successive phases of parasite enteric invasion, larval migration, and muscle encystment (Fig. 219-1). Most light infections (those with<10 larvae per gram of muscle) are asymptomatic, whereas heavy infections (which can involve >50 larvae per gram of muscle) can be life-threatening. Invasion of the gut by large numbers of parasites occasionally provokes diarrhea during the first week after infection. Abdominal pain, constipation, nausea, or vomiting also may be prominent. The prolonged and fulminant diarrhea noted with Arctic trichinellosis probably reflects a response to repeated infection.

Symptoms due to larval migration and muscle invasion begin to appear in the second week after infection. The migrating *Trichinella* larvae provoke a marked local and systemic hypersensitivity reaction, with fever and hypereosinophilia. Periorbital and facial edema is common, as are hemorrhages in the subconjunctivae, retina, and nail beds ("splinter" hemorrhages). A maculopapular rash, headache, cough, dyspnea, or dysphagia sometimes develops. Myocarditis with tachyarrhythmias or heart failure -- and, less commonly, encephalitis or pneumonitis -- may develop and accounts for most deaths of patients with trichinellosis.

Upon onset of larval encystment in muscle 2 to 3 weeks after infection, symptoms of myositis with myalgias, muscle edema, and weakness develop, usually overlapping with the inflammatory reactions to migrating larvae. The most commonly involved muscle groups include the extraocular muscles; the biceps; and the muscles of the jaw, neck, lower back, and diaphragm. Peaking about 3 weeks after infection, symptoms subside only gradually during a prolonged convalescence.

Laboratory Findings and Diagnosis Blood eosinophilia develops in >90% of patients with symptomatic trichinellosis and may peak at a level of>50% between 2 and 4 weeks after infection. Serum levels of IgE and muscle enzymes, including creatine phosphokinase, lactate dehydrogenase, and aspartate aminotransferase, are elevated in most symptomatic patients. Patients should be questioned thoroughly about their consumption of pork or wild-animal meat and about illness in other individuals who ate the same meat. A presumptive clinical diagnosis can be based on fevers, eosinophilia, periorbital edema, and myalgias after a suspect meal. A rise in the titer of parasite-specific antibody, which usually does not occur until after the third week of infection, confirms the diagnosis. Alternatively, a definitive diagnosis requires surgical biopsy of at least 1 g of involved muscle; the yields are highest near tendon insertions. The fresh muscle tissue should be compressed between glass slides and examined microscopically, because larvae may be overlooked by examination of routine histopathologic sections alone.

TREATMENT

Current anthelmintic drugs are ineffective against *Trichinella* larvae in muscle. Fortunately, most lightly infected patients recover uneventfully with bed rest, antipyretics, and analgesics. Glucocorticoids like prednisone (1 mg/kg daily for 5 days) are beneficial for severe myositis and myocarditis. Mebendazole and albendazole, like thiabendazole, appear to be active against enteric stages of the parasite, but their efficacy against encysted larvae has not been conclusively demonstrated.

Prevention Larvae may be killed by cooking pork until it is no longer pink or by freezing it at -15°C for 3 weeks. However, Arctic *T. nativa* larvae in walrus or bear meat are relatively resistant and may remain viable despite freezing.

VISCERAL AND OCULAR LARVA MIGRANS

Visceral larva migrans is a syndrome caused by nematodes that are normally parasitic for nonhuman host species. In humans, the nematode larvae do not typically develop into adult worms but instead migrate through host tissues and elicit eosinophilic inflammation. The most common form of visceral larva migrans is toxocariasis due to larvae of the canine ascarid *Toxocara canis* or, less commonly, the feline ascarid *T. cati*. Rare cases with eosinophilic meningoencephalitis have been caused by the raccoon ascarid *Baylisascaris procyonis*.

Life Cycle and Epidemiology The canine roundworm *T. canis* is distributed among dogs worldwide. Ingestion of infective eggs by dogs is followed by liberation of *Toxocara* larvae, which penetrate the gut wall and migrate intravascularly into the canine liver, muscle, and other tissues, where most remain in a developmentally arrested state. During pregnancy, some larvae resume migration in bitches and infect puppies prenatally (through transplacental transmission) or after birth (through suckling). Thus, in lactating bitches and puppies, larvae return to the intestinal tract and develop into adult worms, which produce eggs that are released in the feces. Humans acquire toxocariasis mainly by eating soil contaminated by puppy feces containing infective *T. canis* eggs. Visceral larva migrans is most common among children who habitually eat dirt, but most toxocaral infections are subclinical. Reported rates of *Toxocara* seropositivity range from 2% in an unselected American population to >20% among kindergarten children in the United States and England.

Pathogenesis and Clinical Features Clinical disease most commonly afflicts preschool children. After humans ingest *Toxocara* eggs, the larvae hatch and penetrate the intestinal mucosa, from which they are carried by the circulation to a wide variety of organs and tissues. The larvae invade the liver, lungs, central nervous system, and other sites, releasing toxic products and provoking intense local eosinophilic granulomatous responses. The degree of clinical illness depends on larval number and tissue distribution, reinfection, and host immune responses. Most light infections are asymptomatic and may be manifest only by blood eosinophilia. Characteristic symptoms of visceral larva migrans include fever, malaise, anorexia and weight loss, cough, wheezing, and rashes. Hepatosplenomegaly is common. These features are often accompanied by extraordinary peripheral eosinophilia, which may approach 90%. Uncommonly, seizures or behavioral disorders develop. The rare deaths in this disease are due to severe neurologic, pneumonic, or myocardial involvement.

Diagnosis In addition to prominent eosinophilia, leukocytosis and hypergammaglobulinemia are usually evident. Transient pulmonary infiltrates are apparent on chest x-rays of about half of patients with symptoms of pneumonitis. The clinical diagnosis can be confirmed by an enzyme-linked immunosorbent assay for toxocaral antibodies. Stool examination, while important in the evaluation of unexplained eosinophilia, is worthless for toxocariasis, since the larvae do not develop into egg-producing adults in humans.

The ocular form of the larva migrans syndrome occurs when *Toxocara* larvae invade the eye. An eosinophilic granulomatous mass, most commonly in the posterior pole of the retina, develops around the entrapped larva. The retinal lesion can mimic retinoblastoma in appearance, and mistaken diagnosis of the latter condition can lead to unnecessary enucleation. The spectrum of eye involvement also includes endophthalmitis, uveitis, and chorioretinitis. Unilateral visual disturbances, strabismus, and eye pain are the most common presenting symptoms. In contrast to visceral larva migrans, ocular toxocariasis usually develops in older children or young adults with no history of pica; these patients seldom have eosinophilia or visceral manifestations.

TREATMENT

The vast majority of *Toxocara* infections are self-limited and resolve without specific therapy. In patients with severe myocardial, central nervous system, or pulmonary involvement, glucocorticoids may be employed to reduce inflammatory complications. Available anthelmintic drugs, including diethylcarbamazine, mebendazole, and albendazole, have not been shown conclusively to alter the course of larva migrans. Control measures include prohibiting dog excreta in public parks and playgrounds, deworming dogs, and preventing pica in children. Treatment of ocular disease is unsatisfactory, and the role of glucocorticoids or anthelmintic drugs in management is controversial.

CUTANEOUS LARVA MIGRANS

Cutaneous larva migrans ("creeping eruption") is a serpiginous skin eruption (Fig. 219-CD1) caused by burrowing larvae of animal hookworms, usually the dog and cat hookworm *Ancylostoma braziliense*. The larvae hatch from eggs passed in dog and cat feces and mature in the soil. Humans become infected after skin contact with soil in areas frequented by dogs and cats, such as areas underneath house porches or scrub vegetation. Cutaneous larva migrans is especially prevalent among children and in regions with warm humid climates, including the southeastern United States.

