic level include liver necrosis with Councilman bodies (intracellular inclusions that correlate with extensive collections of viral nucleocapsids), interstitial pneumonitis, cerebral glial nodules, and small infarcts. Antigen and virions are abundant in fibroblasts, interstitium, and (to a lesser extent) the appendages of the subcutaneous tissues in fatal cases; escape through small breaks in the skin or possibly through sweat glands may occur and, if so, may be correlated with the established epidemiologic risk of close contact with patients and the touching of the deceased. Inflammatory cells are not prominent, even in necrotic areas.

In addition to sustaining direct damage from viral infection, patients infected with Ebola virus (Zaire subtype) have high circulating levels of proinflammatory cytokines, which presumably contribute to the severity of the illness. In fact, the virus interacts intimately with the cellular cytokine system. It is resistant to the antiviral effects of interferon a, although this mediator is amply induced. Viral infection of endothelial cells selectively inhibits the expression of MHC class I molecules and blocks the induction of several genes by the interferons. In addition, glycoprotein expression inhibitsaV integrin expression, an effect that has been shown in vitro to lead to detachment and subsequent death of endothelial cells.

Acute infection is associated with high levels of circulating virus and viral antigen. Clinical improvement takes place when viral titers decrease concomitantly with the onset of a virus-specific immune response, as detected by enzyme-linked immunosorbent assay (ELISA) or fluorescent antibody test. In fatal cases, there is usually little evidence of an antibody response and there is extensive depletion of spleen and lymph nodes. Recovery is apparently mediated by the cellular immune response: convalescent-phase plasma has little in vitro virus-neutralizing capacity and is not protective in passive transfer experiments in monkey and guinea pig models.

CLINICAL MANIFESTATIONS

After an incubation period of ~7 to 10 days (range, 3 to 16 days), the patient abruptly develops fever, severe headache, malaise, myalgia, nausea, and vomiting. Continued fever is joined by diarrhea (often severe), chest pain (accompanied by cough), prostration, and depressed mentation. In light-skinned patients (and less often in blacks), a maculopapular rash appears around day 5 to 7 and is followed by desquamation. Bleeding may begin about this time and is apparent from any mucosal site and into the skin. In some epidemics, fewer than half of patients have had overt bleeding, and this manifestation has been absent even in some fatal cases. Additional

findings include edema of the face, neck, and/or scrotum; hepatomegaly; flushing; conjunctival injection; and pharyngitis. Around 10 to 12 days after the onset of disease, the sustained fever may break, with improvement and eventual recovery of the patient. Recrudescence of fever may be associated with secondary bacterial infections or possibly with localized virus persistence. Late hepatitis, uveitis, and orchitis have been reported, with isolation of virus from semen or detection of polymerase chain reaction (PCR) products in vaginal secretions for several weeks.

LABORATORY FINDINGS

Leukopenia is common early on; neutrophilia has its onset later. Platelet counts fall below (sometimes much below) 50,000/uL. Laboratory evidence of disseminated intravascular coagulation may be found, but its clinical significance and the need for therapy are controversial. Serum levels of alanine and aspartate aminotransferases (particularly the latter) rise progressively, and jaundice develops in some cases. The serum amylase level may be elevated, and this elevation may be associated with abdominal pain suggesting pancreatitis. Proteinuria is usual; decreased kidney function is proportional to shock.

DIAGNOSIS

Most patients acutely ill with Ebola or Marburg viruses have high concentrations of virus in blood. Antigen-detectionELISA is a sensitive, robust diagnostic modality. Virus isolation and reverse transcriptasePCR are also effective and provide additional sensitivity in some cases. Patients who are recovering develop IgM and IgG antibodies that are best detected by ELISA but are also reactive in the less specific fluorescent antibody test. Skin biopsies are an extremely useful adjunct in postmortem diagnosis of Ebola and, to a lesser extent, Marburg virus infections because of the presence of large amounts of viral antigen, the relative safety of obtaining the sample, and the freedom from cold-chain requirements for formalin-fixed tissues.

TREATMENT

No virus-specific therapy is available, and, given the extensive viral involvement in fatal cases, supportive treatment may not be as useful as was once hoped. Vigorous treatment of shock should take into account the likelihood of vascular leak in the pulmonary and systemic circulation and of myocardial functional compromise. The membrane fusion mechanism of Ebola resembles that of retroviruses, and the identification of "fusogenic" sequences suggests that inhibitors of cell entry may be developed. Despite the poor neutralizing capacity of polyclonal convalescent-phase sera, phage display of immunoglobulin mRNA from convalescent bone marrow has produced monoclonal antibodies that have in vitro neutralizing capacity and mediate protection in guinea pig models.

PREVENTION

No vaccine is available, but barrier nursing precautions in African hospitals can greatly decrease the spread of the virus beyond the index case and thus prevent epidemics of filoviruses and other agents as well.

SECTION 15 -FUNGAL AND ALGAL INFECTIONS

200. DIAGNOSIS AND TREATMENT OF FUNGAL INFECTIONS - *John E. Bennett*

MYCOLOGY FUNDAMENTALS

Fungi can appear microscopically as either rounded, budding forms (yeastlike organisms) or hyphae (molds; Fig. 200-CD1). Yeastlike colonies are smooth, while mold colonies are fuzzy; fungi that grow as yeasts include species of *Candida* and *Cryptococcus*, while fungi that grow as molds include species of *Aspergillus*, *Rhizopus*, and dermatophytes (ringworm fungi). The fungi that cause histoplasmosis, blastomycosis, sporotrichosis, coccidioidomycosis, and paracoccidioidomycosis are called *dimorphic* ("having two forms") because they are spherical in tissue but grow like molds when cultured at room temperature. *Candida* species other than *Candida glabrata* appear in tissue as both budding yeasts and tubular elements called *pseudohyphae*. *Pneumocystis carinii* is closer to fungi than to parasites by ribosomal sequences (Chap. 209). Because the drugs used to treat *Pneumocystis* pneumonia are also used to treat parasitic or bacterial infections, those drugs will not be discussed in this chapter.

Many fungi can form two different types of spores and are given different names, depending on the spore-bearing structures. When the spores are produced by mitosis, the fungus is said to be an *anamorph*, or to be in the imperfect state. Many fungi can have different sporulating structures in which genetic recombination occurs, often as a result of coculture with a strain of the opposite mating type. A fungus producing those distinctive spores is said to be a *teleomorph*, or to be in the perfect state. Diagnostic laboratories usually use the name of the anamorph because they do not use culture conditions that would produce the teleomorph. One exception is *Scedosporium apiospermum*, which is often observed as a teleomorph in the diagnostic laboratory and identified as *Pseudallescheria boydii*.

Most fungi that are pathogenic for humans are saprophytes in nature; they cause infection when airborne spores reach the lung or paranasal sinus or when hyphae or spores are accidentally inoculated into the skin or cornea. Acquisition of infection from another person or an animal has been reported in the case of ringworm but is very rare in other mycoses. Thus, hospitalized patients with fungal infections do not require special isolation. Most fungi infect hosts preferentially by one route and only infrequently by other routes. For example, the agents of ringworm, pityriasis versicolor, and piedra infect the epidermis and its appendages. Sporotrichosis and mycetoma usually arise from subcutaneous inoculation. Inhalation is the route of inoculation for the agents of most deep mycoses. Ingestion of fungi rarely causes infection; *Candida albicans*, a normal commensal in the mouth and intestine, reaches deeper tissues only when mucosal or cutaneous barriers are breached by disease, surgery, trauma, or catheterization. Histoplasmosis, blastomycosis, coccidioidomycosis, and paracoccidioidomycosis have been called "endemic" mycoses to emphasize their restricted geographic distribution. Some fungi, such as *Aspergillus*, are said to be opportunists in that they usually infect hosts with compromised immunity. This distinction is relative, not absolute.

Immunity after exposure to fungi may confer partial protection against reinfection. Residents of areas in which mycoses are endemic are less subject to infection than are newcomers. Predisposing factors are helpful in defining host defense. Immunoglobulin deficiencies do not appear to predispose to any mycosis, whereas neutropenia is common among patients who develop invasive aspergillosis or deep candidiasis. Cell-mediated immunity appears to be of paramount importance in most other deep mycoses.

DIAGNOSIS

Many fungi can be identified to the genus or even the species level by microscopic examination of smears or biopsy specimens. Calcofluor white staining with fluorescence microscopy is a sensitive technique for smears of sputum, bronchoalveolar lavage fluid, or pus. India ink smear remains the method of choice for detecting cryptococci in cerebrospinal fluid (CSF). *Candida* yeast cells and pseudohyphae are the only fungi that are usually gram-positive on smears. For other fungi, Gram's staining is distinctly suboptimal. For histopathology slides, Gomori methenamine silver and a neutral counterstain are preferred.

The method used has a marked effect on the rapidity and sensitivity of blood cultures for fungi except in the case of *Candida* species, which are relatively easy to grow. For most other fungi, concentration of the blood by lysis centrifugation and culture on solid medium constitute the optimal technique. Commercially available nucleic acid hybridization techniques can speed the identification of slow-growing molds, such as *Histoplasma capsulatum* and *Coccidioides immitis*. Serology has limited value, but testing of serum orCSF for cryptococcal antigen or antibody to *C. immitis* can be diagnostic. Detection of *Histoplasma* antigen in urine or serum is helpful in diagnosis and in following the results of treatment for disseminated histoplasmosis. Skin testing with fungal antigens is not useful in detecting active infection.

ANTIFUNGAL THERAPY

TOPICAL AGENTS

Imidazoles and Triazoles (See also "Systemic Antifungals," below) These synthetic compounds act by inhibiting ergosterol synthesis in the fungal cell wall and, when given topically, may cause direct damage to the fungal cytoplasmic membrane. The imidazoles available for cutaneous application include clotrimazole, econazole, ketoconazole, sulconazole, oxiconazole, and miconazole. Vaginal formulations include four imidazoles (miconazole, clotrimazole, tioconazole, and butoconazole) and one triazole (terconazole). As yet, no substantial differences in the efficacy of or local intolerance to the various topical azoles have become apparent. All are effective in the treatment of cutaneous candidiasis, tinea (pityriasis) versicolor, and mild to moderately severe ringworm of the glabrous skin. Vaginal formulations are effective for vulvovaginal candidiasis. Clotrimazole is poorly absorbed from the gastrointestinal tract, but the oral troche is useful as a topical treatment for oral and esophageal candidiasis.

Polyene Macrolide Antibiotics These broad-spectrum antifungal agents combine with sterol in the fungal cytoplasmic membrane, increasing membrane permeability.

Topically, they are not active against ringworm but are effective against candidiasis of the skin and mucous membranes. Nystatin and amphotericin B suspensions are effective in oral thrush, and vaginal troches are effective in vulvovaginal candidiasis. Both nystatin and amphotericin B are available in topical preparations for cutaneous candidiasis.

Other Topical Antifungals Ciclopirox olamine, haloprogin, terbinafine, and naftifine have the same clinical spectrum among the cutaneous mycoses as the imidazoles. Tolnaftate and undecylenic acid are effective against ringworm but not candidiasis. Keratolytic agents, such as salicylic acid, are helpful as accessory drugs for some hyperkeratotic skin lesions.

SYSTEMIC ANTIFUNGALS

Griseofulvin Griseofulvin is a useful drug in the treatment of certain kinds of ringworm; however, it is ineffective in the treatment of candidiasis. The microcrystalline and ultramicrocrystalline preparations differ in dose but not in efficacy. Absorption of both is enhanced when the drug is ingested with fat-containing foods. Griseofulvin interacts with phenobarbital and coumarin-type anticoagulants.

Terbinafine Oral terbinafine (250 mg once daily) is at least as effective as itraconazole and more effective than griseofulvin in onychomycosis and ringworm. Treatment duration ranges from 3 months for fingernails to 6 months for toenails. Gastrointestinal distress is the most common side effect. Rash, hepatitis, and pancytopenia have occurred, but serious adverse effects have been uncommon. Terbinafine decreases cyclosporine levels. Cimetidine increases and rifampin decreases terbinafine levels in blood.

Imidazoles and Triazoles

General Features The azole antifungals include imidazoles and triazoles. Fluconazole, itraconazole, and investigational azoles are all triazoles, so named because they have three nitrogens in the ring structure. This class has less impact on human hormonal synthesis and less hepatotoxicity than the only widely used systemic imidazole, ketoconazole. Itraconazole has many structural features in common with ketoconazole; however, it has a broader spectrum of activity and has largely replaced ketoconazole.

Reported interactions of itraconazole and fluconazole with other drugs are listed inTable 200-1. Ketoconazole interactions (not listed) appear to be the same as those listed for itraconazole. Azole interactions with any one class of drugs, such as benzodiazepines, HMG-CoA reductase inhibitors, or drugs that decrease gastric acidity, should be considered to apply to all drugs of that class until proven otherwise. Fluconazole differs substantially from itraconazole: unlike that of itraconazole, the absorption of fluconazole is independent of food or gastric acid, and fluconazole has much less effect on the hepatic metabolism of other drugs than does itraconazole. High fluconazole blood levels engendered by azotemia or by dosages above those used in pharmacologic studies may lead to new and profound drug interactions.

All azoles have the potential for embryotoxicity and teratogenicity. In fact, it seems likely

that azoles should not be given during pregnancy without a discussion of the serious risks and possible benefits with the mother. Four infants born to mothers taking at least 400 mg of fluconazole daily for coccidioidal meningitis have had severe bone, craniofacial, or cardiac abnormalities. Similarity of these abnormalities to those in pregnant animals given fluconazole suggests that fluconazole caused the defects.

Itraconazole Itraconazole is useful in the treatment of blastomycosis, histoplasmosis, candidiasis, coccidioidomycosis, sporotrichosis, pseudallescheriasis, onychomycosis, ringworm, tinea versicolor, and some cases of aspergillosis. Its efficacy in mycoses of the central nervous system has been modest at best. Almost no bioactive drug appears in urine. Itraconazole is metabolized in the liver, with the hydroxy metabolite accounting for at least half of the antifungal activity in serum. Food increases absorption of itraconazole capsules by about threefold but substantially reduces absorption of the cyclodextrin suspension. Ability of the suspension to exert a topical as well as a systemic effect probably accounts for its improved efficacy in oropharyngeal candidiasis. The usual dosage of either oral itraconazole formulation is 100 to 200 mg once daily for oropharyngeal and esophageal candidiasis. For deep infections, itraconazole capsules are given at an initial dosage of 600 to 800 mg daily for 3 days and a subsequent dosage of 200 to 400 mg once daily continued for 6 to 12 months. Itraconazole blood levels are helpful in documenting absorption of oral itraconazole when the drug is used for the treatment of deep mycoses. An intravenous formulation is commercially available and should be considered for initial therapy in hospitalized patients in whom itraconazole absorption may be suboptimal. Immunosuppressed patients with rapidly progressing pseudallescheriasis, an infection that does not respond to amphotericin B, are candidates for intravenous itraconazole treatment.

Fluconazole This triazole can be administered in tablet form, as a suspension, or as an intravenous infusion. With a half-life of about 31 h, fluconazole can be given once a day. Approximately 80% of the drug is excreted unchanged in the urine. Patients with creatinine clearance rates of 21 to 50 mL/min and 11 to 20 mL/min should have their fluconazole doses reduced by 50 and 75%, respectively. The drug penetrates the CSFand other body fluids very well.

Nausea and abdominal distress are the most common forms of dose-limiting fluconazole toxicity. An allergic rash may develop and is particularly common among patients infected with HIV. Fatal cases of Stevens-Johnson syndrome have been described in the HIV-infected population. Alopecia commonly follows prolonged administration of ³400 mg daily but resolves when therapy is discontinued. Rare cases of anaphylaxis, hepatic necrosis, and neutropenia have been described.

Fluconazole is useful in the treatment of oropharyngeal and esophageal candidiasis in adults. A single 150-mg tablet is effective in vulvovaginal candidiasis. Catheter-acquired candidemia in the immunocompetent host responds to 400 mg of fluconazole daily in conjunction with the removal of the infected catheter. Treatment should be continued for 10 to 14 days after the patient has become afebrile. Fluconazole is also effective in initial and maintenance therapy for cryptococcal meningitis in patients with AIDS, although most of these patients should initially receive a 2-week course of intravenous amphotericin B. Patients with coccidioidal meningitis can often be given fluconazole rather than intrathecal amphotericin B as maintenance therapy.

The incidence of deep candidiasis among recipients of allogeneic bone marrow transplants can be reduced by the administration of fluconazole (400 mg daily) for 75 days after initiation of the transplantation-preparative regimen. Prophylaxis in other neutropenic patients has not appeared useful. Fluconazole (200 mg daily) reduced the incidence of cryptococcosis and mucosal candidiasis among AIDS patients whose CD4+ cell counts were <200/uL and was particularly effective among those with counts of<50/uL. However, this regimen is not recommended because it does not reduce mortality, is expensive, and can lead to drug resistance.

Fluconazole is less effective than itraconazole in blastomycosis, histoplasmosis, and sporotrichosis. The drug is not active in aspergillosis or mucormycosis.

Amphotericin B A colloidal deoxycholate complex of the polyene drug amphotericin B is available for intravenous or intrathecal administration. In-line filters with a 0.22-um pore diameter may trap some of the colloid. The catabolism of amphotericin B is extremely slow and is not influenced by renal failure, hepatic failure, or hemodialysis. The drug's penetration intoCSF and vitreous humor is poor; however, the concentrations in pleural, peritoneal, and articular exudates are adequate for many mycoses. Histoplasmosis, blastomycosis, paracoccidioidomycosis, candidiasis, and cryptococcosis are the most responsive mycoses; coccidioidomycosis, extraarticular sporotrichosis, aspergillosis, and mucormycosis are less responsive; and chromoblastomycosis, mycetoma, and pseudallescheriasis respond little, if at all. The usual course is 0.5 to 0.7 mg/kg daily for 8 to 10 weeks. Infusions are generally given in 5% dextrose over 2 to 4 h.

Initial doses of amphotericin B occasionally cause marked febrile reactions that may be poorly tolerated by adult patients with limited cardiac or pulmonary function. It may be prudent to give such patients an initial 1-mg test dose followed by rapidly escalating doses, depending on tolerance. Premedication with aspirin or acetaminophen or the addition of hydrocortisone (25 mg) to the infusion decreases chills and fever. Azotemia during treatment is usual, the extent depending on the daily dose. Saline infusions have been advocated to reduce azotemia. Permanent loss of renal function is related to the total dose of amphotericin B; this condition is generally noted in adults who have received >3 g. Other side effects include anemia, hypokalemia, renal tubular acidosis, nausea, anorexia, weight loss, phlebitis, and occasionally hypomagnesemia. Intrathecal amphotericin B has been used in coccidioidal meningitis and refractory cryptococcal meningitis, although this therapy is associated with considerable toxicity.

Three lipid formulations of amphotericin B are commercially available in the United States: amphotericin B lipid complex (ABLC), amphotericin B colloidal dispersion (ABCD), and liposomal amphotericin B (L-AB). All cause less nephrotoxicity than the older amphotericin B deoxycholate complex (ABD). Acute, febrile infusion-related reactions occur with all three lipid formulations but are most severe with ABCD. The recommended duration for initial infusions of ABCD is 1 mg/kg per hour, somewhat slower than the 2-h duration of ABLC or L-AB infusions, with the intent of decreasing febrile reactions. Premedication with acetaminophen is also an option. Use of these remarkably expensive formulations should be confined to patients who cannot tolerate the nephrotoxicity of ABD. Although the lipid formulations are also approved for patients

failing to respond to ABD, there is no indication that these formulations are more effective than ABD for any mycosis.

Flucytosine Flucytosine (5-fluorocytosine) is a synthetic oral drug useful in cryptococcosis, candidiasis, and chromoblastomycosis. Within the fungal cell, flucytosine is converted to the antimetabolite 5-fluorouracil. Drug resistance appears rather rapidly when flucytosine is used alone. For this reason, the drug is generally used in combination with amphotericin B. The usual dose of flucytosine is 25 to 37.5 mg/kg every 6 h. Flucytosine is well absorbed from the gastrointestinal tract. The drug penetrates well into theCSF and is excreted unchanged in the urine. Even modest reductions in renal function may elevate flucytosine blood levels into the toxic range (³100 to 125 ug/mL). Elevated levels are associated with a significant incidence of neutropenia and thrombocytopenia and also seem to predispose to colitis, the other major toxic effect of this drug. Hepatotoxicity is idiosyncratic and uncommon. An allergic rash may develop.

201. HISTOPLASMOSIS - *John E. Bennett*

ETIOLOGIC AGENT

Histoplasma capsulatum is a dimorphic fungus that grows as a mold in nature or on Sabouraud's agar at room temperature. Hyphae bear both large and small spores, which are used for identification. Nucleic acid hybridization can also be used to identify the organism in culture. *H. capsulatum* grows as a small budding yeast in host tissue and on enriched agar, such as blood cysteine glucose, at 37°C. Despite its name, the fungus is unencapsulated. Coculture of isolates with opposite mating types can produce different sporulating structures in which genetic recombination occurs. When these structures, referred to as a *teleomorph* or the *perfect state*, are seen in culture, the name *Ajellomyces capsulatus* is used.

EPIDEMIOLOGY

Infection with *H. capsulatum* has been encountered in many areas of the world but is much more frequent in certain areas. Within the United States, infection is most common in the southeastern, mid-Atlantic, and central states. Endemicity is probably contingent on the availability of proper conditions in nature for growth of the fungus. *H. capsulatum* prefers moist surface soil, particularly soil enriched by droppings of certain birds and bats. The fungus has been isolated repeatedly from such sites, and many case clusters have occurred 5 to 18 days after the exposure of groups of people to dust while (for example) cleaning dirt-floored chicken coops; raking soil beneath bird-roosting sites; exploring caves; and cleaning, remodeling, or demolishing old buildings. Skin-test reactivity in many endemic areas indicates that³80% of residents over age 16 have been exposed.

PATHOGENESIS AND PATHOLOGY

Microconidia, or small spores, of *H. capsulatum* are small enough to reach the alveoli on inhalation and are transformed there to budding forms. With time, an intense granulomatous reaction occurs. Caseation necrosis or calcification may mimic tuberculosis. In children, the primary infection usually heals completely but may leave spotty calcification in the hilar nodes or lung. Transient dissemination may leave calcified granulomas in the spleen. In adults, a rounded mass of scar tissue, with or without central calcification, may remain in the lung. This mass has been called a *histoplasmoma*. Previous exposure is thought to confer some protection against reinfection, but infection in persons with prior positive skin tests clearly has occurred.

In a small proportion of patients, histoplasmosis becomes a progressive, potentially fatal infection. The disease occurs either as chronic fibrocavitary pneumonia or, less commonly, as disseminated infection. Patients with either form lack a history of acute primary pulmonary histoplasmosis. Chronic pulmonary infection favors otherwise healthy males over the age of 40. A history of cigarette use or the presence of emphysema is elicited from nearly all patients with chronic progressive pulmonary histoplasmosis. An acute, rapidly fatal disseminated infection is most likely to be encountered among young children and immunosuppressed patients, including those with AIDS. A more chronic but equally lethal disseminated infection is more common

among previously healthy adults.

CLINICAL MANIFESTATIONS

The vast majority of infections are either asymptomatic or mild, and the diagnosis is elusive. Cough, fever, malaise, and chest x-ray findings of hilar adenopathy with or without one or more areas of pneumonitis are typical features. Erythema nodosum and erythema multiforme have been reported in a few outbreaks. Hilar adenopathy may cause temporary compression of the right-middle-lobe bronchus in children and young adults. Subacute pericarditis may develop, probably by extension from contiguous lymph nodes. Rarely, hilar nodes undergo a caseous, granulomatous reaction with perinodal fibrosis. Mediastinal structures become encased by progressive fibrosis, and compression of the pulmonary veins, superior vena cava, pulmonary arteries, and esophagus may take place over many years. Late in mediastinal disease, only rare nonviable *Histoplasma* cells can be found in caseous residua of lymph nodes.

Chronic pulmonary histoplasmosis is characterized by a gradual onset (over weeks or months) of increasing productive cough, weight loss, and sometimes night sweats. Chest x-ray reveals uni- or bilateral fibronodular apical infiltrates. Approximately one-third of cases stabilize or improve spontaneously early in the course. The remainder progress insidiously. Retraction and cavitation of the upper lobes occur, with spread to the apex of the lower lobes and other areas of the lung. Emphysema and bulla formation further compromise pulmonary function. Death from cor pulmonale, bacterial pneumonia, or histoplasmosis occurs after months or years.

Acute disseminated histoplasmosis may be mistaken for miliary tuberculosis (Chap. 169). Common findings include fever, emaciation, hepatosplenomegaly, lymphadenopathy, jaundice, anemia, leukopenia, and thrombocytopenia. A high index of suspicion is necessary in patients with AIDS, in whose cases there may be other explanations for the abnormalities caused by disseminated histoplasmosis (Fig. 201-CD1). All these features may be noted in chronic dissemination as well, but chronic disease tends to be more localized. Indurated ulcers of the mouth, tongue, nose, or larynx are reported in about one-fourth of cases. Other focal findings include granulomatous hepatitis, Addison's disease, gastrointestinal ulceration, endocarditis, and chronic meningitis. Chest x-ray abnormalities are evident in half of cases and characteristically consist of discrete nodules or a miliary pattern.

Infection with *H. capsulatum var. duboisii* is rare outside of Africa. The yeast form is larger in tissue than that of *H. capsulatum var. capsulatum*. Clinical manifestations resemble those of blastomycosis more than those of histoplasmosis in that skin and bone lesions are very common.

DIAGNOSIS

Culture of the etiologic organism is the preferred method for diagnosis of histoplasmosis but is often difficult. Blood cultures are best done by the lysis-centrifugation technique, with plates held at 30°C for at least 2 weeks. Approximately 15 mL of blood should be cultured from adults. Routine blood cultures in broth are generally unsuitable. Cultures of bone marrow, mucosal lesions, liver, and bronchoalveolar lavage fluid are

diagnostically useful in disseminated histoplasmosis. Sputum culture is the preferred method for the diagnosis of chronic pulmonary histoplasmosis. However, growth may require 2 to 4 weeks to become visible, and other organisms may overgrow the plate. Diagnosis based on Giemsa-stained smears of blood or bronchoalveolar lavage fluid or on methenamine silver staining of infected lung, bone marrow, lymph node, or mucosal lesions requires considerable expertise, although these techniques yield results rapidly and provide specimens that can easily be sent to a referral laboratory. Organisms may be very scanty in lesions with marked caseous necrosis. An assay for *Histoplasma* antigen in blood or urine is commercially available and is useful both for diagnosis and for monitoring of the response to therapy in patients with AIDS who have disseminated infection. Diagnosis by antigen detection requires confirmation by culture or histopathology because false-positive results have occasionally been obtained. Tests for antibody to *H. capsulatum* have been of limited value in diagnosis. Histoplasmin skin testing has proven useful in epidemiologic studies but not in clinical diagnosis. Neither skin testing nor serology has been predictive of histoplasmosis in patients infected with HIV.

TREATMENT

Acute pulmonary histoplasmosis requires no therapy. Oral itraconazole (200 mg/d) can be given to shorten the course of illness, although this effect has not been proven. Patients with mediastinal fibrosis may benefit from surgery, but their ultimate prognosis is poor. All patients with disseminated or chronic fibronodular pulmonary histoplasmosis should receive chemotherapy. Intravenous amphotericin B (0.6 mg/kg daily) is the drug of choice for the initial treatment of patients with disseminated histoplasmosis who are severely ill or immunosuppressed or whose infection involves the central nervous system; the regimen can be changed to itraconazole (200 mg twice daily) once clinical improvement is evident in these patients. Measuring itraconazole trough blood levels should be considered in those patients (e.g., patients with AIDS) who may not be absorbing the drug well (Chap. 200). Itraconazole suspension, taken fasting, is better absorbed than the capsule formulation. Fluconazole is reliably absorbed, even in patients taking drugs to block gastric acid secretion, but at doses up to 400 mg/d has been less effective in treatment of chronic pulmonary or disseminated histoplasmosis. Patients with AIDS whose disseminated histoplasmosis has responded to 10 weeks of therapy should receive itraconazole (200 mg/d) for life to prevent relapse. It remains unknown whether patients with a sustained response to highly active antiretroviral therapy can discontinue maintenance therapy with itraconazole.

Immunocompetent patients can initially be given itraconazole (200 mg twice daily) and are generally treated for 6 to 12 months. Ketoconazole (400 to 800 mg once daily) can be used instead of itraconazole for the treatment of immunocompetent patients without central nervous system disease when the lower cost is more important than the higher incidence of side effects. Alternatively, immunocompetent patients can be given a 10-week course of amphotericin B (0.5 mg/kg daily).

Long-term maintenance therapy with an azole is not recommended for patients other than those with AIDS. However, relapse of chronic pulmonary and disseminated histoplasmosis is not rare and warrants careful follow-up for 1 year after therapy.

Back to Table of Contents

202. COCCIDIOIDOMYCOSIS - *John E. Bennett*

ETIOLOGIC AGENT

Coccidioides immitis has two forms, growing as a white fluffy mold on most culture media but as a nonbudding spherical form (a spherule) in host tissue or under special conditions. The organism reproduces in host tissue by forming small endospores within mature spherules. After rupture of the spherule, the released endospores enlarge, become spherules, and repeat the cycle. The fungus is identified by its appearance and by the formation of thick-walled, barrel-shaped spores, called *arthrospores*, in the hyphae of the mold form.

EPIDEMIOLOGY, PATHOGENESIS, AND PATHOLOGY

C. immitis is a soil saprophyte found in certain arid regions of the United States, Mexico, Central America, and South America. Within the United States, most cases of infection with *C. immitis* are acquired in California, Arizona, and western Texas. A few cases are acquired by exposure to fomites from endemic areas (e.g., in cotton bales).

Infection in humans and animals results from inhalation of wind-borne arthrospores from soil sites. This primary pulmonary infection is symptomatic in only 40% of cases, with symptoms ranging from a mild influenza-like illness to severe pneumonia. Mild self-limited infections may come to medical attention because of case clusters or hypersensitivity reactions: erythema nodosum, erythema multiforme, toxic erythema, arthralgia, arthritis, conjunctivitis, or episcleritis. Case clusters occur 10 to 14 days after a group of susceptible individuals is exposed to dust in an endemic area through such activities as archaeologic excavation, rock hunting, military maneuvers, or construction work. Windstorms can carry spores to adjacent nonendemic areas and cause case clusters. The usual course of primary pneumonia is complete healing, although an area of pneumonitis (detected on radiographs) may heal by the formation of a coinlike lesion called a *coccidioidoma*. Less commonly, a single thin-walled cavity remains as a chronic sequela in the area of consolidation. Alternatively, an area of consolidation may persist as chronic pneumonia or progress to fibronodular cavitary disease.

Pleural effusion may be the only manifestation of primary infection. Spontaneous healing of this form is common.

An uncommon but dreaded complication of coccidioidomycosis is dissemination beyond the lung and hilar lymph nodes. Dissemination is especially frequent among blacks, Filipinos, Native Americans, Mexican-Americans, pregnant women, and immunosuppressed patients, including those with AIDS.

C. immitis incites a chronic granulomatous reaction in host tissue, often with caseation necrosis. Lung and hilar node lesions may show calcification. Both IgM and IgG antibodies to *C. immitis* are induced by infection, but neither type of antibody appears to be protective. The amount of specific IgG antibody is a rough measure of the antigenic mass (i.e., of the intensity of infection), and a high titer is a poor prognostic sign. Appearance of delayed hypersensitivity to antigens of *C. immitis* is most common in clinical forms of disease with a good prognosis, such as self-limited primary pulmonary

disease. In skin tests for *Coccidioides* antigens, about half of patients with disseminated disease have negative results that portend a poor outcome.

CLINICAL MANIFESTATIONS

Symptomatic primary pulmonary infection is manifested by fever, cough, chest pain, malaise, and sometimes the hypersensitivity reactions listed above. Chest radiographs may show an infiltrate, hilar adenopathy, or pleural effusion. Mild peripheral-blood eosinophilia may be found. Spontaneous improvement begins after several days to 2 weeks of illness and usually culminates in complete recovery.

The symptoms of a chronic thin-walled cavity include cough or hemoptysis in half of cases; the other half are asymptomatic. Chronic progressive pulmonary coccidioidomycosis causes cough, sputum production, variable degrees of fever, and weight loss. The first indications of dissemination usually appear during primary infection. Reactivation with dissemination in later years occurs occasionally, especially if Hodgkin's disease, non-Hodgkin's lymphoma, renal transplantation, AIDS, or immunosuppression of some other etiology has supervened. Dissemination should be suspected when fever, malaise, hilar or paratracheal lymphadenopathy, elevated sedimentation rate, and high complement fixation titers signal abnormal persistence in patients with primary pulmonary coccidioidomycosis. With time, lesions appear in the bone, skin, subcutaneous tissue, meninges, joints, and other sites. Chronic meningitis presents as headache of indolent onset, with or without other signs of disseminated coccidioidomycosis. Cultures and smears of cerebrospinal fluid (CSF) are most often negative, but antibody is usually detectable in CSF by complement fixation. Skin lesions are indolent and maculopapular; soft tissue and bony lesions contain pus and may present as a draining sinus. Without treatment, disseminated coccidioidomycosis progresses to death over weeks to years.

Disseminated coccidioidomycosis can progress rapidly in patients with advanced HIV infection. Fever with skin or bone lesions may be the first sign. Those who present with diffuse pulmonary infiltrates have a poor prognosis. Blood cultures are positive late in the disease, if at all.

DIAGNOSIS

When coccidioidomycosis is suspected, sputum, urine, and pus should be examined for *C. immitis* by wet smear and culture. *The laboratory request should indicate clearly that coccidioidomycosis is suspected, because the mold form must be handled with extreme care to prevent infection of laboratory personnel.* On biopsy, smaller spherules must be distinguished from nonbudding forms of *Blastomyces* and *Cryptococcus*, but the appearance of the mature spherule is diagnostic.

Serologic tests are very helpful in the diagnosis of coccidioidomycosis. Latex agglutination and agar gel diffusion tests are useful in screening sera for antibody to *Coccidioides*. The complement fixation test is used forCSFdeterminations and for the confirmation and quantitation of serum antibody detected by screening tests. The number of cases with a positive complement fixation test depends on the severity of disease and on the laboratory performing the test. Positive tests are least common

among patients with solitary pulmonary cavities or primary pulmonary infection, while sera from patients with disseminated disease in multiple organs are nearly all positive. Seroconversion is helpful in primary pulmonary coccidioidomycosis but may not occur for up to 8 weeks after onset. A positive complement fixation test of unconcentrated CSF is diagnostic of meningitis. Rarely, a parameningeal focus causes a positive complement fixation test of CSF.

Conversion of the skin test from negative to positive (³5 mm of induration at 24 or 48 h) with spherulin may take place between days 3 and 21 of symptoms in primary pulmonary coccidioidomycosis. Skin testing can be helpful in epidemiologic studies, such as investigations of case clusters or the definition of endemic areas. The utility of skin testing as a diagnostic tool is limited by the persistence of positive tests resulting from remote exposures to *Coccidioides* and by the frequency of negative skin tests among patients with either thin-walled cavities or disseminated coccidioidomycosis. A positive skin test has not predicted dissemination in HIV-infected patients. The presence of complement-fixing antibody to *C. immitis* in AIDS patients should prompt a search for active infection.

TREATMENT

Primary pulmonary coccidioidomycosis usually resolves spontaneously. Some physicians give a few weeks of treatment with intravenous amphotericin B or itraconazole to patients with unusually severe or protracted primary infection in the hope of aborting disseminated or chronic pulmonary disease.

Patients with severe or rapidly progressing disseminated coccidioidomycosis are first given intravenous amphotericin B at a dose of 0.5 to 0.7 mg/kg daily. Patients whose condition improves after 2 to 3 months of treatment with amphotericin B or who have more indolent disseminated infection are given itraconazole (200 mg twice daily) or fluconazole (400 to 600 mg/d). These oral agents are useful for long-term suppression of infection, and treatment should be continued for years. Patients with coccidioidal meningitis usually are initially given fluconazole (400 to 800 mg/d) but may require intrathecal amphotericin B. Hydrocephalus is a frequent complication of uncontrolled meningitis. Surgical debridement of bone lesions or drainage of abscesses can be helpful. The prognosis for ultimate cure of disseminated coccidioidomycosis is guarded.

Resection of chronic progressive pulmonary lesions is a helpful adjunct to chemotherapy when infection is confined to the lung and to one lobe. A single thin-walled cavity tends to close spontaneously and ordinarily is not resected. Such a cavity responds poorly to chemotherapy.

(Bibliography omitted in Palm version)

Back to Table of Contents

203. BLASTOMYCOSIS - *John E. Bennett*

ETIOLOGIC AGENT

Blastomyces dermatitidis is a dimorphic fungus that grows at room temperature as a white or tan mold but grows within the host or at 37°C as budding, round yeastlike cells. The fungus can be identified on the basis of its appearance, its dimorphism, the small spores borne on hyphae of the mold form, or the results of nucleic acid hybridization. When isolates of the two opposite mating types are grown close together on special culture medium, such as yeast extract or soil extract agar, sporulating structures that characterize the perfect state (teleomorph), called *Ajellomyces dermatitidis*, appear.

EPIDEMIOLOGY

The infection is restricted by geography and age. Blastomycosis is uncommon in any locality, but most cases occur in the southeastern, central, and mid-Atlantic areas of the United States, with occasional cases in other localities in the United States and Canada. Cases have also been encountered in Africa, Mexico, Central America, and (rarely) South America. Most patients are between 20 and 69 years old. The male-to-female ratio is about 10:1. There is no occupational predisposition to the development of blastomycosis.

PATHOGENESIS AND PATHOLOGY

Infection with *B. dermatitidis* appears to be acquired by inhalation of the fungus from soil, decomposed vegetation, or rotting wood. Several case clusters have resulted from participation in recreational activities in wooded areas along waterways. Infection is not transmissible from person to person. The initial pulmonary infection may either heal spontaneously or become chronic. Spread to other portions of the lung, cavitation, or endobronchial lesions may be found in patients with chronic disease. Whether or not the lung lesion resolves spontaneously, infection commonly spreads hematogenously to the skin, subcutaneous tissue, bone, prostate, epididymis, or mucosa of the nose, mouth, or larynx. Less commonly, infection spreads to the brain, meninges, liver, lymph nodes, or spleen. Dissemination may not be evident for weeks or years after the appearance of the lung lesion. Progressive infection is only rarely attributable to an underlying disease, to HIV infection, or to immunosuppressive treatment. The inflammatory response includes lymphocytes, giant cells, and neutrophils. Pseudoepitheliomatous hyperplasia may be striking and may lead to a mistaken diagnosis of squamous cell carcinoma.

CLINICAL MANIFESTATIONS

A few patients have acute, self-limited pneumonia. Fever, productive cough, myalgia, and malaise usually resolve within a month. Pulmonary infiltrates clear slowly as *B. dermatitidis* disappears from the sputum.

In the vast majority of patients, blastomycosis has an indolent onset and a chronically progressive course. Fever, cough, weight loss, lassitude, skin lesions, and chest ache are common. Skin lesions favor exposed areas and enlarge over many weeks from pimples to well-circumscribed, verrucous, crusted, or ulcerated lesions (Fig. 203-CD1).

Pain and regional lymphadenopathy are minimal. Large chronic lesions may undergo central healing with scarring and contracture. Mucous membrane lesions resemble squamous cell carcinoma. Chest x-ray findings are abnormal in two-thirds of patients, with one or more pneumonic or nodular infiltrates. Calcification, hilar adenopathy, and large pleural effusions are rare. Osteolytic lesions may be found in nearly any bone and present as a cold abscess or a draining sinus. Extension to a contiguous joint may cause indolent swelling, pain, and restricted motion. Prostatic and epididymal lesions clinically resemble those of tuberculosis.

DIAGNOSIS

The diagnosis of blastomycosis is made by demonstration of the fungus in a culture of sputum, pus, or urine. An expert can diagnose blastomycosis on the basis of the appearance of the organism in wet smear or histopathologic section. The fungus may be visible in a sputum cytology smear but is easily overlooked.

TREATMENT

A few patients have developed only transitory lung lesions, but no guidelines are known to distinguish these patients from those whose disease will progress locally or disseminate. Therefore, every patient should receive treatment. Intravenous amphotericin B is the drug of choice for patients with rapidly progressive infections, severe illness, or central nervous system lesions. Skin and noncavitary lung lesions should be treated for about 8 to 10 weeks. The recommended total dose for an adult is about 2 g. Cavitary lung disease or infection extending beyond the lung and skin should be treated for about 10 to 12 weeks with ³2.5 g.

Oral itraconazole (200 mg twice daily with food) is the drug of choice for the treatment of patients who have indolent nonmeningeal blastomycosis of mild to moderate severity and who take the drug reliably. Therapy with itraconazole is continued for 6 to 12 months.

The mortality rate in appropriately treated cases is£15%.

(Bibliography omitted in Palm version)

Back to Table of Contents

204. CRYPTOCOCCOSIS - *John E. Bennett*

ETIOLOGIC AGENT

Cryptococcosis is an infection caused by the yeastlike fungus *Cryptococcus neoformans*. This fungus reproduces by budding and forms round, yeastlike cells. Within the host and on certain culture media, a large polysaccharide capsule surrounds each yeast cell. The fungus grows well in smooth, creamy-white colonies on Sabouraud's or other simple media at 20 to 37°C. Identification of the organism is based on gross and microscopic appearance, biochemical test results, and growth at 37°C. The results of nucleic acid hybridization or the formation of brown pigment on Niger seed agar can also be used for identification.

The fungus has four capsular serotypes, designated A, B, C, and D. There are also two mating types. Coculture of opposite mating types creates a transient diploid state called *Filobasidiella neoformans* var. neoformans for serotypes A and D and *F. neoformans* var. bacillispora for serotypes B and C. Organisms not cultured under mating conditions are designated *C. neoformans* var. neoformans for serotypes A and D and *C. neoformans* var. gattii for serotypes B and C; a simple color medium distinguishes the two varieties.

EPIDEMIOLOGY

Weathered pigeon droppings commonly contain serotype A or D (*C. neoformans* var. *neoformans*). *C. neoformans* var. *gattii* has been isolated from the litter around trees of the species *Eucalyptus camaldulensis* and *E. tereticornis*. Eucalyptus isolates have so far typed as serotype B. The distribution of these eucalyptus species in Australia corresponds to the distribution of infections due to *C. neoformans* var. *gattii* in that country. The high prevalence of these trees in other subtropical climates has been postulated to explain the relative restriction of such infections to warm climates.

Cryptococcosis due to *C. neoformans* var. *neoformans* is a common complication of late infection with HIV. The incidence appears to be declining in some areas of the United States, probably as a result of highly active antiretroviral therapy and use of fluconazole for oropharyngeal candidiasis. Patients who have undergone solid-organ transplantation or glucocorticoid therapy and those with sarcoidosis are also at increased risk for infections with *C. neoformans* var. *neoformans*. Almost all such infections are caused by serotype A, although serotype D occurs in up to 20% of cases in Western Europe. Infections with var. *gattii* have been rare among AIDS patients and other immunocompromised patients, even in subtropical climates, where var. *gattii* infection occurs in previously healthy individuals.

Animals, particularly cats, can acquire cryptococcosis but have not transmitted the infection to other animals or to humans. The source from which humans acquire the infection is unknown, with the rare exception of cases acquired through a transplanted cornea, kidney, or other solid organ. Cryptococcosis is rare before puberty.

PATHOGENESIS AND PATHOLOGY

Infection is thought to be acquired by inhalation of fungus into the lungs. Pulmonary infection has a tendency toward spontaneous resolution and is frequently asymptomatic. Silent hematogenous spread to the brain leads to clusters of cryptococci in the perivascular areas of cortical gray matter, in the basal ganglia, and, to a lesser extent, in other areas of the central nervous system. The inflammatory response around these foci is usually scant. In the more chronic cases, a dense basilar arachnoiditis is typical. Lung lesions are characterized by intense granulomatous inflammation. Cryptococci are best seen in tissue by staining with methenamine silver or periodic acid-Schiff. Although a strongly positive result on mucicarmine staining of tissue is diagnostic, staining varies from intense to absent.

CLINICAL MANIFESTATIONS

Most patients have *meningoencephalitis* at the time of diagnosis. This form of the infection is invariably fatal without appropriate therapy; death occurs any time from 2 weeks to several years after the onset of symptoms. Early manifestations include headache, nausea, staggering gait, dementia, irritability, confusion, and blurred vision. Both fever and nuchal rigidity are often mild or lacking. Papilledema is evident in one-third of cases at the time of diagnosis. Cranial nerve palsies, typically asymmetric, occur in about one-fourth of cases. Other lateralized signs are rare. With progression of the infection, deepening coma and signs of brainstem compression appear. Autopsy often reveals cerebral edema in more acute cases and hydrocephalus in more chronic cases.

Pulmonary cryptococcosis causes chest pain in about 40% of patients and cough in 20%. The chest x-ray shows one or more dense infiltrates, which are often well circumscribed. Cavitation, pleural effusions, and hilar adenopathy are infrequent. Calcification is not evident, and fibrotic stranding is rarely noticeable.

Ten percent of patients with cryptococcosis have skin lesions, and the vast majority of patients with skin lesions have disseminated infection (Fig. 204-CD1). One or a few asymptomatic tiny papular lesions appear and slowly enlarge; they display a tendency toward central softening leading to ulceration. Osteolytic lesions occur in 4% of cases and usually present as a cold abscess. Rare manifestations of cryptococcosis include prostatitis, endophthalmitis, hepatitis, pericarditis, endocarditis, and renal abscess.

DIAGNOSIS

Fever and headache in a patient with AIDS or with risk factors forHIVinfection suggest the possibility of cryptococcosis, toxoplasmosis, or central nervous system lymphoma. Evidence of a focal lesion on magnetic resonance imaging is unusual in cryptococcosis. Most cryptococcal cerebral mass lesions occur in patients infected with *C. neoformans* var. *gattii* who also have meningitis. In patients without AIDS, meningitis due to *C. neoformans* resembles that due to *Mycobacterium tuberculosis*, *Histoplasma capsulatum*, *Coccidioides immitis*, or metastatic cancer. Lumbar puncture is the single most useful diagnostic test. An india ink smear of centrifuged cerebrospinal fluid (CSF) sediment reveals encapsulated yeast in more than half of cases, although artifacts can cause confusion. In patients without AIDS, levels of glucose in CSF are reduced in half of all cases; protein levels are usually increased; and lymphocytic pleocytosis is usually

found. CSF abnormalities are less pronounced in patients with AIDS, although india ink smear is more often positive.

Approximately 90% of patients with cryptococcal meningoencephalitis, including all those with a positiveCSFsmear, have capsular antigen detectable in CSF or serum by latex agglutination. An enzyme immunoassay for cryptococcal antigen is also available. Occasional false-positive results in the above tests make culture the definitive diagnostic test and have prevented serum antigen from being a useful screening test in asymptomatic patients with AIDS. *C. neoformans* is often present in urine from patients with meningoencephalitis. Fungemia occurs in 10 to 30% of patients and is particularly common among patients with AIDS.

Pulmonary cryptococcosis mimics malignancy with regard to radiographic findings and symptoms. Sputum culture is positive in only 10% of cases, and serum antigen tests are positive in only one-third. Occasionally, *C. neoformans* appears in one or more sputum specimens as an endobronchial saprophyte. Biopsy is usually required for diagnosis.

Cutaneous cryptococcosis may be mistaken for a comedo, basal cell carcinoma, or sarcoidosis. In patients with AIDS, skin lesions may be numerous and are sometimes mistaken for molluscum contagiosum. Biopsy reveals myriad cryptococci. Osseous cryptococcosis resembles tuberculosis.

TREATMENT

Patients with AIDS and cryptococcosis are treated initially with intravenous amphotericin B (0.7 mg/kg daily) for at least 2 weeks and until their clinical condition is stable; thereafter, they receive fluconazole. The addition of flucytosine (25 mg/kg every 6 h) to amphotericin B for 2 weeks has minimal impact on morbidity and mortality. After treatment with amphotericin B, fluconazole (400 mg) is given once daily. Daily doses of 800 mg have been used with marginal changes in toxicity or efficacy. The addition of flucytosine to fluconazole increases gastrointestinal intolerance. After infection is controlled, treatment with a smaller dose of fluconazole (200 mg/d) is continued indefinitely. Itraconazole is less effective than fluconazole for maintenance therapy. It is not yet known whether patients whose CD4+ T lymphocyte counts have exhibited a sustained rise in response to antiretroviral therapy can safely discontinue fluconazole maintenance therapy.

In patients without AIDS, the therapeutic goal is to cure the infection, not merely to control its symptoms. A single intensive course is given until cultures from all previously positive sites (particularlyCSF) become convincingly negative. Normalization of the glucose level in lumbar CSF is desirable, but complete clearing of CSF or serum antigen during therapy is not essential. Amphotericin B (0.6 to 0.7 mg/kg daily for^{3}10 weeks) is the best-studied regimen. Flucytosine has been added to amphotericin B to accelerate the culture response, but grave toxicity can result unless flucytosine blood levels are kept below 100 ug/mL. Case reports have described patients without HIV infection who have responded to fluconazole or liposomal amphotericin B, but the dose and duration of treatment required to cure cryptococcal meningitis are undefined. Amphotericin B lipid complex and amphotericin B colloidal dispersion are not recommended pending further study.

Hydrocephalus may be the presenting manifestation or a later complication of cryptococcosis. Blindness, dementia, and personality change are among the other sequelae. Daily lumbar puncture orCSFshunting has been advocated -- in the hope of averting permanent blindness -- for patients with marked cerebral edema who have incipient blurred vision.

Patients with extraneural cryptococcosis most often require treatment with intravenous amphotericin B, with or without flucytosine. Observation or excision of lesions may suffice for some patients who have previously been healthy; who have a single focus in lung, skin, or bone; and who have no cryptococci in CSF, urine, or blood.

PREVENTION

Fluconazole (200 mg/d) has been shown to decrease the incidence of cryptococcosis in HIV-infected patients with CD4+ cell counts of<200/uL and particularly in those with counts of<50/uL. Weekly fluconazole has not provided this protection. Daily fluconazole has not conferred a survival advantage; in light of its cost and the currently low incidence of cryptococcosis in patients with AIDS in the United States, prophylaxis is strongly discouraged.

205. CANDIDIASIS - *John E. Bennett*

ETIOLOGIC AGENTS

Candida albicans is the most common cause of mucosal candidiasis and is responsible for about half of all cases of candidemia in hospitalized patients. A small proportion of *C. albicans* isolates have been transferred to a new species, *C. dubliniensis*. *C. tropicalis*, *C. parapsilosis*, *C. guilliermondii*, *C. glabrata* (formerly *Torulopsis glabrata*), *C. krusei*, and a few other *Candida* species also cause potentially fatal bloodstream infection. Many of these non-*albicans* species can enter the bloodstream through an intravascular catheter. *Candida* species, taken together, are the fifth most common cause of nosocomial bloodstream infections in the United States.

All *Candida* species pathogenic for humans are also encountered as commensals of humans, particularly in the mouth, stool, and vagina. These species grow rapidly at 25° to 37°C on simple media as oval, budding cells. In special culture media and in tissue, hyphae or elongated branching structures called *pseudohyphae* are formed. *C. glabrata* differs from other members of the genus in that it forms no true hyphae or pseudohyphae in vitro or in infected tissue. *C. albicans* and *C. dubliniensis* can be identified presumptively by their ability to form germ tubes in serum or by the formation of thick-walled large spores called *chlamydospores*. Final identification of all *Candida* species requires biochemical tests.

PATHOGENESIS

Candidiasis is often preceded by increased colonization of the mouth, vagina, and stool with *Candida* due to broad-spectrum antibiotic therapy. Additional local and systemic factors favor infection. Oropharyngeal thrush is particularly likely to occur in neonates and in patients with diabetes mellitus, HIV infection, or dentures. Vulvovaginal candidiasis (Chap. 132) is especially common in the third trimester of pregnancy. *Candida* from the perineum can enter the urinary tract via an indwelling bladder catheter. Cutaneous candidiasis most often involves macerated skin, such as that in the diapered area of infants, under pendulous breasts, or on hands constantly in water or covered by occlusive gloves. *Candida* can pass from the colonized surface into deep tissue when the integrity of the mucosa or skin is violated, as, for example, by perforation of the gastrointestinal tract through trauma, surgery, or peptic ulceration or by mucosal damage due to cytotoxic agents used for cancer chemotherapy. Although *Candida* is not normally a resident of the skin, secretions from the mouth, rectum, or vagina as well as drainage from surgical wounds or tracheostomy sites can contaminate the hub or skin site of a catheter in an umbilical or central vein. Intravenous drug abuse or third-degree burns can also provide a skin portal for *Candida* that can lead to deep candidiasis. Once *Candida* has passed the integumentary barrier, very low birth weight (in neonates) and neutropenia or glucocorticoid therapy (in any patient) markedly compromise host defense. Hematogenous seeding is particularly evident in the retina, kidney, spleen, and liver.

CLINICAL MANIFESTATIONS

Oral thrush (Figs. 205-CD1 and205-CD2) presents as discrete and confluent adherent

white plaques on the oral and pharyngeal mucosa, particularly in the mouth and on the tongue. These lesions are usually painless, but fissuring at the corners of the mouth can be painful. Unexplained oropharyngeal thrush raises the possibility of HIV infection. Oral thrush is common in acute HIV infection and becomes increasingly common as the CD4+ cell count falls. At CD4+ counts <50/uL, esophageal thrush also becomes common. HIV infection appears not to be an independent risk factor for vulvovaginal thrush.

Cutaneous candidiasis (Figs. 205-CD3,205-CD4, and205-CD5) presents as red macerated intertriginous areas, paronychia, balanitis (Fig. 205-CD6), or pruritus ani. Candidiasis of the perineal and scrotal skin may be accompanied by discrete pustular lesions on the inner aspects of the thighs. *Chronic mucocutaneous candidiasis* or *candidal granuloma* typically presents as circumscribed hyperkeratotic skin lesions, crumbling dystrophic nails, partial alopecia in areas of scalp lesions, and both oral and vaginal thrush. Systemic infection is very rare, but disfigurement of the face and hands can be severe. Other findings may include chronic epidermophytosis, dental dysplasia, and hypofunction of the parathyroid, adrenal, or thyroid gland. A variety of defects in T cell function have been described in these patients. Vulvovaginal thrush (Chap. 132, Fig 205-CD7) causes pruritus, discharge, and sometimes pain on intercourse or urination. Speculum examination reveals an inflamed mucosa and a thin exudate, often with white curds.

Esophageal candidiasis is often asymptomatic but can cause substernal pain or a sense of obstruction on swallowing. Most lesions are in the distal third of the esophagus and appear on endoscopy as areas of redness and edema, focal white patches, or ulcers. Biopsy or brushing is required for diagnosis and for detection of concomitant infections, particularly herpes simplex in patients with hematologic malignancies and cytomegalovirus infection in AIDS patients. Esophagography (barium swallow) is diagnostically insensitive but may reveal spasm or mucosal irregularities. *Candida* esophagitis can cause bleeding and impaired alimentation. Hematogenous dissemination from the esophagus probably occurs in some neutropenic patients but is rarely reported in HIV-infected patients.

Candida can cause cystitis, pyelitis, or renal papillary necrosis in an obstructed urinary tract. When a colonized urinary tract is operated on or instrumented, candidemia may result. However, most patients with *Candida* cultured from the urine simply have bladder colonization from a Foley catheter or a sizable volume of residual urine. Contamination of a voided midstream specimen by vaginal *Candida* is also common.

Candidemia originating from an intravascular catheter may clear in the immunocompetent patient when the catheter is removed. Focal seeding of the retina can take place even if candidemia clears and the patient becomes afebrile. Unilateral or bilateral small white retinal exudates appear within 2 weeks of the onset of candidemia. Lesions may regress spontaneously or enlarge slowly. The vitreous humor becomes cloudy, and the patient notices blurring, ocular pain, or a scotoma. Retinal detachment, vitreous abscess, and extension to the anterior chamber can occur over the ensuing weeks. These retinal lesions, present in ~10% of nonneutropenic patients with candidemia, are the principal reason that systemic antifungal therapy is recommended for all patients with candidemia. Funduscopy should be performed to be certain that

retinal lesions, if present, resolve completely. Most cases with ocular involvement have occurred in nonneutropenic patients. In contrast, so-called hepatosplenic candidiasis is usually recognized in patients with acute leukemia who are recovering from profound neutropenia. This entity, better called *chronic disseminated candidiasis*, originates from intestinal seeding of the portal and venous circulation. Fever, modestly elevated serum concentrations of alkaline phosphatase, and multiple small abscesses evident on ultrasonography, magnetic resonance imaging, or computed tomography of the liver, spleen, or kidney suggest the diagnosis. During acute candidemia in neutropenic patients, small erythematous papules may appear anywhere on the skin (Plate IID-57D,Fig. 205-CD8). If the patient does not expire promptly from disseminated candidiasis, the lesions will develop a necrotic center. Painful muscle lesions may also be found. Punch biopsy of a skin lesion helps distinguish this extremely grave condition from *Malassezia* folliculitis, a similar-appearing but benign condition that can involve the cape area of the chest or the extremities of a sweaty febrile patient.

Hematogenous seeding in the neutropenic patient is occasionally visible radiologically as tiny pulmonary nodules. *Candida* pneumonia, apart from hematogenous candidiasis, is very rare. Organisms seeding a native or prosthetic cardiac valve originate principally from central venous catheters; occasionally, valvular seeding is encountered in intravenous drug abusers. Emboli to large arteries, such as the iliac or femoral artery, are characteristic. Intravenous injection of impure brown heroin has caused a clinical syndrome consisting of *Candida* endophthalmitis and purulent folliculitis, sometimes accompanied by vertebral osteomyelitis. This diffuse folliculitis favors hairy areas, including the scalp and bearded facial skin.

Candida can cause indolent arthritis, most commonly of the knee, in patients who have received glucocorticoid injections into the joint, in patients who are immunosuppressed, and in low-birth-weight neonates. Prosthetic joints may become infected during implantation. Scanty growth of *Candida* from joint fluid can cause the laboratory to incorrectly dismiss the organism as a contaminant.

Hematogenous dissemination can lead to brain abscess or chronic meningitis. Diagnosis of infections of ventriculoperitoneal shunts is difficult because symptoms are indolent and cultures of lumbar fluid are usually sterile.

DIAGNOSIS

Demonstration of pseudohyphae on wet smear with confirmation by culture is the procedure of choice for diagnosing superficial candidiasis (Fig. 205-CD9). Scrapings for the smear may be obtained from skin, nails, and oral and vaginal mucosa. Culture alone is not diagnostic; however, recovery of *Candida* species from multiple superficial sites in immunosuppressed patients may portend visceral invasion.

Deeper lesions due to *Candida* may be diagnosed by histologic section of biopsy specimens or by culture of cerebrospinal fluid, blood, joint fluid, or surgical specimens. Blood cultures are useful in the diagnosis of *Candida* endocarditis and intravenous catheter-induced sepsis but are positive less often in other forms of disseminated disease. Serologic tests for antibody or antigen are not useful.

TREATMENT

Cutaneous candidiasis of macerated areas responds to measures that reduce moisture and chafing plus topical application of an antifungal agent in a nonocclusive base. Nystatin powder or a cream containing ciclopirox or an azole is useful. Clotrimazole, miconazole, econazole, ketoconazole, sulconazole, and oxiconazole are available as creams or lotions. *Candida* vulvovaginitis responds better to an azole than to nystatin suppositories. There is little difference in efficacy among miconazole, clotrimazole, tioconazole, butoconazole, and terconazole vaginal formulations. Systemic treatment of *Candida* vulvovaginitis with a single 150-mg capsule of fluconazole is more convenient than topical treatment but also poses a higher risk of adverse effects. Clotrimazole troches, used five times a day, are more effective in oral and esophageal candidiasis than nystatin suspension. Oral fluconazole (100 to 200 mg once daily) is more convenient and more effective in esophagitis than clotrimazole troches. Esophagitis not responding to fluconazole may warrant repeat endoscopy to exclude other conditions. Itraconazole suspension (100 to 200 mg/d) alleviates *Candida* esophagitis in some patients in whom fluconazole treatment fails. Amphotericin B suspension has limited use but can be tried in patients whose oropharyngeal candidiasis does not respond to azoles.

Management of recurrent oropharyngeal candidiasis in the HIV-infected patient presents special problems. Patients with CD4+ cell counts <100/uL who have received prolonged fluconazole therapy are at risk of developing azole resistance, requiring an increased dose to mount a response, relapsing early, and eventually failing to respond well to any dose of fluconazole. The increasing azole resistance in this population suggests that HIV-infected patients with oropharyngeal candidiasis should be treated for each individual episode and that only when episodes become intolerably frequent should weekly or daily preventive therapy be given and even then at the lowest dose required to maintain remission. In contrast, AIDS patients with *Candida* esophagitis are so prone to relapse that preventive therapy with fluconazole is recommended for all proven cases. Most HIV-infected patients with azole-resistant oropharyngeal candidiasis also have esophagitis. Nearly all patients with azole-resistant oropharyngeal or esophageal candidiasis respond to intravenous amphotericin B (0.3 to 0.5 mg/kg daily) but relapse promptly after the completion of therapy.

Bladder thrush responds to bladder irrigations with amphotericin B (50 ug/mL for 5 days). If no bladder catheter is in place, oral fluconazole can be used to control candiduria. In all forms of superficial candidiasis, relapse after successful treatment is common unless the underlying factor can be eliminated.

Intravenous amphotericin B is the drug of choice in disseminated candidiasis. The deoxycholate formulation is usually given at a dosage of 0.5 to 0.7 mg/kg daily. Open, noncomparative studies of the lipid formulations of amphotericin B have suggested that they may be useful in disseminated candidiasis, but the optimal dose and formulation remain unknown. Fluconazole in an adult dose of 100 mg/d is probably the drug of choice for chronic mucocutaneous candidiasis.

In immunocompetent patients with intravenous catheter-acquired *C. albicans* fungemia, the catheter should be removed in conjunction with the administration of either

fluconazole (400 mg/d) or amphotericin B (0.5 mg/kg daily). Patients with suppurative phlebitis of a peripheral vein should have the infected portion of the vein excised. Therapy for candidemia is continued for 2 weeks after the patient becomes afebrile. The *Candida* species involved should be considered in choosing between fluconazole and amphotericin B. *C. krusei* and *C. inconspicua* are rare causes of candidemia but are resistant to fluconazole in vitro. *C. glabrata* exhibits intermediate susceptibility to fluconazole, but too few cases have been studied to determine whether candidemia involving that species will respond as well to fluconazole as to amphotericin B. Strains of *C. lusitaniae* resistant to amphotericin B but susceptible to azoles have been encountered. Intravenous amphotericin B, with or without flucytosine, is the preferred treatment for *Candida* endophthalmitis, although cures have been reported with fluconazole. Pars plana vitrectomy may facilitate diagnosis and cure when a *Candida* vitreous abscess is present. Injection of amphotericin B into the vitreous humor can also be helpful.

Injection of amphotericin B into an infected joint, pleural cavity, or peritoneum is rarely indicated. Removal of prostheses, including prosthetic joints, cardiac valves, peritoneal dialysis catheters, and central venous catheters, is usually essential. Collections of pus, such as those in the postoperative abdomen, need to be drained surgically or by percutaneous, computed tomography-guided catheterization; an exception relates to the numerous small abscesses in liver, spleen, or kidney in chronic disseminated candidiasis, which cannot be drained effectively and require prolonged antifungal therapy. In general, treatment should continue until the patient with chronic disseminated candidiasis has been afebrile and nonneutropenic for at least 2 weeks. Defects may persist on imaging studies long after cure. Relapse during another episode of neutropenia is common unless the patient is receiving amphotericin B. Repeat cytotoxic therapy or even bone marrow transplantation can be undertaken in patients with prior chronic disseminated candidiasis, but amphotericin B should be given prophylactically during neutropenia.

Fluconazole can decrease the incidence of deep candidiasis in recipients of allogeneic bone marrow transplants when 400 mg is given daily until engraftment. Although the incidence of superficial candidiasis is also decreased by fluconazole prophylaxis, superficial infection can be readily detected and treated. Aspergillosis is not prevented by prophylactic fluconazole. Studies of leukemic and other neutropenic patients have found no beneficial effect of prophylactic fluconazole.

206. ASPERGILLOSIS - *John E. Bennett*

ETIOLOGIC AGENTS

Aspergillus fumigatus is the most common cause of aspergillosis, but *A. flavus*, *A. niger*, and several other species can also cause disease. *Aspergillus* is a mold with septate hyphae about 2 to 4 um in diameter. The fungus is identified by its gross and microscopic appearance in culture.

PATHOGENESIS AND PATHOLOGY

All the common species of *Aspergillus* that cause disease in humans are ubiquitous in the environment, growing on dead leaves, stored grain, compost piles, hay, and other decaying vegetation. Inhalation of *Aspergillus* spores must be extremely common, but disease is rare. Invasion of lung tissue is confined almost entirely to immunosuppressed patients, in roughly 90% of whom two of the following three conditions will be operative: a granulocyte count in peripheral blood of<500/uL, treatment with supraphysiologic doses of adrenal glucocorticoids, and a history of treatment with cytotoxic drugs such as cyclosporine. Invasive aspergillosis is an occasional complication of AIDS. *Aspergillus* infection is characterized by hyphal invasion of blood vessels, thrombosis, necrosis, and hemorrhagic infarction. Chronic granulomatous disease of childhood also predisposes to invasive pulmonary aspergillosis, but in that situation the inflammatory response is a pyogranuloma and blood vessel invasion is rare.

Massive inhalation of *Aspergillus* spores by healthy persons can lead to acute, diffuse, self-limited pneumonitis. Epithelioid granulomas with giant cells and central pyogenic areas containing hyphae are detected in these cases. Spontaneous recovery taking several weeks is the usual course.

Aspergillus can colonize the damaged bronchial tree, pulmonary cysts, or cavities of patients with underlying lung disease. Balls of hyphae within cysts or cavities (aspergillomas), usually in the upper lobe, may reach several centimeters in diameter and may be visible on chest x-ray. Tissue invasion does not occur. The term *allergic bronchopulmonary aspergillosis* denotes the condition of patients with preexisting asthma who have eosinophilia, IgE antibody to *Aspergillus*, and fleeting pulmonary infiltrates from bronchial plugging.

CLINICAL MANIFESTATIONS

Endobronchial saprophytic pulmonary aspergillosis presents as chronic productive cough, often with hemoptysis, in a patient with prior chronic lung disease, such as tuberculosis, sarcoidosis, bronchiectasis, or histoplasmosis. *Aspergillus* may be spread from its endocavitary or endobronchial site to the pleura during the course of bacterial lung abscess or surgery. Patients reported to have chronic necrotizing *Aspergillus* pneumonia appear in most instances to have had saprophytic endobronchial colonization and a pulmonary process attributable to another disease, with or without superimposed bacterial infections. Patients with chronic pneumonia and *Aspergillus* in the sputum should be assumed to have either pneumonia of a different etiology (e.g., histoplasmosis) or *Aspergillus* pneumonia with underlying immunosuppression (e.g.,

chronic granulomatous disease or infection with HIV).

Invasive aspergillosis in the immunocompromised host presents as an acute, rapidly progressive, densely consolidated pulmonary infiltrate and is most common among patients with acute leukemia and recipients of tissue transplants. Infection progresses by direct extension across tissue planes and by hematogenous dissemination to lung, brain, and other organs. Computed tomography (CT) has been particularly valuable in suggesting the diagnosis of invasive pulmonary aspergillosis in patients with neutropenia. The earliest CT finding is one or more small pulmonary nodules. As a nodule enlarges, the dense central core of infarcted tissue becomes surrounded by edema or hemorrhage, forming a hazy rim called the *halo sign*. This rim disappears in a few days as the dense core enlarges. When bone marrow function recovers, the infarcted central core cavitates, creating the *crescent sign*. *Aspergillus* may invade immunosuppressed patients through the skin at a site of minor trauma or through the upper airway mucosa. Early lesions in the nose should be sought in patients with neutropenia who have fever and minimal epistaxis. Scarlet-red patches of the mucosa rapidly become necrotic and white, then black. Rapid extension into the adjacent paranasal sinus, orbit, or face is usual, with or without the appearance of lung lesions.

Aspergillus sinusitis in immunocompetent patients may take three forms. A ball of hyphae may form in a chronically obstructed paranasal sinus, without tissue invasion. Much less commonly, a chronic, fibrosing granulomatous inflammation associated with *Aspergillus* hyphae within tissue may begin in the sinus and spread slowly to the orbit and the brain. *Aspergillus* is also a cause of allergic fungal sinusitis, but dark-walled fungi (e.g., *Cladosporium*, *Alternaria*) are more common in this setting. Patients usually have a history of chronic allergic rhinitis, sometimes with nasal polyps, but are otherwise healthy, presenting with painless proptosis, nasal obstruction, or dull aching pain. OnCT or magnetic resonance imaging, a solid soft tissue mass pushing out the lateral wall of the ethmoid sinus or the medial wall of the maxillary sinus may be detected. On sinus exploration, the mucosa is found to be thickened and inflamed but intact. Within the sinus cavity, sticky mucopus with strands of neutrophils, eosinophils, Charcot-Leyden crystals, and occasional hyphae can be found.

Aspergillosis in HIV-infected patients most commonly involves the lung, presenting as fever, cough, and dyspnea. Typically, the CD4 cell count is below 50/uL. Roughly half of these patients have neutropenia or have recently been treated with glucocorticoids. Bilateral diffuse or focal pulmonary infiltrates with a tendency to cavitate constitute the most common radiologic manifestation. Well-localized, white, necrotic pseudomembranes full of hyphae or ulcers may develop in the trachea or the major bronchi. Progression of bronchitis to pneumonia is usual, but hematogenous dissemination is uncommon. Either allergic or invasive *Aspergillus* sinusitis can occur in HIV-infected patients; the allergic form can develop even at CD4 cell counts above 50/uL.

The growth of *Aspergillus* on cerumen and detritus within the external auditory canal is termed *otomycosis*. Trauma to the cornea may cause *Aspergillus* keratitis. Endophthalmitis follows the introduction of *Aspergillus* into the globe by trauma or surgery. *Aspergillus* may infect intracardiac or intravascular prostheses.

DIAGNOSIS

The repeated isolation of *Aspergillus* from sputum or the demonstration of hyphae in sputum or bronchoalveolar lavage fluid suggests endobronchial colonization or infection. Even a single isolation of *Aspergillus* from the sputum of a neutropenic patient with pneumonia, particularly a child or a nonsmoker, suggests the diagnosis of invasive aspergillosis. In patients with advanced AIDS, fever, and cough, the isolation of *Aspergillus* from respiratory secretions raises the possibility of aspergillosis and thus should prompt bronchoscopy. Fungus ball of the lung is usually detectable by chest x-ray. IgG antibody to *Aspergillus* antigens is demonstrable in the serum of many colonized patients and of virtually all patients with fungus ball.

Biopsy is usually required for the diagnosis of invasive aspergillosis of the lung, nose, paranasal sinus, bronchi, or sites of dissemination. Blood cultures are rarely positive, even in patients with infected cardiac valves (native or prosthetic). Detection of galactomannan antigen in serum suggests the diagnosis, but false-positives are frequent, particularly in children. *Aspergillus* hyphae can be identified presumptively by histology, but culture is required for confirmation and for determination of the species. Only culture can reliably distinguish aspergillosis from pseudallescheriasis; drug therapy for these two diseases differs.

TREATMENT

Patients with severe hemoptysis due to fungus ball of the lung may benefit from lobectomy. Poor pulmonary function in residual lung and dense pleural adhesions around the lesion can complicate the resection. Systemic chemotherapy is of no value in endobronchial or endocavitary aspergillosis.

Treatment with intravenous amphotericin B (1.0 to 1.5 mg/kg daily) has resulted in the arrest or cure of invasive aspergillosis when immunosuppression is not severe. Liposomal amphotericin B at daily doses of 1 to 4 mg/kg has given results that seem roughly comparable to those obtained with amphotericin B deoxycholate. Itraconazole (200 mg twice daily) is useful in some less immunosuppressed patients with indolent or slowly progressive invasive aspergillosis. Surgery is the only treatment needed for fungus ball of the sinus and for allergic fungal sinusitis. Antifungal therapy has little effect on either entity if used alone, but chronic suppressive therapy has been begun postoperatively for relapse of allergic fungal sinusitis. The prognosis for cure of invasive aspergillosis in the paranasal sinus is very poor when the patient has profound and unremitting neutropenia. The prognosis is better in less immunosuppressed patients.

207. MUCORMYCOSIS - *John E. Bennett*

ETIOLOGIC AGENTS

Species of *Rhizopus*, *Rhizomucor*, and *Cunninghamella* are the most common causes of mucormycosis, but species of *Apophysomyces*, *Saksenaea*, *Mucor*, and *Absidia* also are occasionally responsible for this infection. The organism in tissue is composed of broad, rarely septate hyphae of uneven diameter (6 to 50 um). The organisms are inexplicably difficult to grow from infected tissue. When growth does take place, it is rapid and profuse on most media at room temperature. Identification is based on the gross and microscopic appearance of the mold.

Zygomycosis is a term that includes mucormycosis and entomophthoramycosis. The latter is a tropical infection of the subcutaneous tissue or paranasal sinuses caused by species of *Basidiobolus* and *Conidiobolus*, respectively.

EPIDEMIOLOGY AND PATHOLOGY

Rhizopus and *Rhizomucor* species are ubiquitous, appearing on decaying vegetation, dung, and foods of high sugar content. Mucormycosis is uncommon and is largely confined to patients with serious preexisting diseases. Mucormycosis originating in the paranasal sinuses and nose predominantly affects patients with poorly controlled diabetes mellitus. Patients who have undergone organ transplantation, who have a hematologic malignancy, or who are receiving long-term deferoxamine therapy are predisposed to mucormycosis of either sinus or lung. Gastrointestinal mucormycosis occurs in a variety of conditions, including uremia, severe malnutrition, and diarrheal diseases. The infection is acquired from nature, with no person-to-person spread. In all forms of mucormycosis, vascular invasion by hyphae is a prominent feature. Ischemic or hemorrhagic necrosis is the foremost histologic finding.

CLINICAL MANIFESTATIONS

Mucormycosis originating in the nose and paranasal sinuses produces a characteristic clinical picture. Low-grade fever, dull sinus pain, and sometimes nasal congestion or a thin, bloody nasal discharge are followed in a few days by double vision, increasing fever, and obtundation. Examination reveals a unilateral generalized reduction of ocular motion, chemosis, and proptosis. The nasal turbinates on the involved side may be dusky red or necrotic. A sharply delineated area of necrosis, strictly respecting the midline, may appear in the hard palate. The skin of the cheek may become inflamed. Fungal invasion of the globe or ophthalmic artery leads to blindness. Opacification of one or more sinuses is detected by computed tomography (CT) or by magnetic resonance imaging (MRI). Carotid arteriography may show invasion or obstruction of the carotid siphon. Coma is due to direct invasion of the frontal lobe. Early symptoms mimic those of bacterial sinusitis. Clouding of the sensorium may be attributed to diabetic acidosis. Cavernous sinus thrombosis may be considered when orbital invasion occurs. Without treatment, the patient may die after an interval ranging from a few days to a few weeks.

Pulmonary mucormycosis manifests as progressive severe pneumonia accompanied by

high fever and toxicity. The necrotic center of large infiltrates may cavitate. Hematogenous spread to other areas of the lung, as well as to the brain and other organs, is common. Survival beyond 2 weeks is unusual. Gastrointestinal invasion presents as one or more ulcers that tend to perforate. Hematogenous dissemination can originate from the gastrointestinal tract, lung, or paranasal sinuses. Sometimes no portal of entry can be found.

DIAGNOSIS

CTor MRIis very helpful in assessing the extent of sinusitis before surgery and in evaluating the patient afterward. CT is better for detecting bony erosion; MRI better visualizes extension into the frontal lobe or carotid artery in the siphon. Lesions of the lung and craniofacial structures are best diagnosed by biopsy and histologic section. Cultural confirmation should be attempted. Wet smear of crushed tissue can provide a rapid diagnosis. Cultures of blood and cerebrospinal fluid are negative. Smear and culture of sputum may be positive during cavitation of a lung lesion.

TREATMENT

Regulation of diabetes mellitus and a decrease in the dose of immunosuppressive drugs facilitate the treatment of mucormycosis. Extensive debridement of craniofacial lesions appears to be very important. Orbital exenteration may be required. Intravenous amphotericin B is clearly of value in craniofacial mucormycosis and should be employed in the other forms of mucormycosis as well. The maximal tolerated doses are given until progression is halted. With the deoxycholate formulation, 1 to 1.5 mg/kg daily is indicated. Therapy is continued for a total of 10 to 12 weeks. Azoles are of no value. Appropriate management results in cure of about half of craniofacial infections. The survival of patients with pulmonary, gastrointestinal, or disseminated mucormycosis is rare.

208. MISCELLANEOUS MYCOSES AND ALGAL INFECTIONS - *John E. Bennett*

CHROMOBLASTOMYCOSIS (FIG. 208-CD1)

This chronic subcutaneous mycosis, rarely seen in the United States, presents as a verrucoid, ulcerated, or crusted skin lesion. The disease follows the introduction of any of several fungi into subcutaneous tissue by thorns or bits of vegetation. The infection spreads over ensuing months and years to contiguous tissue, causing few symptoms. The appearance of thick-walled, dark-colored, rounded forms ("copper pennies") in histopathologic section is diagnostic. Surgical excision is the treatment of choice. Itraconazole has ameliorated some relatively small and incompletely excised lesions.

DERMATOPHYTOSIS

Definition Dermatophytosis, also known as ringworm or tinea, is a chronic fungal infection of the skin, hair, or nails.

Etiology Species of *Trichophyton*, *Microsporum*, and *Epidermophyton* are called *dermatophytes.* These organisms grow in and remain confined to the keratinous structures of the body. Other mycoses, such as candidiasis, pityriasis versicolor, and tinea nigra, sometimes include fungal invasion of keratinous structures but traditionally are not called dermatophytoses.

Pathology and Pathogenesis Dermatophyte species are referred to as *anthropophilic*, *zoophilic*, or *geophilic*, depending on whether their usual reservoir in nature appears to be humans, animals, or soil, respectively. The infectivity of organisms from all these sources is low, and outbreaks are largely confined to occasional clusters of cases of scalp infection in children. Acquisition of a dermatophytosis appears to be favored by minor trauma, maceration, and poor hygiene of the skin. Infection does not seem to confer solid immunity: Repeated infection with the same species is common, particularly with anthropophilic species. The infrequency of scalp infection among adults has been attributed to local factors rather than immunity.

Invasion of the stratum corneum by dermatophytes may cause inflammation that is either mild or (particularly with zoophilic fungi) intense. Shedding of the stratum corneum is increased by inflammation. To the extent that fungal growth cannot keep up with shedding, inflammation may help terminate infection. Conversely, infection is probably favored when shedding is reduced by treatment with glucocorticoids and cytotoxic drugs. Antifungal drugs interfere with the ability of fungal growth to keep up with shedding.

Clinical Manifestations The disease varies with the site of infection and the fungal species involved. Foot infection (athlete's foot, tinea pedis) may present as fissuring of the toe webs, scaling of the plantar surfaces, or vesicles around the toe webs and soles. Interdigital lesions may be pruritic or, when bacterial superinfection occurs, may be painful. Hand infection is less common but resembles foot infection.

Scalp dermatophytosis (tinea capitis; Fig. 208-CD4) is characterized by areas of alopecia and scaling. In so-called endothrix infection, the hair shaft breaks off at the skin

surface, leaving the hairs visible as black dots in the scalp. Some forms of scalp infection include an area of intense boggy suppuration called a *kerion*.

Dermatophytosis of the glabrous skin (tinea corporis, Plate IID-51) presents as circumscribed lesions with a wide variety of appearances, including scales, vesicles, and pustules. Inflammation may be minimal or intense. Central healing of less inflamed lesions may take place. The serpiginous border of inflammation is the source of the name *ringworm*.

Dermatophytosis of the bearded area (tinea barbae) appears as a pustular folliculitis. Onychomycosis (tinea unguium; Fig. 208-CD5) presents as a white discoloration of the nails or as thickening, chalkiness, and crumbling of the nails. Peeling and fissuring of paronychial nail folds or keratotic debris under the nail edge also may be evident.

Diagnosis Discolored hairs, scales, and keratotic debris under infected nails should be collected for KOH smear and culture. In the scraping of skin lesions, a drop of water on the skin site may keep the removed scales from flying off and thus may aid in their collection. Culture is important in distinguishing dermatophytes from *Candida* and fungal saprophytes growing in keratinaceous debris.

TREATMENT

Noninflammatory lesions of the trunk, groin, hands, and feet usually respond to twice-daily applications of clotrimazole, miconazole, ketoconazole, econazole, naftifine, terbinafine, or ciclopirox olamine cream. Hyperkeratotic lesions of the palms and soles respond slowly to these agents and may benefit from Whitfield's ointment initially to thin the keratin. Ointment should not be used between the toes, in the groin, or in the gluteal crease because maceration promotes bacterial infection.

Ringworm that is moderately severe, that is unresponsive to topical therapy, or that involves the scalp, nails, or bearded area should be treated systemically. Once-daily therapy with itraconazole (200 mg), terbinafine (250 mg), microcrystalline griseofulvin (500 mg), or ultramicrocrystalline griseofulvin (375 mg) is effective. Treatment must be continued until all infected keratin is gone. Cutting off infected hair and cleansing interdigital webs can expedite cure. Secondary bacterial infection of the foot may require soaks or antibacterial agents. The likelihood of relapse of dermatophyte foot infections may be decreased by keeping the feet clean and dry. For nail infections, itraconazole or terbinafine is preferred. In distal subungual onychomycosis, a single course of either drug results in initial improvement in half of patients, of whom half relapse. Results are better with fingernails than with toenails and for more distal rather than lateral nail involvement. To save money, itraconazole can be given as a double dose (400 mg) for 1 week each month with only marginal loss of efficacy. The duration of therapy is 2 to 3 months for fingernails and 4 to 6 months for toenails.

PROTOTHECOSIS

Prototheca species are ubiquitous achlorophyllic algae that enter the skin through contaminated wounds and cause localized infections in the olecranon bursa, skin, subcutaneous tissue, tendon sheaths, or deeper tissue. Diagnosis is based on culture or

histopathologic demonstration of sporangia with endospores in tissue. Surgical debridement and treatment with intravenous amphotericin B are useful.

FUSARIOSIS

Fusarium species can cause localized or hematogenously disseminated infection. Localized infection results from contaminated wounds. Almost all patients with hematogenously disseminated infection are severely immunosuppressed and profoundly neutropenic. Skin lesions occur in two-thirds of patients. Several painful red indurated lesions appear on the extremities or sometimes the trunk. These lesions often develop an ecchymotic center that ulcerates. A portal of infection is not usually apparent. Blood cultures have been positive in 59% of cases. Amphotericin B is probably the drug of choice for the treatment of fusariosis, but recovery depends on the diminution of neutropenia.

MALASSEZIA INFECTION (PITYRIASIS)

Malassezia furfur is part of the normal flora of the human skin but can cause tinea (pityriasis) versicolor (Fig. 208-CD6) or catheter-acquired sepsis. Tinea versicolor appears as asymptomatic, well-delineated, hyperpigmented or hypopigmented macules centered on the upper trunk and upper arms. Confluent lesions may cover large areas, making the border difficult to find. A fine "branny" scale or folliculitis is sometimes visible. When examined microscopically by KOH mount, skin sections are seen to contain characteristic round and elongated cells (Fig. 208-CD7). On inspection with Wood's light, lesions either do not fluoresce or appear yellow-green. *Erythrasma* (Fig. 141-CD1) resembles tinea versicolor but is characterized by gram-positive bacilli on smear and coral-red fluorescence. Azole creams are effective for the treatment of small areas of tinea versicolor; however, the application of selenium sulfide shampoo (Selsun) for 10 min daily, followed by showering to remove the shampoo, is more practical for large areas. Itraconazole is also effective. Catheter-acquired sepsis due to *M. furfur* develops in patients (particularly neonates) receiving intravenous lipid. The organism requires special culture conditions for growth, and the infection is cured by catheter removal.