After larvae penetrate the skin, erythematous lesions form along the tortuous tracts of their migration through the dermal-epidermal junction; the larvae advance several centimeters in a day. The intensely pruritic lesions may occur anywhere on the body and can be numerous if the patient has lain on the ground. Vesicles and bullae may form later. The animal hookworm larvae do not mature in humans and, without treatment, will die out after several weeks, with resolution of skin lesions. The diagnosis is made readily on clinical grounds, and a skin biopsy only rarely yields diagnostic parasite material. Symptoms can be alleviated by thiabendazole administered orally (25 mg/kg bid) or topically (10% aqueous or petroleum jelly suspension) for 2 to 5 days, by ivermectin (a single dose of 150 to 200 ug/kg), or by albendazole (200 mg bid for 2 days).

ANGIOSTRONGYLUS CANTONENSIS INFECTION

A. cantonensis, the rat lungworm, is the most common cause of human eosinophilic meningitis.

Life Cycle and Epidemiology This infection occurs principally in Southeast Asia and the Pacific Basin. *A. cantonensis* larvae produced by adult worms in the rat lung migrate to the gastrointestinal tract and are expelled with the feces. They develop into infective larvae in land snails and slugs. Humans acquire the infection by ingesting raw infected mollusks; vegetables contaminated by mollusk slime; or crabs, freshwater shrimp, and certain marine fish that have themselves eaten infected mollusks. The larvae then migrate to the brain.

Pathogenesis and Clinical Features The parasites eventually die in the central nervous system, but not before initiating pathologic consequences that, in heavy infections, can result in permanent neurologic sequelae or death. Migrating larvae cause proteolytic damage and marked local eosinophilic inflammation and hemorrhage, with subsequent necrosis and granuloma formation around dying worms. Clinical symptoms develop between 2 and 35 days after the ingestion of larvae. Patients usually present with an insidious or abrupt excruciating frontal, occipital, or bitemporal headache. Neck stiffness, nausea and vomiting, and paresthesias are also common. Fever, cranial and extraocular nerve palsies, seizures, paralysis, and lethargy are uncommon.

Laboratory Findings Examination of the cerebrospinal fluid is mandatory in suspected cases and usually reveals an elevated opening pressure, a white blood cell count of 150 to 2000/uL, and an eosinophilic pleocytosis of>20%. The protein concentration is usually elevated and the glucose level normal. The motile larvae of *A. cantonensis* are only rarely seen in the cerebrospinal fluid. Peripheral-blood eosinophilia may be mild. The diagnosis is generally based on the clinical presentation of eosinophilic meningitis together with a compatible epidemiologic history.

TREATMENT

Specific chemotherapy is not of benefit in angiostrongyliasis; larvicidal agents may actually exacerbate inflammatory brain lesions. Management consists of supportive measures, including the administration of analgesics, sedatives, and -- in severe cases -- glucocorticoids. In most patients, cerebral angiostrongyliasis has a self-limited course, and recovery is complete. The infection may be prevented by adequately cooking snails, crabs, and prawns and inspecting vegetables for mollusk infestation. Other parasitic causes of eosinophilic meningitis in endemic areas may include gnathostomiasis, paragonimiasis, schistosomiasis, and neurocysticercosis.

GNATHOSTOMIASIS

Infection of human tissues with larvae of *Gnathostoma spinigerum* can cause eosinophilic meningoencephalitis, migratory cutaneous swellings, or invasive masses of the eye and visceral organs.

Life Cycle and Epidemiology Human gnathostomiasis occurs in many countries and is notably endemic in Southeast Asia and parts of China and Japan. In nature, the mature adult worms parasitize the gastrointestinal tract of dogs and cats. First-stage larvae hatch from eggs passed into water and are ingested by *Cyclops* species (water fleas). Infective third-stage larvae develop in the flesh of many animal species (including fish,

frogs, eels, snakes, chickens, and ducks) that have eaten either infected *Cyclops* or another infected second intermediate host. Humans typically acquire the infection by eating raw or undercooked fish or poultry. The raw fish dishes of *somfak* in Thailand and *sashimi* in Japan account for most cases of human gnathostomiasis. Some cases in Thailand result from the local practice of applying frog or snake flesh as a poultice.

Pathogenesis and Clinical Features Clinical symptoms are due to the aberrant migration of a single larva into cutaneous, visceral, neural, or ocular tissues. After invasion, larval migration may cause local inflammation, with pain, cough, or hematuria accompanied by fever and eosinophilia. Painful, itchy, migratory swellings may develop in the skin, particularly in the distal extremities or periorbital area. Cutaneous swellings usually last about a week but often recur intermittently over many years. Larval invasion of the eye can provoke a sight-threatening inflammatory response. Finally, invasion of the central nervous system results in eosinophilic meningitis with myeloencephalitis, a serious complication due to ascending larval migration along a large nerve track. Patients characteristically present with agonizing radicular pain and paresthesias in the trunk or a limb, which are followed shortly by paraplegia. Cerebral involvement, with focal hemorrhages and tissue destruction, is often fatal.

Diagnosis and Treatment Cutaneous migratory swellings with marked peripheral eosinophilia, supported by an appropriate geographic and dietary history, generally constitute an adequate basis for a clinical diagnosis of gnathostomiasis. However, patients may present with ocular or cerebrospinal involvement without antecedent cutaneous swellings. In the latter case, eosinophilic pleocytosis is demonstrable (usually along with hemorrhagic or xanthochromic cerebrospinal fluid), but worms are almost never recovered from the cerebrospinal fluid. Surgical removal of the parasite from subcutaneous or ocular tissue, though rarely feasible, is both diagnostic and therapeutic. Albendazole (400 to 800 mg daily for 21 days) may be helpful. At present, cerebrospinal involvement is managed with supportive measures and generally with a course of glucocorticoids. Gnathostomiasis can be prevented by adequate cooking of fish and poultry in endemic areas.

220. INTESTINAL NEMATODES - *Peter F. Weller*, *Thomas B. Nutman*

More than a billion people worldwide are infected with one or more species of intestinal nematodes. Table 220-1 summarizes biologic and clinical features of infections due to the major intestinal parasitic nematodes. These parasites are most common in regions with poor fecal sanitation, particularly in developing countries in the tropics and subtropics but also in the United States. Although nematode infections are not usually fatal, they contribute to malnutrition and diminished work capacity. Humans may on occasion be infected with nematode parasites that ordinarily infect animals; these zoonotic infections include trichostrongyliasis, anisakiasis, capillariasis, and abdominal angiostrongyliasis.

Intestinal nematodes are roundworms; they range in length from 1 mm to many centimeters when mature (Table 220-1). Their life cycles are complex and highly varied; some species, including *Strongyloides stercoralis* and *Enterobius vermicularis*, can be transmitted directly from person to person, while others, such as *Ascaris lumbricoides*, *Necator americanus*, and *Ancylostoma duodenale*, require a soil phase for development. Because most helminth parasites do not self-replicate, the acquisition of a heavy burden of adult worms requires repeated exposure to the parasite in its infectious stage, whether larva or egg. Hence, clinical disease, as opposed to asymptomatic infection, generally develops only with prolonged residence in an endemic area. In persons with marginal nutrition, intestinal helminth infections may impair growth and development. Eosinophilia and elevated serum IgE levels are features of many helminthic infections and, when unexplained, should always prompt a search for occult helminthiasis. Significant protective immunity to intestinal nematodes appears not to develop in humans, although mechanisms of parasite immune evasion and host immune responses to these infections have not been elucidated in detail.

ASCARIASIS

A. lumbricoides is the largest intestinal nematode parasite of humans, reaching up to 40 cm in length. Most infected individuals have low worm burdens and are asymptomatic. Clinical disease arises from larval migration in the lungs or effects of the adult worms in the intestines.