MYCETOMA

Etiology *Actinomycetoma* refers to infection by actinomycetes of the genera *Nocardia*, *Nocardiopsis*, *Streptomyces*, and *Actinomadura*. *Eumycetoma* (Fig. 208-CD8) is caused by true fungi of many different genera. The predominant agent varies with the locality.

Pathogenesis and Pathology The pathogens live in the soil and enter the skin through minor trauma. The most common site of infection is the foot. The infection runs a relentless course over many years, with destruction of contiguous bone and fascia. Grains are found in purulent foci surrounded by fibrosis and a mononuclear cell inflammatory response.

Clinical Manifestations Mycetoma is a chronic suppurative infection originating in subcutaneous tissue and characterized by the presence of grains, which are tightly clumped colonies of the causative agent. The infected site is characterized by painless

swelling, woody induration, and sinus tracts that discharge pus intermittently. Systemic symptoms do not develop, and spread to distant sites in the body does not take place.

Diagnosis Although the clinical picture is characteristic, mycetoma is sometimes confused with chronic osteomyelitis or botryomycosis. The diagnosis requires demonstration of grains in pus from the draining sinus or in biopsy sections. Many histologic sections may need to be examined to locate a grain.

TREATMENT

Actinomycetoma may respond to prolonged combination chemotherapy -- e.g., with streptomycin and either dapsone or trimethoprim-sulfamethoxazole. Eumycetoma rarely responds to chemotherapy; some cases caused by *Madurella mycetomatis* have appeared to respond to ketoconazole or itraconazole.

PARACOCCIDIOIDOMYCOSIS

Etiology Formerly called *South American blastomycosis*, this mycosis is caused by *Paracoccidioides brasiliensis*. A dimorphic fungus, *P. brasiliensis* grows as a budding yeast in tissue but may be grown as either a yeast or a mold on culture medium. The organism is identified by its gross and microscopic appearance.

Pathogenesis and Pathology Infection is thought to be acquired by inhalation of spores from environmental sources, possibly soil. Pulmonary infection produces few symptoms initially. Hematogenous spread to the mucous membranes of the mouth and nose, the lymph nodes, and other sites causes patients to seek medical attention. In fatal cases, the infection spreads to the adrenals, the gastrointestinal tract, and many other viscera.

Clinical Manifestations Common signs include indurated ulcers of the mouth, oropharynx, larynx, and nose; enlarged and draining lymph nodes; lesions of the skin and genitalia; and productive cough, weight loss, dyspnea, and sometimes fever. Paracoccidioidomycosis is acquired only in South America, Central America, and Mexico, but its extreme indolence may delay its recognition until many years after the patient has left the endemic area. Chest radiography most often shows bilateral patchy pneumonia.

Diagnosis Cultures of sputum, pus, and mucosal lesions are often diagnostic. The diagnosis can be made by smear or histologic section, although confirmation by culture is preferable. Serologic tests are useful in suggesting the diagnosis and monitoring the response to therapy.

TREATMENT

Relatively mild cases of paracoccidioidomycosis may be cured by 1 year of treatment with oral ketoconazole or itraconazole (200 to 400 mg daily). More advanced cases are treated with intravenous amphotericin B followed by itraconazole.

PHAEOHYPHOMYCOSIS

This is the name given to infections caused by fungi with dark-walled hyphae, excluding those given conventional names like chromoblastomycosis. Although an extraordinary variety of fungi and clinical syndromes are encompassed by this definition, most patients have brain abscess, subcutaneous abscess, or allergic fungal sinusitis. Most of the brain abscesses are due to *Cladophialophora bantiana*, *Ochroconis gallopavum*, *Exophiala dermatitidis*, *Bipolaris* species, and *Ramichloridium mackenziei*. Patients are previously healthy. Subcutaneous abscesses are usually single, arise at the site of minor trauma, and occur in both immunosuppressed and immunocompetent individuals. A large number of dematiaceous (dark-walled) mold species cause subcutaneous phaeohyphomycosis as well as allergic fungal sinusitis. The latter entity develops in patients with allergic rhinitis and presents as an expanding mucoid mass in one or more paranasal sinuses. The tenacious mucus contains eosinophils, Charcot-Leyden crystals, and occasional hyphae. Surgical excision of phaeohyphomycotic lesions is important. Antifungal therapy may retard recurrences but is of little value unless surgical excision has been performed.

PSEUDALLESCHERIASIS

Etiology Also called *Petriellidium boydii*, *Pseudallescheria boydii* is a mold frequently found in soil. When the fungus is isolated in the imperfect state, it is called *Scedosporium apiospermum*.

Pathogenesis and Pathology Wind-borne spores of *P. boydii*, arising from the soil, are the presumed source of infection. The fungus grows as a mold within tissue, causing necrosis and abscess formation.

Clinical Manifestations *P. boydii* resembles *Aspergillus* in its ability to colonize the endobronchial tree, to form fungus balls in the lungs or paranasal sinuses, and to invade the cornea or globe of the eye, the soft tissues, the joints, or the bones after trauma or surgery and in its propensity to invade the lungs and paranasal sinuses of immunosuppressed hosts, including patients with AIDS. Hyphae of *P. boydii* in tissue may be difficult to distinguish from those of *Aspergillus*. Infection with *P. boydii* is much less common than that with *Aspergillus*. Intravascular hyphae, a hallmark of invasive aspergillosis, are also found in pseudallescheriasis. Near-drowning in polluted water has led to severe *P. boydii* pneumonia, often with dissemination and fatal brain abscesses.

Diagnosis Demonstration of hyphae in tissue and culture confirmation are required for diagnosis.

TREATMENT

Itraconazole at the maximal tolerated doses is the regimen of choice. Surgical drainage or debridement can be helpful. The prognosis is poor.

Scedosporium prolificans, a fungus closely related to *P. boydii*, has caused infections in bones, joints, or soft tissue, usually after trauma. These infections have responded to surgical debridement. Disseminated infection with *S. prolificans* in immunosuppressed patients has been fatal. The response to treatment with all antifungal agents has been

poor.

SPOROTRICHOSIS

Etiology *Sporothrix schenckii* lives as a saprophyte on plants in many areas of the world. In nature and on culture at room temperature, the fungus grows as a mold; within host tissue or at 37°C on enriched media, it grows as a budding yeast. It is identified by its appearance in mold and yeast forms.

Pathogenesis and Pathology Infection results from the inoculation of *S. schenckii* into subcutaneous tissue through minor trauma. Nursery workers, florists, and gardeners acquire the illness from roses, sphagnum moss, and other plants. Infection may be limited to the site of inoculation (plaque sporotrichosis) or extend along proximal lymphatic channels (lymphangitic sporotrichosis). Spread beyond an extremity -- the usual site of infection -- is rare, and hematogenous dissemination from the skin remains unproven. The portal for osteoarticular, pulmonary, and other extracutaneous forms of sporotrichosis is unknown but is likely the lung.

Untreated sporotrichosis persists for months. The inflammatory response includes both the clustering of neutrophils and a marked granulomatous response with epithelioid cells and giant cells.

Clinical Manifestations In lymphangitic sporotrichosis, which is by far the most common manifestation, a nearly painless red papule forms at the site of inoculation. Over the next several weeks, similar nodules form along proximal lymphatic channels (Fig. 208-CD9). The nodules intermittently discharge small amounts of pus. Ulceration may occur. The proximal extension of these lesions, often with skip areas, is quite distinctive but may be mimicked by lesions of *Nocardia brasiliensis*, *Mycobacterium marinum*, or (in rare cases) *Leishmania brasiliensis* or *Mycobacterium kansasii*.

Plaque sporotrichosis manifests as a nontender red maculopapular granuloma confined to the site of inoculation. Osteoarticular sporotrichosis presents as mono- or polyarticular arthritis of indolent onset and progression over months or years, involving the elbows, knees, wrists, ankles, and (rarely) smaller joints of the extremities. Periarticular bone develops areas of demineralization detectable on x-ray, and draining sinuses may appear over joints and bursae. Hematogenous spread to the skin may take place during polyarticular disease, but none of the skin lesions shows lymphangitic spread. Immunosuppression, including that due to advanced infection with HIV, predisposes to hematogenous spread. Pulmonary sporotrichosis usually presents as a single chronic cavitary upper-lobe lung lesion. Chronic meningitis can develop in the absence of skin or lung lesions. *S. schenckii* is difficult to recover from cerebrospinal fluid.

Diagnosis Culture of pus, joint fluid, sputum, or a skin biopsy specimen is the preferred method of diagnosis. The appearance of *S. schenckii* in tissue is quite variable. In skin lesions, the organisms are hard to find.

TREATMENT

Cutaneous sporotrichosis can be cured with a saturated solution of potassium iodide given orally in increasing divided doses of up to 4.5 to 9 mL/d for adults, as tolerated. Gastrointestinal disturbance or acneiform rash over the cape area and face is common, but therapy should be continued for 1 month after the resolution of all lesions. Itraconazole (100 to 200 mg daily) is an effective and better-tolerated alternative. Extracutaneous sporotrichosis rarely responds to iodides, but more than half of cases have been cured by prolonged courses of intravenous amphotericin B. Itraconazole (200 mg once or twice daily) is effective in some cases of extracutaneous sporotrichosis.

TRICHOSPORONOSIS

A recent change in taxonomy of the genus *Trichosporon* has moved most of the agents causing deep infections from *T. beigelii* into the species *T. asahii*, with a few categorized as *T. mucoides*. White piedra of the scalp is caused by *T. ovoides* and that of the pubic hair by *T. inkin*. *T cutaneum* and *T. asteroides* cause superficial infections. Most of what is currently known about *Trichosporon* infections is not species specific, so the following description refers to *T. beigelii*. *T. capitatum*, which causes disseminated infection in patients with neutropenia, was previously reclassified as *Blastoschizomyces capitatus* and will not be covered here.

T. beigelii can colonize the human gastrointestinal tract and skin and can enter the bloodstream of patients with severe neutropenia through an inapparent source. Hematogenously disseminated infection is manifested by fever and often by the development of several erythematous or purpuric tender papules anywhere on the body. Lesions can form large, tense hemorrhagic bullae. In some patients, native or prosthetic cardiac valves become infected. In tissue, hyphae and yeastlike cells are seen. Amphotericin B is probably the drug of choice for treatment, but recovery is dependent on the return of bone marrow function.

209. *PNEUMOCYSTIS CARINII* INFECTION - *Peter D. Walzer*

DEFINITION AND DESCRIPTION

Pneumocystis carinii is an opportunistic pathogen whose natural habitat is the lung. The organism is an important cause of pneumonia in the compromised host.

Although the taxonomic status of *P. carinii* has long been controversial, molecular studies during the past decade have clearly placed the organism among the fungi. This classification is based on analysis of gene sequences for ribosomal RNA, mitochondrial proteins, and major enzymes. The cell wall of *P. carinii* containsb-1,3-glucan; drugs that inhibitb-glucan synthesis in fungi are highly active against *P. carinii* in animal models. However, in contrast to most fungi, *P. carinii* lacks ergosterol and is not susceptible to antifungal drugs that inhibit ergosterol synthesis.

Study of the basic biology of *P. carinii* has been severely hampered by the lack of a reliable in vitro cultivation system. Major developmental stages of the organism include the small (1- to 4-um) pleomorphic trophozoite or trophic form; the 5- to 8-um cyst, which has a thick cell wall and contains up to eight intracystic bodies; and the precyst, an intermediate stage. The life cycle of *P. carinii* probably involves asexual replication by the trophic form and sexual reproduction by the cyst, which ends in release of the intracystic bodies; an intracellular stage has not been identified. Ultrastructurally, *P. carinii* has a primitive organelle system, but little is known about its metabolism.

P. carinii contains two prominent antigen groups. The 95- to 140-kDa major surface glycoprotein (MSG) complex represents a family of proteins encoded by multiple genes. The MSG complex is highly immunogenic, contains shared and species-specific antigenic determinants, and exhibits protective B and T cell epitopes in animal models. The MSG complex plays a pivotal role in the host-parasite relationship in *P. carinii* infection. It facilitates adherence to host proteins via extracellular matrix proteins, surfactant proteins, and the mannose receptor; and its ability to undergo antigenic variation may represent a mechanism by which *P. carinii* evades the host immune response. The other antigen, which migrates as a band of 35 to 55 kDa, is the most common antigen recognized by the host and thus may serve as a marker of infection.

EPIDEMIOLOGY

P. carinii has a worldwide distribution among humans and has been detected in a variety of animals. The organisms found in these hosts are morphologically identical, but recent studies have revealed a high degree of genetic diversity and host specificity. Serologic surveys indicate that most healthy children have been exposed to the organism by 3 to 4 years of age. Animal model experiments have demonstrated that *P. carinii* is transmitted by the airborne route. Person-to-person transmission has been suggested by the occurrence of outbreaks of pneumocystosis among institutionalized debilitated infants and in hospitals caring for immunosuppressed patients. On the basis of animal studies, the incubation period is thought to be 4 to 8 weeks.

PATHOGENESIS AND PATHOLOGY

The host factors that predispose to the development of pneumocystosis involve defects in cellular and humoral immunity. People at risk for the disease include patients infected with HIV; persons receiving immunosuppressive therapy (particularly glucocorticoids) for cancer, organ transplantation, and other disorders; children with primary immunodeficiency diseases; and premature malnourished infants. The central role of CD4+ cells in host resistance to *P. carinii* has been shown by research in experimental animals and by studies that have correlated the risk of pneumocystosis in HIV-infected patients with CD4+ cell counts. Evidence supporting the importance of impaired humoral immunity consists of the occurrence of pneumocytosis in patients and animals with B cell defects and the beneficial effect of passively administered antibodies.

The principal host effector cells against *P. carinii* are alveolar macrophages, which ingest and kill the organism, releasing a variety of inflammatory mediators. Tumor necrosis factora and interleukin (IL) 1 are important in the early host defenses against *P. carinii*, but the role of other cytokines is less clear. Recent evidence suggests that HIV alters the mannose receptor-mediated binding and phagocytosis of *P. carinii*.

After being inhaled, *P. carinii* takes up residence in the alveoli, where it attaches tightly to type I cells but maintains an extracellular existence. In some cases, the organism remains in the host for long periods, and pneumonia develops by reactivation of latent infection; in other cases, pneumonia arises from a new bout of infection. As the immune system of the host becomes compromised, *P. carinii* organisms propagate and gradually fill the alveoli. This scenario is accompanied by a complex series of events that result in increased alveolar-capillary permeability and damage to type I cells. Surfactant abnormalities include a fall in bronchoalveolar lavage (BAL) fluid phospholipids and an increase in surfactant proteins A and D. Contributions of the host inflammatory response to lung injury are suggested by the correlation of increasedIL-8 levels and neutrophil counts in BAL fluid from patients with relatively severe disease.

On lung sections stained with hematoxylin and eosin, the alveoli are filled with a typical foamy, vacuolated exudate. Severe disease may include interstitial edema, fibrosis, and hyaline membrane formation. The host inflammatory changes usually consist of hypertrophy of alveolar type II cells, a typical reparative response, and a mild mononuclear cell interstitial infiltrate. Malnourished infants display an intense plasma cell infiltrate that gave the disease its early name: interstitial plasma cell pneumonia.

CLINICAL FEATURES

Patients with *P. carinii* pneumonia develop dyspnea, fever, and nonproductive cough. Symptoms in non-HIV-infected patients often begin after the glucocorticoid dose has been tapered and typically last 1 to 2 weeks. HIV-infected patients are usually ill for several weeks or longer and have relatively subtle manifestations. However, the clinical picture in individual patients is quite variable, and a high index of suspicion and elicitation of a careful history are key factors in early detection.

Physical findings include tachypnea, tachycardia, and cyanosis, but lung auscultation reveals few abnormalities. The white blood cell count is variable and is usually governed by the patient's underlying disease. Assessment of arterial blood gases demonstrates hypoxia, an increased alveolar-arterial oxygen gradient (PA_{O2}-Pa_{O2}), and respiratory

alkalosis. There also may be changes in pulmonary function test values (diffusing capacity) and increased uptake with nuclear imaging techniques (gallium scan). Elevated serum concentrations of lactate dehydrogenase (LDH) have been reported; they probably reflect lung parenchymal damage but are not specific to *P. carinii* infection. In general, laboratory abnormalities are less severe in HIV-infected patients than in non-HIV-infected patients.

The classic findings on chest radiography consist of bilateral diffuse infiltrates beginning in the perihilar regions (Fig. 209-1), but various atypical manifestations (nodular densities, cavitary lesions) have also been reported. Patients who receive aerosolized pentamidine have an increased frequency of upper-lobe infiltrates and pneumothorax. Early in the course of pneumocystosis, the chest radiograph may be normal.

Although *P. carinii* usually remains confined to the lungs, cases of disseminated infection have occurred in both HIV-infected and non-HIV-infected patients. One risk factor for extrapulmonary spread in patients with HIV is the administration of aerosolized pentamidine. The most common sites of extrapulmonary involvement are the lymph nodes, spleen, liver, and bone marrow. Clinical manifestations range from incidental findings at autopsy to specific organ involvement. Histopathologic examination reveals the presence of *P. carinii* and the characteristic associated foamy material. Treatment for the extrapulmonary forms of pneumocystosis is the same as that for pneumonia.

DIAGNOSIS

Because the clinical picture of *P. carinii* infection can be produced by many other infectious and noninfectious agents, the diagnosis must be based on specific identification of the organism. A definitive diagnosis is made by histopathologic staining. Traditional stains have included reagents such as methenamine silver, toluidine blue, and cresyl echt violet, which selectively stain the wall of *P. carinii* cysts, and reagents such as Wright-Giemsa, which stain the nuclei of all developmental stages. Other reagents include nonspecific fluorochrome stains (calcofluor white) and Papanicolaou's stain. Immunofluorescence with monoclonal antibodies is more sensitive than histologic staining but is also more expensive. DNA amplification by the polymerase chain reaction offers the greatest sensitivity and may find a place in the routine diagnosis of *P. carinii* when commercial kits become available.

The successful diagnosis of pneumocystosis depends upon the collection of proper specimens. In general, the yield from different diagnostic procedures is higher in HIV-infected patients than in non-HIV-infected patients because of the higher organism burden in the former group. Sputum induction has gained popularity as a simple, noninvasive technique; this procedure requires trained and dedicated personnel, and its success has varied at different institutions. Fiberoptic bronchoscopy withBAL, which is more sensitive than sputum induction, remains the mainstay of *P. carinii* diagnosis. This procedure also provides information about the organism burden, the host inflammatory response, and the presence of other opportunistic infections. Transbronchial biopsy and open lung biopsy, which are the most invasive procedures, are reserved for situations in which a diagnosis cannot be made by BAL.

COURSE AND PROGNOSIS

In the typical case of untreated *P. carinii* pneumonia, progressive respiratory embarrassment leads to death. Therapy is most effective when instituted early in the course of the disease, before there is extensive alveolar damage. If induced sputum is nondiagnostic andBALcannot be performed in a timely manner, it is reasonable to begin empiric therapy with drugs active against *P. carinii*. However, this practice does not obviate the need for a specific etiologic diagnosis. With improvements in management, the case-fatality rate has been lowered to about 15% in HIV-infected patients but remains high (40%) in non-HIV-infected patients. The most widely used prognostic indicators have been the arterial oxygen pressure and the alveolar-arterial oxygen gradient. Other factors that may influence survival include neutrophil counts and IL-8 levels in BAL fluid, chest radiographic abnormalities, serumLDH and albumin levels, and the expertise of the hospital in caring for patients with HIV infection. Concurrent pulmonary infections complicate management, but the presence of cytomegalovirus usually does not affect the outcome of pneumocystosis.

TREATMENT

Trimethoprim-sulfamethoxazole (TMP-SMZ), which acts by inhibiting folic acid synthesis, is considered the drug of choice for all forms of pneumocystosis. The daily dosage, administered orally or intravenously in three or four divided doses, is 15 to 20 mg TMP/kg and 75 to 100 mg SMZ/kg. Therapy is continued for 14 days in non-HIV-infected patients and for 21 days in persons infected with HIV. Since HIV-infected patients respond more slowly than non-HIV-infected patients, it is prudent to wait at least 7 days after the initiation of treatment before concluding that therapy has failed. The addition of drugs to an existing regimen is no more effective than switching regimens and may increase the risk of toxicity. TMP-SMZ is well tolerated by non-HIV-infected patients, but more than half of HIV-infected patients experience serious adverse reactions, including fever, rash, neutropenia, thrombocytopenia, hepatitis, and hyperkalemia.

Several alternative regimens are available for the treatment of mild to moderate cases of *P. carinii* pneumonia: TMP (15 mg/kg per day orally) plus dapsone (100 mg/d orally), clindamycin (600 mg every 6 h intravenously or 300 to 450 mg every 6 h orally) plus primaquine (15 to 30 mg of base per day orally), or atovaquone alone (750 mg twice daily orally). Dapsone and primaquine should be used with caution in patients with glucose-6-phosphate dehydrogenase deficiency.

Two alternative drugs are available for the treatment of moderate to severe forms of pneumocystosis. Pentamidine, which has been used against *P. carinii* for many years, is administered as a single daily dose of 4 mg/kg by slow intravenous infusion. Pentamidine is highly toxic; its major side effects are hypotension, cardiac arrhythmias, dysglycemias, azotemia, electrolyte changes, and neutropenia. Trimetrexate is administered intravenously as a single daily dose of 45 mg/m^2; in conjunction with trimetrexate therapy, folinic acid is given orally or intravenously at a dose of 20 mg/m^2every 6 h to prevent bone marrow suppression.

Patients with HIV frequently experience deterioration in respiratory function shortly after receiving anti-*P. carinii* drugs. Several studies have shown that the administration of

glucocorticoids to patients with HIV and moderate to severe pneumocystosis (a P_{O2} of£70 mmHg or a PA_{O2}-Pa_{O2} of³35 mmHg) can prevent this problem and improve the rate of survival. The administration of steroids should be started early in the course of the illness (usually when antimicrobial drugs are begun) for maximal benefit; the recommended regimen is 40 mg of prednisone orally twice daily on days 1 to 5, 40 mg/d on days 6 to 10, and 20 mg/d on days 11 to 20. This regimen has generally proven to be safe despite concern about its effects on other opportunistic infections. The use of steroids as adjunctive therapy in HIV-infected patients with mild pneumocystosis or in non-HIV-infected patients remains to be evaluated.

PREVENTION

Primary prophylaxis is indicated for HIV-infected patients at high risk of developing pneumocystosis -- that is, those who have CD4+ cell counts of <200/uL, unexplained fever [>37.8°C (100° F)] for ³2 weeks, or a history of oropharyngeal candidiasis. Guidelines for the administration of primary prophylaxis to other immunocompromised hosts are less clear. Secondary prophylaxis is indicated for all patients who have recovered from *P. carinii* pneumonia. Among HIV-infected patients, the risk of recurrent episodes of pneumocystosis is high and lifelong; among non-HIV-infected patients, the risk is lower and exists for as long as the immunosuppressive condition persists.

Several antimicrobial drugs are effective in preventing pneumocystosis, although some concern has been raised about possible resistance. One double-strength tablet ofTMP-SMZ(160 mg TMP, 800 mg SMZ) per day is the prophylactic regimen of choice. The major limitation of TMP-SMZ treatment is the high frequency of adverse reactions among HIV-infected patients. Recommended alternative regimens include TMP-SMZ at a reduced dose (80 mg TMP, 400 mg SMZ) or frequency (3 times per week), dapsone alone at a daily oral dose of 100 mg, dapsone at a dose of 50 mg/d combined with weekly oral doses of pyrimethamine (50 mg) and folinic acid (25 mg), pentamidine at a monthly dose of 300 mg administered by Respigard nebulizer, and atovaquone at an oral dose of 1500 mg/d.

Although there are no specific recommendations for preventing the spread of *P. carinii* in health care facilities, it seems prudent to prevent direct contact between patients with pneumocystosis and other susceptible hosts.

SECTION 16 -PROTOZOAL AND HELMINTHIC INFECTIONS: GENERAL CONSIDERATIONS

210. APPROACH TO THE PATIENT WITH PARASITIC INFECTION - *Peter F. Weller*

Because diverse parasitic organisms may infect humans, a range of factors are germane to an assessment of the possible parasitic etiology of a patient's disease. These factors include issues related to the patient's history, immune status, and presenting clinical and laboratory characteristics, especially eosinophilia. Complementing historical information, a full clinical evaluation and laboratory testing provide additional data to direct the assessment for parasitic infection. The specific tests required, ranging from standard blood biochemical assays to imaging of selected organs, are dictated by the nature of the patient's illness. Additional diagnostic testing for parasitic infections (Chap. 211) completes the evaluation.

HISTORY

Geographic History The history can provide valuable information about potential exposures to parasitic infections. A history of travel to, residence or work in, or immigration from areas of the world in which various parasites not endemic in the United States are encountered offers a clue to possible parasitic or other infectious etiologies of a patient's disease (Chap. 123). Some parasitic infections may become manifest early after a traveler's return home; paramount among these in terms of preventable mortality is malaria. If a patient has been in a region of the world where malaria is endemic (even only briefly, as in an airport layover), fever mandates a consideration of malaria, whether or not malaria chemoprophylaxis has been used. Falciparum malaria, which in a nonimmune patient may progress rapidly to serious and even life-threatening consequences (Chap. 214), is a potential medical emergency and must be considered at the initial evaluation, even if symptoms and fever patterns are suggestive of less specific flulike or gastrointestinal illness. Rarely, malaria transmission has been reported within the United States.

For patients with a history of recent travel, the onset of gastrointestinal symptoms only after return suggests protozoal diseases characterized by a 1- to 2-week delay between acquisition and appearance of symptoms -- notably, giardiasis, cyclosporiasis, and cryptosporidiosis (Chap. 218). Gastrointestinal symptoms lasting longer than a week also suggest protozoan etiologies, including giardiasis, amebiasis, and cyclosporiasis. For patients who have traveled less recently, information on the specific countries and the types of regions (urban or rural) visited and on the nature and duration of the visit, whether for general tourism or for activities related to specific occupations, is helpful in concert with presenting clinical features and hematologic and other laboratory findings. Diseases that may become manifest only some years after an individual leaves an endemic region include schistosomiasis, some forms of filariasis, strongyloidiasis, echinococcosis, and cysticercosis.

For the illnesses of patients who have never left the United States, various parasitic etiologies should be considered, depending on the presenting disease. Trichomoniasis, trichinellosis, strongyloidiasis, giardiasis, cryptosporidiosis, cyclosporiasis, echinococcosis, and pinworm are among the parasitic infections endemic in settings

within the United States. Diseases that are more frequent where there is fecal contamination of soil or other environmental sites include hookworm, ascariasis, trichuriasis, amebiasis, and strongyloidiasis; dermal exposure, as by walking barefoot on soil contaminated with parasitic larvae, predisposes residents of such an area as well as travelers to the acquisition of cutaneous larva migrans, hookworm, and strongyloidiasis.

Dietary History If more than one patient develops similar symptoms in a given situation, common-source water- or foodborne diseases (giardiasis, cryptosporidiosis, cyclosporiasis) should be considered. Waterborne infections are more likely to be acquired from surface water supplies, ranging from mountain streams to municipal reservoirs. Likewise, attention to dietary history may be helpful. Trichinellosis should be considered when the patient may have consumed contaminated pork, bear, walrus, or other meat from carnivores. Ingestion of undercooked fish predisposes to anisakiasis and to infection with other fish-dwelling nematodes, tapeworms (*Diphyllobothrium latum*), or flukes (*Nanophyetus salmincola*). Ingestion of snails or of produce contaminated with land snails can lead to infection with *Angiostrongylus cantonensis* (eosinophilic meningitis;Chap. 219). Ingestion of more exotic animal foodstuffs, including snakes, can result in the transmission of gnathostomiasis (Chap. 219). For children with a propensity for pica, ingestion of soil containing *Toxocara* eggs may lead to visceral larva migrans. Consumption of ground-grown vegetables, including those shipped in from distant fields contaminated with human feces, provides an opportunity for the ingestion of nematode eggs of *Ascaris lumbricoides* or *Trichuris trichiura*.

Other Exposure Histories An antecedent blood transfusion raises the possibility of malaria (especially that due to *Plasmodium malariae* or *P. falciparum*), babesiosis, or Chagas' disease. A history of wading or swimming in fresh water is germane to the acquisition of schistosomiasis or avian schistosome dermatitis. Fresh water may be a source of infection with free-living amebae, and these protozoa may cause meningoencephalitis or ocular infections. Arthropod vector-borne parasitic infections include malaria and lymphatic filariasis (carried by mosquitoes) and babesiosis (carried by ticks); the latter is transmitted in some regions of the United States.

Residence in an institutional setting where fecal-oral hygiene may be imperfect raises the possibility of giardiasis, cryptosporidiosis, or strongyloidiasis. Child-care centers provide opportunities for young children and their family members to acquire giardiasis, cryptosporidiosis, and pinworm infections. Trichomoniasis is transmitted sexually; giardiasis, cryptosporidiosis, amebiasis, and strongyloidiasis can be transmitted during anal intercourse or oral-anal contact.

IMMUNE STATUS

The patient's immune status is relevant in determining which parasitic infections need to be considered. In patients infected with HIV-1, especially those with depressed CD4+ lymphocyte counts, specific protozoan diseases may develop opportunistically. These infections include toxoplasmosis, isosporiasis, cyclosporiasis, cryptosporidiosis, visceral leishmaniasis, American trypanosomiasis, microsporidiosis, and infections with free-living amebae (*Acanthamoeba* and related genera). In individuals infected with human T-lymphotropic virus type 1, strongyloidiasis is a prominent consideration.

Patients who are asplenic are at risk not only for overwhelming infections due to encapsulated bacteria but also for fulminant infections caused by intraerythrocytic protozoa, including malaria and babesiosis. Patients with hypogammaglobulinemia or cystic fibrosis may develop refractory giardiasis. In patients developing symptoms of enterocolitis while receiving glucocorticoids, the possibility of an exacerbation of unsuspected strongyloidiasis or amebic colitis should be considered.

EOSINOPHILIA

Eosinophilia may offer a hematologic clue to the presence of some parasites. Only two protozoan parasites have been associated with eosinophilia: *Isospora belli* and, on occasion, *Dientamoeba fragilis*. The detection of eosinophilia generally mandates a consideration of the multicellular helminthic parasites that characteristically elicit interleukin 5-mediated eosinophilia. (Helminth-elicited eosinophilia, however, may be suppressed by glucocorticoid therapy or by intercurrent bacterial or viral infections.) The magnitude of eosinophilia tends to correlate with the extent of tissue invasion by helminths. Marked blood eosinophilia (more than 3000 eosinophils per microliter) develops during the early transpulmonary migration of intestinal nematodes, including *Ascaris* and hookworms, at a time when eggs (whose presence confirms the diagnosis) have not yet been produced in the intestinal tract.

Eosinophilia is also marked in the early stages of fluke infections, including schistosomiasis (Katayama fever), paragonimiasis, clonorchiasis, and fascioliasis; during the stage of muscle invasion in trichinellosis; during tissue migration of adult worms in loiasis and gnathostomiasis; and with heavy infections in visceral larva migrans. Eosinophilia persisting for more than a year may be indicative of hookworm infection, strongyloidiasis, visceral larva migrans (especially in children), filarial infection (including onchocerciasis, loiasis, and tropical pulmonary eosinophilia), fluke infections (including schistosomiasis, fascioliasis, clonorchiasis, and paragonimiasis), and cysticercosis. Leakage of fluids from echinococcal cysts can cause intermittent increases in eosinophilia.

Eosinophilia sometimes provides the only clue to the presence of helminthic infection and should prompt an evaluation for such infection. Serologic testing for schistosomiasis, filariasis, visceral larva migrans, and strongyloidiasis will be helpful in an assessment for some of the diseases most likely to elicit eosinophilia. Serologic evaluation for strongyloidiasis is especially important since autoinfection may permit persistence of the organisms for decades and put the patient at risk for disseminated disease if immunosuppressive glucocorticoids are later administered for any reason.

(Bibliography omitted in Palm version)

211. LABORATORY DIAGNOSIS OF PARASITIC INFECTIONS - *Charles E. Davis*

The cornerstone for the diagnosis of parasitic infections is a thorough history of the patient's illness. Epidemiologic aspects of the illness are especially important because the risks of acquiring many parasites are closely related to occupation, recreation, or travel to areas of high endemicity. Without a basic knowledge of the epidemiology and life cycles of the major parasites, it is difficult to approach the diagnosis of parasitic infections systematically. Accordingly, the medical classification of important human parasites in this chapter emphasizes their geographic distribution, their transmission, and the anatomic location and stages of their life cycle in humans. The text and tables are intended to serve as a guide to the correct diagnostic procedures for the major parasitic infections and to direct the reader to other chapters that contain more comprehensive information about each infection.Tables 211-1,211-2, and211-3summarize the geographic distributions, the anatomic locations, and the laboratory methods employed for the diagnosis of flatworm, roundworm, and protozoal infections, respectively.

In addition to selecting the correct diagnostic procedures, physicians must counsel their patients to ensure that specimens are collected properly and arrive at the laboratory promptly. For example, the diagnosis of bancroftian filariasis is unlikely to be confirmed by the laboratory unless blood is drawn near midnight, when the nocturnal microfilariae are active. Laboratory personnel and surgical pathologists should be notified in advance when a parasitic infection is suspected. Continuing interaction with the laboratory staff and the surgical pathologists increases the likelihood that parasites in body fluids or biopsy specimens will be examined carefully by the most capable individuals.

INTESTINAL PARASITES

Most helminths and protozoa exit the body in the fecal stream. The patient or the patient's attendant should be instructed to collect feces in a clean cardboard container and to record the time of collection on the container. Contamination with water, which could contain free-living protozoa, or with urine should be avoided. Fecal samples should be collected before ingestion of barium or other contrast agents for radiologic procedures and before treatment with antidiarrheal agents and antacids, because these substances change the consistency of the feces and interfere with microscopic detection of parasites. Because of the cyclic shedding of most parasites in the feces, a minimum of three samples collected on alternate days should be examined. When delays in transport to the laboratory are unavoidable or specimens must be shipped by mail, fecal samples should be kept in polyvinyl alcohol to preserve protozoal trophozoites. Refrigeration will also preserve trophozoites for a few hours and protozoal cysts and helminthic ova for several days.

Analysis of fecal samples consists of both a macroscopic and a microscopic examination. Watery or loose stools are more likely to contain protozoal trophozoites, but protozoal cysts and all stages of helminths may be found in formed feces. If adult worms or tapeworm segments are observed, they should be transported promptly to the laboratory or washed and preserved in fixative for later examination. The only tapeworm with motile segments is *Taenia saginata*, the beef tapeworm, which patients sometimes bring to the physician. Motility is an important distinguishing characteristic, because the

ova of *T. saginata* and *T. solium*, the cause of cysticercosis, are morphologically indistinguishable.

Microscopic examination of feces (Table 211-4) is not complete until direct wet mounts have been evaluated and concentration techniques as well as permanent stains have been applied. Before accepting a report of negativity for ova and parasites as final, the physician should insist that the laboratory undertake each of these procedures. Some intestinal parasites are more readily detected in material other than feces. For example, use of the string test (or one of its commercial substitutes) to sample duodenal contents is sometimes necessary to detect *Giardia lamblia*, *Cryptosporidium*, and *Strongyloides* larvae. Use of the "Scotch tape" technique to detect pinworm ova on the perianal skin sometimes also reveals ova of *T. saginata* deposited perianally when the motile segments disintegrate (Table 211-4).

Two routine solutions are used to make wet mounts for the identification of the various life stages of helminths and protozoa: physiologic saline for trophozoites, cysts, ova, and larvae and dilute iodine solution for protozoal cysts and ova. Iodine solution must never be used to examine specimens for trophozoites because it kills the parasites and thus eliminates their characteristic motility.

The two most common concentration procedures for detecting small numbers of cysts and ova are formalin-ether sedimentation and zinc sulfate flotation. The formalin-ether technique is preferable, because all parasites sediment but not all float. Slides permanently stained for trophozoites should be prepared before concentration. Additional slides stained for cysts and ova may be made from the concentrate.

In many instances, especially in the differentiation of *Entamoeba histolytica* from other amebas, identification of parasites from wet mounts or concentrates must be considered tentative. Permanently stained smears allow study of the cellular detail necessary for definitive identification. The iron-hematoxylin stain is excellent for critical work, but trichrome staining, which can be completed in 1 h, is a satisfactory alternative that also reveals parasites in specimens preserved in polyvinyl alcohol fixative.

BLOOD AND TISSUE PARASITES

Invasion of tissue by protozoa and helminths renders the choice of diagnostic techniques more difficult. For example, physicians must understand that aspiration of an amebic liver abscess rarely reveals *E. histolytica* because the trophozoites are located primarily in the abscess wall. They must remember that the urine sediment offers the best opportunity to detect *Schistosoma haematobium* in the Ethiopian youngster or the American traveler who returns from Africa with hematuria (Table 211-5).Tables 211-1,211-2, and211-3, which offer a quick guide to the geographic distribution and anatomic locations of the major tissue parasites, should help the physician to select the appropriate body fluid or biopsy site for microscopic examination.Tables 211-5,211-6, and211-7provide additional information about the identification of parasites in samples from specific anatomic locations. The laboratory procedures for detection of parasites in other body fluids are similar to those used in the examination of feces. The physician should insist on wet mounts, concentration techniques, and permanent stains for all body fluids. The trichrome or iron-hematoxylin stain is satisfactory for all tissue

helminths in body fluids other than blood, but microfilarial worms and blood protozoa are more easily visualized when stained with Giemsa or Wright's stain.

The most common parasites detected in Giemsa-stained blood smears are the plasmodia, microfilariae, and African trypanosomes (Table 211-5). Most patients with Chagas' disease present in the chronic phase, when *Trypanosoma cruzi* is no longer microscopically detectable in blood smears. Wet mounts are sometimes more sensitive than stained smears for the detection of microfilariae and African trypanosomes because these active parasites cause noticeable movement of the erythrocytes in the microscopic field. Nuclepore filtration of blood facilitates the detection of microfilariae. The intracellular amastigote forms of *Leishmania* spp. and *T. cruzi* can sometimes be visualized in stained smears of peripheral blood, but aspirates of the bone marrow, liver, and spleen are the best sources for microscopic detection and culture of *Leishmania* in kala-azar and of *T. cruzi* in chronic Chagas' disease.

The diagnosis of malaria and the critical distinction among the various *Plasmodium* spp. are made by microscopic examination of stained thick and thin blood films (Table 211-6;Plates VI-3,VI-4,VI-5,VI-6,VI-7,VI-8,VI-9,VI-10,VI-11,VI-12,VI-13,VI-14,VI-15,VI-16,VI-17,VI-18, VI-19,VI-20,VI-21,VI-22,VI-23,VI-24,VI-25,VI-26,VI-27,VI-28,VI-29,VI-30,VI-31,VI-32, andVI-33). Most malariologists prefer Giemsa stain because of its overall high quality, suitability for staining of both thick and thin smears, and stability in tropical climates. Wright's stain can produce high-quality thin smears and is widely used in the Americas, but it deteriorates rapidly in the tropics because its methanol base is highly hygroscopic. Specimens of capillary or venous blood should be obtained every 4 to 12 h until a diagnosis is established. The thin smear is made on clean slides exactly like a blood film for a white blood cell differential. The thick film is made by placing one drop of blood on the slide and stirring it in a circular motion to a diameter of about 2 cm. The erythrocytes in the thick film are lysed with water, but the thin film is fixed in methanol to preserve erythrocyte morphology.

Although most tissue parasites stain with the traditional hematoxylin and eosin, surgical biopsy specimens should also be stained with appropriate special stains. The surgical pathologist who is accustomed to applying silver stains for *Pneumocystis carinii* to induced sputum and transbronchial biopsies may have to be reminded to examine wet mounts and iron-hematoxylin-stained preparations of pulmonary specimens for helminthic ova and *E. histolytica*. The clinician should also be able to advise the surgeon and pathologist about optimal techniques for the identification of parasites in specimens obtained by certain specialized minor procedures (Table 211-7). For example, the excision of skin snips for the diagnosis of onchocerciasis, the collection of rectal snips for the diagnosis of schistosomiasis, and punch biopsy of skin lesions for the identification and culture of cutaneous and mucocutaneous species of *Leishmania* are simple procedures, but the diagnosis can be missed if the specimens are improperly obtained or processed.

NONSPECIFIC TESTS

Eosinophilia is a common accompaniment of infections with most of the tissue helminths; absolute numbers of eosinophils may be high in trichinosis and the migratory

phases of filariasis (Table 211-8). Intestinal helminths provoke eosinophilia only during pulmonary migration of the larval stages. Eosinophilia is not a manifestation of protozoal infections, with the possible exceptions of those due to *Isospora* and *Dientamoeba fragilis*.

Like the hypochromic, microcytic anemia of heavy hookworm infections, other nonspecific laboratory abnormalities may suggest parasitic infection in patients with appropriate geographic and/or environmental exposures. Biochemical evidence of cirrhosis or an abnormal urine sediment in an African immigrant certainly raises the possibility of schistosomiasis, and anemia and thrombocytopenia in a febrile traveler or immigrant are among the hallmarks of malaria. Computed tomography and magnetic resonance imaging also contribute to the diagnosis of infections with many tissue parasites and have become invaluable adjuncts in the diagnosis of neurocysticercosis and cerebral toxoplasmosis.

ANTIBODY AND ANTIGEN DETECTION

Useful antibody assays for many of the important tissue parasites are available; those listed inTable 211-9 can be obtained from the Centers for Disease Control and Prevention (CDC) in Atlanta. The results of most serologic tests not listed in the tables and not offered by the CDC should be interpreted with caution.

The value of antibody assays is limited in the case of the filarial worms and plasmodia. The detection of antibody to plasmodia is of limited use for establishing the diagnosis of malaria in individual patients because diagnostic titers develop slowly and the tests must be sent to the CDC. Filarial antigens cross-react with those from other nematodes, and antibody assays do not distinguish between past and current infection. In contrast, a negative result in an American or European traveler virtually rules out the diagnosis of bancroftian or brugian filariasis. Promising new assays for filarial antigens and antibodies in lymphatic filariasis are not yet available in commercial kits or from theCDC.

Despite these specific limitations, the restricted geographic distribution of many tropical parasites increases the diagnostic usefulness of antibody detection in travelers from industrialized countries. On the other hand, a large proportion of the world has been exposed to *Toxoplasma gondii*, and the presence of IgG antibody does not constitute proof of active disease.

Fewer antibody assays are available for the diagnosis of infection with intestinal parasites. Cross-reactivity and lack of efficient cultivation techniques, along with the ability to establish diagnoses without invasive procedures, have discouraged intensive investigation of these methods. *E. histolytica* is the major exception. Sensitive, specific serologic tests are invaluable in the diagnosis of amebiasis. Commercial kits for the detection of antigen by enzyme-linked immunosorbent assay or of whole organisms by fluorescent antibody assay are now available for several protozoan parasites (Table 211-9).

MOLECULAR TECHNIQUES

DNA hybridization with probes that are repeated many times in the genome of a specific

parasite and amplification of a specific DNA fragment by the polymerase chain reaction (PCR) are promising techniques for the diagnosis of parasitic infections. Although molecular techniques for the detection of many parasites are already being used in insect vectors, animal models, and human trials, few are available for routine use in patients at this time. The only available commercial kit is that for the identification of *Trichomonas vaginalis* by hybridization of secretions from vaginal swabs with synthetic oligonucleotide probes. TheCDC will perform PCR for microsporidia, cryptosporidia, *Cyclospora*, and *E. histolytica* on stools (frozen or fixed in either potassium dichromate or ethanol) and on biopsy and bronchoalveolar lavage samples (fixed in methanol or ethanol). For *Plasmodium* and *Babesia*, PCR is performed on blood treated with EDTA or collected in IsoCode Stix (Schleicher and Schuell).

(Bibliography omitted in Palm version)

212. THERAPY FOR PARASITIC INFECTIONS - *Thomas A. Moore*

Over the last few decades, the reach of some parasitic diseases such as malaria has extended because of factors such as deforestation, population shifts, global warming, and other climatic events (e.g., "El Nino"). Efforts to combat this trend are complicated by the development and spread of drug resistance among parasites and the limited introduction of new antiparasitic agents. However, significant advances toward the reduction of the burden of parasitic disease have been made. The generous donation of ivermectin and albendazole for global eradication programs has improved the health of countless individuals and offers the promise of disease eradication. The expanded use of traditionally nonparasitic agents, such as amphotericin B for visceral leishmaniasis, has offered hope against the specter of drug resistance. The introduction of newer agents, such as triclabendazole, also appears promising.

Currently recommended treatment options for most parasitic diseases of humans are listed inTable 212-1. A brief summary of some of the agents can be found below; each agent is listed by its generic name. Many of the agents are approved by the Food and Drug Administration (FDA) but are considered investigational for the treatment of certain infections; these drugs are marked accordingly in Table 212-1. Drugs marked in the text with an asterisk (*) are available only through the Centers for Disease Control and Prevention (CDC) Drug Service (telephone: 404-639-3670). Other drugs, marked with a dagger (+), are available only through the manufacturer; contact information for these manufacturers may be available from the CDC. Information on dosing in children and pregnant women can be obtained in the references at the end of the chapter.

Albendazole This benzimidazole derivative has recently become generally available and is active against a broad range of helminths and protozoa. All benzimidazoles act by binding to freeb-tubulin, inhibiting the polymerization of tubulin and the microtubule-dependent uptake of glucose. In helminths, the result is the depletion of glycogen stores, but this fundamental disruption of cellular metabolism also offers treatment for a wide range of parasitic diseases. Like all benzimidazoles, albendazole is poorly absorbed from the gastrointestinal tract. However, since the active metabolite attains higher serum and cyst concentrations than mebendazole, it is more effective against echinococcal disease. Significant adverse reactions are usually limited to prolonged use and include abdominal pain and reversible hepatic dysfunction. Rarely, leukopenia and reversible alopecia occur. Albendazole is contraindicated in early pregnancy.

Artesunate and Artemether Artesunate, artemether, and the parent compound artemisinin are sesquiterpene lactones derived from the wormwood plant *Artemisia annua*. These agents have become first-line treatments for severe falciparum malaria in some areas of the world where drug resistance is a major problem. They are rapidly effective against the asexual blood forms of *Plasmodium* spp., including multidrug-resistant *P. falciparum*, but they are not active against intrahepatic forms. Their mechanism of action is not completely understood, but they are believed to act by converting to free radicals and other intermediates in the presence of intraparasitic iron; the result is alkylation of parasite proteins or membrane damage. Artemisinin derivatives presently show no cross-resistance with known antimalarials and thus are important for treating severe malaria in areas of multidrug resistance. However, long treatment

courses are required and, when these agents are used alone, recrudescence may occur. Artemisinin and its derivatives are cleared rapidly from the circulation, and their short half-lives limit their use for prophylaxis. Adverse events are usually infrequent and mild and include drug fever and contact dermatitis. Animal data suggest that neurotoxicity can develop if the compounds are administered chronically, and cerebellar dysfunction has been reported in persons treated with artesunate. These drugs are not available in the United States.

Amphotericin B Amphotericin exerts its effect by inserting itself into the cytoplasmic membrane of the organism and binding sterols, causing membrane permeability. Amphotericin B deoxycholate, a lipophilic polyene drug, is an effective agent for the treatment of leishmaniasis and amebic meningoencephalitis due to *Naegleria* spp., but its use is associated with significant nephrotoxicity and occasional allergic reactions. Three lipid-complexed formulations of amphotericin B have been released: amphotericin B colloidal dispersion (ABCD), amphotericin B lipid complex (ABLC), and liposomal amphotericin B. These agents are effective against antimony-resistant visceral leishmaniasis and offer the benefits of shorter courses and less toxicity.

Atovaquone Atovaquone is a hydroxynaphthoquinone that exerts its broad-spectrum antiprotozoal activity via inhibition of parasite mitochondrial electron transport. Although it has relatively poor bioavailability, atovaquone exhibits potent activity against toxoplasmosis when used with pyrimethamine. When combined with proguanil or doxycycline, it is effective for both treatment and prophylaxis of malaria. Side effects are rare but can include nausea and a maculopapular rash.

Azithromycin An azalide antibiotic, azithromycin has been used to treat a number of protozoal infections such as babesiosis, malaria, toxoplasmosis, and cryptosporidiosis. Azithromycin acts by inhibiting protein synthesis; in apicomplexan parasites, this inhibition occurs in the plastid. Most adverse reactions are gastrointestinal (diarrhea, nausea, abdominal pain) and uncommon and rarely require discontinuation of the drug.

Benznidazole This oral nitroimidazole derivative is used to treat acute Chagas' disease, and cure rates of 80 to 90% have been recorded. Benznidazole acts by generating oxygen radicals to which the parasite is more sensitive than mammalian cells because of a relative deficiency in antioxidant enzymes. Adverse effects are frequent and include rashes, nausea, paresthesias, and leukopenia. The safety of benznidazole in early pregnancy has not been established, but the drug should be used immediately after the first trimester to prevent congenital transmission. Benznidazole is currently unavailable in the United States.

Bithionol* Bithionol is a phenolic substance structurally related to hexachlorophene. Its antihelminthic activity is poorly understood, but the agent is believed to inhibit oxidative phosphorylation. Bithionol is no longer manufactured. A dwindling supply is available from the CDC for treatment of fascioliasis and paragonimiasis. The drug's distribution is limited to physicians treating patients with one of these diseases who are unable to use praziquantel because of previous idiosyncratic or allergic reactions or in whom a course of praziquantel has failed to eradicate infection. Significant side effects are common and include abdominal pain, diarrhea, and urticaria.

Chloroquine The best-known of the 4-aminoquinolines, chloroquine has marked, rapid schizonticidal and gametocidal activity against blood forms of *P. ovale* and *P. malariae* and against susceptible strains of *P. vivax* and *P. falciparum*. It is not active against intrahepatic forms (*P. vivax* and *P. ovale*). Chloroquine is concentrated in the acidic food vacuoles of intraerythrocytic parasites, where it reaches levels 600-fold higher than plasma levels. The drug inhibits a parasite heme polymerase that protects the parasite from the membrane-damaging byproducts of hemoglobin degradation; as a result of this inhibition, the parasite is effectively killed with its own metabolic waste. Chloroquine resistance appears to arise as a result of a decreased level of chloroquine uptake. This drug is safe for use in pregnancy. Adverse reactions include pruritus, transient headaches, and nausea.

Clindamycin This macrolide is an effective adjunct for the treatment of several protozoal infections, including toxoplasmosis, malaria, and babesiosis. The most significant potential adverse reaction is the development of *Clostridium difficile*-associated diarrhea. When administered with quinine, clindamycin is active against drug-resistant falciparum malaria; this combination is the therapy of choice for babesiosis.

Diethylcarbamazine* A piperazine derivative with a long history of successful use, this drug remains the treatment of choice for lymphatic filariasis and loiasis and has also been used for visceral larva migrans. Diethylcarbamazine exerts effects on helminths, including immobilization due to a decrease in muscle activity, disruption of microtubule formation, and alteration of helminthic surface membranes resulting in enhanced killing by the host's immune system. In addition, this agent enhances adherence properties of eosinophils. It is safe for use in pregnancy and well tolerated. Significant adverse events associated with the drug, including encephalopathy and death, are attributable to the parasite burden, which is best assessed by the degree of microfilaremia. Use in patients with onchocerciasis can precipitate a Mazzotti reaction with pruritus, fever, and arthralgias. Untoward effects produced directly by diethylcarbamazine usually involve the gastrointestinal tract and are dose-related.

Eflornithine (Difluoromethylornithine, DFMO)+ This ornithine derivative has specific activity against all stages of infection with *Trypanosoma brucei gambiense* and acts by irreversibly inhibiting ornithine decarboxylase -- an enzyme critical to the formation of polyamines, which are essential to trypanosomatids. Eflornithine readily crosses the blood-brain barrier and is excreted mainly by the kidneys. Its use is contraindicated in pregnancy. Adverse reactions, which are usually mild and reversible, include pancytopenia, diarrhea, and transient hearing loss.

Furazolidone This nitrofuran derivative, which is an effective alternative agent for the treatment of giardiasis, acts by damaging parasite DNA. Since it is the only agent active against *Giardia* that is available in liquid form, it is often used to treat young children. Side effects include allergic reactions, nausea, vomiting, and disulfiram-like reactions when ingested with alcohol. Because hemolytic anemia due to glutathione instability can occur, furazolidone treatment is contraindicated in mothers who are breast-feeding and in neonates.

Halofantrine An oral alternative drug for treatment of malaria due to

chloroquine-resistant *P. falciparum*, this 9-phenanthrenemethanol is one of three classes of arylaminoalcohols first identified as potential antimalarial agents by the World War II Malaria Chemotherapy Program. Its activity is believed to be similar to that of chloroquine. Halofantrine is generally well tolerated; the most commonly reported adverse effects are abdominal pain and diarrhea. The incidence of pruritus is lower than that with chloroquine. Halofantrine causes dose-related prolongation of the PR and QT intervals, and its use is contraindicated in persons who have cardiac disease or who have taken mefloquine in the preceding 3 weeks. Halofantrine treatment is also contraindicated in pregnant and lactating women. The drug is currently unavailable in the United States.

Iodoquinol This hydroxyquinoline is an effective luminal agent for the treatment of amebiasis, balantidiasis, and infection with *Dientamoeba fragilis*. Its mechanism of action is unknown. Adverse effects include headache, diarrhea, nausea, vomiting, abdominal pain, pruritus, fever, seizures, and encephalopathy. Most serious are the reactions related to prolonged high-dose therapy, which should not occur if the dosage regimens recommended inTable 212-1 are followed. Because the drug contains iodine, it should be used with caution in patients with thyroid disease.

Ivermectin This derivative of avermectin is used to treat infections caused by a wide range of helminths. It is the drug of choice for the treatment of onchocerciasis, strongyloidiasis, and cutaneous larva migrans. While active against the intestinal helminths *Ascaris lumbricoides* and *Enterobius vermicularis*, it is variably effective in trichuriasis and ineffective against hookworms. Recent data suggest that ivermectin acts by opening neuromuscular membrane-associated glutamate-dependent chloride channels (unique to nematodes and arthropods) -- an event resulting in an influx of chloride ions, worm paralysis, and subsequent death by immune or other mechanisms. Ivermectin is generally safe, easy to administer, and well tolerated, but encephalopathy and occasional deaths have been reported when the drug is given to persons with high burdens of *Loa loa* microfilaremia. Ivermectin is not approved for use during pregnancy.

Mebendazole This benzimidazole derivative is widely used for treatment of intestinal helminths and exhibits activity against *Echinococcus granulosus*. Benzimidazoles block parasite microtubule assembly and glucose uptake. Because mebendazole is poorly absorbed, its incidence of side effects is low, but its usefulness in treating tissue helminths is limited. Transient abdominal pain and diarrhea sometimes occur, usually in persons with massive parasite burdens. The use of mebendazole is contraindicated in pregnancy.

Mefloquine Like quinine and chloroquine, this quinoline is active only against the asexual erythrocytic stages of malarial parasites. The mode of action of mefloquine is similar to that of chloroquine, but mefloquine is not concentrated so extensively in the food vacuole and may act on alternative targets in the parasite. Taken as a single dose, it is the preferred drug for prophylaxis of chloroquine-resistant malaria; high doses can be used for treatment. The development of drug-resistant strains of *P. falciparum* in parts of Africa and Southeast Asia is ominous, but mefloquine is still an effective drug in most of the world. It is well tolerated by most persons, but its safety in pregnancy is unknown. Adverse effects are usually dose-related and include nausea and dizziness. Psychosis and seizures occur rarely, but treatment of patients with neuropsychiatric

conditions warrants caution. Concomitant use of quinine, quinidine, or drugs causing b-adrenergic blockade may produce electrocardiographic disturbances or cardiac arrest.

Melarsoprol* This trivalent arsenical is used for the treatment of late-stage East African trypanosomiasis and is not uniformly effective. The drug enters the parasite via an adenosine transporter; resistant strains lack this transport system. Arsenicals react avidly with sulfhydryl groups on proteins and inhibit their function. This is the likely mechanism of action and the cause of the severe adverse effects commonly seen. Encephalopathy is the most serious side effect, usually occurring within 4 days of the initiation of therapy and resulting in death in 6% of recipients.

Metrifonate This organophosphorus compound has selective activity against *Schistosoma haematobium*. It is partially metabolized to 2,2-dimethyldichlorovinyl phosphate (DDVP), a highly active chemical that irreversibly inhibits the acetylcholinesterase enzyme. Schistosomal cholinesterase is more susceptible to this metabolite than is the corresponding human enzyme. Metrifonate's exact mechanism of action is uncertain, but it is believed to inhibit tegumental acetylcholine receptors that mediate glucose transport. Although the drug is well tolerated, recipients experience a transient decrease in plasma cholinesterase activity and should not be exposed to neuromuscular blocking agents or organophosphate insecticides for at least 48 h after treatment. Metrifonate's safety in pregnancy is not established. The drug is currently unavailable in the United States.

Metronidazole Of the nitroimidazoles, only metronidazole has been licensed in the United States. This drug hasFDAapproval only for the treatment of amebiasis and trichomoniasis, although it is currently the drug of choice for giardiasis and trichomoniasis and is an alternative agent for balantidiasis. Metronidazole is reduced by anaerobic metabolism, and the metabolite acts as an electron sink, depriving anaerobes of reducing equivalents. Covalent binding or other interactions of intermediate metabolites of metronidazole with parasite macromolecules may partly explain the efficacy of this agent. Its benefit in dracunculiasis appears to be due to a reduction in inflammation rather than to any specific antihelminthic effect. Metronidazole is generally well tolerated despite common side effects such as nausea, headache, and a metabolic aftertaste. Alcohol should be avoided due to disulfiram-like effects. Although metronidazole has not been approved or recommended for use during pregnancy, it has not been associated with birth defects.

Nifurtimox* This nitrofuran compound is an effective oral agent for the treatment of acute Chagas' disease. Intracellular reduction followed by auto-oxidation yielding oxygen radicals has been suggested as the mode of action of nifurtimox on *Trypanosoma cruzi* and as the basis of its toxicity in humans. Prolonged use is required, but the course may have to be interrupted due to drug toxicity, which develops in 40 to 70% of recipients. Adverse reactions are common, dose related, and reversible. They include nausea, vomiting, abdominal pain, insomnia, seizures, and polyneuritis. Nifurtimox should be avoided in early pregnancy.

Nitazoxanide+This 5-nitrothiazole compound appears to be a safe and effective alternative agent for the treatment of cryptosporidiosis. Its mechanism of action is unknown. It is currently available only from Romark Laboratories in the United States.

Oxamniquine This tetrahydroquinoline derivative is an effective alternative agent for the treatment of schistosomiasis, although susceptibility to this drug exhibits regional variation. In treated adult schistosomes, oxamniquine produces marked tegumental alterations similar to those seen with praziquantel but less rapid (evident 4 to 8 days after treatment). Patients should be warned that their urine may have an intense orange-red color. Side effects are uncommon and usually mild, although hallucinations and seizures have been reported. Oxamniquine has not been shown to be teratogenic or embryotoxic, but its use in pregnancy has not been approved.

Paromomycin This aminoglycoside is an effective oral agent for the treatment of infections due to intestinal protozoa. Like other aminoglycosides, it is poorly absorbed after oral administration and binds to the 30S ribosomal RNA in the aminoacyl-tRNA site, resulting in inhibition of protein synthesis. Paromomycin is well tolerated and safe for use in pregnancy.

Pentamidine Isethionate This diamine is an effective alternative agent for some forms of leishmaniasis and trypanosomiasis. While its mechanism of action remains undefined, it is known to exert a wide range of effects, including interaction with trypanosomal kinetoplast DNA, interference with polyamine synthesis through a decrease in the activity of ornithine decarboxylase, and inhibition of RNA polymerase, ribosomal function, and the synthesis of nucleic acids and proteins. Adverse reactions are common and include hypotension, pancreatitis, hypoglycemia, arrhythmias, and reversible renal failure.

Praziquantel This heterocyclic prazino-isoquinoline derivative is highly active against a broad spectrum of trematodes and cestodes. It disrupts the parasite tegument, resulting in contracture with loss of adherence to host tissues and ultimately disintegration or expulsion. Drug levels are reduced by concomitantly administered glucocorticoids, but cimetidine can be used to offset this problem. Praziquantel is generally well tolerated, but seizures may result in persons with neurocysticercosis. Patients with schistosomiasis who have heavy parasite burdens may develop abdominal discomfort, nausea, headache, dizziness, and drowsiness. Although praziquantel has not been shown to be mutagenic, teratogenic, or embryotoxic, it is preferable to delay treatment until after delivery unless immediate intervention is essential. Because praziquantel is excreted in breast milk, it is recommended that women not nurse on the day(s) of drug administration or for 72 h thereafter.

Primaquine Phosphate This drug is the only agent available for eradication of the hepatic stage of malarial parasites. In order to be effective, it must be metabolized by the host. Although their parasiticidal activity remains unclear, the metabolites are believed to affect both pyrimidine synthesis and the mitochondrial electron transport chain. The major adverse effect of this drug is acute hemolysis in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Primaquine phosphate is otherwise well tolerated. Its use in pregnancy is contraindicated.

Proguanil (Chloroguanide) This agent, which inhibits plasmodial dihydrofolate reductase, is used with atovaquone for oral treatment of uncomplicated malaria or with chloroquine for prophylaxis in parts of Africa without widespread chloroquine-resistant *P.*

falciparum. Proguanil is quite well tolerated at the usually prescribed doses, but higher doses can produce nausea, vomiting, abdominal pain, and diarrhea. It is not available in the United States.

Pyrantel Pamoate This safe, well-tolerated, and inexpensive pyrimidine derivative depolarizes the neuromuscular junctions of most intestinal nematodes, resulting in irreversible paralysis and allowing natural expulsion of the worms with the host's feces. The drug is poorly absorbed from the gastrointestinal tract and is usually effective in a single dose. It has minimal toxicity at the oral doses used to treat intestinal helminthic infection.

Pyrimethamine When combined with short-acting sulfonamides, this diaminopyrimidine is effective in malaria, toxoplasmosis, and isosporiasis. Unlike mammalian cells, the parasites that cause these infections cannot utilize preformed pyrimidines obtained through salvage pathways but rather rely completely on de novo synthesis of pyrimidines, for which folate derivatives are essential cofactors.

Pyrimethamine-sulfadoxine is an effective adjunctive agent for the oral treatment of uncomplicated malaria due to chloroquine-resistant organisms. However, its usefulness as a first-line agent is limited by the development of resistant strains of *P. falciparum* and *P. vivax*.

When combined with sulfadiazine, pyrimethamine is the treatment of choice for toxoplasmosis, but the duration of the required course of therapy often results in the development of folate deficiency requiring folinic acid supplementation. Sulfadiazine crystals can cause hematuria, and allergic drug reactions due to sulfadiazine often require a switch to clindamycin.

Quinacrine* Quinacrine is the only drug approved by theFDA for the treatment of giardiasis. It is not commercially available but can be obtained from alternative sources through theCDC Drug Service. Quinacrine intercalates into parasite DNA and inhibits nucleic acid synthesis. Side effects are common and include nausea and vomiting, headache, and skin discoloration. Alcohol is best avoided due to a disulfiram-like effect.

Quinine and Quinidine When combined with another agent, the cinchona alkaloid quinine is effective for the oral treatment of both uncomplicated malaria due to chloroquine-resistant strains and babesiosis. Quinine acts rapidly against the asexual blood stages of all forms of human malaria. For severe malaria, only quinidine (the dextroisomer of quinine) is available in the United States. Its use requires cardiac monitoring, and dose reduction is necessary in persons with severe renal impairment. Both quinine and quinidine can produce hypoglycemia. Symptoms of cinchonism (tinnitus, headache, nausea, and visual disturbances) are dose-related and reversible.

Spiramycin+This macrolide antibiotic is used to treat acute toxoplasmosis in pregnancy and congenital toxoplasmosis. Although not yet licensed in the United States, it is available through theFDA. Complications of treatment are rare but can include life-threatening ventricular arrhythmias in neonates.

Sodium Stibogluconate* and Meglumine Antimonate These pentavalent antimony

compounds are first-line agents for the treatment of all forms of leishmaniasis. Despite their use in leishmaniasis for almost 100 years, their mechanism of action against *Leishmania* spp. remains unknown. Presumably, the compounds interfere with parasite metabolism. The drugs are taken up by the reticuloendothelial system, and their activity against *Leishmania* spp. may be enhanced by this localization. Resistance is a major problem in some areas of the world. Side effects are common and generally reversible but require temporary interruption of therapy in many cases. Chemical pancreatitis is almost universal, although it is often asymptomatic. In rare instances, pentavalent antimony compounds produce prolongation of the QT interval, and sudden death due to arrhythmia or cardiac failure has been reported. Arthralgias, myalgias, and headaches occur frequently. Since the drugs' safety in pregnancy has not been established, their use should be avoided if possible in pregnant women. These agents may be used in children >18 months of age.

Suramin* This derivative of urea is the drug of choice for the early stage of African trypanosomiasis. The drug acts by forming stable complexes with proteins, inhibiting multiple enzymes. Suramin has a variety of potentially severe side effects, including anaphylaxis, exfoliative dermatitis, paresthesias, photophobia, and renal dysfunction.

Tetracycline and Doxycycline These antibiotics are useful in the treatment of balantidiasis and *D. fragilis* infection as well as in the oral treatment of uncomplicated malaria due to chloroquine-resistant strains. The tetracyclines inhibit protein synthesis in prokaryotic ribosomes, and they probably have the same activity in parasites. Potential side effects in adults include nausea, vomiting, and photosensitivity dermatitis. Because they can impair normal development of bones and teeth, tetracyclines are contraindicated in pregnant women and children <8 years of age.

Thiabendazole This benzimidazole derivative is a potent antihelminthic agent, but its use in strongyloidiasis and other infections is limited by frequent, severe side effects. Patients most often report dizziness, headache, nausea, and vomiting. Less commonly, hepatitis and severe hypersensitivity reactions develop. The drug's mechanism of action is similar to that of other benzimidazoles. Treatment with thiabendazole is contraindicated in pregnancy.

Tinidazole This nitroimidazole is effective for the treatment of amebiasis, giardiasis, and trichomoniasis. Its mechanism of action and side effects are similar to those seen with metronidazole, but adverse events appear to be less frequent and severe with tinidazole. In addition, tinidazole is potentially curative in a single dose. This agent is currently unavailable in the United States.

Triclabendazole This benzimidazole is effective against paragonimiasis and all stages of *Fasciola hepatica*, a trematode with inherent resistance to praziquantel. The sulfoxide metabolite, which is believed to be responsible for the drug's activity, binds to fluke tubulin and disrupts microtubule-based processes. Triclabendazole is safe and well tolerated and offers single-dose cure. It is currently unavailable in the United States.

Trimethoprim-Sulfamethoxazole This synergistic antifolate compound is active against cyclosporiasis, isosporiasis, and encephalitis due to *Toxoplasma gondii*. Trimethoprim is a dihydrofolate reductase inhibitor whose effect is enhanced by

sulfamethoxazole. Adverse effects, which can be severe, are usually attributable to the sulfonamide component and involve allergic skin reactions, bone marrow suppression, and hemolysis.

SECTION 17 -PROTOZOAL INFECTIONS

213. AMEBIASIS AND INFECTION WITH FREE-LIVING AMEBAS - *Sharon L. Reed*

AMEBIASIS

DEFINITION

Amebiasis is an infection with the intestinal protozoan *Entamoeba histolytica*. About 90% of infections are asymptomatic, and the remaining 10% produce a spectrum of clinical syndromes ranging from dysentery to abscesses of the liver or other organs.

LIFE CYCLE AND TRANSMISSION

E. histolytica is acquired by ingestion of viable cysts from fecally contaminated water, food, or hands. Food-borne exposure is most prevalent and is particularly likely when food handlers are shedding cysts or food is being grown with feces-contaminated soil, fertilizer, or water. Less common means of transmission include contaminated water, oral and anal sexual practices, and -- in rare instances -- direct rectal inoculation through colonic irrigation devices. Motile trophozoites are released from cysts in the small intestine and, in most patients, remain as harmless commensals in the large bowel. After encystation, infectious cysts are shed in the stool and can survive for several weeks in a moist environment. In some patients, the trophozoites invade either the bowel mucosa, causing symptomatic colitis, or the bloodstream, causing distant abscesses of the liver, lungs, or brain. The trophozoites may not encyst in patients with active dysentery, and motile hematophagous trophozoites are frequently present in fresh stools. Trophozoites are rapidly killed by exposure to air or stomach acid, however, and therefore cannot cause infection.

EPIDEMIOLOGY

About 10% of the world's population is infected with *Entamoeba*, the majority with noninvasive *Entamoeba dispar*. Amebiasis results from infection with *E. histolytica* and is the third most common cause of death from parasitic disease (after schistosomiasis and malaria). Areas of highest incidence (due to inadequate sanitation and crowding) include most developing countries in the tropics, particularly Mexico, India, and nations of Central and South America, tropical Asia, and Africa. The main groups at risk in developed countries are travelers, recent immigrants, homosexual men, and inmates of institutions.

The wide spectrum of clinical disease is caused in part by infection with the two different species of *Entamoeba*. Isolates of *E. histolytica* from patients with invasive amebiasis have unique isoenzymes, surface antigens, DNA markers, and virulence properties and now are recognized as a distinct species from the noninvasive *E. dispar*.

Most asymptomatic carriers, including homosexual men and AIDS patients, harbor *E. dispar* and have self-limited infections. These observations suggest that *E. dispar* is incapable of causing invasive disease, since *Cryptosporidium* and *Isospora belli*, which also cause only self-limited illnesses in immunocompetent people, cause devastating

diarrhea in patients with AIDS. However, host factors play a role as well. In one study, 10% of asymptomatic patients who were colonized with *E. histolytica* went on to develop amebic colitis, while the rest remained asymptomatic and cleared the infection within 1 year.

PATHOGENESIS AND PATHOLOGY

Both trophozoites (Fig. 213-1) and cysts (Fig. 213-2) are found in the intestinal lumen, but only trophozoites of *E. histolytica* invade tissue. The trophozoite is 20 to 60 um in diameter and contains vacuoles and a nucleus with a characteristic central karyosome. In animals, depletion of intestinal mucus, diffuse inflammation, and disruption of the epithelial barrier occur before trophozoites actually come into contact with the colonic mucosa. Trophozoites attach to colonic mucus and epithelial cells by a galactose-inhibitable lectin. The earliest intestinal lesions are microulcerations of the mucosa of the cecum, sigmoid colon, or rectum that release erythrocytes, inflammatory cells, and epithelial cells. Proctoscopy reveals small ulcers with heaped up margins and normal intervening mucosa. Submucosal extension of ulcerations under viable-appearing surface mucosa causes the classic "flask-shaped" ulcer containing trophozoites at the margins of dead and viable tissues. Although neutrophilic infiltrates may accompany the early lesions in animals, human intestinal infection is marked by a paucity of inflammatory cells, probably in part because of the killing of neutrophils by trophozoites. Treated ulcers characteristically heal with little or no scarring. Occasionally, however, full-thickness necrosis and perforation occur.

Rarely, intestinal infection results in the formation of a mass lesion, or *ameboma*, in the bowel lumen. The overlying mucosa is usually thin and ulcerated, while other layers of the wall are thickened, edematous, and hemorrhagic; this condition results in exuberant formation of granulation tissue with little fibrous-tissue response.

A number of virulence factors have been linked to the ability of *E. histolytica* to invade through the interglandular epithelium. One is an extracellular cysteine proteinase that degrades collagen, elastin, secretory IgA, and the anaphylatoxins C3a and C5a. Other enzymes may disrupt glycoprotein bonds between mucosal epithelial cells in the gut. Amebas can lyse neutrophils, monocytes, lymphocytes, and cells of colonic and hepatic cell lines. The cytolytic effect of amebas appears to require direct contact with target cells and may be linked to the release of phospholipase A and pore-forming peptides.

Liver abscesses are always preceded by intestinal colonization, which may be asymptomatic. Blood vessels may be compromised early by lysis of the wall and thrombus formation. Trophozoites invade veins to reach the liver through the portal venous system. *E. histolytica* is resistant to complement-mediated lysis, a property critical to survival in the bloodstream. In contrast, *E. dispar* is rapidly lysed by complement and is thus restricted to the bowel lumen. Inoculation of amebas into the portal system of hamsters results in an acute cellular infiltrate consisting predominantly of neutrophils. Later, the neutrophils are lysed by contact with amebas, and the release of neutrophil toxins may contribute to necrosis of hepatocytes. The liver parenchyma is replaced by necrotic material that is surrounded by a thin rim of congested liver tissue. The necrotic contents of a liver abscess are classically described as "anchovy paste," although the fluid is variable in color and is composed of bacteriologically sterile

granular debris with few or no cells. Amebas, if seen, tend to be found near the capsule of the abscess.

Clinical infection does not induce immunity to recurrent colonization with *E. histolytica*, but repeated episodes of colitis or liver abscess are unusual. Antibody is not protective; titers correlate with the length of illness rather than with the severity of disease. Studies of animals suggest that cell-mediated immunity may be important for protection, although patients with AIDS appear not to be predisposed to more severe disease.

CLINICAL SYNDROMES

Intestinal Amebiasis The most common type of amebic infection is asymptomatic cyst passage. Even in highly endemic areas, most patients harbor *E. dispar*.

Symptomatic amebic colitis develops 2 to 6 weeks after the ingestion of infectious cysts. Lower abdominal pain and mild diarrhea develop gradually and are followed by malaise, weight loss, and diffuse lower abdominal or back pain. Cecal involvement may mimic acute appendicitis. Patients with full-blown dysentery may pass 10 to 12 stools per day. The stools contain little fecal material and consist mainly of blood and mucus. In contrast to those with bacterial diarrhea, fewer than 40% of patients with amebic dysentery are febrile. Virtually all patients have heme-positive stools.

More fulminant intestinal infection, with severe abdominal pain, high fever, and profuse diarrhea, is rare and occurs predominantly in children. Patients may develop toxic megacolon, in which there is severe bowel dilation with intramural air. Patients receiving glucocorticoids are at risk for severe amebiasis. Uncommonly, patients develop a chronic form of amebic colitis, which can be confused with inflammatory bowel disease. The association between severe amebiasis complications and glucocorticoid therapy emphasizes the importance of excluding amebiasis when inflammatory bowel disease is suspected. An occasional patient presents with only an asymptomatic or tender abdominal mass caused by an ameboma, which is easily confused with cancer on barium studies. A positive serologic test or biopsy can prevent unnecessary surgery in this setting. The syndrome of postamebic colitis -- persistent diarrhea following documented cure of amebic colitis -- is controversial; no evidence of recurrent amebic infection can be found, and re-treatment usually has no effect.

Amebic Liver Abscess Extraintestinal infection by *E. histolytica* most often involves the liver. Of travelers who develop an amebic liver abscess after leaving an endemic area, 95% do so within 5 months. Young patients with an amebic liver abscess are more likely than older patients to present in the acute phase with prominent symptoms of <10 days duration. Most patients are febrile and have right-upper-quadrant pain, which may be dull or pleuritic in nature and radiate to the shoulder. Point tenderness over the liver and right-sided pleural effusion are common. Jaundice is rare. Although the initial site of infection is the colon, fewer than one-third of patients with an amebic abscess have active diarrhea. Older patients from endemic areas are more likely to have a subacute course lasting 6 months, with weight loss and hepatomegaly. About one-third of patients with chronic presentations are febrile. Thus, the clinical diagnosis of an amebic liver abscess may be difficult to establish because the symptoms and signs are often nonspecific. Since 10 to 15% of patients present only with fever, amebic liver abscess

must be considered in the differential diagnosis of fever of unknown origin (Chap. 125).

Complications of Amebic Liver Abscess Pleuropulmonary involvement, which is reported in 20 to 30% of patients, is the most frequent complication of amebic liver abscess. Manifestations include sterile effusions, contiguous spread from the liver, and rupture into the pleural space. Sterile effusions and contiguous spread usually resolve with medical therapy, but frank rupture into the pleural space requires drainage. A hepatobronchial fistula may cause cough productive of large amounts of necrotic material that may contain amebas. This dramatic complication carries a good prognosis. Abscesses that rupture into the peritoneum may present as an indolent leak or an acute abdomen and require both percutaneous catheter drainage and medical therapy. Rupture into the pericardium, usually from abscesses of the left lobe of the liver, carries the gravest prognosis; it can occur during medical therapy and requires surgical drainage.

Other Extraintestinal Sites The genitourinary tract may become involved by direct extension of amebiasis from the colon or by hematogenous spread of the infection. Painful genital ulcers, characterized by a punched-out appearance and profuse discharge, may develop secondary to extension from either the intestine or the liver. Both these conditions respond well to medical therapy. Cerebral involvement has been reported in fewer than 0.1% of patients in large clinical series. Symptoms and prognosis depend on the size and location of the lesion.

DIAGNOSTIC TESTS

Laboratory Diagnosis Stool examinations, serologic tests, and noninvasive imaging of the liver are the most important procedures in the diagnosis of amebiasis. Fecal findings suggestive of amebic colitis include a positive test for heme, a paucity of neutrophils, and the presence of Charcot-Leyden crystal protein (double pyramid-shaped crystals normally found in the cytoplasm of eosinophils). The definitive diagnosis of amebic colitis is made by the demonstration of hematophagous trophozoites of *E. histolytica* (Fig. 213-1). Because trophozoites are killed rapidly by water, drying, or barium, it is important to examine at least three fresh stool specimens. Examination of a combination of wet mounts, iodine-stained concentrates, and trichrome-stained preparations of fresh stool and concentrates for cysts (Fig. 213-2) or trophozoites (Fig. 213-1) confirms the diagnosis in 75 to 95% of cases. Cultures of amebas are more sensitive but are not routinely available. If stool examinations are negative, sigmoidoscopy with biopsy of the edge of ulcers may increase the yield, but this procedure is dangerous during fulminant colitis because of the risk of perforation. Trophozoites in a biopsy specimen from a colonic mass confirm the diagnosis of ameboma, but trophozoites are rare in liver aspirates. Accurate diagnosis requires experience, since the trophozoites may be confused with neutrophils and the cysts must be differentiated morphologically from *Entamoeba hartmanni*, *Entamoeba coli*, and *Endolimax nana*, which do not cause clinical disease and do not warrant therapy. Unfortunately, the cysts of *E. histolytica* cannot be distinguished microscopically from those of *E. dispar*. Therefore, the microscopic diagnosis of *E. histolytica* can be made only by the detection of *Entamoeba* trophozoites that have ingested erythrocytes (Fig. 213-1). Diagnostic tests based on the detection of the galactose-inhibitable lectin of *E. histolytica* are now available and compare favorably with the polymerase chain reaction and with isolation in culture

followed by isoenzyme analysis in terms of sensitivity.

Serology is an important addition to the methods used for the parasitologic diagnosis of invasive amebiasis. Kits for the performance of agar gel diffusion assays and ELISAs are commercially available, and the results of these tests are positive in more than 90% of patients with colitis, amebomas, or liver abscess. Positive results in conjunction with the appropriate clinical syndrome suggest active disease because serologic findings usually revert to negative within 6 to 12 months. Even in highly endemic areas such as South Africa, fewer than 10% of asymptomatic individuals have a positive amebic serology. The interpretation of the indirect hemagglutination test is more difficult because titers may remain positive for as long as 10 years.

Up to 10% of patients with acute amebic liver abscess may have negative serologic findings; in suspected cases with an initially negative result, testing should be repeated in a week. In contrast to carriers of *E. dispar*, most asymptomatic carriers of *E. histolytica* develop antibodies. Thus, serologic tests are helpful in assessing the risk of invasive amebiasis in asymptomatic, cyst-passing individuals in nonendemic areas. Serologic tests also should be performed in patients with ulcerative colitis before the institution of glucocorticoid therapy to prevent the development of severe colitis or toxic megacolon owing to unsuspected amebiasis.

Routine hematology and chemistry tests are usually not very helpful in the diagnosis of invasive amebiasis. About three-fourths of patients with an amebic liver abscess have leukocytosis (>10,000 cells/uL); this condition is particularly likely if symptoms are acute or complications have developed. Invasive amebiasis does not elicit eosinophilia. Anemia, if present, is usually multifactorial. Even with large liver abscesses, liver enzyme levels are normal or minimally elevated. The alkaline phosphatase level is most often elevated and may remain so for months. Aminotransferase elevations suggest acute disease or a complication.

Radiographic Studies Radiographic barium studies are potentially dangerous in acute amebic colitis. Amebomas are usually identified first by a barium enema, but biopsy is necessary for differentiation from carcinoma.

Radiographic techniques such as ultrasonography, computed tomography (Fig. 213-3), and magnetic resonance imaging are all useful for detection of the round or oval hypoechoic cyst. More than 80% of patients who have had symptoms for >10 days have a single abscess of the right lobe of the liver. Approximately 50% of patients who have had symptoms for <10 days have multiple abscesses. Findings associated with complications include large abscesses (>10 cm) in the superior part of the right lobe, which may rupture into the pleural space; multiple lesions, which must be differentiated from pyogenic abscesses; and lesions of the left lobe, which may rupture into the pericardium. Because abscesses resolve slowly and may increase in size in patients who are responding clinically to therapy, frequent follow-up ultrasonography may prove confusing. Complete resolution of a liver abscess within 6 months can be anticipated in two-thirds of patients, but 10% may have persistent abnormalities for a year.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis of intestinal amebiasis includes bacterial diarrheas caused by *Campylobacter*; enteroinvasive *Escherichia coli*; and *Shigella*, *Salmonella*, and *Vibrio* species. Although the typical patient with amebic colitis has less prominent fever than in these other conditions as well as heme-positive stools with few neutrophils, correct diagnosis requires bacterial cultures, microscopic examination of stools, and amebic serologic testing. As has already been mentioned, amebiasis must be ruled out in any patient thought to have inflammatory bowel disease.

Because of the variety of presenting signs and symptoms, amebic liver abscess can easily be confused with pulmonary or gallbladder disease or with any febrile illness with few localizing signs, such as malaria or typhoid fever. The diagnosis should be considered in members of high-risk groups who have recently traveled outside the United States and in inmates of institutions. Once radiographic studies have identified an abscess in the liver, the most important differential diagnosis is between amebic and pyogenic abscess. Patients with pyogenic abscess typically are older and have a history of underlying bowel disease or recent surgery. Amebic serology is helpful, but aspiration of the abscess, with Gram's staining and culture of the material, may be required for differentiation of the two diseases.

TREATMENT

Intestinal Disease The drugs used to treat amebiasis can be classified according to their primary site of action. Luminal amebicides are poorly absorbed and reach high concentrations in the bowel, but their activity is limited to cysts and trophozoites close to the mucosa. Only two luminal drugs are available in the United States: iodoquinol and paromomycin (Table 213-1). Indications for the use of luminal agents include eradication of cysts in patients with colitis or a liver abscess and treatment of asymptomatic carriers. The majority of asymptomatic individuals who pass cysts are colonized with *E. dispar*, which does not warrant specific therapy. However, unless the presence of *E. dispar* can be proven by specific antigen detection tests and the lack of an antibody response, it may be prudent to treat asymptomatic individuals who pass cysts.

Tissue amebicides reach high concentrations in the blood and tissue after oral or parenteral administration. The development of nitroimidazole compounds, especially metronidazole, was a major advance in the treatment of invasive amebiasis. Patients with amebic colitis should be treated with intravenous or oral metronidazole (750 mg three times daily for 5 to 10 days). Side effects include nausea, vomiting, abdominal discomfort, and a disulfiram-like reaction. Other imidazole compounds, such as tinidazole and ornidazole, are as effective but are not available in the United States. All patients should also receive a full course of therapy with a luminal agent, since metronidazole does not eradicate cysts. Resistance to metronidazole has not been identified. Relapses are not uncommon and probably represent reinfection or failure to eradicate amebas from the bowel because of an inadequate dosage or duration of therapy.