Life Cycle Adult worms live in the lumen of the small intestine. Mature female *Ascaris* worms are extraordinarily fecund, each producing up to 240,000 eggs a day, which pass with the feces. Ascarid eggs, which are remarkably resistant to environmental stresses, become infective after several weeks of maturation in the soil and can remain infective for years. After infective eggs are swallowed, larvae hatched in the intestine invade the mucosa, migrate through the circulation to the lungs, break into the alveoli, ascend the bronchial tree, and return via swallowing to the small intestine, where they develop into adult worms. Between 2 and 3 months elapse between initial infection and egg production. The adult worms live for ~1 to 2 years.

Epidemiology *Ascaris* is widely distributed in tropical and subtropical regions as well as in other humid areas, including the rural southeastern United States. Transmission typically occurs through fecally contaminated soil and is due either to a lack of sanitary facilities or to the use of human manure ("night soil") as fertilizer. With their propensity

for hand-to-mouth fecal carriage, younger children in impoverished rural areas are most affected. Infection outside endemic areas, though uncommon, can occur from eggs borne on transported vegetables.

Clinical Features During the lung phase of larval migration, about 9 to 12 days after egg ingestion, patients may develop an irritating nonproductive cough and burning substernal discomfort that is aggravated by coughing or deep inspiration. Dyspnea and blood-tinged sputum are less common. Fever is usually reported, with temperatures sometimes exceeding 38.5°C (101.3°F). Eosinophilia develops during this symptomatic phase and subsides slowly over weeks. Chest x-rays may reveal evidence of eosinophilic pneumonitis (Loffler's syndrome), with round or oval infiltrates a few millimeters to several centimeters in size. These infiltrates may be transient and intermittent, clearing after several weeks. Where there is seasonal transmission of the parasite, seasonal pneumonitis with eosinophilia may develop in previously infected and sensitized hosts.

In established infections, adult worms in the small intestine usually cause no symptoms. In heavy infections, particularly in children, a large bolus of entangled worms can cause pain and small-bowel obstruction, sometimes complicated by perforation, intussusception, or volvulus. Single worms may cause disease when they migrate into aberrant sites. A large worm can enter and occlude the biliary tree, causing biliary colic, cholecystitis, cholangitis, pancreatitis, or (rarely) intrahepatic abscesses. Migration of an adult worm up the esophagus can provoke coughing and oral expulsion of the worm. In highly endemic areas, intestinal and biliary ascariasis can rival acute appendicitis and gallstones as causes of surgical acute abdomen.

Laboratory Findings Most cases of ascariasis can be diagnosed by the microscopic detection of characteristic mamillated *Ascaris* eggs (65 by 45 um) in fecal samples. Occasionally, patients present after passing an adult worm -- identifiable by its large size and smooth cream-colored surface -- in the stool or through the mouth or nose. During the early transpulmonary migratory phase, when eosinophilic pneumonitis occurs, larvae can be found in sputum or gastric aspirates before diagnostic eggs appear in the stool. The eosinophilia that is prominent during this early stage usually decreases to minimal levels in established infection. The large adult worms may be visualized, occasionally serendipitously, on contrast studies of the gastrointestinal tract. A plain abdominal film may reveal masses of worms in gas-filled loops of bowel in patients with intestinal obstruction. Pancreaticobiliary worms can be detected by ultrasound and endoscopic retrograde cholangiopancreatography; the latter method also has been used to extract biliary *Ascaris* worms.

TREATMENT

Ascariasis should always be treated to prevent potentially serious complications. Mebendazole or albendazole (which is considered an investigational drug by the Food and Drug Administration for this indication) is effective. These benzimidazoles are contraindicated in pregnancy and in heavy infections, in which they may provoke ectopic migration. Pyrantel pamoate and piperazine citrate are safe in pregnancy. Mild diarrhea and abdominal pain are uncommon side effects of these agents. Partial intestinal obstruction should be managed with nasogastric suction, intravenous fluid

administration, and instillation of piperazine through the nasogastric tube, but complete obstruction and its severe complications require immediate surgical intervention.

HOOKWORM

One-fourth of the world's population is infected with one of the two hookworm species (*A. duodenale* and *N. americanus*). Most infected individuals are asymptomatic. Hookworm disease develops from a combination of factors -- a heavy worm burden, a prolonged duration of infection, and an inadequate iron intake -- and results in iron-deficiency anemia and, on occasion, hypoproteinemia.

Life Cycle Adult hookworms, which are about 1 cm long, use buccal teeth (*Ancylostoma*) or cutting plates (*Necator*) to attach to the small-bowel mucosa and suck blood (0.2 mL/d per *Ancylostoma* adult) and interstitial fluid. The adult hookworms produce thousands of eggs daily. The eggs are deposited with feces in soil, where rhabditiform larvae hatch and develop over a 1-week period into infectious filariform larvae. Infective larvae penetrate the skin and reach the lungs by way of the bloodstream. There they invade alveoli and ascend the airways before being swallowed and reaching the small intestine. The prepatent period from skin invasion to appearance of eggs in the feces is about 6 to 8 weeks, but it may be longer with *A. duodenale*. Larvae of *A. duodenale*, if swallowed, can survive and develop directly in the intestinal mucosa. Adult hookworms may survive over a decade but usually live about 6 to 8 years for *A. duodenale* and 2 to 5 years for *N. americanus*.

Epidemiology *A. duodenale* is prevalent in southern Europe, North Africa, and northern Asia, and *N. americanus* is the predominant species in the western hemisphere and equatorial Africa. The two species overlap in many tropical regions, particularly Southeast Asia. In most areas, older children have the greatest incidence and intensity of hookworm infection. In rural areas where fields are fertilized with night soil, older working adults also may be heavily affected.

Clinical Features Most hookworm infections are asymptomatic. Infective larvae may provoke pruritic maculopapular dermatitis ("ground itch") at the site of skin penetration as well as serpiginous tracts of subcutaneous migration (similar to cutaneous larva migrans) in previously sensitized hosts. Larvae migrating through the lungs occasionally cause mild transient pneumonitis, but this condition develops less frequently in hookworm infection than in ascariasis. In the early intestinal phase, infected persons may develop epigastric pain (often with postprandial accentuation), inflammatory diarrhea, or other abdominal symptoms accompanied by eosinophilia. The major consequence of chronic hookworm infection is iron deficiency. Symptoms are minimal if iron intake is adequate, but marginally nourished individuals develop symptoms of progressive iron-deficiency anemia and hypoproteinemia, including weakness, shortness of breath, and skin depigmentation.

Laboratory Findings The diagnosis is established by the finding of characteristic 40- by 60-um oval hookworm eggs in the feces. Stool-concentration procedures may be required to detect light infections. Eggs of the two species are indistinguishable. In a stool sample that is not fresh, the eggs may have hatched to release rhabditiform larvae, which need to be differentiated from those of *S. stercoralis*. Hypochromic

microcytic anemia, occasionally with eosinophilia or hypoalbuminemia, is characteristic of hookworm disease.

TREATMENT

Hookworm infection can be eradicated with several safe and highly effective anthelmintic drugs, including mebendazole, albendazole, and pyrantel pamoate (Chap. 212). Mild iron-deficiency anemia often can be treated with oral iron alone. Severe hookworm disease with protein loss and malabsorption necessitates nutritional support and oral iron replacement along with deworming.

Ancylostoma caninum This parasite, the canine hookworm, has been identified as a cause of human eosinophilic enteritis, especially in northeastern Australia. In this zoonotic infection, adult hookworms attach to the small intestine (where they may be visualized by endoscopy) and elicit abdominal pain and intense local eosinophilia. Treatment with mebendazole (100 mg twice daily for 3 days) is effective.

STRONGYLOIDIASIS

S. stercoralis is distinguished by its ability, unusual among helminths, to replicate in the human host. This capacity permits ongoing cycles of autoinfection as infective larvae are internally produced. Strongyloidiasis can thus persist for decades without further exposure of the host to exogenous infective larvae. In immunocompromised hosts, large numbers of invasive *Strongyloides* larvae can disseminate widely and can be fatal.