Amebic Liver Abscess Metronidazole is the drug of choice for amebic liver abscess. The usefulness of nitroimidazoles in single-dose or abbreviated regimens is important in endemic areas where access to hospitalization is limited. With early diagnosis and therapy, mortality from uncomplicated amebic liver abscess is<1%. The second-line

therapeutic agents emetine and chloroquine should be avoided if possible because of the potential cardiovascular and gastrointestinal side effects of the former and the higher relapse rates with the latter. There is no evidence that combined therapy with two drugs is more effective than the single-drug regimen. Studies of South Africans with liver abscesses demonstrated that 72% of patients without intestinal symptoms had bowel infection with *E. histolytica*; thus, all treatment regimens should include a luminal agent to eradicate cysts and prevent further transmission. Amebic liver abscess recurs rarely.

Aspiration of Liver Abscesses More than 90% of patients respond dramatically to metronidazole therapy with decreases in both pain and fever within 72 h. Indications for aspiration of liver abscesses are (1) the need to rule out a pyogenic abscess, particularly in patients with multiple lesions; (2) the failure to respond clinically in 3 to 5 days; (3) the threat of imminent rupture; and (4) the prevention of rupture of left-lobe abscesses into the pericardium. There is no evidence that aspiration, even of large abscesses (up to 10 cm), accelerates healing. Percutaneous drainage may be successful even if the liver abscess has already ruptured. Surgery should be reserved for instances of bowel perforation and rupture into the pericardium.

PREVENTION

Amebic infection is spread by ingestion of food or water contaminated with cysts. Since an asymptomatic carrier may excrete up to 15 million cysts per day, prevention of infection requires adequate sanitation and eradication of cyst carriage. In high-risk areas, infection can be minimized by the avoidance of unpeeled fruits and vegetables and the use of bottled water. Because cysts are resistant to readily attainable levels of chlorine, disinfection by iodination (tetraglycine hydroperiodide) is recommended. There is no effective prophylaxis.

INFECTION WITH FREE-LIVING AMEBAS

EPIDEMIOLOGY

Free-living amebas of the genera *Acanthamoeba*, *Naegleria*, and *Balamuthia* are distributed throughout the world and have been isolated from a wide variety of fresh and brackish water, including that from lakes, taps, hot springs, swimming pools, and heating and air-conditioning units, and even from the nasal passages of healthy children. Encystation may protect the protozoa from desiccation and food deprivation. The persistence of *Legionella pneumophila* in water supplies may be attributable in part to chronic infection of free-living amebas, particularly *Naegleria*.

NAEGLERIA INFECTIONS

Primary amebic meningoencephalitis caused by *Naegleria fowleri* follows the aspiration of water contaminated with trophozoites or cysts or the inhalation of contaminated dust, leading to invasion of the olfactory neuroepithelium. After an incubation period of 2 to 15 days, severe headache, high fever, nausea, vomiting, and meningismus develop. Photophobia and palsies of the third, fourth, and sixth cranial nerves are common. Rapid progression to seizures and coma may follow, and most patients die within a week. Infection is most common in otherwise healthy children or young adults, who

often report recent swimming in lakes or heated swimming pools.

Diagnosis depends on the detection of motile trophozoites in wet mounts of fresh spinal fluid. Other laboratory findings resemble those for fulminant bacterial meningitis, with elevated intracranial pressure, high white blood cell counts (up to 20,000 cells/uL), and elevated protein concentrations and low glucose levels in cerebrospinal fluid. The diagnosis should be considered in any patient who has purulent meningitis without evidence of bacteria on Gram's staining, antigen detection assay, and culture. The prognosis is uniformly poor. Only four survivors, treated with high-dose amphotericin B and rifampin, have been reported. Antibodies to *Naegleria* spp. have been detected in normal adults; serologic testing is not useful in the diagnosis of acute infection.

ACANTHAMOEBA INFECTIONS

Granulomatous Amebic Encephalitis Infection with *Acanthamoeba* species follows a more indolent course and occurs typically in chronically ill or debilitated patients. Risk factors include lymphoproliferative disorders, chemotherapy, glucocorticoid therapy, lupus erythematosus, and AIDS. Infection usually reaches the central nervous system hematogenously from a primary focus in the sinuses, skin, or lungs. In the central nervous system, the onset is insidious, and the syndrome often mimics a space-occupying lesion. Altered mental status, headache, and stiff neck may be accompanied by focal findings such as cranial nerve palsies, ataxia, and hemiparesis. In the United States, cutaneous ulcers or hard nodules containing amebas were detected in 8 of 13 AIDS patients with disseminated *Acanthamoeba* infection.

Examination of the cerebrospinal fluid for trophozoites may be diagnostically helpful, but lumbar puncture may be contraindicated because of increased intracerebral pressure. Computed tomography frequently reveals cortical and subcortical lesions of decreased density consistent with embolic infarcts. In other patients, multiple enhancing lesions with edema may mimic the computed tomographic appearance of toxoplasmosis. Demonstration of the trophozoites and cysts of *Acanthamoeba* on wet mounts or in biopsy specimens establishes the diagnosis. Culture on nonnutrient agar plates seeded with *Escherichia coli* may also be helpful. Fluorescein-labeled antiserum is available from the Centers for Disease Control and Prevention (CDC) for the detection of protozoa in biopsy specimens. At least nine cases of granulomatous amebic encephalitis have been reported in patients with AIDS, in whom the disease may have an accelerated course (with survival for only 3 to 40 days) because of their difficulty in forming granulomas. Although studies in animals suggest that rifampin may be useful, the infection is almost uniformly fatal.

Keratitis The incidence of keratitis caused by *Acanthamoeba* has increased in the past 20 years, in part as a result of improved diagnosis. The first of these infections to be recognized were associated with trauma to the eye and exposure to contaminated water. At present, most infections are linked to extended-wear contact lenses. Risk factors include the use of homemade saline, the wearing of lenses while swimming, and inadequate disinfection. Since contact lenses presumably cause microscopic trauma, the early corneal findings may be nonspecific. The first symptoms usually include tearing and the painful sensation of a foreign body. Once infection is established, progression is rapid; the characteristic clinical sign is an annular, paracentral corneal

ring representing a corneal abscess. Deeper corneal invasion and loss of vision may follow.

The differential diagnosis includes bacterial, mycobacterial, and herpetic infection. The irregular polygonal cysts of *Acanthamoeba* (Fig. 213-4) may be identified in corneal scrapings or biopsy material, and trophozoites can be grown on special media. Cysts are resistant to available drugs, and the results of medical therapy have been disappointing. Some reports have suggested partial responses to propamidine isethionate eyedrops. Severe infections usually require keratoplasty.

BALAMUTHIA INFECTIONS

Balamuthia mandrillaris, a free-living ameba previously referred to as a leptomyxid ameba, is an important etiologic agent of amebic meningoencephalitis in immunocompetent hosts. The course is typically subacute, with focal neurologic signs, fever, seizures, and headaches leading to death within 1 week to several months after onset. Examination of cerebrospinal fluid reveals mononuclear pleocytosis, elevated protein levels, and normal to low glucose concentrations. Multiple hypodense lesions are usually detected with imaging studies. The diagnosis is almost always made post-mortem, and specific identification may require immunofluorescence with antibodies from theCDC to differentiate the trophozoites from *Acanthamoeba*.

214. MALARIA AND BABESIOSIS: DISEASES CAUSED BY RED BLOOD CELL PARASITES - *Nicholas J. White, Joel G. Breman*

"Humanity has but three great enemies: Fever, famine and war; of these by far the greatest, by far the most terrible, is fever."

William Osler

MALARIA

Malaria is a protozoan disease transmitted by the bite of infected *Anopheles* mosquitoes. It is the most important of the parasitic diseases of humans, with transmission in 103 countries affecting more than 1 billion people and causing between 1 and 3 million deaths each year. Malaria has now been eradicated from North America, Europe, and Russia but, despite enormous control efforts, has resurged in many parts of the tropics. Added to this resurgence are the increasing problems of drug resistance of the parasite and insecticide resistance of the vectors. Occasional local transmission following importation of malaria has occurred recently in several southern and eastern areas of the United States and in Europe, indicating the continual danger to nonmalarious countries. Malaria remains today, as it has been for centuries, a heavy burden on tropical communities, a threat to nonendemic countries, and a danger to travelers.

ETIOLOGY AND PATHOGENESIS

Four species of the genus *Plasmodium* cause nearly all malarial infections in humans (although rare infections involve species normally affecting other primates). These are *P. falciparum*, *P. vivax*, *P. ovale*, and *P. malariae* (Table 214-1). Almost all deaths are caused by falciparum malaria. Human infection begins when a female anopheline mosquito inoculates plasmodial sporozoites from its salivary gland during a blood meal (Fig. 214-1). These microscopic motile forms of the malarial parasite are carried rapidly via the bloodstream to the liver, where they invade hepatic parenchymal cells and begin a period of asexual reproduction. By this amplification process (known as intrahepatic or preerythrocytic schizogony or merogony), a single sporozoite eventually may produce 10,000 to more than 30,000 daughter merozoites. The swollen liver cell eventually bursts, discharging motile merozoites into the bloodstream; at this point the symptomatic stage of the infection begins. In *P. vivax* and *P. ovale* infections, a proportion of the intrahepatic forms do not divide immediately but remain dormant for months to years before reproduction begins. These dormant forms, or hypnozoites, are the cause of the relapses that characterize infection with these two species.

After entry into the bloodstream, merozoites rapidly invade erythrocytes and become trophozoites. Attachment is mediated via a specific erythrocyte surface receptor. In the case of *P. vivax*, this receptor is related to the Duffy blood-group antigen Fy^a or Fy^b. Most West Africans and people with origins in that region carry the Duffy-negative FyFy phenotype and are therefore resistant to *P. vivax* malaria. During the early stage of intraerythrocytic development, the small "ring forms" of the four parasitic species appear similar under light microscopy. As the trophozoites enlarge, species-specific characteristics become evident, pigment becomes visible, and the parasite assumes an

irregular or ameboid shape. By the end of the 48-h intraerythrocytic life cycle (72 h for *P. malariae*), the parasite has consumed nearly all the hemoglobin and grown to occupy most of the red cell. Multiple nuclear divisions take place (merogony), and the red cell ruptures to release 6 to 30 daughter merozoites, each capable of invading a new red cell and repeating the cycle. The disease in human beings is caused by the direct effects of red cell invasion and destruction by the asexual parasite and the host's reaction. After a series of asexual cycles (*P. falciparum*) or immediately (*P. vivax*, *P. ovale*, *P. malariae*), some of the parasites develop into morphologically distinct long-lived sexual forms (gametocytes) that can transmit malaria.

After being ingested in the blood meal of a biting female anopheline mosquito, the male and female gametocytes form a zygote in the insect's midgut. This zygote matures into an ookinete, which penetrates and encysts in the mosquito's gut wall. The resulting oocyst expands by asexual division until it bursts to liberate myriad motile sporozoites, which then migrate in the hemolymph to the salivary gland of the mosquito to await inoculation into another human at the next feeding.

EPIDEMIOLOGY

Malaria occurs throughout most of the tropical regions of the world (Fig. 214-2). *P. falciparum* predominates in Africa, New Guinea, and Haiti; *P. vivax* is more common in Central America and the Indian subcontinent. The prevalence of these two species is approximately equal in South America, eastern Asia, and Oceania. *P. malariae* is found in most endemic areas, especially throughout sub-Saharan Africa, but is much less common than the other species mentioned. *P. ovale* is relatively unusual outside of Africa and, where it is found, comprises <1% of isolates.

The epidemiology of malaria is complex and may vary considerably even within relatively small geographic areas. Endemicity traditionally has been defined in terms of parasitemia rates or palpable-spleen rates in children 2 to 9 years of age as hypoendemic (<10%), mesoendemic (11 to 50%), hyperendemic (51 to 75%), and holoendemic (>75%). In holo- and hyperendemic areas -- e.g., certain regions of tropical Africa or coastal New Guinea, where there is intense *P. falciparum* transmission and there can be more than one human bite per infected mosquito per day -- people are infected repeatedly throughout their lives. Here, morbidity and mortality during childhood are considerable. Immunity against disease is hard won in these areas, and the young-childhood burden of disease is high; by adulthood, however, most malarial infections are asymptomatic. This situation, with frequent year-round infection, is termed *stable transmission* and generally occurs where there is holo- and hyperendemicity. In areas where transmission is low, erratic, or focal, full protective immunity is not acquired, and symptomatic disease may occur at all ages. This situation usually exists in hypoendemic areas and is termed *unstable transmission*. Even in areas with stable transmission, there is often an increased incidence coinciding with increased mosquito breeding during the rainy season. Malaria behaves like an epidemic disease in some areas, particularly those with unstable malaria, such as northern India, Sri Lanka, Southeast Asia, Ethiopia, southern Africa, and Madagascar. An epidemic can develop when there are changes in environmental, economic, or social conditions, such as heavy rains following drought or migrations (usually of refugees or workers) from a nonmalarious region to an area of high transmission; a breakdown in malaria control

and prevention services can intensify epidemic conditions. This situation usually results in considerable mortality among all age groups.

The principal determinants of the epidemiology of malaria are the number (density), the human-biting habits, and the longevity of the anopheline mosquito vectors. Not all anophelines can transmit malaria, and those that do vary considerably in their efficiency as malaria vectors. More specifically, the transmission of malaria is directly proportional to the density of the vector, the square of the number of human bites per day per mosquito, and the tenth power of the probability of the mosquito's surviving for 1 day. Mosquito longevity is particularly important, because the portion of the parasite's life cycle that takes place within the mosquito -- from gametocyte ingestion to subsequent inoculation (sporogony) -- lasts for 8 to 30 days, depending on ambient temperature; thus, to transmit malaria, the mosquito must survive for longer than 7 days. In general, at temperatures below 16 to 18°C, sporogony is not completed and transmission does not occur. Therefore, the most effective mosquito vectors of malaria are those such as *A. gambiae*, which are long-lived, occur in high densities in tropical climates, breed readily, and bite humans in preference to other animals. The entomologic inoculation rate -- the number of sporozoite-positive mosquito bites per year -- is the most common measure of malarial transmission and varies from <1 in some parts of Latin America and Southeast Asia to >300 in parts of tropical Africa.

ERYTHROCYTE CHANGES IN MALARIA

After invading an erythrocyte, the growing parasite progressively consumes and degrades intracellular proteins, principally hemoglobin. The potentially toxic heme is polymerized to biologically inert hemozoin, or malaria pigment. The parasite also alters the red cell membrane by changing its transport properties, exposing cryptic surface antigens, and inserting new parasite-derived proteins. The red cell becomes more irregular in shape, more antigenic, and less deformable.

In *P. falciparum* infections, membrane protuberances appear on the erythrocyte's surface in the second 24 h of the asexual cycle. These "knobs" extrude a high-molecular-weight, antigenically variant, strain-specific, adhesive protein (PfEMP1) that mediates attachment to receptors on venular and capillary endothelium -- an event termed *cytoadherence*. Several receptors have been identified, of which intercellular adhesion molecule 1 is probably the most important in the brain, chondroitin sulfate B in the placenta, and CD36 in most other organs. Thus the infected erythrocytes stick inside the small blood vessels. At the same stage, these *P. falciparum*-infected red cells may also adhere to uninfected red cells to form rosettes. The processes of cytoadherence and rosetting are central to the pathogenesis of falciparum malaria. They result in the sequestration of red cells containing mature forms of the parasite in vital organs (particularly the brain), where they interfere with microcirculatory flow and metabolism. Sequestered parasites continue to develop out of reach of the principal host defense mechanism: splenic processing and filtration. As a consequence, only the younger ring forms of the asexual parasites are seen in the peripheral blood in falciparum malaria, and the level of peripheral parasitemia underestimates the true number of parasites within the body. Severe malaria is also associated with reduced deformability of the uninfected erythrocytes, which compromises their passage through the partially obstructed capillaries and venules and shortens red cell survival.

In the other three "benign" malarias, sequestration does not occur, and all stages of the parasite's development are evident on peripheral blood smears. Whereas *P. vivax*, *P. ovale*, and *P. malariae* show a marked predilection for either old red cells or reticulocytes and produce a level of parasitemia seldom exceeding 2%, *P. falciparum* can invade erythrocytes of all ages and may be associated with very high levels of parasitemia.

HOST RESPONSE

Initially, the host responds to plasmodial infection by activating nonspecific defense mechanisms. Splenic immunologic and filtrative clearance functions are augmented in malaria, and the removal of both parasitized and uninfected erythrocytes is accelerated. The parasitized cells escaping splenic removal are destroyed when the schizont ruptures. The material released induces the activation of macrophages and the release of proinflammatory mononuclear cell-derived cytokines, which cause fever and exert other pathologic effects. Temperatures of³40°C damage mature parasites; in untreated infections, the effect of such temperatures is to synchronize further the parasitic cycle with eventual production of the regular fever spikes and rigors that originally served to characterize the different malarias. These regular fever patterns (tertian, every 2 days; quartan, every 3 days) are seldom seen in patients who receive prompt and effective antimalarial treatment.

The geographic distributions of sickle cell disease, thalassemia, and glucose-6-phosphate dehydrogenase (G6PD) deficiency closely resemble that of malaria before the introduction of control measures. This observation suggests that these genetic disorders confer protection against death from falciparum malaria. For example, HbA/S heterozygotes (sickle cell trait) have a sixfold reduction in the risk of dying from severe falciparum malaria. This decrease in risk appears to be related to impaired parasite growth at low oxygen tensions. In Melanesia, children witha-thalessemia appear to have more frequent malaria (both vivax and falciparum) in the early years of life, and this pattern of infection appears to protect against severe disease. In Melanesian ovalocytosis, rigid erythrocytes resist merozoite invasion and the intraerythrocytic milieu is hostile.

The specific immune response to malaria eventually controls the infection and, with exposure to sufficient strains, confers protection from high-level parasitemia and disease but not from infection. As a result of this state of infection without illness (premunition), asymptomatic parasitemia is common among adults and older children living in regions with stable and intense transmission (i.e., holo- or hyperendemic areas). Immunity is specific for both the species and the strain of infecting malarial parasite. Both humoral immunity and cellular immunity are necessary for protection, but the mechanisms of each are incompletely understood (Fig. 214-1). Immune individuals have a polyclonal increase in serum levels of IgM, IgG, and IgA, although much of this antibody is unrelated to protection. Antibodies to a variety of parasitic antigens presumably act in concert to limit in vivo replication of the parasite. In the case of falciparum malaria, the most important of these is the antigenically variant protein PfEMP1 mentioned above. Passively transferred IgG from immune adults has been shown to reduce levels of parasitemia in children, and passive transfer of maternal

antibody contributes to the relative protection of infants from severe malaria in the first months of life. This complex immunity to disease is lost when a person lives outside an endemic area for several months or longer.

Several factors retard the development of cellular immunity to malaria. These factors include the absence of major histocompatibility antigens on the surface of infected red cells, which precludes direct T cell recognition; malaria antigen-specific immune unresponsiveness; and the enormous strain diversity of malarial parasites along with the ability of the parasites to express immunodominant variant antigens on the erythrocyte surface that change during the period of infection. Strain diversity also has an impact on the heterogeneity of the humoral antibody response. Immunity to all strains is never achieved. Parasites may persist in the blood for months (or, in the case of *P. malariae*, for many years) if treatment is not given. The complexity of the immune response in malaria, the sophistication of the parasites' evasion mechanisms, and the lack of a good in vitro correlate with clinical immunity have all slowed progress toward an effective vaccine.

CLINICAL FEATURES

The first symptoms of malaria are nonspecific; the lack of a sense of well-being, headache, fatigue, abdominal discomfort, and muscle aches followed by fever are all similar to the symptoms of a minor viral illness. In some instances, a prominence of headache, chest pain, abdominal pain, arthralgia, myalgia, or diarrhea may suggest another diagnosis. Although headache may be severe in malaria, there is no neck stiffness or photophobia resembling that in meningitis. While myalgia may be prominent, it is not usually as severe as in dengue fever, and the muscles are not tender as in leptospirosis or typhus. Nausea, vomiting, and orthostatic hypotension are common. The classic malarial paroxysms, in which fever spikes, chills, and rigors occur at regular intervals, suggest infection with *P. vivax* or *P. ovale*. The fever is irregular at first (that of falciparum malaria may never become regular); the temperature of nonimmune individuals and children often rises above 40°C in conjunction with tachycardia and sometimes delirium. Although childhood febrile convulsions may occur with any of the malarias, generalized seizures are specifically associated with falciparum malaria and may herald the development of cerebral disease. Many clinical abnormalities have been described in acute malaria, but most patients with uncomplicated infections have few abnormal physical findings other than fever, malaise, mild anemia, and (in some cases) a palpable spleen. Anemia may be quite common among young children living in areas with stable transmission, particularly where there is parasite resistance to chloroquine or other drugs. Splenic enlargement is very common among otherwise-healthy individuals in malaria-endemic areas and reflects repeated infections; however, in nonimmune individuals with malaria, the spleen takes several days to become palpable. Slight enlargement of the liver is also common, particularly in young children. Mild jaundice is common in adults; it may develop in patients with otherwise uncomplicated falciparum malaria and usually resolves over 1 to 3 weeks. Malaria is not associated with a rash like those seen in meningococcal septicemia, typhus, enteric fever, viral exanthems, and drug reactions. Petechial hemorrhages in the skin or mucous membranes -- features of viral hemorrhagic fevers and leptospirosis -- develop only rarely in severe falciparum malaria.

Severe Falciparum Malaria Appropriately treated, uncomplicated falciparum malaria carries a mortality rate of ~0.1%. However, once vital organ dysfunction occurs or the proportion of erythrocytes infected increases to>3%, mortality rises steeply. The major manifestations of severe falciparum malaria are shown inTable 214-2.

Cerebral Malaria Coma is a characteristic and ominous feature of falciparum malaria and, despite treatment, is associated with death rates of ~20% among adults and 15% among children. Lesser degrees of obtundation, delirium, and abnormal behavior should also be taken very seriously. The onset may be gradual or sudden following a convulsion.

Cerebral malaria manifests as diffuse symmetric encephalopathy; focal neurologic signs are unusual. Although some passive resistance to head flexion may be detected, signs of meningeal irritation are lacking. The eyes may be divergent and a pout reflex is common, but other primitive reflexes are usually absent. The corneal reflexes are preserved except in deep coma. Muscle tone may be either increased or decreased. The tendon reflexes are variable, and the plantar reflexes may be flexor or extensor; the abdominal and cremasteric reflexes are absent. Flexor or extensor posturing may be documented. Approximately 15% of patients have retinal hemorrhages; with pupillary dilatation and indirect ophthalmoscopy, this figure increases to 30 to 40%. Other abnormalities include discrete spots of retinal opacification (30 to 60%), papilledema (8% of children, rare in adults), cotton wool spots (<5%), and decolorization of a retinal vessel or segment of vessel (occasional cases). Convulsions, usually generalized and often repeated, occur in up to 50% of children with cerebral malaria. More covert seizure activity is common, particularly in children, and may manifest as repetitive tonic-clonic eye movements. Whereas adults rarely suffer neurologic sequelae, ~10% of children surviving cerebral malaria -- especially those with hypoglycemia, severe anemia, repeated seizures, and deep coma -- have some residual neurologic deficit when they regain consciousness; hemiplegia, cerebral palsy, cortical blindness, deafness, and impaired cognition and learning -- all of varying duration -- have been reported.

Hypoglycemia An important and common complication of severe malaria, hypoglycemia is associated with a poor prognosis and is particularly problematic in children and pregnant women. Hypoglycemia in malaria results from a failure of hepatic gluconeogenesis and an increase in the consumption of glucose by both host and parasite. To compound the situation, quinine and quinidine -- drugs used commonly for the treatment of severe chloroquine-resistant malaria -- are powerful stimulants of pancreatic insulin secretion. Hyperinsulinemic hypoglycemia is especially troublesome in pregnant women receiving quinine treatment. In severe disease, the clinical diagnosis of hypoglycemia is difficult: the usual physical signs (sweating, gooseflesh, tachycardia) are absent, and the neurologic impairment caused by hypoglycemia cannot be distinguished from that caused by malaria.

Lactic Acidosis Lactic acidosis commonly coexists with hypoglycemia in patients with malaria and is an important contributor to death from severe malaria. In adults, coexisting renal impairment often compounds the acidosis. Acidotic breathing, sometimes called respiratory distress, is a sign of poor prognosis. It is often followed by circulatory failure refractory to volume expansion or inotropic drugs or by respiratory arrest. The plasma concentrations of bicarbonate or lactate are the best biochemical

prognosticators in severe malaria. Lactic acidosis is caused by the combination of anaerobic glycolysis in tissues where sequestered parasites interfere with microcirculatory flow, lactate production by the parasites, and a failure of hepatic and renal lactate clearance. The prognosis of lactic acidosis is poor.

Noncardiogenic Pulmonary Edema Adults with severe falciparum malaria may develop noncardiogenic pulmonary edema even after several days of antimalarial therapy. This manifestation may also develop in otherwise-uncomplicated vivax malaria, where recovery is usual. The pathogenesis of this variant of the adult respiratory distress syndrome is unclear. The mortality rate is >80%. This condition can be aggravated by overly vigorous administration of intravenous fluid.

Renal Impairment Renal impairment is common among adults with severe falciparum malaria but rare among children. The pathogenesis of renal failure is unclear but may be related to erythrocyte sequestration interfering with renal microcirculatory flow and metabolism. Clinically and pathologically, this syndrome manifests as acute tubular necrosis; renal cortical necrosis never develops. Mortality in the initial phase of hypercatabolic acute renal failure is high; in survivors, urine flow resumes in a median of 4 days, and serum creatinine levels return to normal in a mean of 17 days (Chap. 269). Dialysis or hemofiltration considerably enhances the likelihood of a patient's survival.

Hematologic Abnormalities Anemia results from accelerated red cell destruction and removal by the spleen in conjunction with ineffective erythropoiesis. In severe malaria, both infected and uninfected red cells show reduced deformability, which correlates with prognosis and development of anemia. Splenic clearance of cells is also increased. In nonimmune individuals and in areas with unstable transmission, anemia can develop rapidly and transfusion is often required. In many areas of Africa, children may develop severe anemia as a result of repeated malarial infections. Anemia is a common consequence of antimalarial drug resistance, which results in repeated or continued infection.

Slight coagulation abnormalities are common in falciparum malaria, and mild thrombocytopenia is usual. As mentioned above, fewer than 5% of patients with severe malaria have significant bleeding with evidence of disseminated intravascular coagulation. Hematemesis, presumably from stress ulceration or acute gastric erosions, may also occur.

Liver Dysfunction Mild hemolytic jaundice is common in malaria. Severe jaundice is associated with *P. falciparum* infections, is more common among adults than among children, and results from hemolysis, hepatocyte injury, and cholestasis. When accompanied by other vital organ dysfunction (often renal impairment), liver dysfunction carries a poor prognosis. Hepatic dysfunction contributes to hypoglycemia, lactic acidosis, and impaired drug metabolism.

Other Complications Aspiration pneumonia following convulsions is an important cause of death in cerebral malaria. Chest infections and catheter-induced urinary tract infections are common among patients who are unconscious for>3 days. Septicemia may complicate severe malaria; in endemic areas *Salmonella* bacteremia has been associated specifically with *P. falciparum* infections.

Malaria in Pregnancy In hyper- and holoendemic areas, falciparum malaria in primi- and secundigravid women is associated with low birth weight (average reduction, ~170 g) and consequently increased infant and childhood mortality. In general, infected mothers in areas of stable transmission remain asymptomatic despite intense parasitization of the placenta due to sequestration of parasitized erythrocytes in the placental microcirculation. Maternal HIV infection predisposes pregnant women to a higher prevalence of malaria and parasite density and predisposes their newborns to congenital malaria infection and low birth weight.

In areas with unstable transmission of malaria, pregnant women are prone to severe infections and are particularly vulnerable to high-level parasitemia with anemia, hypoglycemia, and acute pulmonary edema. Fetal distress, premature labor, and stillbirth or low birth weight are common results. Congenital malaria occurs in fewer than 5% of newborns whose mothers are infected and is related directly to the parasite density in maternal blood and in the placenta. *P. vivax* malaria in pregnancy is also associated with a reduction in birth weight (average, 100 g), but, in contrast with the situation in falciparum malaria, this effect is greater in multigravid than in primigravid women.

Malaria in Children Most of the estimated 1 to 3 million persons who die of falciparum malaria each year are young African children. Convulsions, coma, hypoglycemia, metabolic acidosis, and severe anemia are relatively common among children with severe malaria, whereas deep jaundice, acute renal failure, and acute pulmonary edema are unusual. Severely anemic children may present with labored deep breathing, which in the past has been attributed incorrectly to "anemic congestive cardiac failure" but is in fact usually caused by metabolic acidosis, often compounded by hypovolemia. In general, children tolerate antimalarial drugs well and respond rapidly to treatment.

Transfusion Malaria Malaria can be transmitted by blood transfusion, needle-stick injury, sharing of needles by infected drug addicts, or organ transplantation. The incubation period in these settings is often short because there is no preerythrocytic stage of development. The clinical features and management of these cases are the same as for naturally acquired infections, although falciparum malaria tends to be especially severe in drug addicts. Radical chemotherapy with primaquine is unnecessary for *P. vivax* and *P. ovale* infections.

CHRONIC COMPLICATIONS OF MALARIA

Tropical Splenomegaly (Hyperreactive Malarial Splenomegaly) Chronic or repeated malarial infections produce hypergammaglobulinemia; normochromic, normocytic anemia; and, in certain situations, splenomegaly. Some residents of malaria-endemic areas in tropical Africa and Asia exhibit an abnormal immunologic response to repeated infections that is characterized by massive splenomegaly, hepatomegaly, marked elevations in serum titers of IgM and malarial antibody, hepatic sinusoidal lymphocytosis, and (in Africa) peripheral B cell lymphocytosis. This syndrome has been associated with the production of cytotoxic IgM antibodies to suppressor (CD8+) lymphocytes, antibodies to CD5+ T cells, and an increase in the ratio of CD4+ T cells to CD8+ T cells. It is believed that these events lead to uninhibited B cell production of IgM

and the formation of cryoglobulins (IgM aggregates and immune complexes). This immunologic process stimulates reticuloendothelial hyperplasia and clearance activity and eventually produces splenomegaly. Patients with hyperreactive malarial splenomegaly (HMS) present with an abdominal mass or a dragging sensation in the abdomen and occasional sharp abdominal pains suggesting perisplenitis. Anemia and some degree of pancytopenia are usually evident, but in many cases malarial parasites cannot be found in peripheral blood smears. Vulnerability to respiratory and skin infections is increased; many patients die of overwhelming sepsis. Persons with HMS who are living in endemic areas should receive antimalarial chemoprophylaxis: the results are usually good. In nonendemic areas, treatment is advised. In some cases refractory to therapy, clonal lymphoproliferation may develop and then evolve into a malignant lymphoproliferative disorder.

Quartan Malarial Nephropathy Chronic or repeated infections with *P. malariae*, and possibly other malarial species, may cause soluble immune-complex injury to the renal glomeruli, resulting in the nephrotic syndrome. Other, unidentified factors must contribute to this process since only a very small proportion of infected patients develop renal disease. The histologic appearance is that of focal or segmental glomerulonephritis with splitting of the capillary basement membrane. Subendothelial dense deposits are seen on electron microscopy, and immunofluorescence reveals deposits of complement and immunoglobulins; in samples of renal tissue from children, *P. malariae* antigens are often visible. A coarse-granular pattern of basement membrane immunofluorescent deposits (predominantly IgG3) with selective proteinuria carries a better prognosis than a fine-granular, predominantly IgG2 pattern with nonselective proteinuria. Quartan nephropathy usually responds poorly to treatment with either antimalarial agents or glucocorticoids and cytotoxic drugs.

Burkitt's Lymphoma and Epstein-Barr Virus Infection It is possible that malaria-related immunosuppression provokes infection with lymphoma viruses. Burkitt's lymphoma is strongly associated with Epstein-Barr virus. The prevalence of this childhood tumor is high in malarious areas of Africa.

DIAGNOSIS

Demonstration of the Parasite The diagnosis of malaria rests on the demonstration of asexual forms of the parasite in peripheral blood smears subjected to Romanovsky staining. Following a negative blood smear, repeat smears should be made if there is a high degree of suspicion. Giemsa at pH 7.2 is preferred; Wright's, Field's, or Leishman's stain can also be used. Both thin and thick blood smears should be examined (See Plates VI-3,VI-4,VI-5,VI-6,VI-7,VI-8,VI-9,VI-10,VI-11,VI-12,VI-13,VI-14,VI-15,VI-16,VI-17,VI-18, VI-19,VI-20, andVI-21and Plates VI-23,VI-24,VI-25,VI-26,VI-27,VI-28,VI-29,VI-30,VI-31,VI-32, andVI-33).

The thin blood smear should be rapidly air-dried, fixed in anhydrous methanol, and stained, and the red cells in the tail of the film should then be examined under oil immersion. The level of parasitemia is expressed as the number of parasitized erythrocytes among 1000 cells, and this figure is converted to the number of parasitized erythrocytes per microliter. Simple, sensitive, and specific antibody-based diagnostic

stick or card tests that detect *P. falciparum*-specific, histidine-rich protein (HRP) 2 or lactate dehydrogenase antigens in finger-prick blood samples have been introduced. Some of these tests carry a second antibody, which allows falciparum malaria to be distinguished from the less dangerous malarias. The relationship between parasitemia and prognosis is complex; in general, patients with>10_5parasites per microliter are at increased risk of dying, but nonimmune patients may die with much lower counts and semi-immune persons may tolerate parasitemia levels many times higher with only minor symptoms. In severe malaria, a poor prognosis is indicated by a predominance of more mature *P. falciparum* parasites (i.e., >20% of parasites with visible pigment), by the presence of circulating schizonts in the peripheral blood film, or by the presence of phagocytosed malarial pigment in>5% of neutrophils. Gametocytes may remain evident for several days after treatment has begun; unless trophozoites are also visible on the blood film, their presence does not constitute evidence of drug resistance.

The thick blood film should be of uneven thickness. The smear should be dried thoroughly and stained without fixing. As many layers of erythrocytes overlie one another and are lysed during the staining procedure, the thick film has the advantage of concentrating the parasites (by 20- to 40-fold compared with a thin blood film) and thus increasing diagnostic sensitivity. Both parasites and white cells are counted, and the number of parasites per unit volume is calculated from the total leukocyte count. Alternatively, a white count of 8000/uL is assumed. A minimum of 200 white cells should be counted. Interpretation of thick films requires some experience because artifacts are common. Before a thick smear is judged to be negative, 100 to 200 fields should be examined under oil immersion. Phagocytosed malarial pigment is sometimes seen inside peripheral blood monocytes or polymorphonuclear leukocytes and may provide a clue to recent infection if malarial parasites are not detectable. After the clearance of the parasites, malarial pigment is often evident for several days in peripheral blood phagocytes, bone marrow aspirates, or smears of fluid expressed after intradermal puncture. Staining of parasites with the fluorescent dye acridine orange allows more rapid diagnosis of cases in which the level of parasitemia is low.

Laboratory Findings Normochromic, normocytic anemia is usually documented. The leukocyte count is generally low to normal, although it may be raised in very severe infections. The erythrocyte sedimentation rate, degree of plasma viscosity, and level of C-reactive protein are high. The platelet count is usually reduced to ~10_5/uL. Severe infections may be accompanied by prolonged prothrombin and partial thromboplastin times and by severe thrombocytopenia. Levels of antithrombin III are reduced even in mild infection. In uncomplicated malaria, plasma concentrations of electrolytes, blood urea nitrogen, and creatinine are usually normal. Findings in severe malaria may include metabolic acidosis, with low plasma concentrations of glucose, sodium, bicarbonate, calcium, phosphate, and albumin together with elevations in lactate, blood urea nitrogen, creatinine, urate, muscle and liver enzymes, and conjugated and unconjugated bilirubin. Hypergammaglobulinemia is usual in immune and semi-immune subjects, and urinalysis generally gives normal results. In adults and children with cerebral malaria, the mean opening pressure at lumbar puncture is ~160 mm of cerebrospinal fluid (CSF); the CSF is usually normal or has a slightly elevated total protein level [<1.0 g/L (100 mg/dL)] and cell count (<20/uL).

PREVENTION

In most of the tropics, the eradication of malaria is not yet feasible because of the widespread distribution of *Anopheles* breeding sites; the great number of infected persons; and inadequacies in resources, infrastructure, and control programs. Where possible, the disease is contained by judicious use of insecticides to kill the mosquito vector, rapid diagnosis and appropriate patient management, and administration of chemoprophylaxis to high-risk groups. Malaria researchers are intensifying their efforts to better understand parasite-human-mosquito-environmental interactions and develop more effective control and prevention interventions. Despite the enormous investment in efforts to develop a malaria vaccine, no safe, effective, long-lasting vaccine is likely to be available for general use in the near future (Chap. 122). While there is promise for one or more malaria vaccines on the more distant horizon, prevention and control measures continue to rely on antivector and drug use strategies.

Personal Protection Against Malaria Simple measures to reduce the frequency of mosquito bites in malarious areas are very important. These measures include the avoidance of exposure to mosquitoes at their peak feeding times (usually dusk and dawn, but also throughout the night) and the use of insect repellents, suitable clothing, and insecticide-impregnated bed nets. Widespread use of bed nets, particularly those treated with residual pyrethroids, reduces the incidence of malaria and has been shown to reduce mortality in western and eastern Africa.

Chemoprophylaxis (Table 214-3) Few areas of therapeutics are as controversial as antimalarial drug prophylaxis. Recommendations for prophylaxis depend on knowledge of local patterns of plasmodial drug sensitivity and the likelihood of acquiring malarial infection. Chemoprophylaxis is never entirely reliable, and malaria should always be considered in the differential diagnosis of fever in patients who have traveled to endemic areas, even if they are taking prophylactic antimalarial drugs.

Pregnant women traveling to malarious areas should be warned about the potential risks. All pregnant women at risk in endemic areas should be encouraged to attend regular antenatal clinics and should receive either prophylaxis with chloroquine or proguanil (chloroguanide) or intermittent treatment with pyrimethamine-sulfadoxine, provided there is not high-level resistance to these drugs. In addition, antimalarial prophylaxis should be considered for children between the ages of 3 months and 4 years in areas where malaria causes high childhood mortality; such prophylaxis may not be logistically or economically feasible in many countries. Children born to nonimmune mothers in endemic areas (usually expatriates moving to these areas) should receive prophylaxis from birth.

Travelers should start taking antimalarial drugs at least 1 week before departure so that any untoward reactions can be detected and therapeutic antimalarial blood concentrations will be present when needed. Antimalarial prophylaxis should continue for 4 weeks after the traveler has left the endemic area.

Mefloquine has become the antimalarial prophylactic agent of choice for much of the tropics because it is usually effective against multidrug-resistant falciparum malaria and is reasonably well tolerated. Mild nausea, dizziness, fuzzy thinking, disturbed sleep patterns, and malaise are relatively common. Approximately 1 in every 10,000 recipients

develops an acute reversible neuropsychiatric reaction manifested by confusion, psychosis, convulsions, or encephalopathy. The role of mefloquine prophylaxis in pregnancy remains uncertain; in studies in Africa, mefloquine prophylaxis was found to be effective and safe during pregnancy. However, in one study from Thailand, treatment of malaria with mefloquine was associated with an increased risk of stillbirth.

Daily administration of doxycycline is an effective alternative to mefloquine that also exhibits some causal (preerythrocytic) prophylactic activity. Doxycycline is generally well tolerated but may cause vulvovaginal thrush, diarrhea, and photosensitivity and cannot be used by children <8 years old or by pregnant women. The combination drug atovaquone-proguanil hydrochloride (3.75/1.5 mg/kg, or 250/100 mg daily, adult dose) has recently been shown to be a very effective alternate to mefloquine chemoprophylaxis in drug-resistant areas. This drug must be taken with food or a milky drink because it is highly lipophilic: it is well-tolerated by adults and children.

Chloroquine remains the drug of choice for the prevention of infection with drug-sensitive *P. falciparum* and with the other human malarial species (although chloroquine-resistant *P. vivax* has been reported from parts of eastern Asia, Oceania, and South America). Unfortunately, there are few areas of the world with chloroquine-sensitive *P. falciparum*. Chloroquine is generally well tolerated, although some patients are unable to take the drug because of malaise, headache, or (in dark-skinned patients) pruritus. A concomitant filarial infection may provoke or aggravate chloroquine-induced pruritus. Chloroquine is considered safe in pregnancy. With chronic administration for>5 years, a characteristic dose-related retinopathy may develop, but this condition is rare at the doses used for antimalarial prophylaxis. Idiosyncratic or allergic reactions are also rare. Skeletal and cardiac myopathy are potential problems with protracted prophylactic use; they occur most often at the high doses used in the treatment of rheumatoid arthritis. Neuropsychiatric reactions and skin rashes are unusual. Amodiaquine, a related aminoquinoline, is associated with a high risk of agranulocytosis (~1 person in 2000 with continuous use) and should not be used for prophylaxis.

In the past, the dihydrofolate reductase inhibitors pyrimethamine and proguanil (chloroguanide) have been administered widely, but resistant strains of both *P. falciparum* and *P. vivax* have limited their use. Whereas antimalarial quinolines such as chloroquine act on the erythrocyte stage of parasitic development, the dihydrofolate reductase inhibitors also inhibit preerythrocytic growth in the liver (causal prophylaxis) and development in the mosquito (sporonticidal activity). Proguanil is safe and well tolerated, although mouth ulceration occurs in ~8% of persons using this drug; it is considered safe for antimalarial prophylaxis in pregnancy. The prophylactic use of the combination of pyrimethamine and sulfadoxine is not recommended because of an unacceptable incidence of severe toxicity, principally exfoliative dermatitis and other skin rashes, agranulocytosis, hepatitis, and pulmonary eosinophilia. The combination of pyrimethamine with dapsone (0.2/1.5 mg/kg weekly; 25/200 mg maximum) is a second-line alternative available in some countries and can be used in areas with chloroquine-resistant *P. falciparum*. This combination is generally well tolerated; however, resistance is increasing, and dapsone may cause methemoglobinemia and allergic reactions and (at higher doses) may pose a significant risk of agranulocytosis. Primaquine (0.5 mg/kg, or 30 mg daily) has also proved safe and effective in clinical

trials in drug-resistant areas and can be considered when all other options are containdicated. Proguanil and the pyrimethamine-dapsone combination are not available in the United States.