Life Cycle In addition to a parasitic cycle of development, *Strongyloides* can undergo a free-living cycle of development in the soil. This adaptability facilitates the parasite's survival in the absence of mammalian hosts. Rhabditiform larvae passed in feces can transform into infectious filariform larvae either directly or after a free-living phase of development. Humans acquire strongyloidiasis when filariform larvae in fecally contaminated soil penetrate the skin or mucous membranes. The larvae then travel through the bloodstream to the lungs, where they break into the alveolar spaces, ascend the bronchial tree, are swallowed, and thereby reach the small intestine. There the larvae mature into adult worms that penetrate the mucosa of the proximal small bowel. The minute (2-mm-long) parasitic adult female worms reproduce by parthenogenesis; parasitic adult males do not exist. Eggs hatch locally in the intestinal mucosa, releasing rhabditiform larvae that migrate to the lumen and pass with the feces into soil. Alternatively, rhabditiform larvae in the bowel can develop directly into filariform larvae that penetrate the colonic wall or perianal skin and enter the circulation to repeat the migration that establishes ongoing internal reinfection. This autoinfection cycle allows strongyloidiasis to persist for decades after the host has left an endemic area.

Epidemiology *S. stercoralis* is spottily distributed in tropical areas and other hot, humid regions and is particularly common in Southeast Asia, sub-Saharan Africa, and Brazil. In the United States, the parasite is endemic in parts of the South and is found in residents of mental institutions who practice poor hygiene and in immigrants and military veterans who have lived in endemic areas abroad.

Clinical Features In uncomplicated strongyloidiasis, many patients are asymptomatic

or have mild cutaneous and/or abdominal symptoms. Recurrent urticaria, often involving the buttocks and wrists, is the most common cutaneous manifestation. Migrating larvae can elicit a pathognomonic serpiginous eruption, *larva currens* ("running larva" Fig. 220-CD1) -- a pruritic, raised, erythematous lesion that advances as rapidly as 10 cm/h along the course of larval migration. Adult parasites burrow into the duodenojejunal mucosa and can cause abdominal (usually midepigastric) pain, which resembles peptic ulcer pain except that it is aggravated by food ingestion. Nausea, diarrhea, gastrointestinal bleeding, mild chronic colitis, and weight loss can occur. Small-bowel obstruction may develop with early, heavy infection. Pulmonary symptoms are rare in uncomplicated strongyloidiasis. Eosinophilia is common, with levels fluctuating over time.

The ongoing autoinfection cycle of strongyloidiasis is normally contained by unknown factors of the host's immune system. Abrogation of host immunity, especially with glucocorticoid therapy and much less commonly with other immunosuppressive medications, leads to hyperinfection, with the generation of large numbers of filariform larvae. Colitis, enteritis, or malabsorption may develop. In disseminated strongyloidiasis, larvae may invade not only gastrointestinal tissues and the lungs but also the central nervous system, peritoneum, liver, and kidney. Moreover, bacteremia may develop because of the entry of enteric flora through disrupted mucosal barriers. Gram-negative sepsis, pneumonia, or meningitis may complicate or dominate the clinical course. Eosinophilia is often absent in severely infected patients. Disseminated strongyloidiasis, particularly in patients with unsuspected infection who are given glucocorticoids, can be fatal. Strongyloidiasis is a frequent complication of infection with human T cell lymphotropic virus type I, but disseminated strongyloidiasis is not common among patients infected with HIV.

Diagnosis In uncomplicated strongyloidiasis, the finding of rhabditiform larvae in feces is diagnostic. The eggs are almost never detectable because they hatch in the intestine. Rhabditiform larvae are 200 to 250 um long, with a short buccal cavity that distinguishes them from hookworm rhabditiform larvae. Single stool examinations detect only about one-third of uncomplicated infections, in which few larvae are passed. Serial examinations and the use of the agar plate detection method improve the sensitivity of stool diagnosis. In uncomplicated -- but not hyperinfection -- strongyloidiasis, stool examinations may be repeatedly negative. If stool examinations are negative, *Strongyloides* can be assayed by sampling of the duodenojejunal contents by aspiration or biopsy. An enzyme-linked immunosorbent assay for antibodies to excretory-secretory or somatic antigens of *Strongyloides* is a sensitive method of diagnosing uncomplicated infections. In disseminated strongyloidiasis, filariform larvae (550 um long) should be sought in stool as well as in samples obtained from sites of potential larval migration, including sputum, bronchoalveolar lavage fluid, or surgical drainage fluid.

TREATMENT

Even in the asymptomatic state, strongyloidiasis must be treated because of the potential for fatal hyperinfection. Ivermectin (200 ug/kg daily for 1 or 2 days) is more effective and better tolerated than thiabendazole (25 mg/kg bid for 2 days), whose common adverse effects include nausea, vomiting, diarrhea, dizziness, and neuropsychiatric disturbances. Because thiabendazole is not uniformly effective, stool

examinations, eosinophil counts, and monitoring of clinical symptoms should be continued after treatment. For disseminated strongyloidiasis, treatment should be extended for at least 5 to 7 days or until the parasites are eradicated.

Strongyloides fulleborni This unusual species, which has been encountered in Africa and Papua New Guinea, is thought to be transmitted from person to person and through maternal milk. *S. fulleborni* releases membranous sacs filled with eggs into the stool. Most commonly affected are infants and young children, who present with abdominal distention, respiratory distress, vomiting, or diarrhea.

TRICHURIASIS

Most infections with the whipworm *Trichuris trichiura* are asymptomatic, but heavy infections may cause gastrointestinal symptoms. Like the other soil-transmitted helminths, whipworm is distributed globally in the tropics and subtropics and is most common among poor children.

Life Cycle A broad posterior section and a thin anterior portion give *Trichuris* its characteristic whiplike shape. The adult worms reside in the colon and cecum, the anterior portions threaded into the superficial mucosa. Thousands of eggs laid daily by adult female worms pass with the feces and mature in the soil. After ingestion, infective eggs hatch in the duodenum, releasing larvae that mature before migrating to the large bowel. The entire cycle takes about 3 months, and adult worms may live for several years.

Clinical Features Tissue reactions to whipworms are mild. Most infected individuals have no symptoms or eosinophilia. Heavy infections may result in abdominal pain, anorexia, and bloody or mucoid diarrhea resembling inflammatory bowel disease. Rectal prolapse can result from massive infections in children, who often suffer from malnourishment and other diarrheal illnesses. Moderately heavy whipworm burdens also contribute to growth retardation.

Diagnosis and Treatment The characteristic 50- by 20-um lemon-shaped whipworm eggs are readily detected on stool examination. Adult worms, which are 3 to 5 cm long, occasionally can be seen on proctoscopy. Mebendazole or albendazole is safe and effective for treatment (Chap. 212).

ENTEROBIASIS (PINWORM)

E. vermicularis is more common in temperate countries than in the tropics. More than 40 million Americans, particularly schoolchildren, are estimated to be infected with pinworms.

Life Cycle and Epidemiology *Enterobius* adult worms are about 1 cm long and dwell in the bowel lumen. The gravid female worm migrates nocturnally out into the perianal region and releases up to 10,000 immature eggs. The eggs become infective within hours and are transmitted by hand-to-mouth passage. The larvae hatch and mature entirely within the intestine. This life cycle takes about 1 month, and adult worms survive for about 2 months. Self-infection results from perianal scratching and transport of

infective eggs on the hands or under the nails to the mouth. Owing to the ease of person-to-person spread, pinworm infections are common among family members and institutionalized populations.

Clinical Features Most pinworm infections are asymptomatic. Perianal pruritus is the cardinal symptom. The itching is often worse at night owing to the nocturnal migration of the female worms, and it may lead to excoriation and bacterial superinfection. Heavy infections have been claimed to cause abdominal pain and weight loss. On rare occasions, pinworms invade the female genital tract, causing vulvovaginitis and pelvic or peritoneal granulomas. Eosinophilia or elevated levels of serum IgE are rare.

Diagnosis Since pinworm eggs are not usually released in the bowel, the diagnosis cannot be made by looking for eggs in the feces. Instead, eggs deposited in the perianal region are detected by the application of clear cellulose acetate tape to the perianal region in the morning. After the tape is transferred to a microscope slide, low-power examination will reveal the characteristic pinworm eggs, which are oval, measure 55 by 25 um, and are flattened along one side.

TREATMENT

All affected individuals should be given a dose of mebendazole or pyrantel pamoate, with treatment repeated after 10 to 14 days (Chap. 212). Treatment of household members is also advocated to eliminate asymptomatic reservoirs of potential reinfection.

TRICHOSTRONGYLIASIS

Trichostrongylus species that are normally parasites of herbivorous animals occasionally infect humans, particularly in Asia and Africa. This parasite has been termed *pseudo hookworm* because of similarities to the hookworms in life cycle and egg morphology. Humans acquire the infection by accidentally ingesting *Trichostrongylus* larvae on contaminated leafy vegetables. The larvae do not migrate in humans but mature directly into adult worms in the small bowel. These worms ingest far less blood than hookworms; most infected people are asymptomatic, but heavy infections may give rise to mild anemia and eosinophilia. *Trichostrongylus* eggs encountered on stool examination resemble those of hookworms but are larger (85 by 115 um). Appropriate treatment consists of mebendazole or albendazole (Chap. 212).

ANISAKIASIS

Anisakiasis is a gastrointestinal infection caused by the accidental ingestion in uncooked saltwater fish of nematode larvae belonging to the family Anisakidae. The incidence of anisakiasis in the United States has increased as a result of the growing popularity of raw fish dishes. Most cases occur in Japan, the Netherlands, and Chile, where raw fish -- sushi, pickled green herring, and seviche, respectively -- are national culinary staples. Anisakid nematodes parasitize large sea mammals such as whales, dolphins, and seals. As part of a complex parasitic life cycle involving marine food chains, infectious larvae migrate to the musculature of a variety of fish. Both *Anisakis simplex* and *Pseudoterranova decipiens* have been implicated in human anisakiasis, but an identical gastric syndrome may be caused by the red larvae of eustrongylid parasites

of fish-eating birds.

When humans consume infected raw fish, live larvae may be coughed up within 48 h. Alternatively, larvae may immediately penetrate the mucosa of the stomach. Within hours, violent upper abdominal pain accompanied by nausea and occasionally vomiting ensues, mimicking an acute abdomen. The diagnosis can be established by direct visualization on upper endoscopy, outlining of the worm by contrast radiographic studies, or histopathologic examination of extracted tissue. In experienced hands, the first technique is preferable because extraction of the burrowing larvae by endoscopic technique is curative. In addition, larvae may pass to the small bowel, where they penetrate the mucosa and provoke a vigorous eosinophilic granulomatous response. Symptoms may appear 1 or 2 weeks after the infective meal, with intermittent abdominal pain, diarrhea, nausea, and fever resembling the manifestations of Crohn's disease. The diagnosis may be suggested by barium studies and confirmed by curative surgical resection of a granuloma in which the worm is embedded. Anisakid eggs are not found in the stool, since the larvae do not mature in humans. Anisakid larvae in saltwater fish are killed by cooking to 60°C, freezing at-20°C for 3 days, or commercial blast freezing, but not usually by salting, marinating, or cold smoking. No medical treatment is available; if possible, surgical or endoscopic removal should be undertaken.

CAPILLARIASIS

Intestinal capillariasis is caused by ingestion of raw fish infected with *Capillaria philippinensis*. Subsequent autoinfection can lead to a severe wasting syndrome. The disease occurs in the Philippines and Thailand and, on occasion, elsewhere in Asia. The natural cycle of *C. philippinensis* involves fish from fresh and brackish water. When humans eat infected raw fish, the larvae mature in the intestine into adult worms, which produce invasive larvae that cause intestinal inflammation and villus loss. Capillariasis has an insidious onset with nonspecific abdominal pain and watery diarrhea. If untreated, progressive autoinfection can lead to protein-losing enteropathy and severe malabsorption and ultimately to death from cachexia, cardiac failure, or superinfection. The diagnosis is established by identification of the characteristic peanut-shaped (20- by 40-um) eggs on stool examination. Severely ill patients require hospitalization and supportive therapy in addition to prolonged anthelmintic treatment with mebendazole or albendazole (Chap. 212).

ABDOMINAL ANGIOSTRONGYLIASIS

Abdominal angiostrongyliasis is found in Latin America and Africa. The zoonotic parasite *Angiostrongylus costaricensis* causes eosinophilic ileocolitis after the ingestion of contaminated vegetation. *A. costaricensis* normally parasitizes the cotton rat and other rodents, with slugs and snails serving as intermediate hosts. Humans become infected by accidentally ingesting infective larvae in mollusk slime deposited on fruits and vegetables; children are at highest risk. The larvae penetrate the gut wall and migrate to the mesenteric artery, where they develop into adult worms. Eggs deposited in the gut wall provoke an intense eosinophilic granulomatous reaction, and adult worms may cause mesenteric arteritis, thrombosis, or frank bowel infarction. Symptoms may mimic those of appendicitis, including abdominal pain and tenderness, fever, vomiting, and a palpable mass in the right iliac fossa. Leukocytosis and eosinophilia are

prominent. A barium enema may reveal ileocecal filling defects, but a definitive diagnosis is usually made surgically with partial bowel resection. Pathologic study reveals a thickened bowel wall with eosinophilic granulomas surrounding the *Angiostrongylus* eggs. In nonsurgical cases, the diagnosis rests solely on clinical grounds because larvae and eggs cannot be detected in the stool. Medical therapy for abdominal angiostrongyliasis (thiabendazole; Chap. 212) is of uncertain efficacy. Careful observation and surgical resection for severe symptoms are the mainstays of treatment.

221. FILARIASIS AND RELATED INFECTIONS (LOIASIS, ONCHOCERCIASIS, AND DRACUNCULIASIS) - *Thomas B. Nutman*, *Peter F. Weller*

Filarial worms are nematodes that dwell in the subcutaneous tissues and the lymphatics. Eight filarial species infect humans (Table 221-1); of these, four -- *Wuchereria bancrofti*, *Brugia malayi*, *Onchocerca volvulus*, and *Loa loa* -- are responsible for most serious filarial infections. Filarial parasites, which infect an estimated 170 million persons worldwide, are transmitted by specific species of mosquitoes or other arthropods and have a complex life cycle including infective larval stages carried by insects and adult worms that reside in either lymphatic or subcutaneous tissues of humans. The offspring of adults are microfilariae, which, depending on their species, are 200 to 250 um long and 5 to 7 um wide, may or may not be enveloped in a loose sheath, and either circulate in the blood or migrate through the skin (Table 221-1). To complete the life cycle, microfilariae are ingested by the arthropod vector and develop over 1 to 2 weeks into new infective larvae. Adult worms live for many years, whereas microfilariae survive from 3 to 36 months.

Usually, infection is established only with repeated and prolonged exposures to infective larvae. Since the clinical manifestations of filarial diseases develop relatively slowly, these infections should be considered chronic diseases with possible long-term debilitating effects. In terms of the nature, severity, and timing of clinical manifestations, patients with filariasis who are native to endemic areas and undergo lifelong exposure may differ significantly from those who are travelers or who have recently moved to these areas. Characteristically, the disease is more acute and intense in newly exposed individuals than in natives of endemic areas.