Because of the increasing spread and intensity of plasmodial resistance to chloroquine in Africa and other areas of the world (Fig. 214-2), the Centers for Disease Control and Prevention (CDC;http://www.cdc.gov/travel/index.htm), which recommends a weekly dose of mefloquine for all travelers, maintains an updated 24-h travel and malaria information audiotape that can be accessed by touch-tone telephone (888-232-3228). Regional and disease-specific documents may be requested from the CDC Fax Information Service (888-232-3299). Consultation for the evaluation of prophylaxis failures or treatment of malaria can be obtained from state and local health departments and the CDC (770-488-7788).

TREATMENT

When a patient in or from a malarious area presents with fever, thick and thin blood smears should be prepared and examined immediately to confirm the diagnosis and identify the species of infecting parasite. Repeat blood smears should be performed at least every 12 h for 2 days if the first smears are negative. Patients with severe malaria or those unable to take oral drugs should receive parenteral antimalarial therapy. If there is any doubt about the resistance status of the infecting organism, then quinine or quinidine should be given. Several drugs are available for oral treatment, and the choice of drug depends on the likely sensitivity of the infecting parasites. Despite recent evidence of chloroquine resistance in *P. vivax* (from parts of Indonesia, Oceania, and Brazil), chloroquine remains the treatment of choice for the "benign" human malarias (*P. vivax*, *P. ovale*, *P. malariae*). Characteristics of various antimalarial agents are shown inTable 214-4, and drug regimens approved by the U.S. Food and Drug Administration are detailed inTable 214-5. The availability of antimalarial drugs varies considerably between countries. Many of the drugs used to treat malaria in endemic areas are not available in temperate countries such as the United States.

Severe Malaria Because of resistance, chloroquine can no longer be relied upon in most countries for the treatment of severe malaria. The antiarrhythmic quinidine gluconate is as effective as quinine and, as it is more readily available, has replaced quinine for the treatment of malaria in the United States. The administration of quinidine must be closely monitored if dysrrhythmias and hypotension are to be avoided. Total plasma levels in excess of 8 ug/mL, a QT_cinterval of >0.6 s, or QRS widening beyond 25% of baseline are indications for slowing infusion rates. If arrhythmia or saline-unresponsive hypotension develops, treatment with this drug should be discontinued. Quinine is safer than quinidine; cardiovascular monitoring is not required except when the recipient has cardiac disease. In some areas of Asia, the Chinese drugs derived from artemisinin (artemether and artesunate) have become first-line treatments for severe malaria. These agents are rapidly effective against multidrug-resistant falciparum malaria and are at least as effective as and safer than quinine or quinidine. They are not available in the United States.

Severe falciparum malaria constitutes a medical emergency requiring intensive nursing care and careful management. The patient should be weighed and, if comatose, placed

on his or her side. Frequent evaluation of the patient's condition is essential. Ancillary drugs such as high-dose glucocorticoids, urea, heparin, and dextran are of no value.

Parenteral antimalarial treatment should be started as soon as possible. An initial loading dose should be given so that therapeutic concentrations are reached as soon as possible. Both quinine and quinidine will cause dangerous hypotension if injected rapidly; when given intravenously, they must be administered carefully by rate-controlled infusion only. The optimal therapeutic range for quinine and quinidine in severe malaria is not known with certainty, but total plasma concentrations of 8 to 15 mg/mL for quinine and 3.5 to 8.0 mg/mL for quinidine are effective and do not cause serious toxicity. The systemic clearance and apparent volume of distribution of these alkaloids are markedly reduced and plasma protein binding is increased in severe malaria, so that the blood concentrations attained with a given dose are higher. If the patient remains seriously ill or in acute renal failure for>2 days, the maintenance doses of quinine or quinidine should be reduced by 30 to 50% to prevent toxic accumulation of the drugs. The initial doses should never be reduced. If one of the artemisinin derivatives or chloroquine is given, dose reductions are unnecessary, even in renal failure. Exchange transfusion should be considered for severely ill patients, although the precise indications for this procedure have not been agreed upon. It has been recommended that -- if safe and feasible -- exchange should be considered for parasitemia levels of 5 to 15% and is indicated for parasitemia levels of>15%. The role of prophylactic intramuscular phenobarbital in preventing convulsions in cerebral malaria also remains uncertain.

When the patient is unconscious, the blood glucose level should be measured every 4 to 6 h, and values below 2.2 mmol/L (40 mg/dL) should prompt treatment with intravenous dextrose. All patients treated with intravenous quinine or quinidine should receive a continuous infusion of 5 to 10% dextrose. The parasite count and hematocrit level should be measured every 6 to 12 h. Anemia develops rapidly; if the hematocrit falls below 20%, then whole blood (preferably fresh) or packed cells should be transfused slowly, with careful attention to circulatory status. Renal function should be checked daily. Judicious use of small doses of a diuretic to prevent fluid overload may be needed, particularly in the elderly. Children presenting with severe anemia and acidotic breathing are often hypovolemic; in this situation, resuscitation with crystalloids or blood is indicated. Accurate assessment is vital. Management of fluid balance is difficult in severe malaria, particularly in adults, because of the thin dividing line between overhydration (leading to pulmonary edema) and underhydration (contributing to renal impairment). If necessary, pulmonary artery occlusion pressures should be measured and maintained in the low-normal range. As soon as the patient can take fluids, oral therapy should be substituted for parenteral treatment.

Uncomplicated Malaria Infections due to *P. vivax*, *P. malariae*, *P. ovale*, and known sensitive strains of *P. falciparum* should be treated with oral chloroquine (total dose, 25 mg of base/kg). In Africa, chloroquine-resistant strains are usually sensitive to sulfadoxine/pyrimethamine. Where there is resistance to the latter combination, either (1) quinine plus tetracycline or doxycycline (or clindamycin) or (2) mefloquine should be used; tetracycline and doxycycline cannot be given to pregnant women or to children<8 years of age. Oral quinine is extremely bitter and regularly produces cinchonism comprising tinnitus, high-tone deafness, nausea, vomiting, and dysphoria. Compliance is poor with the required 5- to 7-day regimens of this drug. Mefloquine should be given

at a total dosage of 25 mg/kg (15 mg/kg followed 8 to 12 h later by 10 mg/kg) and, where available and approved for use, combined with artesunate or artemether (4 mg/kg per day for 3 days). Although significant resistance to mefloquine has been documented in Thailand, Burma, Vietnam, and Cambodia, this agent is usually effective against multidrug-resistant strains of *P. falciparum* outside these areas. Artemether-lumefantrine and atovaquone-proguanil are recently introduced, well-tolerated antimalarial drugs used in 3-day regimens. They are both effective against multidrug-resistant falciparum malaria.

Patients should be monitored for vomiting for 1 h after the administration of any oral antimalarial drug. Symptom-based treatment, with tepid sponging and acetaminophen administration, lowers fever and thereby reduces the patient's propensity to vomit these drugs. Minor central nervous system reactions (nausea, dizziness, sleep disturbances) are common. The incidence of serious adverse neuropsychiatric reactions to mefloquine treatment is ~1 in 1000 in Asia but may be as high as 1 in 200 among Africans and Caucasians. All the antimalarial quinolines (chloroquine, mefloquine, and quinine) exacerbate the orthostatic hypotension associated with malaria, and all are tolerated better by children than by adults. Pregnant women, young children, patients unable to tolerate oral therapy, and nonimmune subjects (e.g., travelers) with suspected malaria should be evaluated carefully and hospitalization considered. If there is any doubt as to the identity of the infecting malarial species, treatment for falciparum malaria should be given. A negative blood smear does not rule out malaria; thick blood films should be checked 1 and 2 days later to exclude the diagnosis. Nonimmune subjects receiving treatment for malaria should have daily parasite counts performed until negative thick films indicate clearance of the parasite. If the level of parasitemia does not fall below 25% of the admission value in 48 h or if parasitemia has not cleared by 7 days (and compliance is assured), drug resistance is likely and the regimen should be changed. Quinine (or quinidine) and tetracycline should be reserved for multidrug-resistant infections, but if falciparum malaria has been contracted in an area of known drug sensitivity, then treatment with chloroquine, sulfadoxine/pyrimethamine, or mefloquine is preferable because these agents are better tolerated and simpler to administer.

Primaquine (0.3 mg of base/kg; 15 mg of base, adult dose) should be given daily for 14 days to patients with *P. vivax* or *P. ovale* infections after laboratory tests forG6PDdeficiency have proved negative. A dose of 22.5 to 30 mg for an adult is recommended for infections acquired in Southeast Asia and Oceania. If the patient has a mild variant of G6PD deficiency, primaquine can be given in a dose of 0.6 mg of base/kg (45 mg maximum) once weekly for 8 weeks.

PREVENTING DRUG RESISTANCE

In much of the tropics, drug-resistant *P. falciparum* is increasing in distribution, frequency, and intensity. There is a growing belief among malariologists that, to prevent resistance, falciparum malaria should no longer be treated with single drugs in endemic areas; the same rationale has been applied in the treatment of tuberculosis and HIV/AIDS. This strategy is based upon simultaneous use of two or more drugs with different modes of action: one, an artemisinin derivative (artesunate, artemether, or dihydroartemisinin), given for 3 days; and the other, a slower-acting antimalarial. In areas where *P. falciparum* is still sensitive, chloroquine is used as the second drug;

where there is low-grade chloroquine resistance (e.g., many areas of Africa), either amodiaquine or sulfadoxine/pyrimethamine can be used in combination with the artemisinin derivative. Where there is also resistance to sulfadoxine/pyrimethamine, the combinations artesunate plus mefloquine, artemether plus lumefantrine, or quinine plus tetracycline or clindamycin can be considered (although tetracycline cannot be given to pregnant women or to children <8 years of age). Atovaquone/proguanil, which is also effective against drug-resistant malaria, can also be combined with artesunate to prevent the emergence of resistance. While significant resistance to mefloquine occurs in Thailand, Burma, and Cambodia, the mefloquine/artesunate combinations are still reliably effective in these areas. The artemisinin derivatives and lumefantrine (all unlicensed in the United States) and atovaquone-proguanil are tolerated well with no significant adverse effects.

COMPLICATIONS

Acute Renal Failure If the level of blood urea nitrogen or creatinine rises despite adequate rehydration, fluid administration should be restricted to prevent volume overload. The indications for dialysis are the same as those in other forms of hypercatabolic acute renal failure (Chap. 269). Even with adequate peritoneal dialysis, secondary bacterial infections are common in the tropics, and hemodialysis or hemofiltration is preferable. Some patients pass small volumes of urine sufficient to allow control of fluid balance; these cases can be managed conservatively if other indications for dialysis do not arise. Renal function usually improves within days, but full recovery may take weeks.

Acute Pulmonary Edema Patients should be positioned at 45° and given oxygen and intravenous diuretics. Pulmonary artery occlusion pressures may be normal, indicating increased pulmonary capillary permeability. Positive pressure ventilation should be started early if the immediate measures fail (Chap. 233).

Hypoglycemia An initial slow injection of 50% dextrose (0.5 g/kg) should be followed by an infusion of 10% dextrose (0.10 g/kg per hour). The blood glucose level should be checked regularly thereafter, as recurrent hypoglycemia is common, particularly in patients receiving quinine or quinidine. In severely ill patients, hypoglycemia commonly occurs together with metabolic (lactic) acidosis and carries a poor prognosis.

Other Complications Patients who develop spontaneous bleeding should be given fresh blood and intravenous vitamin K. Convulsions should be treated with intravenous or rectal benzodiazepines and, if necessary, respiratory support. Aspiration pneumonia should be suspected in any unconscious patient with convulsions, particularly with persistent hyperventilation; intravenous antimicrobial agents and oxygen should be administered, and pulmonary toilet should be undertaken. Treatment for systemic *Salmonella* and other infections common in African children with falciparum malaria should be considered. Hypoglycemia or gram-negative septicemia should be suspected when the condition of any patient suddenly deteriorates for no obvious reason during antimalarial treatment.

BABESIOSIS

Babesiosis is a protozoan disease of animals that is transmitted by ticks; humans are infected incidentally and initially develop a nonspecific febrile illness. *Babesia* organisms enter red blood cells and resemble malarial parasites morphologically, thus posing a diagnostic problem.

ETIOLOGY AND NATURAL CYCLE

Of the more than 100 species of *Babesia*, *B. microti* and *B. divergens* are the two that cause most human infections. Ixodid (hard-bodied) ticks, in particular *Ixodes scapularis* (*I. dammini*) and *I. ricinus*, are the vectors of the parasite. Ticks ingest *Babesia* while feeding, and the parasite multiplies within the tick's gut wall. The organisms then spread to the salivary glands; their inoculation into a vertebrate host by a tick larva, nymph, or adult completes the cycle of transmission. Asexual reproduction of *Babesia* within red blood cells produces two or four parasites.

EPIDEMIOLOGY

While *Babesia* infections in wild and domestic animals are distributed globally, almost all *B. microti* infections in the United States occur along the northeastern coast, including Nantucket Island, Martha's Vineyard, and Cape Cod in Massachusetts; Block Island in Rhode Island; Long Island, Shelter Island, and Fire Island in New York; and the nearby mainland, including Connecticut. Cases also have been reported from Wisconsin, Minnesota, Virginia, Maryland, Georgia, and Mexico. *Babesia* isolates from patients in Washington and California have been characterized as WA-1-type parasites, a category that is genetically and antigenically distinct from *B. microti*. A strain isolated in Missouri differs from these isolates, suggesting that babesiosis may be an "emerging infection." The deer tick, *I. scapularis*, is the vector associated with *B. microti*. In Europe, *B. divergens* has been responsible for the majority of the 22 reported cases of babesiosis; Yugoslavia, Russia, France, the United Kingdom, and Ireland have accounted for most of these infections.

Transfusions are another source of babesiosis. In the more than 20 transfusion-associated cases reported, parasites were uncommonly detected in blood donors, but serologic testing of their blood for *Babesia* gave positive results.

Infections with *B. divergens* have occurred sporadically in previously splenectomized patients in several countries in Europe. *I. ricinus* is probably the vector in these cases, as it is for the transmission of this organism among cattle. The infected persons were predisposed to illness by their asplenic status.

I. scapularis feeds on rodents as a larva and a nymph and on deer as an adult; nymphs are abundant during the spring and summer and feed on humans readily. In some endemic areas, the seroprevalence in the human population may be >2%. This figure indicates that asymptomatic infection is more frequent than is generally thought.

CLINICAL PRESENTATION

The incubation period for *B. microti* infection is about 1 to 4 weeks. Immunosuppressed patients, splenectomized individuals, and the elderly have the most severe illness. The

clinical presentation varies widely; symptoms and signs include a gradual onset of irregular fever, chills, sweating, muscle pain, and fatigue. Mild hepatosplenomegaly and mild hemolytic anemia may develop. The level of parasitemia may exceed 10%. The illness may continue for weeks or months.

Patients infected with *B. divergens* have a more severe illness, with a rapid onset of chills, fever, nausea, vomiting, and hemolytic anemia progressing to jaundice, hemoglobinemia, and renal failure. *B. divergens* infections are often fatal.

DIAGNOSIS

Whether or not they have a history of exposure to ticks or tick bites, febrile persons living in endemic areas should have Giemsa-stained thick and thin blood films (see Plate VI-22) examined for small intraerythrocytic parasites. *B. microti* appears as a small ring form resembling *P. falciparum*. Unlike infection with *Plasmodium*, however, that with *Babesia* does not cause the production of pigment in parasites, nor are schizonts or gametocytes formed. Dividing within red blood cells, *B. microti* can form four daughter parasites attached by strands of cytoplasm; these "tetrad" forms are seen infrequently in human blood films but are a distinguishing feature. An indirect immunofluorescence antibody test is useful for the diagnosis of infection with *B. microti* but does not replace the blood smear. The serum antibody titer rises 2 to 4 weeks after the onset of illness and then wanes over 6 to 12 months; cross-reactions can occur with other species of *Babesia* and with *Plasmodium*.

About 50% of patients infected with *B. microti* have antibody to *Borrelia burgdorferi*, the agent of Lyme disease (Chap. 176); this figure varies with the geographic area. The occurrence of mixed infections is not surprising since both organisms are transmitted by *I. scapularis*. This tick species is also a potential vector of human granulocytic ehrlichiosis; the same tick may carry more than one tick-borne disease. Intraperitoneal inoculation of blood from patients with babesiosis into hamsters or gerbils results in detectable parasitemia within 2 to 4 weeks.

TREATMENT

B. microti infections in patients with intact spleens are often self-limiting without treatment, although symptoms may persist for months with or without treatment. Because silent parasitemia may have prolonged symptoms and signs, treatment is advised for all patients infected with *Babesia*. Treatment with the combination of quinine sulfate (650 mg of salt orally tid) plus clindamycin (600 mg orally tid or 1.2 g parenterally bid) for 7 to 10 days is usually effective but may not always eliminate parasites. The pediatric dose is 20 to 40 mg/kg per day for quinine sulfate and 25 mg/kg per day for clindamycin, both given in three divided doses over 7 to 10 days. Atovaquone suspension (750 mg bid) plus azithromycin (500 to 1000 mg/d) may be effective when quinine and clindamycin fail. Especially severe infections with high-level *B. microti* parasitemia in asplenic patients have been successfully treated with exchange transfusions in addition to quinine and clindamycin.

215. LEISHMANIASIS - *Barbara L. Herwaldt*

OVERVIEW

DEFINITION

The term *leishmaniases* refers collectively to various clinical syndromes caused by obligate intracellular protozoa of the genus *Leishmania* (order Kinetoplastida). Leishmaniasis is endemic in diverse ecologic settings in the tropics, the subtropics, and southern Europe that range from deserts to rain forests and from rural to periurban areas. It typically is a vector-borne zoonosis, with rodents and canids as common reservoir hosts and humans as incidental hosts. In humans, visceral, cutaneous, and mucosal leishmaniasis result from infection of macrophages throughout the mononuclear-phagocyte system, in the skin, and in the naso-oropharyngeal mucosa, respectively. Current challenges include the emergence of leishmaniasis in new geographic areas and host populations (e.g., visceral leishmaniasis in persons infected with HIV) as well as the need for field-applicable, rapid diagnostic tests and for effective, safe, and affordable oral therapies, control measures, and immunoprophylactic agents.

ETIOLOGY

The organisms that cause the various forms of leishmaniasis in humans are listed inTable 215-1. Visceral leishmaniasis is typically but not exclusively caused by organisms of the *Leishmania donovani* complex; Old World cutaneous leishmaniasis by *L. tropica*, *L. major*, and *L. aethiopica*; New World (or American) cutaneous leishmaniasis by organisms of the *L. mexicana* complex and the *Viannia* subgenus; and mucosal leishmaniasis by some organisms in the *Viannia* subgenus.

LIFE CYCLE

Leishmania parasites are transmitted by the bite of female phlebotomine sandflies [genus *Phlebotomus* (Old World) or *Lutzomyia* (New World)]. As the flies attempt to feed, they regurgitate the parasite's flagellated promastigote stage into the skin of mammalian hosts. Promastigotes attach to receptors on macrophages, are phagocytized, and transform within phagolysosomes into the nonflagellated amastigote stage, which multiplies by binary fission. After rupture of infected macrophages, amastigotes are phagocytized by other macrophages. If ingested by feeding sandflies, amastigotes transform back into promastigotes, which require at least 7 days to become infective.

IMMUNOLOGY

Advances in the understanding of the immunology of leishmaniasis have made this parasitic disease the paradigm for studies of the T cell subsets and cytokines that govern resistance and susceptibility to intracellular pathogens. The paradigm is best demonstrated in murine *L. major* infection. In inbred mice, production of interferon g (IFN-g) by T_H1 and natural killer cells confers resistance. Interleukin (IL)12 induces naive T cells to differentiate into T_H1 cells and induces T cells and natural killer cells to produce IFN-g. In contrast, expansion of IL-4-producing T_H2 cells mediates

susceptibility.

Not all aspects of leishmaniasis in mice, whose susceptibility to leishmanial infection is genetically determined, apply to human infection, for which the genetic determinants are being investigated. However, a consistent principle is that healing and resistance to reinfection are associated with expanding numbers of *Leishmania*-specific T_H1 cells, production ofIFN-g, and activation of macrophages to kill intracellular amastigotes. In human visceral leishmaniasis,IL-10 appears to be associated with pathology; in addition, IL-4 may contribute to progression of disease.

GENERAL DIAGNOSTIC PRINCIPLES

Definitive diagnosis of leishmaniasis requires demonstration of the parasite. To identify amastigotes by light-microscopic examination, the specimen obtained from an infected site (e.g., thin smear, histologic section) should be stained with Giemsa or another Romanovsky stain and presumptive amastigotes (2 to 4 um in diameter) examined under oil immersion for the presence of a nucleus and a rod-shaped kinetoplast (Fig. 215-1); the latter is a specialized mitochondrial structure that contains extranuclear DNA. Other means of parasitologic confirmation include in vitro culture (e.g., on Novy-MacNeal-Nicolle medium), animal inoculation, and use of molecular techniques that are under investigation (e.g., polymerase chain reaction).

The *Leishmania* species that infect humans are morphologically similar. They can be distinguished by isoenzyme analysis of cultured promastigotes, determination of monoclonal antibody specificity, or various molecular methods.

Indirect immunologic methods for diagnosis include serologic assays and tests for *Leishmania*-specific cell-mediated immunity (e.g., skin testing for delayed-type hypersensitivity reactions). The usefulness of such methods depends in part on the clinical syndrome (see below). Traditional serologic assays (e.g., indirect immunofluorescent antibody testing) do not reliably distinguish past from current infection, and no leishmanin skin-test preparation has been approved for use in the United States. Advances in molecular methods (e.g., production of recombinant/synthetic antigens) may lead to the development of better diagnostic techniques.

GENERAL THERAPEUTIC PRINCIPLES

For a given case of leishmaniasis, it is important to consider whether the patient's illness could result in substantial morbidity or in death and therefore requires expeditious treatment with a regimen that generally is highly effective. For decades, the pentavalent antimonial (Sb^V) compounds sodium stibogluconate and meglumine antimonate have been the mainstays of antileishmanial therapy (Table 215-2). Toxicity (with such manifestations as myalgia, arthralgia, fatigue, elevated aminotransferase levels, chemical pancreatitis, and electrocardiographic abnormalities) becomes increasingly common as the course of treatment progresses but usually does not limit therapy and is reversible.

The traditional parenteral alternatives to Sb^V -- amphotericin B and pentamidine

isethionate -- are generally considered more apt to induce serious or irreversible toxicity (e.g., nephrotoxicity). However, these agents are being advocated for use in some situations (see below; Table 215-2), in part because of the benefits of new formulations (e.g., lipid formulations of amphotericin B) or dosage regimens of these drugs and the decreasing effectiveness of Sb^{V} in some settings. Many other agents have been touted as alternatives or adjuncts to Sb^{V}, often on the basis of suboptimal data. Some of these agents may be useful in certain situations, with one caveat: even the results of well-conducted clinical trials are not always generalizable to the treatment of patients in other settings. Most of the nonparenteral agents evaluated to date have at best modest activity against some of the *Leishmania* species.

PREVENTION AND CONTROL

The transmission of *Leishmania* species typically is focal, with local "hot spots," in part because of the limited flight range of sandflies; these insects have a short, hopping flight style and usually remain within a few hundred meters of their breeding site. They rest in dark, moist places in habitats ranging from deserts to rain forests; peridomestic sandflies rest in debris or rubble near buildings.

Personal protective measures include the avoidance of outdoor activities when sandflies are most active (dusk to dawn); the use of mechanical barriers such as screens and bed-nets that keep out sandflies, which are about one-third the size of mosquitoes; the wearing of protective clothing; and the application of insect repellent to exposed skin. Impregnation of clothing, bed-nets, and screens with permethrin may also be useful, as may spraying of dwellings with residual-action insecticide. Vaccine strategies are being investigated. Treatment of human cases is an effective control measure only where humans are the primary reservoirs of infection. Vector control and elimination of reservoir hosts may be useful in select settings -- for example, where transmission is intra- or peridomiciliary.

VISCERAL LEISHMANIASIS

More than 90% of the world's cases of visceral leishmaniasis occur in Bangladesh, northeastern India (particularly Bihar State), Nepal, Sudan, and northeastern Brazil. The causative species typically are those of the *L. donovani* complex (Table 215-1). The organisms can be transmitted not only by sandflies but also congenitally and parenterally (e.g., through blood transfusions or sharing of needles). Infection begins in macrophages at the inoculation site (e.g., in dermal macrophages at the site of a sandfly bite) and disseminates throughout the mononuclear-phagocyte system in the context of both specific (i.e., to leishmanial antigens) and nonspecific (e.g., to tuberculin) anergy.

CLINICAL MANIFESTATIONS

Visceral infection can remain subclinical or become symptomatic, with an acute, subacute, or chronic course. In some settings, inapparent infections far outnumber clinically apparent ones; malnutrition is among the risk factors for the development of disease. The incubation period usually ranges from weeks to months but can be as long as years. Whereas the general term *visceral leishmaniasis* covers a broad spectrum of severity and manifestations, the term *kala-azar* (Hindi for "black fever," indicating that

the skin of some patients turns gray) generally conjures up the classic image of profoundly cachectic, febrile patients who are heavily infected with parasites and have life-threatening disease. Splenomegaly (with the spleen most often soft and nontender) typically is more impressive than hepatomegaly, and the spleen can in fact be massive; both splenomegaly and hepatomegaly result from reticuloendothelial cell hyperplasia. Peripheral lymphadenopathy is common in some settings, including Sudan.

The abnormal laboratory findings associated with advanced disease include pancytopenia -- anemia, leukopenia (neutropenia, marked eosinopenia, relative lymphocytosis and monocytosis), and thrombocytopenia -- as well as hypergammaglobulinemia (chiefly involving IgG, from polyclonal B cell activation) and hypoalbuminemia. Causes of anemia can include bone-marrow infiltration, hypersplenism, autoimmune hemolysis, and bleeding.

Some patients develop post-kala-azar dermal leishmaniasis. This syndrome is manifested by skin lesions (including macules, papules, nodules, and patches) that typically are most prominent on the face. These lesions can develop during therapy or within a few months thereafter (e.g., in East Africa) or can develop years later (e.g., in India); relapse of visceral infection can occur. Persons with persistent skin lesions can serve as reservoir hosts of infection.

Viscerotropic leishmaniasis caused by *L. tropica*, which typically is dermotropic, was recognized among U.S. soldiers who participated in Operation Desert Storm in the Persian Gulf. The affected persons had light parasite burdens and nonspecific manifestations of visceral infection (e.g., fatigue, fever, and gastrointestinal symptoms).

DIAGNOSIS

Although molecular techniques are under investigation, parasitologic diagnosis of visceral leishmaniasis has traditionally been accomplished by demonstration of the parasite on stained slides or in cultures of a tissue aspirate or a biopsy specimen (e.g., of spleen, liver, bone marrow, or lymph node). The diagnostic yield is highest for splenic aspiration (specifically, as high as 98% vs.<90% for other specimens), but this procedure can cause hemorrhage.

Patients with florid kala-azar commonly have relatively heavy parasite burdens, develop high titers of antibody to *Leishmania* (diagnostically useful but not protective), and have undetectable *Leishmania*-specific cell-mediated immunity (with leishmanin skin-test reactivity as well as lymphocyte proliferation andIFN-gresponses to leishmanial antigens typically noted only after recovery). In contrast, viscerotropic leishmaniasis can be difficult to diagnose because of a light parasite burden and a minimal antibody response. A promising noninvasive serologic method for diagnosing kala-azar uses nitrocellulose paper strips impregnated with K39, a recombinant leishmanial polypeptide; this technique is being field-tested.

The differential diagnosis of visceral leishmaniasis includes other tropical infectious diseases that cause fever or organomegaly (e.g., typhoid fever, miliary tuberculosis, brucellosis, malaria, tropical splenomegaly syndrome, and schistosomiasis) as well as diseases such as leukemia and lymphoma. Post-kala-azar dermal leishmaniasis should

be differentiated from syphilis, yaws, and leprosy.

TREATMENT

Because persons who have kala-azar generally die if not appropriately treated, highly effective therapy is essential, as is close monitoring for bleeding and intercurrent infectious conditions such as pneumonia and diarrhea. Outside of India, treatment with a pentavalent antimonial compound still is common (Table 215-2). The use of an alternative parenteral agent (Table 215-2) should be considered even for first-line therapy if unresponsiveness to Sb^{V}therapy is prevalent, as it is in India, or if nonantimonial therapy would be advantageous for other reasons (e.g., toxicity profile or duration of therapy).

A major advance has been the advent of lipid formulations of amphotericin B, in which various lipids have replaced deoxycholate. These formulations, which passively target amphotericin to macrophage-rich organs, are more costly than conventional amphotericin B but are associated with less nephrotoxicity and can be given in shorter courses. Other parenteral alternatives that have merit in some settings include the aminoglycoside paromomycin (the chemical equivalent of aminosidine; not commercially available as of this writing), which has been used as monotherapy (in India) or as an adjunct to Sb^{V}, and pentamidine. The oral agent miltefosine is being evaluated in clinical trials and preliminarily appears to be highly effective and acceptably tolerated.

Typically, patients feel better and become afebrile during the first week of treatment. Abnormal laboratory findings and splenomegaly may take weeks or months to resolve. The best indicator of permanent cure is freedom from clinical relapse during at least 6 months of follow-up. Repeat tissue sampling is indicated if the patient's status is in question. The persistence of some parasites is not necessarily a poor prognostic indicator, whereas the apparent absence of parasites does not ensure that the patient will not have a relapse.

VISCERAL LEISHMANIASIS IN PERSONS INFECTED WITH HIV

Visceral leishmaniasis has become an important opportunistic infection among persons infected with HIV-1 in geographic areas in which both infections are endemic. To date, most dual infections have been reported from southern Europe, where *L. infantum* (of the *L. donovani* complex) is endemic. In patients infected with HIV, even relatively avirulent *Leishmania* strains can disseminate to the viscera. Clinical leishmaniasis in coinfected patients can represent newly acquired or reactivated infection; most coinfected patients with clinically evident leishmaniasis have fewer than 200 CD4+ lymphocytes per microliter. Recent data suggest that leishmaniasis is a cofactor in the pathogenesis of HIV infection; the lipophosphoglycan (a major surface molecule) of *L. donovani* induces transcription of HIV in CD4+ cells.

A diagnosis of visceral leishmaniasis should be considered for patients infected with HIV who have ever been in leishmaniasis-endemic areas and who have manifestations such as unexplained fever, organomegaly, anemia, or pancytopenia. Coinfected patients can develop unusual manifestations of visceral leishmaniasis, in part because of atypical localization of the parasite (e.g., in the gastrointestinal tract).

The diagnostic sensitivity of classic serologic methods is lower in coinfected than in immunocompetent patients (~50% vs. >90%). However, parasitologic diagnosis by noninvasive means is easier in coinfected patients. Parasites are more commonly found in the circulating blood monocytes of these patients; the sensitivities are ~50% for a Giemsa-stained peripheral-blood smear and ~70% for culture of a buffy-coat preparation. Invasive methods of parasitologic diagnosis (e.g., microscopic examination or culture of a bone marrow aspirate) typically are highly sensitive, especially for previously untreated patients, who commonly have heavy parasite burdens.

Coinfected patients may initially respond well to standard antileishmanial therapy, albeit with more drug toxicity than is experienced by most immunocompetent persons. However, coinfected patients commonly have a chronic or relapsing course, seemingly irrespective of the drug regimens used for induction and suppression therapy.

CUTANEOUS LEISHMANIASIS

Cutaneous leishmaniasis has traditionally been classified as New World (American) or Old World disease. Local names for New World disease include *chiclero ulcer* (Fig. 215-CD1), *pian bois* (bush yaws), and *uta*; those for Old World disease include *oriental sore*, *bouton d'orient*, *Aleppo evil,* and *Baghdad boil*. More than 90% of the world's cases of cutaneous leishmaniasis occur in Afghanistan, Algeria, Iran, Iraq, Saudi Arabia, Syria, Brazil, and Peru. In the Americas, the leishmaniasis-endemic area extends from southern Texas to northern Argentina; the etiologic agents typically are those of the *L. mexicana* complex and the *Viannia* subgenus (Table 215-1) but also include *L. major*-like organisms and *L. chagasi*. Old World cutaneous leishmaniasis is caused by *L. tropica*, *L. major*, and *L. aethiopica* as well as by *L. infantum* and *L. donovani*.

CLINICAL MANIFESTATIONS

The incubation period for clinically evident disease typically ranges from weeks to months. The first manifestation is usually a papule at the site of the sandfly bite but can be regional lymphadenopathy (sometimes bubonic) in *L. (V.) braziliensis* infection. Most skin lesions evolve from papular to nodular to ulcerative (Fig. 215-CD2), with a central depression (which can be several centimeters in diameter) surrounded by a raised indurated border (Fig. 215-2). Some lesions persist as nodules or plaques. Multiple primary lesions, satellite lesions, regional adenopathy, sporotrichoid subcutaneous nodules, lesion pain or pruritus, and secondary bacterial infection are variably present. The infecting species, the location of the lesion, and the host's immune response are among the determinants of the clinical manifestations and chronicity of untreated lesions. For example, in the New World, lesions caused by *L. mexicana* tend to be smaller and less chronic than those caused by *L. (V.) braziliensis*; in the Old World, *L. major* tends to cause "wet" exudative lesions that are less chronic than the "dry" lesions with central crusting that are caused by *L. tropica*. The spontaneous resolution of lesions does not preclude reactivation or reinfection.

The polyparasitic and oligoparasitic ends of the spectrum of cutaneous leishmaniasis are respectively represented by the rare syndromes of diffuse cutaneous leishmaniasis (DCL) and leishmaniasis recidivans, both of which are notoriously difficult to treat. DCL,

caused by *L. aethiopica* (Old World) or by the *L. mexicana* complex (New World), develops in the context of *Leishmania*-specific anergy and is manifested by chronic, disseminated, nonulcerative skin lesions; on histopathologic examination of specimens from these lesions, abundant parasites but few lymphocytes are noted. Leishmaniasis recidivans, a hyperergic variant with scarce parasites, is usually caused by *L. tropica* and manifested by a chronic solitary lesion on the cheek that expands slowly despite central healing.

DIAGNOSIS

Dermal scrapings of debrided ulcerative lesions are useful for histologic examination, aspirates of skin lesions and lymph nodes for in vitro culture, and biopsy specimens for both examination and culture. Although examination of histologic sections of biopsy specimens can help exclude other diagnoses, amastigotes appear larger and are more easily recognizable on Giemsa-stained thin smears (e.g., smears of dermal scrapings, touch preparations of biopsy specimens). As lesions age, amastigotes become scarcer, and parasitologic confirmation becomes more difficult.

Serologic testing is an insensitive means for diagnosing cutaneous leishmaniasis; antibody titers usually are at most minimally elevated except in patients who haveDCL. In contrast, leishmanin skin-test reactivity usually develops during active infection in persons who have simple cutaneous or recidivans leishmaniasis but not in those who have DCL.

Cutaneous leishmaniasis is frequently confused with tropical, traumatic, and venous-stasis ulcers; foreign-body reactions; superinfected insect bites; myiasis; impetigo; fungal infections (e.g., sporotrichosis); mycobacterial infections; and other diseases (e.g., sarcoidosis, neoplasms).DCL and leishmaniasis recidivans should be differentiated from lepromatous leprosy and lupus vulgaris, respectively.

TREATMENT

Decisions about whether and how to treat cutaneous leishmaniasis should take into account whether mucosal dissemination is possible (as it is in the Americas with some organisms in the *Viannia* subgenus;Table 215-1) as well as the location (e.g., on the face), number, size, evolution, and chronicity of the cutaneous lesions. When optimal effectiveness is important, intravenous or intramuscular Sb^{v}therapy is recommended (Table 215-2). In studies in Colombia (predominantly with the *Viannia* subgenus), relatively short courses of treatment with pentamidine (Table 215-2) were effective (cure rate, 96%) and quite well tolerated. Thus pentamidine may be a good parenteral alternative to Sb^{v}. The clinical response to antileishmanial therapy begins with lessening induration; healing often continues after the end of therapy. Relapse typically is manifested by clinical reactivation at the margin of the lesion.

Although many oral agents have been touted for treatment of leishmaniasis, even those that are the most effective typically are moderately active at best and are effective only against some *Leishmania* species or strains. The oral agent miltefosine is being evaluated. In the New World, ketoconazole has some activity against *L. mexicana* and *L. (V.) panamensis* and may be more active than itraconazole (at least against the

Viannia subgenus), which is better tolerated (Table 215-2). Dapsone has looked promising in India but not in Colombia. Adjunctive immunotherapy remains highly experimental but may be useful inDCL. Local or topical therapy can be considered for some cases of infection in which there is no risk of mucosal dissemination (e.g., for relatively benign lesions caused by *L. mexicana* or *L. major*). Examples of local approaches include the application of an ointment containing paromomycin and methylbenzethonium chloride (not licensed in the United States), the intralesional administration of Sb^{V}, heat therapy, and cryotherapy.

MUCOSAL LEISHMANIASIS

Leishmanial infection of the naso-oropharyngeal mucosa is a relatively rare but potentially disfiguring metastatic complication of cutaneous leishmaniasis. Mucosal disease develops despite antileishmanial cell-mediated immunity and most commonly is caused by organisms of the *Viannia* subgenus, typically *L. (V.) braziliensis* but also *L. (V.) panamensis* and *L. (V.) guyanensis*. Although mucosal disease usually becomes clinically evident within several years after the healing of the original cutaneous lesions, cutaneous and mucosal lesions can coexist or appear decades apart. Typically, the original cutaneous lesions of patients who develop mucosal disease were not treated or were suboptimally treated.

Mucosal involvement generally is manifested first by persistent unusual nasal symptoms (e.g., epistaxis), with erythema and edema of the nasal mucosa, and then by progressive, ulcerative, naso-oropharyngeal destruction (Fig. 215-CD3). Supportive laboratory data (e.g., a positive serologic test) are useful, but the scarcity of amastigotes makes parasitologic confirmation difficult. The differential diagnosis includes sarcoidosis, neoplasms, midline granuloma, rhinoscleroma, paracoccidioidomycosis, histoplasmosis, leprosy, syphilis, and tertiary yaws.

Treatment with a pentavalent antimonial compound is moderately effective for mild mucosal disease, whereas advanced disease may not respond to such treatment or may relapse repeatedly (Table 215-2). Amphotericin B (deoxycholate) is the best alternative drug currently available. Patients who develop signs of respiratory compromise during therapy may benefit from the concomitant administration of glucocorticoids.

216. TRYPANOSOMIASIS - *Louis V. Kirchhoff*

CHAGAS' DISEASE

DEFINITION

Chagas' disease, or American trypanosomiasis, is a zoonosis caused by the protozoan parasite *Trypanosoma cruzi*. Acute Chagas' disease is usually a mild febrile illness that results from initial infection with the organism. After spontaneous resolution of the acute illness, most infected persons remain for life in the indeterminate phase of chronic Chagas' disease, which is characterized by subpatent parasitemia, easily detectable antibodies to *T. cruzi*, and an absence of symptoms. In a minority of chronically infected patients, cardiac and gastrointestinal lesions develop that can result in serious morbidity and even death.

LIFE CYCLE AND TRANSMISSION

T. cruzi is transmitted among its mammalian hosts by hematophagous triatomine insects, often called reduviid bugs. The insects become infected by sucking blood from animals or humans who have circulating parasites. Ingested organisms multiply in the gut of the triatomines, and infective forms are discharged with the feces at the time of subsequent blood meals. Transmission to a second vertebrate host occurs when breaks in the skin, mucous membranes, or conjunctivae become contaminated with bug feces that contain infective parasites. *T. cruzi* also can be transmitted by the transfusion of blood donated by infected persons, from mother to fetus, and in laboratory accidents.

PATHOLOGY

An indurated inflammatory lesion called a *chagoma* often appears at the site of the parasite's entry. Local histologic changes include the presence of parasites within leukocytes and cells of subcutaneous tissues and the development of interstitial edema, lymphocytic infiltration, and reactive hyperplasia of adjacent lymph nodes. After dissemination of the organisms through the lymphatics and the bloodstream, muscles (including the myocardium) may become heavily parasitized. The characteristic pseudocysts present in sections of infected tissues are intracellular aggregates of multiplying parasites.

The pathogenesis of chronic Chagas' disease is poorly understood. The heart is the organ most commonly affected, and changes include biventricular enlargement, thinning of the ventricular walls, apical aneurysms, and mural thrombi. Widespread lymphocytic infiltration, diffuse interstitial fibrosis, and atrophy of myocardial cells are often demonstrated, but parasites are rarely seen in myocardial tissue. Conduction-system involvement often affects the right branch and the left anterior branch of the bundle of His. In chronic Chagas' disease of the gastrointestinal tract (megadisease), the esophagus and colon may exhibit varying degrees of dilatation. On microscopic examination, focal inflammatory lesions with lymphocytic infiltration are seen, and the number of neurons in the myenteric plexus may be markedly reduced.

EPIDEMIOLOGY

T. cruzi is found only in the Americas. Wild and domestic mammals harboring *T. cruzi* and infected triatomines are found in spotty distributions from the southern United States to southern Argentina. Humans become involved in the cycle of transmission when infected vectors take up residence in the primitive wood, adobe, and stone houses common in much of Latin America. Thus, human *T. cruzi* infection is a health problem primarily among the poor in rural areas of Central and South America. Most new *T. cruzi* infections in rural settings occur in children, but the incidence is unknown because most cases go undiagnosed. Thousands of individuals also become infected every year through blood transfusions in urban areas. Several dozen patients with HIV and chronic *T. cruzi* infections who underwent acute recrudescence of the latter have been described. These patients generally presented with *T. cruzi* brain abscesses, a manifestation of the illness that does not occur in immunocompetent persons. Currently, it is estimated that 16 to 18 million people, more than a third of whom live in Brazil, are chronically infected with *T. cruzi*. Chronic Chagas' disease is a major cause of morbidity and mortality in many Latin American countries, including Mexico, since many chronically infected persons eventually develop symptomatic cardiac lesions or gastrointestinal disease.