LYMPHATIC FILARIASIS

Lymphatic filariasis is caused by *W. bancrofti*, *B. malayi*, or *B. timori*. The threadlike adult parasites reside in lymphatic channels or lymph nodes, where they may remain viable for more than two decades.

EPIDEMIOLOGY

W. bancrofti, the most widely distributed human filarial parasite, affects an estimated 115 million people and is found throughout the tropics and subtropics, including Asia and the Pacific Islands, Africa, areas of South America, and the Caribbean basin. Humans are the only definitive host for the parasite. Generally, the subperiodic form is found only in the Pacific Islands; elsewhere, *W. bancrofti* is nocturnally periodic. (Nocturnally periodic forms of microfilariae are scarce in peripheral blood by day and increase at night, whereas subperiodic forms are present in peripheral blood at all times and reach maximal levels in the afternoon.) Natural vectors for *W. bancrofti* are *Culex fatigans* mosquitoes in urban settings and anopheline or aedean mosquitoes in rural areas.

Brugian filariasis due to *B. malayi* occurs primarily in China, India, Indonesia, Korea, Japan, Malaysia, and the Philippines. *B. malayi* also has two forms distinguished by the periodicity of microfilaremia. The more common nocturnal form is transmitted in areas of coastal rice fields, while the subperiodic form is found in forests. *B. malayi* naturally

infects cats as well as humans. *B. timori* exists only on islands of the Indonesian archipelago.

PATHOLOGY

The principal pathologic changes result from inflammatory damage to the lymphatics, which is caused by adult worms and not by microfilariae. Adult worms live in afferent lymphatics or sinuses of lymph nodes and cause lymphatic dilatation and thickening of the vessel walls. The infiltration of plasma cells, eosinophils, and macrophages in and around the infected vessels, along with endothelial and connective tissue proliferation, leads to tortuosity of the lymphatics and damaged or incompetent lymph valves. Lymphedema and chronic-stasis changes with hard or brawny edema develop in the overlying skin. These consequences of filariasis are due both to direct effects of the worms and to the immune response of the host to the parasite. These immune responses are believed to cause the granulomatous and proliferative processes that precede total lymphatic obstruction. It is thought that the vessel remains patent as long as the worm remains viable and that death of the worm leads to enhanced granulomatous reaction and fibrosis. Lymphatic obstruction results, and, despite collateralization of the lymphatics, lymphatic function is compromised.

CLINICAL FEATURES

The most common presentations of the lymphatic filariases are asymptomatic (or subclinical) microfilaremia, hydrocele, acute adenolymphangitis (ADL), and chronic lymphatic disease. In areas where *W. bancrofti* or *B. malayi* is endemic, the overwhelming majority of infected individuals have few overt clinical manifestations of filarial infection despite large numbers of circulating microfilariae in the peripheral blood. Although they may be clinically asymptomatic, virtually all persons with *W. bancrofti* or *B. malayi* microfilaremia have some degree of subclinical disease that includes microscopic hematuria and/or proteinuria, dilated (and tortuous) lymphatics (visualized by imaging), and -- in men -- scrotal lymphangiectasia (detectable by ultrasound). Despite these findings, the majority of individuals appear to remain clinically asymptomatic for years; relatively few progress to the acute and chronic stages of infection.

ADLis characterized by high fever, lymphatic inflammation (lymphangitis and lymphadenitis), and transient local edema. The lymphangitis is retrograde, extending peripherally from the lymph node draining the area where the adult parasites reside. Regional lymph nodes are often enlarged, and the entire lymphatic channel can become indurated and inflamed. Concomitant local thrombophlebitis can occur as well. In brugian filariasis, a single local abscess may form along the involved lymphatic tract and subsequently rupture to the surface. The lymphadenitis and lymphangitis involve both the upper and lower extremities in both bancroftian and brugian filariasis, but involvement of the genital lymphatics occurs almost exclusively with *W. bancrofti* infection. This genital involvement can be manifested by funiculitis, epididymitis, scrotal pain, and tenderness. In endemic areas, another type of acute disease -- dermatolymphangioadenitis (DLA) -- is recognized as a syndrome that includes high fever, chills, myalgias, and headache. Edematous inflammatory plaques clearly demarcated from normal skin are seen. Vesicles, ulcers, and hyperpigmentation may

also be noted. There is often a history of trauma, burns, radiation, insect bites, punctiform lesions, or chemical injury. Entry lesions, especially in the interdigital area, are common. DLA is often diagnosed as cellulitis.

If lymphatic damage progresses, transient lymphedema can develop into *lymphatic obstruction* and the permanent changes associated with elephantiasis. Brawny edema follows early pitting edema, and thickening of the subcutaneous tissues and hyperkeratosis occur. Fissuring of the skin develops, as do hyperplastic changes. Superinfection of these poorly vascularized tissues becomes a problem. In bancroftian filariasis, in which genital involvement is common, hydroceles may develop; in advanced stages, this condition may evolve into scrotal lymphedema and scrotal elephantiasis. Furthermore, if there is obstruction of the retroperitoneal lymphatics, the increased renal lymphatic pressure leads to rupture of the renal lymphatics and the development of chyluria, which is usually intermittent and most prominent in the morning.

The clinical manifestations of filarial infections in travelers or transmigrants who have recently entered an endemic region are distinctive. Given a sufficient number of bites by infected vectors, usually over a 3- to 6-month period, recently exposed patients can develop acute lymphatic or scrotal inflammation with or without urticaria and localized angioedema. Lymphadenitis of epitrochlear, axillary, femoral, or inguinal lymph nodes is often followed by retrogradely evolving lymphangitis. Acute attacks are short-lived and, in contrast to filarial fevers in patients native to endemic areas, are usually not accompanied by fever. With prolonged exposure to infected mosquitoes, these attacks, if untreated, become more severe and lead to permanent lymphatic inflammation and obstruction.

DIAGNOSIS

A definitive diagnosis can be made only by detection of the parasites and hence can be difficult. Adult worms localized in lymphatic vessels or nodes are largely inaccessible. Microfilariae can be found in blood, in hydrocele fluid, or (occasionally) in other body fluids. Such fluids can be examined microscopically, either directly or -- for greater sensitivity -- after concentration of the parasites by the passage of fluid through a polycarbonate cylindrical pore filter (pore size, 3 um) or by the centrifugation of fluid fixed in 2% formalin (Knott's concentration technique). The timing of blood collection is critical and should be based on the periodicity of the microfilariae in the endemic region involved. Many infected individuals do not have microfilaremia, and definitive diagnosis in such cases can be difficult. Assays for circulating antigens of *W. bancrofti* permit the diagnosis of microfilaremic and cryptic (amicrofilaremic) infection. Two tests are commercially available: one is an enzyme-linked immunosorbent assay (ELISA) and the other a rapid-format immunochromatographic card test. Both assays have sensitivities that range from 96 to 100% and specificities that approach 100%. There are currently no tests for circulating antigens in brugian filariasis.

Polymerase chain reaction (PCR)-based assays for DNA of *W. bancrofti* and *B. malayi* in blood have been developed. A number of studies indicate that this diagnostic method is of equivalent or greater sensitivity compared with parasitologic methods, detecting patent infection in almost all infected subjects.

In cases of suspected lymphatic filariasis, examination of the scrotum or the female breast using high-frequency ultrasound in conjunction with Doppler techniques may result in the identification of motile adult worms within dilated lymphatics. Worms may be visualized in the lymphatics of the spermatic cord in up to 80% of infected men. Live adult worms have a distinctive pattern of movement within the lymphatic vessels (termed the *filaria dance sign*).

Radionuclide lymphoscintigraphic imaging of the limbs reliably demonstrates widespread lymphatic abnormalities in both asymptomatic microfilaremic persons and those with clinical manifestations of lymphatic pathology. While of potential utility in the delineation of anatomic changes associated with infection, lymphoscintigraphy is unlikely to assume primacy in the diagnostic evaluation of individuals with suspected infection; it is principally a research tool, and the radionuclide-protein conjugates are not commercially available or approved by the U.S. Food and Drug Administration (FDA).

Eosinophilia and elevated serum concentrations of IgE and antifilarial antibody support the diagnosis of lymphatic filariasis. There is, however, extensive cross-reactivity between filarial antigens and antigens of other helminths, including the common intestinal roundworms; thus, interpretations of serologic findings can be difficult. In addition, residents of endemic areas can become sensitized to filarial antigens through exposure to infected mosquitoes without having patent filarial infections.

In acute episodes, lymphatic filariasis must be distinguished from thrombophlebitis, infection, and trauma. Retrogradely evolving lymphangitis is a characteristic feature that helps distinguish filarial lymphangitis from typically ascending bacterial lymphangitis. Chronic filarial lymphedema must be distinguished from the lymphedema of malignancy, postoperative scarring, trauma, chronic edematous states, and congenital lymphatic system abnormalities.

TREATMENT

With new definitions of clinical syndromes in lymphatic filariasis and new tools to assess clinical status (e.g., ultrasound, lymphoscintigraphy, circulating filarial antigen assays), approaches to treatment based on infection status can be considered. Diethylcarbamazine (DEC, 6 mg/kg daily for 12 days), which has both macro- and microfilaricidal properties, remains the treatment of choice for the individual with active lymphatic filariasis (microfilaremia, antigen positivity, or adult worms on ultrasound), although albendazole (400 mg twice daily for 21 days) has demonstrated macrofilaricidal efficacy.

As has already been mentioned, a growing body of evidence indicates that, although they may be asymptomatic, virtually all persons with *W. bancrofti* or *B. malayi* microfilaremia have some degree of subclinical disease (hematuria, proteinuria, abnormalities on lymphoscintigraphy). Thus, early treatment of asymptomatic persons is recommended to prevent further lymphatic damage. ForADL, supportive treatment (including the administration of antipyretics and analgesics) is recommended, as is antibiotic therapy if secondary bacterial infection is likely. Similarly, because lymphatic disease is associated with the presence of adult worms, treatment withDEC is recommended for microfilaria-negative adult-worm carriers.

In persons with chronic manifestations of lymphatic filariasis, treatment regimens that emphasize hygiene, prevention of secondary bacterial infections, and physiotherapy have gained wide acceptance for morbidity control. These regimens are similar to those recommended for lymphedema of most nonfilarial causes and known by a variety of names, including *complex decongestive physiotherapy* and *complex lymphedema therapy*. Hydroceles can be drained repeatedly or managed surgically. In patients with chronic manifestations of lymphatic filariasis, drug treatment should be reserved for cases with evidence of active infection.

The recommended course ofDECtreatment (12 days; total dose, 72 mg/kg) has remained standard for many years; however, data indicate that single-dose DEC treatment with 6 mg/kg may be equally efficacious. The 12-day course provides more rapid short-term microfilarial suppression. Regimens that utilize single-dose DEC or ivermectin or combinations of single doses of albendazole and either DEC or ivermectin have all been demonstrated to have a sustained microfilaricidal effect.

Side effects ofDECtreatment include fever, chills, arthralgias, headaches, nausea, and vomiting. Both the development and the severity of these reactions are directly related to the number of microfilariae circulating in the bloodstream and may represent an acute hypersensitivity reaction to the antigens being released by dead and dying parasites.

PREVENTION AND CONTROL

Avoidance of mosquito bites is usually not feasible for residents of endemic areas, but visitors should make use of insect repellent and mosquito nets.DEC can kill developing forms of filarial parasites and has been shown to be useful as a prophylactic agent in humans.

Community-based intervention is the current approach to elimination of lymphatic filariasis as a public health problem. The underlying tenet of this approach is that mass annual distribution of antimicrofilarial chemotherapy (albendazole with eitherDEC or ivermectin) will profoundly suppress microfilaremia. If the suppression is sustained, then transmission can be interrupted. As an added benefit, these combinations have secondary effects on gastrointestinal helminths. An alternative approach to the control of lymphatic filariasis is the use of salt fortified with DEC. Community use of DEC-fortified salt dramatically reduces microfilarial density with no apparent adverse reactions. Community education and clinical care for persons already suffering from the chronic sequelae of lymphatic filariasis are important components of filariasis control and elimination programs.

TROPICAL PULMONARY EOSINOPHILIA

Tropical pulmonary eosinophilia (TPE) is a distinct syndrome that develops in some individuals infected with lymphatic filarial species. This syndrome affects males and females at a ratio of 4:1, often during the third decade of life. The majority of cases have been reported from India, Pakistan, Sri Lanka, Brazil, and Southeast Asia.

CLINICAL FEATURES

The main features include a history of residence in filarial endemic regions, paroxysmal cough and wheezing that are usually nocturnal (and probably related to the nocturnal periodicity of microfilariae), weight loss, low-grade fever, adenopathy, and pronounced blood eosinophilia (>3000 eosinophils/uL). Chest x-rays may be normal but generally show increased bronchovascular markings; diffuse miliary lesions or mottled opacities may be present in the middle and lower lung fields. Tests of pulmonary function show restrictive abnormalities in most cases and obstructive defects in half. Total serum IgE levels (10,000 to 100,000 ng/mL) and antifilarial antibody titers are characteristically elevated.

PATHOLOGY

InTPEthere is rapid clearance of microfilariae and parasite antigens from the bloodstream by the lungs, and the clinical symptoms result from allergic and inflammatory reactions elicited by the cleared parasites. In some subjects, trapping of microfilariae in other reticuloendothelial organs can cause hepatomegaly, splenomegaly, or lymphadenopathy. A prominent, eosinophil-enriched, intraalveolar infiltrate is often reported. In the absence of successful treatment, interstitial fibrosis can lead to progressive pulmonary damage.

DIFFERENTIAL DIAGNOSIS

TPEmust be distinguished from asthma, Loffler's syndrome, allergic bronchopulmonary aspergillosis, allergic granulomatosis with angiitis (Churg-Strauss syndrome), the systemic vasculitides (most notably periarteritis nodosa and Wegener's granulomatosis), chronic eosinophilic pneumonia, and the idiopathic hypereosinophilic syndrome. In addition to a geographic history of filarial exposure, useful features for distinguishing TPE include wheezing that is solely nocturnal, very high levels of antifilarial antibodies, and a rapid initial response to treatment withDEC.

TREATMENT

DECis used at a dosage of 4 to 6 mg/kg of body weight per day for 14 days. Symptoms usually resolve within 3 to 7 days after the initiation of therapy. Relapse, which occurs in ~12 to 25% of cases (sometimes after an interval of years), requires re-treatment.

ONCHOCERCIASIS

Onchocerciasis ("river blindness") is caused by the filarial nematode *O. volvulus*, which infects an estimated 13 million individuals. The majority of individuals infected with *O. volvulus* live in the equatorial region of Africa extending from the Atlantic coast to the Red Sea. About 70,000 persons are infected in Guatemala and Mexico, with smaller foci in Venezuela, Colombia, Brazil, Ecuador, Yemen, and Saudi Arabia. Onchocerciasis is the second leading cause of infectious blindness worldwide.

ETIOLOGY AND EPIDEMIOLOGY

Infection in humans begins with the deposition of infective larvae on the skin by the bite

of an infected blackfly. The larvae develop into adults, which are typically found in subcutaneous nodules. About 7 months to 3 years after infection, the gravid female releases microfilariae that migrate out of the nodule and throughout the tissues, concentrating in the dermis. Infection is transmitted to other persons when a female fly ingests microfilariae from the host's skin and these microfilariae then develop into infective larvae. Adult *O. volvulus* females and males are about 40 to 60 cm and 3 to 6 cm in length, respectively. The life span of adults can be as long as 18 years, with an average of ~9 years. Because the blackfly vector breeds along free-flowing rivers and streams (particularly in rapids) and generally restricts its flight to an area within several kilometers of these breeding sites, both biting and disease transmission are most intense in these locations.