In recent years, the rate of *T. cruzi* transmission has been decreasing in several endemic countries as a result of successful vector and blood-bank control programs. A major program in the "southern cone" nations of South America (Uruguay, Paraguay, Bolivia, Brazil, Chile, and Argentina), begun in 1991, has provided the framework for much of the progress achieved. If current trends continue, transmission will be essentially eliminated in much of the endemic range by the year 2003.

Acute Chagas' disease is rare in the United States. Five cases of autochthonous transmission and four instances of transmission by blood transfusion have been reported. Moreover, in the last 26 years, seven laboratory-acquired infections and nine imported cases of acute Chagas' disease were reported to the Centers for Disease Control and Prevention (CDC). In contrast, the prevalence of chronic *T. cruzi* infections in the United States has increased considerably in recent years. Since the mid-1970s, enormous numbers of Latin Americans have emigrated to the United States. In one study conducted in Washington, D.C., 5% of Salvadoran and Nicaraguan immigrants were found to have chronic *T. cruzi* infections. Estimates based on the latter study and on studies done in several United States blood banks put the total number of infected immigrants now living in the United States at more than 50,000. The presence of these carriers of *T. cruzi* creates a substantial risk of transmission by blood transfusion, as is evidenced by the four transfusion-associated cases just cited.

CLINICAL COURSE

The first signs of acute Chagas' disease develop at least 1 week after invasion by the parasites. When the organisms enter through a break in the skin, an indurated area of erythema and swelling (the chagoma), accompanied by local lymphadenopathy, may appear. Romana's sign -- the classic finding in acute Chagas' disease, which consists of unilateral painless edema of the palpebrae and periocular tissues -- can result when the conjunctiva is the portal of entry. These initial local signs are followed by malaise, fever, anorexia, and edema of the face and lower extremities. A morbilliform rash may also

appear. Generalized lymphadenopathy and hepatosplenomegaly may develop. Severe myocarditis develops rarely; most deaths in acute Chagas' disease are due to heart failure. Neurologic signs are not common, but meningoencephalitis has been reported. The acute symptoms resolve spontaneously in virtually all patients, who then enter the asymptomatic or indeterminate phase of chronic *T. cruzi* infection.

Symptomatic chronic Chagas' disease becomes apparent years or even decades after the initial infection. The heart is commonly involved, and symptoms are caused by rhythm disturbances, cardiomyopathy, and thromboembolism. Right bundle-branch block is the most common electrocardiographic abnormality, but other types of atrioventricular block, premature ventricular contractions, and tachy- and bradyarrhythmias occur frequently. Cardiomyopathy often results in right-sided or biventricular heart failure. Embolization of mural thrombi to the brain or other areas may take place. Patients with megaesophagus suffer from dysphagia, odynophagia, chest pain, and regurgitation. Aspiration can occur, especially during sleep, and repeated episodes of aspiration pneumonitis are common. Weight loss, cachexia, and pulmonary infection can result in death. Patients with megacolon are plagued by abdominal pain and chronic constipation, and advanced megacolon can cause obstruction, volvulus, septicemia, and death.

DIAGNOSIS

The diagnosis of acute Chagas' disease requires the detection of parasites. Microscopic examination of fresh anticoagulated blood or of the buffy coat is the simplest way to see the motile organisms. Parasites also can be seen in Giemsa-stained thin and thick blood smears. When repeated attempts to visualize the organisms are unsuccessful, mouse inoculation, culture of blood in specialized media, or xenodiagnosis can be performed. In the last technique, uninfected triatomine insects are allowed to feed on the patient's blood. When done properly, all of these methods yield positive results in a high proportion of patients with acute Chagas' disease and in at least half of those with chronic infections. Since early treatment of acute Chagas' disease is extremely important, however, the decision to initiate therapy for *T. cruzi* infection despite negative wet preparations and smears must be made on clinical and epidemiologic grounds before the results of these indirect methods become available. Serologic testing is of limited usefulness in diagnosing acute Chagas' disease.

The diagnosis of chronic Chagas' disease is made by the detection of antibodies that bind to *T. cruzi* antigens. Demonstration of the parasite is not of primary importance. Several highly sensitive serologic tests for antibodies to *T. cruzi* are used widely in Latin America, including complement-fixation and immunofluorescence tests and enzyme-linked immunosorbent assays (ELISAs). However, a persistent problem with these conventional assays is the occurrence of false-positive reactions, typically with sera from patients who have other parasitic infections or autoimmune diseases. For this reason, it is generally recommended that positivity in one assay be confirmed by two other tests and that well-characterized positive and negative comparison sera be included in each run. A highly sensitive and specific method for detecting antibodies to *T. cruzi* [approved by the Clinical Laboratory Improvement Amendment (CLIA) and available in the author's laboratory] employs immunoprecipitation of radiolabeled *T. cruzi* antigens and electrophoresis. Serodiagnostic assays that employ recombinant *T.*

cruzi proteins as target antigens are being developed, as are tests based on the amplification of *T. cruzi* DNA sequences by polymerase chain reaction. However, these tests are not yet available for general use.

TREATMENT

Therapy for Chagas' disease is unsatisfactory. Nifurtimox is the only drug active against *T. cruzi* that is available in the United States. In acute Chagas' disease, nifurtimox markedly reduces the duration of symptoms and parasitemia and decreases the mortality rate. Nevertheless, its efficacy at eradicating parasites is low. Limited studies have shown that only ~70% of acute infections are cured parasitologically by a full course of treatment. Despite its limitations, nifurtimox treatment should be initiated as early as possible in acute Chagas' disease. Moreover, when laboratory accidents occur in which it appears likely that *T. cruzi* infection could become established, nifurtimox therapy should be initiated without waiting for clinical or parasitologic indications of infection.

Common adverse effects of nifurtimox include abdominal pain, anorexia, nausea, vomiting, and weight loss. Neurologic reactions to the drug may include restlessness, disorientation, insomnia, twitching, paresthesia, polyneuritis, and seizures. These symptoms usually disappear when the dosage is reduced or treatment is discontinued. The recommended daily dosage is 8 to 10 mg/kg for adults, 12.5 to 15 mg/kg for adolescents, and 15 to 20 mg/kg for children 1 to 10 years of age. The drug should be given orally in four divided doses each day, and therapy should be continued for 90 to 120 days. Nifurtimox is available from the Drug Service of theCDC in Atlanta, Georgia (telephone number, 770-639-3670).

Benznidazole is a second agent used to treat Chagas' disease. Its efficacy is similar to that of nifurtimox, and its adverse effects include peripheral neuropathy, rash, and granulocytopenia. The recommended oral dosage is 5 mg/kg per day for 60 days. Benznidazole is used widely in Latin America.

The question of whether patients in the indeterminate or chronic symptomatic phases of Chagas' disease should be treated with nifurtimox or benznidazole has been debated for years. Studies of *T. cruzi*-infected laboratory animals and humans suggest that elimination of the parasites reduces the appearance or progression of cardiac pathology. In view of these findings, an international panel of experts has recommended that all patients infected with *T. cruzi* be treated with one drug or the other, regardless of their clinical status or the duration of infection.

The usefulness of allopurinol, fluconazole, and itraconazole for the treatment of acute Chagas' disease has been studied extensively in laboratory animals and to a lesser extent in humans. None of these drugs has exhibited a level of anti-*T. cruzi* activity that warrants its use in patients. Studies in mice have shown that recombinant interferon g decreases the duration and severity of acute *T. cruzi* infection; however, its usefulness in persons with acute Chagas' disease has not been evaluated systematically.

Patients who develop cardiac and/or gastrointestinal disease in association with *T. cruzi* infection should be referred to appropriate subspecialists for further evaluation and

treatment. Cardiac transplantation is an option for patients with end-stage chagasic cardiopathies. Postoperative prophylaxis with nifurtimox or benznidazole should be considered because without it the immunosuppression required after surgery has been shown to result in reactivation of *T. cruzi* infection, often with serious consequences or even death.

PREVENTION

Since drug therapy is unsatisfactory and vaccines are not available, the control of *T. cruzi* transmission in endemic countries must depend on reduction of domiciliary vector populations by spraying of insecticides, improvement of housing, and education. In addition, in endemic areas, programs for the screening of donated blood for *T. cruzi* need to be expanded and improved to reduce rates of transmission by transfusion. Tourists traveling in endemic areas should avoid sleeping in dilapidated houses outside urban areas. Mosquito nets and insect repellent provide additional protection.

In the United States, the question of how best to avoid transmission of *T. cruzi* by blood transfusion is not easily resolved. Since no assay for *T. cruzi* infection has received clearance from the Food and Drug Administration (FDA) for use in blood banks, serologic screening is not yet an option. The FDA currently mandates the use of a questionnaire for identifying and deferring donors at high risk for *T. cruzi* infection. This approach may be effective and not reduce the blood supply intolerably, but it is important to bear in mind that approaches based solely on questionnaires have not been entirely successful at eliminating transfusion-associated transmission of other infectious agents.

In view of the possibly serious consequences of chronic *T. cruzi* infection, it would be prudent for all immigrants from endemic regions to be tested for evidence of infection. Identification of infected persons is also important because the implantation of pacemakers benefits some patients who develop ominous rhythm disturbances. The possibility of congenital transmission is yet another justification for screening.

Laboratory personnel should wear gloves and eye protection when working with *T. cruzi* and infected vectors.

SLEEPING SICKNESS

DEFINITION

Sleeping sickness, or human African trypanosomiasis (HAT), is caused by flagellated protozoan parasites that belong to the *T. brucei* complex and are transmitted to humans by tsetse flies. In untreated patients, the trypanosomes first cause a febrile illness that is followed months or years later by progressive neurologic impairment and death.

THE PARASITES AND THEIR TRANSMISSION

The East African (*rhodesiense*) and the West African (*gambiense*) forms of sleeping sickness are caused, respectively, by two trypanosome subspecies: *T. brucei rhodesiense* and *T. brucei gambiense*. These subspecies are morphologically

indistinguishable but cause illnesses that are epidemiologically and clinically distinct. The parasites are transmitted by blood-sucking tsetse flies of the genus *Glossina*. The insects acquire the infection when they ingest blood from infected mammalian hosts. After many cycles of multiplication in the midgut of the vector, the parasites migrate to the salivary glands. Their transmission takes place when they are inoculated during a subsequent blood meal. The injected trypanosomes multiply in the blood and other extracellular spaces and evade immune destruction in mammalian hosts for long periods by undergoing antigenic variation, in which the antigenic structure of their surface coat of glycoproteins changes periodically.

PATHOGENESIS AND PATHOLOGY

A self-limited inflammatory lesion (trypanosomal chancre) may appear a week or so after the bite of an infected tsetse fly. A systemic febrile illness then evolves as the parasites are disseminated through the lymphatics and bloodstream. SystemicHATwithout central nervous system (CNS) involvement is generally referred to as *stage I disease*. In this stage, widespread lymphadenopathy and splenomegaly reflect marked lymphocytic and histiocytic proliferation and invasion of morular cells, which are plasmacytes that may be involved in the production of IgM. Endarteritis, with perivascular infiltration of both parasites and lymphocytes, may develop in lymph nodes and spleen. Myocarditis develops frequently in patients with stage I disease and is especially common in *T. b. rhodesiense* infections.

Hematologic manifestations that accompany stage IHATinclude moderate leukocytosis, thrombocytopenia, and anemia. High levels of immunoglobulins, consisting primarily of polyclonal IgM, are a constant feature, and heterophile antibodies, antibodies to DNA, and rheumatoid factor are often detected. High levels of antigen-antibody complexes may play a role in the tissue damage and increased vascular permeability that facilitate dissemination of the parasites.

Stage II disease involves invasion of theCNS. The presence of trypanosomes in perivascular areas is accompanied by intense infiltration of mononuclear cells. Abnormalities in cerebrospinal fluid (CSF) include increased pressure, elevated total protein concentration, and pleocytosis. In addition, trypanosomes are frequently found in CSF.

EPIDEMIOLOGY

The trypanosomes that cause sleeping sickness are found only in Africa. Approximately 50 million persons are at risk of acquiringHAT, and tens of thousands of new cases occur every year. Precise data are not available because health statistics are often incomplete in the developing countries where HAT is endemic. Sleeping sickness has undergone a resurgence in recent years, with major epidemics in the Sudan, Ivory Coast, Chad, the Central African Republic, and several other endemic countries.

Humans are the only reservoir of *T. b. gambiense*, which occurs in widely distributed foci in tropical rain forests of Central and West Africa. Gambiense trypanosomiasis is primarily a problem in rural populations; tourists rarely become infected. Trypanotolerant antelope species in savanna and woodland areas of Central and East Africa are the

principal reservoir of *T. b. rhodesiense*. Cattle also can become infected but generally succumb to the parasite. Since risk results for the most part from contact with tsetse flies that feed on wild animals, humans acquire *T. b. rhodesiense* infection only incidentally, usually while working in areas where infected game and vectors are present. In addition, occasional cases occur among visitors to game parks in East Africa. During the past 22 years, 21 cases of importedHAT have been reported to theCDC, most of which were caused by *T. b. rhodesiense*.

CLINICAL COURSE

A painful trypanosomal chancre appears in some patients at the site of inoculation of the parasite. Hematogenous and lymphatic dissemination (stage I disease) is marked by the onset of fever. Typically, bouts of high temperatures lasting several days are separated by afebrile periods. Lymphadenopathy is prominent in *T. b. gambiense* trypanosomiasis. The nodes are discrete, movable, rubbery, and nontender. Cervical nodes are often visible, and enlargement of the nodes of the posterior cervical triangle, or Winterbottom's sign, is a classic finding. Pruritus and maculopapular rashes are common. Inconstant findings include malaise, headache, arthralgias, weight loss, edema, hepatosplenomegaly, and tachycardia.

CNSinvasion (stage II disease) is characterized by the insidious development of protean neurologic manifestations that are accompanied by progressive abnormalities in theCSF. A picture of progressive indifference and daytime somnolence develops (hence the designation "sleeping sickness"), sometimes alternating with restlessness and insomnia at night. A listless gaze accompanies a loss of spontaneity, and speech may become halting and indistinct. Extrapyramidal signs may include choreiform movements, tremors, and fasciculations. Ataxia is frequent, and the patient may appear to have Parkinson's disease, with a shuffling gait, hypertonia, and tremors. In the final phase, progressive neurologic impairment ends in coma and death.

The most striking difference between the West African and East African trypanosomiases is that the latter illness tends to follow a more acute course. Typically, in tourists, systemic signs of infection, such as fever, malaise, and headache, appear before the end of the trip or shortly after the return home. Persistent tachycardia unrelated to fever is common early in the course of *T. b. rhodesiense* trypanosomiasis, and death may result from arrhythmias and congestive heart failure beforeCNSdisease develops. In general, untreated *T. b. rhodesiense* trypanosomiasis leads to death in a matter of weeks to months, often without a clear distinction between the hemolymphatic and CNS stages.

DIAGNOSIS

A definitive diagnosis ofHATrequires detection of the parasite. If a chancre is present, fluid should be expressed and examined directly by light microscopy for the highly motile trypanosomes. The fluid also should be fixed and stained with Giemsa. Material obtained by needle aspiration of lymph nodes early in the course of the illness should be examined similarly. Examination of wet preparations and Giemsa-stained thin and thick films of serial blood samples is also useful. If parasites are not seen in blood, efforts should be made to concentrate the organisms; the simplest method involves the use of

quantitative buffy coat analysis tubes (QBC, Becton-Dickinson, Franklin Lakes, NJ). In these tubes, which are coated with acridine orange, the parasites are separated from blood cells by centrifugation and are easily seen under light microscopy because of the stain. The buffy coat from 10 to 15 mL of anticoagulated blood or the pellet obtained by centrifugation of the eluate from 25 to 50 mL of blood passed through a DEAE-cellulose column also can be examined. Trypanosomes may be seen in material aspirated from the bone marrow; the aspirate can be inoculated into liquid culture medium, as can blood, buffy coat, lymph node aspirates, andCSF. Finally, *T. b. rhodesiense* infection can be detected by inoculation of these specimens into mice or rats, which results in patent parasitemias in a week or two. Although this method is highly sensitive for the detection of *T. b. rhodesiense*, it does not detect *T. b. gambiense* because of host specificity.

It is essential to examineCSF from all patients in whomHAT is suspected. An increase in the CSF cell count is the first abnormality to be detected; increases in opening pressure and in levels of total protein and IgM develop later. Trypanosomes may be seen in the sediment of centrifuged CSF. Any CSF abnormality in a patient in whom trypanosomes have been found at other sites must be viewed as pathognomonic forCNSinvolvement and thus must prompt specific treatment for CNS disease.

A number of serologic assays are available to aid in the diagnosis ofHAT, but their variable sensitivity and specificity mandate that decisions about treatment be based on demonstration of the parasite. These tests are of value for epidemiologic surveys.

TREATMENT

The drugs traditionally used for treatment ofHAT are suramin, pentamidine, and organic arsenicals. An addition to this list is eflornithine (difluoromethylornithine), which was approved by theFDA in November 1990 for the treatment of West African trypanosomiasis. In the United States these drugs can be obtained from theCDC. Therapy for HAT must be individualized on the basis of the infecting organism (*T. b. gambiense* or *T. b. rhodesiense*), the presence or absence ofCNSdisease, adverse reactions, and (occasionally) drug resistance. The choices of drugs for the treatment of HAT are summarized inTable 216-1.

Suramin is highly effective against stage I disease. However, it can cause serious adverse effects and must be administered under the close supervision of a physician. A 100- to 200-mg intravenous test dose should be administered to detect hypersensitivity. The dosage for adults is 1 g intravenously on days 1, 3, 7, 14, and 21. The regimen for children is 20 mg/kg (maximum, 1 g) intravenously on days 1, 3, 7, 14, and 21. The drug is given by slow intravenous infusion of a freshly prepared 10% aqueous solution. Approximately 1 patient in 20,000 has an immediate, severe, and potentially fatal reaction to the drug, developing nausea, vomiting, shock, and seizures. Less severe reactions include fever, photophobia, pruritus, arthralgias, and skin eruptions. Renal damage is the most common important adverse effect of suramin. Transient proteinuria often appears during treatment. A urinalysis should be done before each dose, and treatment should be discontinued if proteinuria increases or if casts and red cells appear in the sediment. Suramin should not be given to patients with renal insufficiency.

Eflornithine is highly effective for treatment of both stages of West African trypanosomiasis. In the trials on which theFDAbased its approval, this agent cured more than 90% of 600 patients with stage II disease. The recommended treatment schedule is 400 mg/kg per day intravenously in four divided doses for 2 weeks. Adverse reactions include diarrhea, anemia, thrombocytopenia, seizures, and hearing loss. The high dosage and duration of therapy required are disadvantages that make widespread use of eflornithine difficult.

Pentamidine is the alternative drug for patients with stage IHAT, although some *T. b. rhodesiense* infections are unresponsive to this agent. The dose for both adults and children is 4 mg/kg per day intramuscularly or intravenously for 10 days. Frequent, immediate adverse reactions include nausea, vomiting, tachycardia, and hypotension. These reactions are usually transient and do not warrant cessation of therapy. Other adverse reactions include nephrotoxicity, abnormal liver function tests, neutropenia, rashes, hypoglycemia, and sterile abscesses.

The arsenical melarsoprol is the drug of choice for the treatment of East African trypanosomiasis withCNSinvolvement. Melarsoprol cures both stages of the disease and therefore is also indicated for the treatment of stage I disease in patients who fail to respond to or cannot tolerate suramin and/or pentamidine. However, because of its relatively high toxicity, melarsoprol is never the first choice for the treatment of stage I disease. The drug should be given to adults in three courses of 3 days each. The dosage is 2 to 3.6 mg/kg per day intravenously in three divided doses for 3 days followed 1 week later by 3.6 mg/kg per day, also in three divided doses and for 3 days. The latter course is repeated 10 to 21 days later. In debilitated patients, suramin is administered for 2 to 4 days before therapy with melarsoprol is initiated. An 18-mg initial dose of the latter drug, followed by progressive increases to the standard dose, has been recommended. For children, a total of 18 to 25 mg/kg should be given over 1 month. A starting dose of 0.36 mg/kg intravenously should be increased gradually to a maximum of 3.6 mg/kg at 1- to 5-day intervals, for a total of 9 or 10 doses.

Melarsoprol is highly toxic and should be administered with great care. The incidence of reactive encephalopathy has been reported to be as high as 18% in some series. Clinical manifestations of reactive encephalopathy include high fever, headache, tremor, impaired speech, seizures, and even coma and death. Treatment with melarsoprol should be discontinued at the first sign of encephalopathy but may be restarted cautiously at lower doses a few days after signs have resolved. Extravasation of the drug results in intense local reactions. Vomiting, abdominal pain, nephrotoxicity, and myocardial damage can occur.

The treatment of patients with stage II East African disease who cannot tolerate melarsoprol is problematic. The combination of the arsenical tryparsamide and suramin is one possible approach, but its efficacy is limited because suramin does not penetrate theCNS well and tryparsamide is much less effective against *T. b. rhodesiense* than it is against *T. b. gambiense*. The schedule for tryparsamide therapy is 30 mg/kg (maximum, 2 g) in a single intravenous dose every 5 days for a total of 12 doses; that for suramin treatment is 10 mg/kg intravenously every 5 days, also for a total of 12 injections. Tryparsamide can cause encephalopathy, fever, vomiting, abdominal pain, rash, tinnitus, and a variety of ocular symptoms. Alternatively, eflornithine can be

administered as outlined above to patients who cannot tolerate melarsoprol, but, as noted, its effectiveness against *T. b. rhodesiense* is variable.

PREVENTION

HATposes complex public-health and epizootic problems in Africa. Considerable progress has been made in some areas through control programs that focus on eradication of vectors and drug treatment of infected humans; however, there is no consensus on the best approach to solving the overall problem, and major epidemics continue to occur. Individuals can reduce their risk of acquiring trypanosomiasis by avoiding areas known to harbor infected insects, by wearing protective clothing, and by using insect repellent. Chemoprophylaxis is not recommended, and no vaccine is available to prevent transmission of the parasites.

217. *TOXOPLASMA* INFECTION - *Lloyd H. Kasper*

DEFINITION

Toxoplasmosis is the disease caused by infection with the obligate intracellular parasite *Toxoplasma gondii*. Acute infection acquired after birth may be asymptomatic but frequently results in the chronic persistence of cysts within the tissues of the host. Both acute and chronic toxoplasmosis are conditions in which the parasite is responsible for the development of clinically evident disease, including lymphadenopathy, encephalitis, myocarditis, and pneumonitis. Congenital toxoplasmosis is an infection of newborns that results from the transplacental passage of parasites from an infected mother to the fetus. These infants usually are asymptomatic at birth but later manifest a wide range of signs and symptoms, including chorioretinitis, strabismus, epilepsy, and psychomotor retardation.

ETIOLOGY

T. gondii is an intracellular coccidian that infects both birds and mammals. There are two distinct stages in the life cycle of *T. gondii*: the nonfeline and feline stages. In the nonfeline stage, tissue cysts that contain bradyzoites or sporulated oocysts are ingested by an intermediate host (e.g., a human, mouse, sheep, or pig). The cyst is rapidly digested by the acidic-pH gastric secretions. Bradyzoites or sporozoites are released, enter the small-intestinal epithelium, and transform into rapidly dividing tachyzoites. The tachyzoites can infect and replicate in all mammalian cells except red blood cells. Once attached to the host cell, the parasite penetrates the cell and forms a parasitophorous vacuole within which it divides. Parasite replication continues until the number of parasites within the cell approaches a critical mass and the cell ruptures, releasing parasites that infect adjoining cells.

As a result of this process, an infected organ soon shows evidence of cytopathology. Most tachyzoites are eliminated by means of the host's humoral and cell-mediated immune responses. Tissue cysts containing many bradyzoites develop 7 to 10 days after the systemic tachyzoite infection. These tissue cysts occur in a variety of host organs but persist principally within the central nervous system (CNS) and muscle. The development of this chronic stage completes the nonfeline portion of the life cycle. Active infection in the immunocompromised host is most likely due to the spontaneous release of encysted parasites that undergo rapid transformation into tachyzoites within the CNS.

The principal stage in the life cycle of the parasite takes place in the cat (the definitive host) and its prey. The parasite's sexual phase is defined by the formation of oocysts within the feline host. This enteroepithelial cycle begins with the ingestion of the bradyzoite tissue cysts and culminates after several intermediate stages in the production of gametes. Gamete fusion produces a zygote, which envelops itself in a rigid wall and is secreted in the feces as an unsporulated oocyst. After 2 to 3 days of exposure to air at ambient temperature, the noninfectious oocyst sporulates to produce eight sporozoite progeny. The sporulated oocyst can be ingested by an intermediate host, such as a person emptying a cat's litter box, a pig rummaging in a barnyard, or perhaps a mouse. It is in the intermediate host that the parasite completes its life cycle.

EPIDEMIOLOGY

T. gondii infects a wide range of mammals and birds. Its seroprevalence depends on the locale and the age of the population. Generally, hot arid climatic conditions are associated with a low prevalence of infection. In the United States and most European countries, the prevalence of seroconversion increases with age and exposure. For example, in the United States, 5 to 30% of individuals 10 to 19 years old and 10 to 67% of those over the age of 50 years show serologic evidence of exposure; seroprevalence increases by approximately 1% per year. In Central America, France, Turkey, and Brazil, the seroprevalence is higher.

TRANSMISSION

Oral Transmission The principal source of human *Toxoplasma* infection remains uncertain. Transmission usually takes place by the oral route and can be attributable to ingestion of either sporulated oocysts from contaminated soil or bradyzoites from undercooked meat. During acute feline infection, a cat may excrete as many as 100 million parasites per day. These very stable sporozoite-containing oocysts are highly infectious and may remain viable for many years in the soil. Humans infected during a well-documented outbreak of oocyst-transmitted infection develop stage-specific antibodies to the oocyst/sporozoite.

Children and adults also can acquire infection from tissue cysts containing bradyzoites. The ingestion of a single cyst is all that is required for human infection. Undercooking or insufficient freezing of meat is an important source of infection in the developed world. In the United States, 10 to 20% of lamb products and 25 to 35% of pork products show evidence of cysts that contain bradyzoites. The incidence in beef is much lower -- perhaps as low as 1%. Direct ingestion of bradyzoite cysts in these various meat products leads to acute infection.

Transmission via Blood or Organs In addition to oral transmission, direct transmission of the parasite by blood or organ products during transplantation takes place at a low rate. Viable parasites can be cultured from refrigerated anticoagulated blood, which may be a source of infection in individuals receiving blood transfusions. *T. gondii* infection also has been reported in kidney and heart transplant recipients who were uninfected before transplantation.

Transplacental Transmission About one-third of all women who acquire infection with *T. gondii* during pregnancy transmit the parasite to the fetus; the remainder give birth to normal, uninfected babies. Of the various factors that influence fetal outcome, gestational age at the time of infection is the most critical (see below). Few data support a role for recrudescent maternal infection as the source of congenital disease. Thus, women who are seropositive before pregnancy usually are protected against acute infection and do not give birth to congenitally infected neonates.

The following general guidelines can be used to evaluate congenital infection. There is essentially no risk if the mother becomes infected³6 months before conception. If infection is acquired <6 months before conception, the likelihood of transplacental

infection increases as the interval between infection and conception decreases. In pregnancy, if the mother becomes infected during the first trimester, the incidence of transplacental infection is lowest (about 15%), but the disease in the neonate is most severe. If maternal infection occurs during the third trimester, the incidence of transplacental infection is greatest (65%), but the infant is usually asymptomatic at birth. Infected infants who are normal at birth may have a higher incidence of learning disabilities and chronic neurologic sequelae than uninfected children. Only a small proportion (20%) of women infected with *T. gondii* develop clinical signs of infection. Often the diagnosis is first appreciated when routine postconception serologic tests show evidence of specific antibody.

PATHOGENESIS

Upon the host's ingestion of either tissue cysts containing bradyzoites or oocysts containing sporozoites, the parasites are released from the cysts by a digestive process. Bradyzoites are resistant to the effect of pepsin and invade the host's gastrointestinal tract. Within enterocytes, the parasites undergo morphologic transformation, giving rise to invasive tachyzoites. These tachyzoites induce a parasite-specific secretory IgA response. From the gastrointestinal tract, parasites are disseminated to a variety of organs, particularly lymphatic tissue, skeletal muscle, myocardium, retina, placenta, and theCNS. At these sites, the parasite infects host cells, replicates, and invades the adjoining cells. In this fashion, the hallmarks of the infection develop: cell death and focal necrosis surrounded by an acute inflammatory response.

In the normal immune host, both the humoral and the cellular immune responses control infection; parasite virulence and tissue tropism may be strain specific. Tachyzoites are sequestered by a variety of immune mechanisms, including induction of parasiticidal antibody, activation of macrophages with radical intermediates, production of interferong (IFN-g), and stimulation of cytotoxic T lymphocytes of the CD8+ phenotype. These antigen-specific lymphocytes are capable of killing both extracellular parasites and target cells infected with parasites. As tachyzoites are cleared from the acutely infected host, tissue cysts containing bradyzoites begin to appear, usually within theCNS and the retina. In the immunocompromised or fetal host, the immune factors necessary to control the spread of tachyzoite infection are lacking. This altered immune state allows the persistence of tachyzoites and gives rise to the progressive focal destruction that results in organ failure (i.e., necrotizing encephalitis, pneumonia, and myocarditis).

Persistence of infection with cysts containing bradyzoites is common in the immunocompetent host. This lifelong infection usually remains subclinical. Although bradyzoites are in a slow metabolic phase, cysts do degenerate and rupture within theCNS. This degenerative process, with the development of new bradyzoite-containing cysts, is the most probable source of recrudescent infection in immunocompromised individuals and the most likely stimulus for the persistence of antibody titers in the immunocompetent host.

PATHOLOGY

Cell death and focal necrosis due to replicating tachyzoites induce an intense mononuclear inflammatory response in any tissue or cell type infected. Tachyzoites

rarely can be visualized by routine histopathologic staining of these inflammatory lesions. However, immunofluorescence staining with parasitic antigen-specific antibodies can reveal either the organism itself or evidence of antigen. In contrast to this inflammatory process caused by tachyzoites, bradyzoite-containing cysts cause inflammation only at the early stages of development, and even this inflammation may be a response to the presence of tachyzoite antigens. Once the cysts reach maturity, the inflammatory process can no longer be detected, and the cysts remain immunologically quiescent within the brain matrix until they rupture.

Lymph Nodes During acute infection, lymph node biopsy demonstrates characteristic findings, including follicular hyperplasia and irregular clusters of tissue macrophages with eosinophilic cytoplasm. Granulomas rarely are evident in these specimens. Although tachyzoites are not usually visible, they can be sought either by subinoculation of infected tissue into mice, with resultant disease, or by the polymerase chain reaction (PCR). PCR amplification of DNA fragments representing either p30 (SAG-1) or p22 (SAG-2) surface antigen or B1 antigen is an effective and sensitive assay for establishing infection of lymph node tissue by tachyzoites.

Eyes In the eye, infiltrates of monocytes, lymphocytes, and plasma cells may produce uni- or multifocal lesions. Granulomatous lesions and chorioretinitis can be observed in the posterior chamber following acute necrotizing retinitis. Other ocular complications of infection include iridocyclitis, cataracts, and glaucoma.

Central Nervous System DuringCNSinvolvement, both focal and diffuse meningoencephalitis can be documented, with evidence of necrosis and microglial nodules. Necrotizing encephalitis in patients without AIDS is characterized by small diffuse lesions with perivascular cuffing in contiguous areas. In the AIDS population, polymorphonuclear leukocytes may be present in addition to monocytes, lymphocytes, and plasma cells. Cysts containing bradyzoites frequently are found contiguous with the necrotic tissue border.

Lungs Among patients with AIDS who die of toxoplasmosis, 40 to 70% have involvement of the heart and lung. Interstitial pneumonitis can develop in the neonate and the immunocompromised patient. Thickened and edematous alveolar septa infiltrated with mononuclear and plasma cells are apparent. This inflammation may extend to the endothelial walls. Tachyzoites and bradyzoite-containing cysts have been observed within the alveolar membrane. Superimposed bronchopneumonia can be caused by other microbial agents.

Heart Cysts and aggregates of parasites in cardiac muscle tissue are evident in patients with AIDS who die of toxoplasmosis. Focal necrosis surrounded by inflammatory cells is associated with hyaline necrosis and disrupted myocardial cells. Pericarditis is associated with toxoplasmosis in some patients.

Other Sites Pathologic changes during disseminated infection are similar to those described for the lymph nodes, eyes, andCNS. In patients with AIDS, the skeletal muscle, pancreas, stomach, and kidneys can be involved, with necrosis, invasion by inflammatory cells, and (rarely) the presence of tachyzoites detectable by routine staining. Large necrotic lesions may cause direct tissue destruction. In addition,

secondary effects from acute infection of these various organs, including pancreatitis, myositis, and glomerulonephritis, have been reported.

HOST IMMUNE RESPONSE

Acute *Toxoplasma* infection evokes a cascade of protective immune responses in the normal host. *Toxoplasma* enters the host at the gut mucosal level and evokes a mucosal immune response that includes the production of antigen-specific secretory IgA. Titers of serum IgA antibody directed at p30 (SAG-1) have been shown to be a useful marker of congenital and acute toxoplasmosis. Milk-whey IgA from acutely infected mothers contains a high titer of antibody to *T. gondii* and can block infection of enterocytes in vitro. In mice, IgA intestinal secretions directed at the parasite are abundant and are associated with the induction of mucosal T cells.

Within the host, *T. gondii* rapidly induces detectable levels of both IgM and IgG serum antibodies. Monoclonal gammopathy of the IgG class can occur in congenitally infected infants. IgM levels may be increased in newborns with congenital infection. The polyclonal IgG antibodies evoked by infection are parasiticidal in vitro in the presence of serum complement and are the basis for the Sabin-Feldman dye test. However, cell-mediated immunity is the major protective response evoked by the parasite during host infection. Macrophages are activated following phagocytosis of antibody-opsonized parasites. This activation can lead to death of the parasite by either an oxygen-dependent or an oxygen-independent process. If the parasite is not phagocytosed and enters the macrophage by active penetration, it continues to replicate, and this replication may represent the mechanism for transport and dissemination to distant organs. *Toxoplasma* stimulates a robust interleukin (IL) 12 response by human dendritic cells. The CD4+ and CD8+ T cell responses are antigen-specific and further stimulate the production of a variety of important lymphokines that expand the T cell and natural killer cell repertoire. *T. gondii* is a potent inducer of a T_H1 phenotype, with IL-12 and IFN-g playing an essential role in the control of the parasites' growth in the host. Regulation of the inflammatory response is at least partially under the control of a T_H2 response that includes the production of IL-4 and IL-10 in seropositive individuals. Both asymptomatic patients and those with active infection may show a depression in the ratio of CD4+ to CD8+ lymphocytes. This shift may be correlated with a disease syndrome but is not necessarily correlated with disease outcome. Human T cell clones of both the CD4+ and the CD8+ phenotypes are cytolytic against parasite-infected macrophages. These T cell clones produce cytokines that are "microbistatic." IL-18, IL-7, and IL-15 upregulate the production of IFN-g and may be important during acute and chronic infection. The effect of IFN-g may be paradoxical, with stimulation of a host downregulatory response as well.

Although in patients with AIDS *T. gondii* infection is believed to be recrudescent, determination of antibody titers is not helpful in establishing reactivation. Because of the severe depletion in CD4+ T cells, quite frequently there is no observed increase in antibody titer during exacerbation of infection. T cells from AIDS patients with reactivation of toxoplasmosis fail to secrete both IFN-g and IL-2. This alteration in the production of these critical immune cytokines contributes to the persistence of infection. *Toxoplasma* infection frequently develops late in the course of AIDS, when the loss of T cell-dependent protective mechanisms, particularly CD8+ T cells, becomes most

pronounced.

CLINICAL MANIFESTATIONS

In persons whose immune systems are intact, acute toxoplasmosis is usually asymptomatic and self-limited. This condition can go unrecognized in 80 to 90% of adults and children with acquired infection. The asymptomatic nature of this infection makes diagnosis difficult in mothers infected during pregnancy. In contrast, the wide range of clinical manifestations in congenitally infected children includes severe neurologic complications such as hydrocephalus, microcephaly, mental retardation, and chorioretinitis. If prenatal infection is severe, multiorgan failure and subsequent intrauterine fetal death can occur. In children and adults, chronic infection can persist throughout life, with little consequence to the immunocompetent host.

Toxoplasmosis in the Immunocompetent Person The most common manifestation of acute toxoplasmosis is cervical lymphadenopathy. The nodes may be single or multiple, are usually nontender, are discrete, and vary in firmness. Lymphadenopathy also may be found in suboccipital, supraclavicular, inguinal, and mediastinal areas. Generalized lymphadenopathy occurs in 20 to 30% of symptomatic patients. Between 20 and 40% of patients with lymphadenopathy also have headache, malaise, fatigue, and fever [usually with a temperature of<40°C (<104°F)]. A smaller proportion of symptomatic individuals have myalgia, sore throat, abdominal pain, maculopapular rash, meningoencephalitis, and confusion. Rare complications associated with infection in the normal immune host include pneumonia, myocarditis, encephalopathy, pericarditis, and polymyositis. Symptoms associated with acute infection usually resolve within several weeks, although the lymphadenopathy may persist for some months. In a recent epidemic, toxoplasmosis was diagnosed correctly in only 3 of the 25 patients who consulted physicians. If toxoplasmosis is considered in the differential diagnosis, routine laboratory and serologic screening should be performed before node biopsy.

The results of routine laboratory studies are usually unremarkable except for minimal lymphocytosis, an elevated sedimentation rate, and a nominal increase in liver aminotransferases. Evaluation of cerebrospinal fluid (CSF) in cases with evidence of encephalopathy or meningoencephalitis shows an elevation of intracranial pressure, mononuclear pleocytosis (10 to 50 cells/mL), a slight increase in protein concentration, and (occasionally) an increase in the gamma globulin level.PCRamplification of the *Toxoplasma* DNA target sequence in the CSF may be beneficial. The CSF of chronically infected individuals is normal.

Ocular Infection Infection with *T. gondii* is estimated to cause 35% of all cases of chorioretinitis in the United States and Europe. Most ocular involvement is believed to be due to congenital infection, with a very low incidence following acquired infection. Between 1 and 3% of all patients with AIDS develop debilitating chorioretinitis due to *T. gondii*. A variety of ocular manifestations are documented, including blurred vision, scotoma, photophobia, and eye pain. Macular involvement occurs with loss of central vision, and nystagmus is secondary to poor fixation. Involvement of the extraocular muscles may lead to disorders of convergence and to strabismus. Ophthalmologic examination should be undertaken in newborns with suspected congenital infection. As the inflammation resolves, vision improves, but episodic flare-ups of chorioretinitis,

which progressively destroy retinal tissue and lead to glaucoma, are common.

The ophthalmologic examination reveals yellow-white, cotton-like patches with indistinct margins of hyperemia. As the lesions age, white plaques with distinct borders and black spots within the retinal pigment become more apparent. Lesions usually are located near the posterior pole of the retina; they may be single but are more commonly multiple. Congenital lesions may be unilateral or bilateral and show evidence of massive chorioretinal degeneration with extensive fibrosis. Surrounding these areas of involvement are a normal retina and vasculature. In patients with AIDS, retinal lesions are often large, with diffuse retinal necrosis, and include both free tachyzoites and cysts containing bradyzoites. Toxoplasmic chorioretinitis may be a prodrome to the development of encephalitis.

Infection of the Immunocompromised Person Patients with AIDS and those receiving immunosuppressive therapy for lymphoproliferative disorders are at greatest risk for developing acute toxoplasmosis. This predilection may be due either to reactivation of latent infection or to acquisition of parasites from exogenous sources such as blood or transplanted organs. In individuals with AIDS, more than 95% of cases of *Toxoplasma* encephalitis are believed to be due to recrudescent infection. In most of these cases, encephalitis develops when the CD4+ cell count falls below 100/uL. In the immunocompromised individual, the disease may be rapidly fatal if untreated. Thus accurate diagnosis and initiation of appropriate therapy are necessary to prevent fulminant infection.

Toxoplasmosis is a principal opportunistic infection of theCNS in persons with AIDS. Although geographic origin may be related to frequency of infection, it has no correlation with the severity of disease in the immunocompromised host. Individuals with AIDS who are seropositive for *T. gondii* are at a very high risk for developing encephalitis. In the United States, about one-third of the 15 to 40% of adult patients with AIDS who are latently infected with the parasite develop *Toxoplasma* encephalitis.

The signs and symptoms of acute toxoplasmosis in the immunocompromised patient are principally within theCNS. More than 50% of patients with clinical manifestations have intracerebral involvement. Clinical findings at the time of presentation range from nonfocal to focal dysfunction. These findings include encephalopathy, meningoencephalitis, and mass lesions. Patients may present with altered mental status (75%), fever (10 to 72%), seizures (33%), headaches (56%), and focal neurologic findings (60%), including motor deficits, cranial nerve palsies, movement disorders, dysmetria, visual-field loss, and aphasia. Patients who present with evidence of diffuse cortical dysfunction develop evidence of focal neurologic disease as the infection progresses. This altered condition is due not only to the necrotizing encephalitis caused by direct invasion of the parasite but also to secondary effects, including vasculitis, edema, and hemorrhage. The onset of infection can range from an insidious process over several weeks to an acute confusional state with fulminant focal deficits, including hemiparesis, hemiplegia, visual-field defects, localized headache, and focal seizures.

Although lesions can occur anywhere within theCNS, the areas most involved appear to be the brainstem, basal ganglia, pituitary gland, and corticomedullary junction. Brainstem involvement gives rise to a variety of neurologic dysfunctions, including

cranial nerve palsy, dysmetria, and ataxia. With basal ganglionic infection, patients may develop hydrocephalus, choreiform movements, and choreoathetosis. Because *Toxoplasma* usually causes encephalitis, meningeal involvement is uncommon, and thusCSFfindings may be unremarkable or may include a modest increase in cell count and in protein -- but not glucose -- concentration.

Cerebral toxoplasmosis needs to be differentiated from other opportunistic infections or tumors within theCNS of those afflicted with AIDS. The differential diagnosis includes herpes simplex encephalitis, cryptococcal meningitis, progressive multifocal leukoencephalopathy, and primary CNS lymphoma. Involvement of the pituitary gland can give rise to panhypopituitarism and hyponatremia from inappropriate secretion of vasopressin (antidiuretic hormone). AIDS-dementia complex may present as cognitive impairment, attention loss, and altered memory. Brain biopsy in those patients who have been treated for *Toxoplasma* encephalitis but who continue to exhibit neurologic dysfunction often fails to identify organisms.

Autopsies of patients infected with *Toxoplasma* have demonstrated the involvement of multiple organs, including the lungs, gastrointestinal tract, pancreas, skin, eyes, heart, and liver. *Toxoplasma* pneumonia can occur and can be confused with *Pneumocystis carinii* infection. Respiratory involvement usually presents as dyspnea, fever, and a nonproductive cough and may rapidly progress to acute respiratory failure with hemoptysis, metabolic acidosis, hypotension, and (occasionally) disseminated intravascular coagulation. Histopathologic studies demonstrate necrosis and a mixed cellular infiltrate. The presence of organisms is a helpful diagnostic indicator, but organisms can also be found in healthy tissue. Infection of the heart is usually asymptomatic but can be associated with cardiac tamponade or biventricular failure. Infections of the gastrointestinal tract and the liver have been documented.

A presumptive clinical diagnosis of toxoplasmic encephalitis in patients with AIDS is based on clinical presentation, history of exposure as evidenced by positive serology, and radiologic evaluation. When these criteria are used, the predictive value is as high as 80%. More than 97% of patients with AIDS and toxoplasmosis have IgG antibody to the parasite in their sera. IgM serum antibody is usually not demonstrable. Intrathecal antibody to *T. gondii* may be present. Neuroradiologic evaluation should include double-dose contrast computed tomography (CT) of the head. By this test, single and frequently multiple contrast-enhancing lesions (<2 cm) may be identified. Magnetic resonance imaging (MRI) usually demonstrates multiple lesions and provides a more sensitive evaluation of the efficacy of therapy than does CT. Patients with primaryCNSlymphoma are four times more likely than patients with *Toxoplasma* encephalitis to have solitary lesions on an MRI scan. A therapeutic trial of anti-*Toxoplasma* medications is frequently used to assess the diagnosis. Treatment of presumptive *Toxoplasma* encephalitis with pyrimethamine/clindamycin results in quantifiable clinical improvement in more than 50% of patients by day 3. By day 7, more than 90% of treated patients show evidence of improvement. In contrast, if patients fail to respond or have lymphoma, clinical signs and symptoms worsen by day 7. Patients in this category require brain biopsy with or without a change in therapy. This procedure can now be performed by a stereotactic CT-guided method that reduces the potential for complications. Brain biopsy for *T. gondii* identifies organisms in 50 to 75% of cases. Some studies indicate thatPCRamplification of target genes significantly increases the

sensitivity of detection of parasites.

Congenital Toxoplasmosis Between 400 and 4000 infants born each year in the United States are affected by congenital toxoplasmosis. Infection of the placenta leads to hematogenous infection of the fetus. As has already been stated, the proportion of fetuses that become infected increases but the clinical severity of the infection declines as gestation proceeds. Persistence of the parasite can ultimately result in reactivation and further damage decades later. Factors associated with relatively severe disabilities include delayed diagnosis and initiation of therapy, neonatal hypoxia and hypoglycemia, profound visual impairment, uncorrected hydrocephalus, and increased intracranial pressure. If treated appropriately, upwards of 70% of children have normal developmental, neurologic, and ophthalmologic findings at follow-up evaluations. Treatment for 1 year with pyrimethamine and sulfonamide is tolerated with minimal toxicity (see below).

DIAGNOSIS

Tissue and Body Fluids The diagnosis of acute toxoplasmosis can be made by isolation of the parasite from blood or other body fluids after subinoculation of the sample into the peritoneal cavity of mice. Mice should be tested for organisms in the peritoneal fluid 6 to 10 days after inoculation. If no parasites are found in the mouse's peritoneal fluid, its anti-*Toxoplasma* serum titer can be evaluated 4 to 6 weeks after inoculation. Isolation of *T. gondii* from the patient's body fluids reflects acute infection, whereas isolation from biopsied tissue is an indication only of the presence of tissue cysts and should not be misinterpreted as acute toxoplasmosis. Persistent parasitemia in patients with latent, asymptomatic infection is rare. Histologic examination of lymph nodes may suggest the characteristic changes described above. Demonstration of tachyzoites in lymph nodes establishes the diagnosis of acute toxoplasmosis. Like subinoculation into mice, histologic demonstration of cysts containing bradyzoites confirms prior infection with *T. gondii* but is nondiagnostic for acute infection.

Serology The procedures just described have great diagnostic value but are limited by difficulties encountered either in the growth of parasites in vivo or in the identification of tachyzoites by histochemical methods. Serologic testing has become the routine method of diagnosis. A wide range of serologic tests that can be used to measure antibody to *T. gondii* are available commercially.

Diagnosis of acute infection with *T. gondii* can be established by detection of the simultaneous presence of IgG and IgM antibody to *Toxoplasma* in serum. The presence of circulating IgA favors the diagnosis of an acute infection. The Sabin-Feldman dye test, the indirect fluorescent antibody test, and the enzyme-linked immunosorbent assay (ELISA) all satisfactorily measure circulating IgG antibody to *Toxoplasma*. Positive IgG titers (>1:10) can be detected as early as 2 to 3 weeks after infection. These titers usually peak at 6 to 8 weeks and decline slowly to a new baseline level that persists for life. It is necessary to measure the serum IgM titer in concert with the IgG titer to better establish the time of infection. The methods currently available for this determination are the double-sandwich IgM-ELISA and the IgM-immunosorbent assay (IgM-ISAGA). Both of these assays are specific and sensitive, and their use precludes the false-positive results associated with rheumatoid factor and antinuclear antibody. The

double-sandwich IgA-ELISA is more sensitive than the IgM-ELISA for detecting congenital infection in the fetus and newborn.

The Immunocompetent Adult or Child For the patient who presents with lymphadenopathy only, a positive IgM titer is an indication of acute infection -- and an indication for therapy, if that is clinically warranted (see "Treatment" below). The serum IgM titer should be determined again in 3 weeks. An elevation in the IgG titer without an increase in the IgM titer suggests that infection is present but that it is not acute. If there is a borderline increase in either IgG or IgM, the titers should be assessed again in 3 to 4 weeks.

Ocular Toxoplasmosis Because of the congenital nature of ocular toxoplasmosis, the serum antibody titer may not correlate with the presence of active lesions in the fundus. In general, a positive IgG titer (measured in undiluted serum if necessary) in conjunction with typical lesions establishes the diagnosis. If lesions are atypical and the titer is in the low-positive range, the diagnosis is presumptive. The parasitic antigen-specific polyclonal IgG assay as well as the parasitic antigen-specificPCR may facilitate the diagnosis.

The Immunocompromised Host As discussed above, in patients with AIDS, the presence of IgG and radiologic findings consistent with toxoplasmosis are grounds for a presumptive diagnosis. Attempts to evaluate rising IgG titers or to determine whether IgM is present are not productive. Serologic evidence of infection virtually always precedes the development of *Toxoplasma* encephalitis. It is therefore important to determine the *Toxoplasma* antibody status of all patients infected with HIV. Antibody titers may range from negative to 1:1024 in patients with AIDS and *Toxoplasma* encephalitis. Fewer than 3% of patients have no demonstrable antibody to *Toxoplasma* at the time of diagnosis. Determination of the intrathecal antibody titer may be useful in identifying prior infection.PCRamplification of genetic material of the parasite found in theCSF may prove diagnostically beneficial in the future.

Patients with toxoplasmic encephalitis have focal or multifocal abnormalities demonstrable byCT orMRI. These findings are not pathognomonic of *Toxoplasma* infection since 40% ofCNSlymphomas are multifocal and 50% are ring-enhancing. Lesions on MRI scan are multiple and are located in both hemispheres, with the basal ganglia and corticomedullary junction most commonly involved. For both MRI and CT scans, the rate of false-negative results is approximately 10%. The finding of a single lesion on an MRI scan increases the suspicion of primary lymphoma and strengthens the argument for the performance of a brain biopsy.

Now used in some centers, SPECT (single-photon emission CT) has been touted as a definitive means of detecting or ruling out *Toxoplasma* infection when a CNS lesion is suspected. In the future, SPECT may well be widely used for this purpose.

As in other conditions, the radiologic response may lag behind the clinical response. Resolution of lesions may take from 3 weeks to 6 months. Some patients show clinical improvement despite worsening radiographic findings.

A presumptive diagnosis of *Toxoplasma* encephalitis should prompt the immediate

initiation of therapy. After 3 weeks, repeat radiologic studies should detect improvement. If glucocorticoids have been administered, radiologic studies should be repeated at the time of discontinuation to determine whether an exacerbation of disease has occurred. If the patient's clinical condition becomes worse, performance of a biopsy must be strongly considered.

Congenital Infection The issue of concern when a pregnant woman has evidence of recent *T. gondii* infection is obviously whether the fetus is infected.PCR of the amniotic fluid to detect the B1 gene of the parasite has replaced fetal blood sampling. Serologic diagnosis is based on the persistence of IgG antibody or a positive IgM titer after the first week of life (a time frame that excludes placental leak). The IgG determination should be repeated every 2 months. An increase in IgM beyond the first week of life is indicative of acute infection. However, up to 25% of infected newborns may be seronegative and have normal routine physical examinations. Thus assessment of the eye and the brain, with ophthalmologic testing,CSFevaluation, and radiologic studies, is important in establishing the diagnosis.

TREATMENT

Current therapeutic protocols are directed at folate metabolism, protein synthesis, or nucleic acid synthesis of the parasite. Pyrimethamine and trimethoprim inhibit the enzyme dihydrofolate reductase. Inhibitors of protein synthesis, including clindamycin, chlortetracycline, and azithromycin, affect growth of the parasite. Inhibitors of purine synthesis, such as arprinocid, may prove to be important. Atovaquone, which blocks pyrimidine salvage, has demonstrated activity against both *T. gondii* and *P. carinii*.

Immunologically competent adults and older children who have only lymphadenopathy do not require specific therapy unless they have persistent and severe symptoms. Patients with ocular toxoplasmosis should be treated for 1 month with pyrimethamine plus either sulfadiazine or clindamycin. Prenatal antibiotic therapy can reduce the number of infants severely affected by *Toxoplasma* infection.

Congenital Infection Congenitally infected neonates are treated with daily oral pyrimethamine (0.5 to 1 mg/kg) and sulfadiazine (100 mg/kg) for 1 year. In addition, therapy with spiramycin (100 mg/kg per day) plus prednisone (1 mg/kg per day) has been shown to be efficacious for congenital infection.

Infection in Immunocompromised Patients Patients with AIDS should be treated for acute toxoplasmosis; in the immunocompromised patient, toxoplasmosis is rapidly fatal if untreated. The mainstay of treatment for *Toxoplasma* encephalitis in immunocompromised patients is a combination regimen. Administered together for 4 to 6 weeks or until radiologic improvement is documented, pyrimethamine (a 200-mg loading dose followed by 50 to 75 mg/d) and sulfadiazine (4 to 6 g/d in four divided doses) block folic acid metabolism and reduce the parasite burden. Leucovorin (calcium folinate, 10 to 15 mg/d) is given as an adjunct to prevent the bone marrow toxicity associated with pyrimethamine. Both pyrimethamine and sulfadiazine cross the blood-brain barrier. A prominent consequence of dual therapy is the high incidence of associated toxicity (40%). Rash may develop during the first 3 weeks in up to 20% of patients but does not preclude the use of this combination. Other complications include

hematologic effects, crystalluria, hematuria, radiolucent renal stones, and nephrotoxicity. During therapy, serum levels of these drugs may be erratic, but such fluctuations have not been correlated with these complications.

Pyrimethamine and sulfadiazine are active only against the tachyzoite stage of the parasite. Thus, after immunocompromised patients complete the initial 4- to 6-week course, they must receive lifelong suppressive therapy with pyrimethamine (25 to 50 mg/d) and sulfadiazine (2 to 4 g/d). If sulfadiazine cannot be tolerated, a combination of pyrimethamine (75 mg/d) plus clindamycin (450 mg tid) can be used. It is possible that pyrimethamine (50 to 75 mg/d) is sufficient for chronic suppressive therapy.

Alternative Regimens Alternative therapies have been established because of the toxicity associated with the long-term antimicrobial therapy necessary for many individuals infected with *T. gondii*. Dapsone (diaminodiphenyl sulfone), with its longer serum half-life and decreased toxicity, is an effective alternative to sulfadiazine. Spiramycin, which has been used in Europe to treat pregnant women, reduces transplacental transmission. However, spiramycin has been ineffective as primary prophylaxis in patients with AIDS. Clindamycin is well absorbed from the gastrointestinal tract, and serum levels peak 1 to 2 h after administration. The combination of oral pyrimethamine (25 to 75 mg/d) plus intravenous clindamycin (1200 to 4800 mg/d) is effective for patients with AIDS who have *Toxoplasma* encephalitis. Toxic effects of clindamycin include nausea, vomiting, neutropenia, rash, and pseudomembranous colitis. Other macrolides that have been evaluated include roxithromycin, clarithromycin, and azithromycin. Evidence suggests that the macrolides are not beneficial by themselves, but a combination of pyrimethamine and clarithromycin appears to be effective. Atovaquone (750 mg tid or qid) is an optional agent for the treatment of individuals who are intolerant of other agents. Glucocorticoids can be used to treat intracerebral edema, but their benefit has not yet been established. It is difficult to assess the benefit of glucocorticoids when they are administered in conjunction with anti-*Toxoplasma* medication. Anticonvulsants are sometimes necessary for the treatment of seizures, but attention should be given to the potential interaction between sulfadiazine and phenytoin. A regimen of trimethoprim-sulfamethoxazole or dapsone plus pyrimethamine with leucovorin may prevent the development of *Toxoplasma* encephalitis in individuals infected with HIV who are seropositive for *T. gondii* after their CD4+ T lymphocyte count falls to 100/uL.

PREVENTION

The chances of primary infection with *Toxoplasma* can be reduced by not eating undercooked meat and by avoiding oocyst-contaminated material (i.e., a cat's litter box). Meat should be heated to 60°C or frozen to kill cysts. Hands should be washed thoroughly after work in the garden, and all fruits and vegetables should be washed. Blood intended for transfusion into *Toxoplasma*-seronegative immunocompromised individuals should be screened for antibody to *T. gondii*. Although such serologic screening is not routinely performed, seronegative women should be screened for evidence of infection several times during pregnancy if they are exposed to environmental conditions that put them at risk for infection with *T. gondii*. HIV-positive individuals should adhere closely to these preventive measures.

218. PROTOZOAL INTESTINAL INFECTIONS AND TRICHOMONIASIS - *Peter F. Weller*

PROTOZOAL INFECTIONS

GIARDIASIS

Giardia lamblia is a cosmopolitan protozoal parasite that inhabits the small intestines of humans and other mammals. Giardiasis is one of the most common parasitic diseases worldwide and causes both endemic and epidemic intestinal disease and diarrhea.

Life Cycle and Epidemiology Infection follows the ingestion of the environmentally hardy cysts, which excyst in the small intestine, releasing trophozoites that multiply by binary fission, occasionally to enormous numbers. *Giardia* remains a pathogen of the proximal small bowel and does not disseminate hematogenously. Trophozoites remain free in the lumen or attach to the mucosal epithelium by means of a ventral sucking disk. As a trophozoite encounters altered conditions, it forms a morphologically distinct cyst, which is the stage of the parasite usually found in the feces. Trophozoites may be present and even predominate in loose or watery stools, but it is the resistant cyst that survives outside the body and is responsible for transmission. Cysts do not tolerate heating, desiccation, or continued exposure to feces but do remain viable for months in cold fresh water. The number of cysts excreted varies widely but can approach 10^7 per gram of stool.

Giardia infections are common in both developed and developing countries. Ingestion of as few as 10 cysts is sufficient to cause infection in humans. Because cysts are infectious when excreted or shortly thereafter, person-to-person transmission occurs where fecal hygiene is poor. Giardiasis, as a symptomatic or an asymptomatic infection, is especially prevalent in day-care centers; person-to-person spread also takes place in other institutional settings with poor fecal hygiene and during homosexual contact. If food is contaminated with *Giardia* cysts after cooking or preparation, food-borne transmission can occur. Waterborne transmission accounts for episodic infections (e.g., in campers and other travelers) and for massive epidemics in metropolitan areas. Surface water, ranging from mountain streams to large municipal reservoirs, can become contaminated with fecally derived *Giardia* cysts; outmoded water systems are subject to cross-contamination from leaking sewer lines. The efficacy of water as a means of transmission is enhanced by the small infectious inoculum of *Giardia*, the prolonged survival of cysts in cold water, and the resistance of cysts to killing by routine chlorination methods that are adequate for controlling bacteria. Viable cysts can be eradicated from water by either boiling or filtration. In the United States, *Giardia* is a common agent identified in waterborne epidemics of gastroenteritis; it is also common in developing countries.

The importance of animal reservoirs as sources of infection for humans is unclear. *Giardia* parasites morphologically similar to those in humans are found in a large number of mammals, including beavers from reservoirs implicated in epidemics, dogs, cats, and ruminants. Although the high degree of isolate heterogeneity noted in humans is consistent with infections originating from different animal sources, animals have not been directly established as sources of human infection.

Giardiasis, like cryptosporidiosis, creates a significant economic burden because of the costs incurred in the installation of water filtration systems required to prevent waterborne epidemics, in the management of epidemics that involve large communities, and in the evaluation and treatment of endemic infections.

Pathophysiology The reasons that some, but not all, infected patients develop clinical manifestations and the mechanisms by which *Giardia* causes alterations in small-bowel function are largely unknown. Although trophozoites adhere to the epithelium, they do not cause invasive or locally destructive alterations. The lactose intolerance and significant malabsorption that develop in a minority of infected adults and children are clinical signs of the loss of brush border enzyme activities. In most infections the morphology of the bowel is unaltered, but in a few cases -- usually in chronically infected, symptomatic patients -- the histopathologic findings (including flattened villi) and the clinical manifestations resemble those of tropical sprue and gluten-sensitive enteropathy. The pathogenesis of diarrhea in giardiasis is not known.

The natural history of *Giardia* infection varies markedly. Infections may be aborted, transient, recurrent, or chronic. Parasite as well as host factors may be important in determining the course of infection and disease. Both cellular and humoral responses develop in human infections, but their precise roles in the control of infection and/or disease are unknown. Because patients with hypogammaglobulinemia commonly suffer from prolonged, severe infections that are poorly responsive to treatment, humoral immune responses appear to be important. The greater susceptibility of the young than of the old and of newly exposed persons than of chronically exposed populations also suggests that at least partial protective immunity may develop. Although no strains of the parasite that are clearly nonpathogenic have been identified, *Giardia* isolates vary biochemically and biologically. The marked biochemical differences among some isolates may help account for the different courses of infection in experimentally infected humans and animals. The surface of trophozoites is covered by a family of related cysteine-rich proteins that undergo surface antigenic variation and may contribute to prolonged and/or repeated infections.

Clinical Manifestations Disease manifestations of giardiasis range from asymptomatic carriage to fulminant diarrhea and malabsorption. Most infected persons are asymptomatic, but in epidemics the proportion of symptomatic cases may be higher. Symptoms may develop suddenly or gradually. In persons with acute giardiasis, symptoms develop after an incubation period that lasts at least 5 to 6 days and usually 1 to 3 weeks. Prominent early symptoms include diarrhea, abdominal pain, bloating, belching, flatus, nausea, and vomiting. Although diarrhea is common, upper intestinal manifestations such as nausea, vomiting, bloating, and abdominal pain may predominate. The duration of acute giardiasis is usually in excess of 1 week, although diarrhea often subsides. Individuals with chronic giardiasis may present with or without having experienced an antecedent acute symptomatic episode. Diarrhea is not necessarily prominent, but increased flatus, loose stools, sulfurous burping, and (in some instances) weight loss occur. Symptoms may be continual or episodic and can persist for years. Some persons who have relatively mild symptoms for long periods recognize the extent of their discomfort only in retrospect. Fever, the presence of blood and/or mucus in the stools, and other signs and symptoms of colitis are uncommon and

suggest a different diagnosis or a concomitant illness. Symptoms tend to be intermittent yet recurring and gradually debilitating, in contrast with the acute disabling symptoms associated with many enteric bacterial infections. Because of the less severe illness and the propensity for chronic infections, patients may seek medical advice late in the course of the illness; however, disease can be severe, resulting in malabsorption, weight loss, growth retardation, dehydration, and (in rare cases) death. A number of extraintestinal manifestations have been described, such as urticaria, anterior uveitis, and arthritis; whether these are caused by giardiasis or concomitant processes is unclear.

Giardiasis can be life-threatening in patients with hypogammaglobulinemia and is typically difficult to treat and eradicate. *Giardia* infections can complicate other preexisting intestinal diseases, such as cystic fibrosis. Although *Giardia* can cause enteric illness in patients with AIDS, neither the course of infection nor the response to treatment differs for patients with and without AIDS.

Diagnosis Giardiasis is diagnosed by the detection of parasite antigen in the feces or by the identification of cysts in the feces or of trophozoites in the feces or small intestines. Cysts are oval, measure 8 to 12 um ´ 7 to 10 um, and characteristically contain four nuclei. Trophozoites are pear-shaped, dorsally convex, flattened parasites with two nuclei and four pairs of flagella. The diagnosis is sometimes difficult to establish. Direct examination of fresh or properly preserved stools as well as concentration methods should be used. Because cyst excretion is variable and may be undetectable at times, repeated examination of stool, sampling of duodenal fluid, and biopsy of the small intestine may be required to detect the parasite. Tests for parasitic antigen in stool are at least as sensitive and specific as good microscopic examinations and are easier to perform. All of these methods occasionally yield false-negative results.

TREATMENT

Cure rates with metronidazole (250 mg tid for 5 days) are usually>80%; those with furazolidone (100 mg qid for 7 to 10 days) are somewhat lower. The latter agent is frequently used to treat children because it is available as a palatable elixir that is not bitter. Quinacrine, the first effective drug for the treatment of giardiasis, is available from a limited number of pharmacies. Albendazole (400 mg/d for 5 days) may be effective.

Patients in whom initial treatment fails can be re-treated with a longer course. Almost all patients respond to therapy and are cured, although some with chronic giardiasis experience delayed resolution of symptoms after eradication of *Giardia*. Those who remain infected after repeated treatments should be evaluated for reinfection through family members, close personal contacts, and environmental sources as well as for hypogammaglobulinemia. In cases refractory to multiple treatment courses, prolonged therapy with metronidazole (750 mg tid for 21 days) has been successful. Tinidazole, not available in the United States, is considered more effective than metronidazole or quinacrine. When children attending day-care centers infect an entire family, treatment of all infected family members, including asymptomatic carriers, may be required to prevent reinfection. Paromomycin, an oral aminoglycoside that is not well absorbed, can be given to symptomatic pregnant women, although the experience accumulated thus far is not a sufficient basis on which to judge how often this agent either eradicates

infection or ameliorates symptoms.

Prevention Although *Giardia* is extremely infectious, disease can be prevented by the exclusive consumption of noncontaminated food and water. Cooking food adequately and boiling or filtering potentially contaminated water prevent infection.

CRYPTOSPORIDIOSIS

The coccidian parasite *Cryptosporidium* is now known to cause diarrheal disease in immunocompetent human hosts and to be especially common among persons with AIDS or other forms of immunodeficiency.

Life Cycle and Epidemiology Cryptosporidiosis is acquired by the consumption of oocysts (50% infectious dose: ~132 oocysts in nonimmune individuals), which excyst to liberate sporozoites that in turn enter and infect intestinal epithelial cells. The parasite's further development involves both asexual and sexual cycles, which produce forms capable of infecting other epithelial cells and of generating oocysts that are passed in the feces. *Cryptosporidium* spp. infect a number of animals and can spread from infected animals to humans. Since oocysts are immediately infectious when passed in feces, person-to-person transmission takes place in day-care centers and among household contacts and medical providers. Waterborne transmission accounts for infections in travelers and for common-source epidemics. Oocysts are quite hardy and resist killing by routine chlorination. Both drinking water and recreational water (e.g., pools, waterslides) have been increasingly recognized as sources of infection.

Pathophysiology Although intestinal epithelial cells harbor the parasite in an intracellular vacuole, the means by which secretory diarrhea is elicited remain uncertain. No characteristic pathologic changes are found by biopsy. The distribution of infection can be spotty within the principal site of infection, the small bowel. Cryptosporidia are found in some patients in the pharynx, stomach, and large bowel and at times in the respiratory tract. Especially in patients with AIDS, involvement of the biliary tract can cause papillary stenosis, sclerosing cholangitis, or cholecystitis.

Clinical Manifestations Asymptomatic infections can occur in both immunocompetent and immunocompromised hosts. In immunocompetent persons, symptoms develop after an incubation period of about a week and consist principally of watery nonbloody diarrhea, at times in conjunction with abdominal pain, nausea, anorexia, fever, and/or weight loss. In these hosts, the illness usually subsides after 1 to 2 weeks, whereas in immunocompromised hosts, especially those with AIDS, diarrhea can be chronic, persistent, and remarkably profuse, causing clinically significant fluid and electrolyte depletion. Stool volumes may range from 1 to 25 L/d. Weight loss, wasting, and abdominal pain may be severe. Biliary tract involvement can manifest as midepigastric or right upper quadrant pain.

Diagnosis Evaluation usually starts with fecal examination for small oocysts, which are 4 to 5 um in diameter and are smaller than the fecal stages of most other parasites. Detection is enhanced by evaluation of stools (obtained on multiple days) by several techniques, including modified acid-fast and direct immunofluorescent stains and enzyme immunoassays. Cryptosporidia also can be identified by light and electron

microscopy at the apical surfaces of intestinal epithelium from biopsy specimens of the small bowel and, less frequently, the large bowel.

TREATMENT

To date, no chemotherapeutic agents effective against *Cryptosporidium* have been identified, although paromomycin (500 to 750 mg qid) may be partially effective for some patients infected with HIV. Improvement in immune status with antiretroviral therapy can lead to amelioration of cryptosporidiosis. Otherwise, treatment includes supportive care with replacement of fluids and electrolytes and administration of antidiarrheal agents. Biliary tract obstruction may require papillotomy or T-tube placement. Prevention requires minimizing exposure to infectious oocysts in human or animal feces. Use of submicron water filters may minimize acquisition of infection from drinking water.

ISOSPORIASIS

The coccidian parasite *Isospora belli* causes human intestinal disease. Infection is acquired by the consumption of oocysts, after which the parasite invades intestinal epithelial cells and undergoes both sexual and asexual cycles of development. Oocysts excreted in stool are not immediately infectious but must undergo further maturation. Although *I. belli* infects many animals, little is known about the epidemiology or prevalence of this parasite in humans. It appears to be most common in tropical and subtropical countries. Acute infections can begin abruptly with fever, abdominal pain, and watery nonbloody diarrhea and can last for weeks or months. In patients who have AIDS or are immunocompromised for other reasons, infections often are not self-limited but rather resemble cryptosporidiosis, with chronic, profuse watery diarrhea. Eosinophilia, which is not found in other enteric protozoan infections, may be detectable. The diagnosis is usually made by detection of the large (~25-um) oocysts in stool by modified acid-fast staining. Oocyst excretion may be low-level and intermittent; if repeated stool examinations are unrevealing, sampling of duodenal contents by aspiration or small-bowel biopsy (often with electron-microscopic examination) may be necessary.

In contrast to cryptosporidiosis, isosporiasis responds to chemotherapy. Trimethoprim-sulfamethoxazole (160/800 mg qid for 10 days and then bid for 3 weeks) has been effective; for patients intolerant of sulfonamides, pyrimethamine (50 to 75 mg/d) can be used. Relapses can occur in persons with AIDS and necessitate maintenance therapy with trimethoprim-sulfamethoxazole (160/800 mg three times a week) or combined sulfadoxine (500 mg) and pyrimethamine (25 mg) once weekly.

CYCLOSPORIASIS

Coccidian parasites of the genus *Cyclospora* have been identified as the causative organisms in diarrheal illness formerly ascribed to blue-green algal or *Cyanobacteria*-like forms. This parasite is globally distributed: illness due to *Cyclospora cayetanensis* has been reported in the United States, Asia, Africa, Latin America, and Europe. The epidemiology of this parasite has not yet been fully defined, but waterborne transmission and especially transmission in imported raspberries have been recognized.

The full spectrum of illness attributable to *Cyclospora* has not been delineated. Some patients may harbor the infection without symptoms, but many with cyclosporiasis have diarrhea, flulike symptoms, and flatulence and burping. The illness can be self-limited, can wax and wane, or (in many cases) can involve prolonged diarrhea, anorexia, and upper gastrointestinal symptoms, with sustained fatigue and weight loss in some instances. Diarrheal illness may persist for longer than a month. *Cyclospora* can cause enteric illness in patients infected with HIV, albeit at an unknown frequency.

The parasite is detectable in epithelial cells of small-bowel biopsy samples and elicits secretory diarrhea by an unknown means. The absence of fecal blood and leukocytes indicates that disease due to *Cyclospora* is not caused by destruction of the small-bowel mucosa. The diagnosis can be made by detection of spherical 8- to 10-um oocysts in the stool, although routine stool O and P examinations are not sufficient. Specific fecal examinations must be requested to detect the oocysts, which are variably acid-fast and are fluorescent when viewed with ultraviolet light microscopy. Cyclosporiasis should be considered in the differential diagnosis of prolonged diarrhea, with or without a history of travel by the patient to other countries.

Cyclosporiasis is effectively treated with trimethoprim-sulfamethoxazole (160/800 mg bid for 7 days). Patients infected with HIV, however, may experience relapses after such treatment and thus may require longer-term suppressive maintenance therapy.

MICROSPORIDIOSIS

Microsporidia are obligate intracellular spore-forming protozoa that infect many animals and cause disease in humans, especially as opportunistic pathogens in AIDS. Microsporidia are members of a distinct phylum, Microspora, which contains dozens of genera and hundreds of species. The various microsporidia are differentiated by their developmental life cycles, by ultrastructural features, and by molecular taxonomy based on ribosomal RNA. The complex life cycles of the organisms result in the production of infectious spores. Currently, six genera of microsporidia -- *Encephalitozoon*, *Pleistophora*, *Nosema*, *Vittaforma*, *Trachipleistophora*, and *Enterocytozoon* -- are recognized as causes of human disease; a seventh genus -- *Microsporidium*, which includes organisms of uncertain taxonomic status -- also causes disease in humans. Though some microsporidia are probably prevalent causes of self-limited or asymptomatic infections in immunocompetent patients, little is known of how microsporidiosis is acquired.

Microsporidiosis is most common among patients with AIDS, less common among patients with other types of immunocompromise, and rare among immunocompetent hosts. In patients with AIDS, intestinal infections with *Enterocytozoon bieneusi* and *Encephalitozoon* (formerly *Septata*) *intestinalis* are increasingly recognized to contribute to chronic diarrhea and wasting; these infections are found in 10 to 40% of patients with chronic diarrhea. Both organisms have been found in the biliary tracts of patients with cholecystitis. *E. intestinalis* may also disseminate to cause fever, diarrhea, sinusitis, cholangitis, and bronchiolitis. In patients with AIDS, *E. hellem* has caused superficial keratoconjunctivitis as well as sinusitis, respiratory tract disease, and disseminated infection. Myositis due to *Pleistophora* has been documented. *Nosema*, *Vittaforma*, and *Microsporidium* have caused stromal keratitis associated with trauma in

immunocompetent patients.

Microsporidia are small gram-positive organisms with mature spores measuring 0.5 to 2 um´ 1 to 4 um. Diagnosis of microsporidial infections in tissue often requires electron microscopy, although intracellular spores can be visualized by light microscopy with hematoxylin and eosin, Giemsa, or tissue Gram's stains. For the diagnosis of intestinal microsporidiosis, modified trichrome or chromotrope 2R-based staining and Uvitex 2B or calcofluor fluorescent staining reveal spores in smears of feces or duodenal aspirates. Definitive therapies for microsporidial infections remain to be established. For superficial keratoconjunctivitis due to *E. hellem*, topical therapy with fumagillin suspension has shown promise (Chap. 211). For enteric infections with *E. bieneusi* and *E. intestinalis* in HIV-infected patients, therapy with albendazole may be efficacious (Chap. 211).

OTHER INTESTINAL PROTOZOA

Balantidiasis *Balantidium coli* is a large ciliated protozoal parasite that can produce a spectrum of large-intestinal disease analogous to amebiasis. The parasite is widely distributed in the world. Since it infects pigs, cases in humans are more common where pigs are raised; in Muslim countries, rodents may be important carriers. Infective cysts can be transmitted from person to person and through water, but many cases are due to the ingestion of cysts derived from porcine feces in association with slaughtering, with use of pig feces for fertilizer, or with contamination of water supplies by pig feces.

Ingested cysts liberate trophozoites, which reside and replicate in the large bowel. Many patients remain asymptomatic, but some have persisting intermittent diarrhea, and a few develop more fulminant dysentery. In symptomatic individuals, the pathology in the bowel -- both gross and microscopic -- is similar to that seen in amebiasis, with varying degrees of mucosal invasion, focal necrosis, and ulceration. Balantidiasis, unlike amebiasis, does not spread hematogenously to other organs. The diagnosis is usually made by detection of the trophozoite stage in stool or sampled colonic tissue. Tetracycline (500 mg qid for 10 days) is an effective therapeutic agent.

***Blastocystis hominis* Infection** *B. hominis*, long considered a nonpathogenic yeast, is believed by some to be a protozoan capable of causing intestinal disease, although its taxonomy and inherent pathogenicity remain uncertain. Some patients who pass *B. hominis* in their stools are asymptomatic, whereas others have diarrhea and associated intestinal symptoms. Diligent evaluation reveals other potential bacterial, viral, or protozoal causes of diarrhea in some but not all patients with symptoms. Because the pathogenicity of *B. hominis* is uncertain and because therapy for *Blastocystis* infection is neither specific nor uniformly effective, patients with prominent intestinal symptoms should be fully evaluated for other infectious causes of diarrhea. If diarrheal symptoms associated with *Blastocystis* are prominent, either metronidazole (750 mg tid for 10 days) or iodoquinol (650 mg tid for 20 days) can be used.

***Dientamoeba fragilis* Infection** *D. fragilis* is unique among intestinal protozoa in that it has a trophozoite stage but not a cyst stage. How trophozoites survive to transmit infection is not known, but the unusually high prevalence of *D. fragilis* infection among persons with pinworm infection raises the possibility that eggs or larvae of *Enterobius* facilitate the transmission of *D. fragilis*. When symptoms develop in patients with *D.*

fragilis infection, they are generally mild and include intermittent diarrhea, abdominal pain, and anorexia. The diagnosis is made by the detection of trophozoites in stool; the lability of these forms accounts for the greater yield when fecal samples are preserved immediately after collection. Since fecal excretion rates vary, examination of several samples obtained on alternate days increases the rate of detection. Iodoquinol (650 mg tid for 20 days), paromomycin (25 to 30 mg/kg per day in three doses for 7 days), or tetracycline (500 mg qid for 10 days) is appropriate for treatment.

Sarcosporidiosis Various *Sarcocystis* spp. of coccidian parasites are widely distributed agents of infection in numerous animals. These parasites have an obligatory cycle of development involving two hosts. Sexual reproduction occurs in the intestine, with sporocysts passed in the feces; asexual multiplication leads to the development of muscle cysts. Humans can develop intestinal infections -- albeit apparently infrequently -- by ingesting muscle-stage cysts in undercooked pork or beef. While the full spectrum of the intestinal disease is not defined, a diarrheal illness can ensue, and sporocysts are found in the stool. Alternatively, ingestion of fecally derived sporocysts can lead to the development of cysts in striated or cardiac muscle. Some patients experience muscle pain and swelling, but the frequency and nature of symptoms elicited by muscle involvement are not clear, and these cysts, measuring 100 to 325 um, also have been found incidentally in muscle specimens. Muscle-stage infections are not followed by further spread in humans. No specific therapy exists for either intestinal or muscle-stage *Sarcocystis* infections in humans.

TRICHOMONIASIS

Various species of trichomonads can be found in the mouth (in association with periodontitis) and occasionally in the gastrointestinal tract. *Trichomonas vaginalis* -- one of the most prevalent protozoal parasites in the United States -- is a pathogen of the genitourinary tract and a major cause of symptomatic vaginitis.

Life Cycle and Epidemiology *T. vaginalis* is a pear-shaped, actively motile organism that measures about 10 by 7 um, replicates by binary fission, and inhabits the lower genital tract of females and the urethra and prostate of males. In the United States, it accounts for about 3 million infections per year in women. While the organism can survive for a few hours in moist environments and could be acquired by direct contact, person-to-person venereal transmission accounts for virtually all cases of trichomoniasis. Its prevalence is greatest among persons with multiple sexual partners and among those with other sexually transmitted diseases.

Clinical Manifestations Most men infected with *T. vaginalis* are asymptomatic, although some develop urethritis and a few have epididymitis or prostatitis. In contrast, infection in women, which has an incubation period of 5 to 28 days, is usually symptomatic and manifests with malodorous vaginal discharge (often yellow), vulvar erythema and itching, dysuria or urinary frequency (in 30 to 50% of patients), and dyspareunia. These manifestations, however, do not clearly distinguish trichomoniasis from other types of infectious vaginitis.

Diagnosis Detection of motile trichomonads by microscopy of wet mounts of vaginal or prostatic secretions has been the conventional means of diagnosis. Although such

microscopy provides an immediate diagnosis, its sensitivity for the detection of *T. vaginalis* is only ~50 to 60% in routine evaluations of vaginal secretions. Direct immunofluorescent antibody staining is more sensitive (70 to 90%) than wet-mount examinations. *T. vaginalis* can be recovered from the urethra of both males and females and is detectable in males after prostatic massage. Culture of the parasite is the most sensitive means of detection; however, the facilities for culture are not generally available, and detection of the organism takes 3 to 7 days.

TREATMENT

Metronidazole is the mainstay of treatment and may be given either as a single 2-g dose or as 250 mg tid for 7 days. All sexual partners must be treated concurrently to prevent reinfection, especially from asymptomatic males. Alternatives to metronidazole for treatment during pregnancy are not readily available, although use of 100-mg clotrimazole vaginal suppositories nightly for 2 weeks may cure some infections in pregnant women. Reinfection often accounts for apparent treatment failures, but strains of *T. vaginalis* exhibiting high-level resistance to metronidazole have been encountered. Treatment of these resistant infections with higher oral doses, parenteral doses, or concurrent oral and vaginal doses of metronidazole has been successful.

SECTION 18 -HELMINTHIC INFECTIONS

219. *TRICHINELLA* AND OTHER TISSUE NEMATODES - *Peter F. Weller, Leo X. Liu*

Nematodes are elongated, symmetric roundworms. Parasitic nematodes of medical significance may be broadly classified as intestinal or tissue nematodes, but such a classification system is imprecise. This chapter covers trichinellosis, visceral and ocular larva migrans, cutaneous larva migrans, cerebral angiostrongyliasis, and gnathostomiasis. All are zoonotic infections caused by incidental exposure to infectious nematodes. The clinical symptoms of these infections are due largely to invasive larval stages that (except in the case of *Trichinella*) do not reach maturity in humans.

TRICHINELLOSIS

Trichinellosis develops after the ingestion of meat containing cysts of *Trichinella* -- for example, pork or other meat from a carnivore. While most infections are mild and asymptomatic, heavy infections can cause severe enteritis, periorbital edema, myositis, and (infrequently) death.

Life Cycle and Epidemiology Five species of *Trichinella* are now recognized as causes of infection in humans. Two species are distributed worldwide: *T. spiralis*, which is found in a great variety of carnivorous and omnivorous animals, and *T. pseudospiralis*, which is found in mammals and birds. *T. nativa* is present in Arctic regions and infects bears; *T. nelsoni* is found in equatorial Africa, where it is common among felid predators and scavengers such as hyenas and bush pigs; and *T. bitovi* is found in temperate areas of Europe and western Asia among carnivores but not among domestic swine.

After the consumption of trichinous meat by the host, encysted larvae are liberated by digestive acid and pepsin (Fig. 219-1). The larvae invade the small-bowel mucosa and mature rapidly into adult worms. After about 1 week, female worms release newborn larvae that migrate via the circulation to striated muscle. The larvae of all species except *T. pseudospiralis* then encyst by inducing a radical transformation in the muscle cell architecture. Although host immune responses may help to expel adult worms, they have little effect on muscle-dwelling larvae.

Human trichinellosis is most often caused by the ingestion of infected pork products and thus can occur in almost any location where the meat of domestic or wild swine is eaten. Human trichinellosis also may be acquired from the meat of other animals, including dogs (in parts of Asia and Africa), horses (in Italy and France), and bears and walruses (in northern regions). Although cattle (being herbivores) are not natural hosts of *Trichinella*, beef has been implicated in outbreaks when contaminated or adulterated with trichinous pork. Laws that prohibit the feeding of uncooked garbage to pigs have greatly reduced the transmission of trichinellosis in the United States. About 40 cases of trichinellosis are reported annually in this country, but most mild cases probably remain undiagnosed. Recent U.S. outbreaks have been attributable to undercooked ethnic pork dishes, homemade and commercial sausage, wild boar meat, and walrus meat.

Pathogenesis and Clinical Features Clinical symptoms of trichinellosis arise from the