PATHOLOGY

Onchocerciasis affects primarily the skin, eyes, and lymph nodes. In contrast to that in lymphatic filariasis, the damage in onchocerciasis is elicited by microfilariae and not by adults. In the skin, there are mild but chronic inflammatory changes that can result in loss of elastic fibers, atrophy, and fibrosis. The subcutaneous nodules, or onchocercomata, consist primarily of fibrous tissues surrounding the adult worm, often with a peripheral ring of inflammatory cells. In the eye, neovascularization and corneal scarring lead to corneal opacities and blindness. Inflammation in the anterior and posterior chambers frequently results in anterior uveitis, chorioretinitis, and optic atrophy. Although punctate opacities are due to an inflammatory reaction surrounding dead or dying microfilariae, the pathogenesis of most manifestations of onchocerciasis is still unclear.

CLINICAL FEATURES

Skin Pruritus and rash are the most frequent manifestations of onchocerciasis. The pruritus can be incapacitating; the rash is typically a papular eruption that is generalized rather than localized to a particular region of the body. Long-term infection results in exaggerated and premature wrinkling of the skin, loss of elastic fibers, and epidermal atrophy that can lead to loose, redundant skin and hypo- or hyperpigmentation. Localized eczematoid dermatitis can cause hyperkeratosis, scaling, and pigmentary changes. Such lesions are often seen in the lower extremities but can be distributed more extensively.

Onchocercomata These subcutaneous nodules, which can be palpable and/or visible, contain the adult worm. In African patients, they are common over the coccyx and sacrum, the trochanter of the femur, the lateral anterior crest, and other bony prominences; in Latin American patients, they tend to develop preferentially in the upper part of the body, particularly on the head, neck, and shoulders. Nodules vary in size and characteristically are firm and not tender. It has been estimated that, for every palpable nodule, there are four deeper nonpalpable ones.

Ocular Tissue Visual impairment is the most serious complication of onchocerciasis and usually affects only those persons with moderate or heavy infections. Lesions may develop in all parts of the eye. The most common early finding is conjunctivitis with photophobia. In the cornea, punctate keratitis -- consisting of acute inflammatory

reactions surrounding dying microfilariae manifested as "snowflake" opacities -- is frequent in younger patients and resolves without apparent complications. Sclerosing keratitis occurs in 1 to 5% of infected persons and is the leading cause of onchocercal blindness in Africa. Anterior uveitis and iridocyclitis develop in ~5% of infected persons in Africa. In Latin America, complications of the anterior uveal tract (pupillary deformity) may cause secondary glaucoma. Characteristic chorioretinal lesions develop as a result of atrophy and hyperpigmentation of the retinal pigment epithelium. Constriction of the visual field and frank optic atrophy may occur.

Lymph Nodes Mild to moderate lymphadenopathy is frequent, particularly in the inguinal and femoral areas, where the enlarged nodes may hang down in response to gravity ("hanging groin"), sometimes predisposing to inguinal and femoral hernias.

Systemic Manifestations Some heavily infected individuals develop cachexia with loss of adipose tissue and muscle mass. Among adults who become blind, there is a three- to fourfold increase in the mortality rate.

DIAGNOSIS

Definitive diagnosis depends on the detection of an adult worm in an excised nodule or, more commonly, of microfilariae in a skin snip. Skin snips are obtained with a corneal-scleral punch, which collects a blood-free skin biopsy sample extending to just below the epidermis, or by lifting of the skin with the tip of a needle and excision of a small (1- to 3-mm) piece with a sterile scalpel blade. The biopsy tissue is incubated in tissue culture medium or in saline on a glass slide or flat-bottomed microtiter plate. After incubation for 2 to 4 h (or occasionally overnight in light infections), microfilariae emergent from the skin can be visualized by low-power microscopy.

Eosinophilia and elevated serum IgE levels are common but, because they occur in many parasitic infections, are not diagnostic in themselves. Assays to detect specific antibodies to *Onchocerca* andPCR to detect onchocercal DNA in skin snips are now in use in specialized laboratories and are highly sensitive and specific.

The *Mazzotti test* is a provocative technique that can be used in cases where the diagnosis of onchocerciasis is still in doubt (i.e., when skin snips and ocular examination reveal no microfilariae). A small dose ofDEC (0.5 to 1.0 mg/kg) is given orally; the development or exacerbation of pruritus or rash within hours is highly suggestive of onchocerciasis.

TREATMENT

The main goals of therapy are to prevent the development of irreversible lesions and to alleviate symptoms. Surgical excision is recommended when nodules are located on the head (because of the proximity of microfilaria-producing adult worms to the eye), but chemotherapy is the mainstay of management. Ivermectin, a semisynthetic macrocyclic lactone active against microfilariae, is the first-line agent for the treatment of onchocerciasis. It is given orally in a single dose of 150 ug/kg, either yearly or semiannually. After treatment, most individuals have few or no reactions. Pruritus, cutaneous edema, and/or maculopapular rash occurs in ~1 to 10% of treated

individuals. In areas of Africa coendemic for *O. volvulus* and *L. loa*, however, ivermectin is contraindicated (as it is for pregnant or breastfeeding women) because of severe posttreatment encephalopathy seen in patients, especially children, who are heavily microfilaremic for *L. loa* (>2000 to 5000 microfilariae per milliliter). Although ivermectin treatment results in a marked drop in microfilarial density, its effect can be short-lived (<6 months in some cases). Thus, it is occasionally necessary to give ivermectin more frequently for persistent symptoms. No currently available agent kills adult *O. volvulus*.

PREVENTION

Vector control has been beneficial in highly endemic areas in which breeding sites are vulnerable to insecticide spraying, but most areas endemic for onchocerciasis are not suited to this type of control. Community-based administration of ivermectin every 6 to 12 months is now being used to interrupt transmission in endemic areas. This measure, in conjunction with vector control, has already helped reduce the prevalence of disease in endemic foci in Africa and Latin America. No drug has proven useful for prophylaxis of *O. volvulus* infection.

LOIASIS

ETIOLOGY AND EPIDEMIOLOGY

Loiasis is caused by *L. loa* (the African eye worm), which is present in the rain forests of West and Central Africa. Adult parasites (females, 50 to 70 mm long and 0.5 mm wide; males, 25 to 35 mm long and 0.25 mm wide) live in subcutaneous tissues; microfilariae circulate in the blood with a diurnal periodicity that peaks between 12:00 noon and 2:00 P.M.

CLINICAL FEATURES

Manifestations of loiasis in natives of endemic areas may differ from those in temporary residents or visitors. Among the indigenous population, loiasis is often an asymptomatic infection with microfilaremia. Infection may be recognized only after subconjunctival migration of an adult worm or may be manifested by episodic Calabar swellings, evanescent localized areas of angioedema and erythema developing on the extremities and less frequently at other sites. Nephropathy, encephalopathy, and cardiomyopathy are rare. In patients who are not residents of endemic areas, allergic symptoms predominate, episodes of Calabar swelling tend to be more frequent and debilitating, microfilaremia is rare, and eosinophilia and increased levels of antifilarial antibodies are characteristic.

PATHOLOGY

The pathogenesis of the manifestations of loiasis is poorly understood. Calabar swellings are thought to result from a hypersensitivity reaction to the adult worm.

DIAGNOSIS

Definitive diagnosis of loiasis requires the detection of microfilariae in the peripheral

blood or the isolation of the adult worm from the eye or from a subcutaneous biopsy specimen from a site of swelling developing after treatment.PCR-based assays for the detection of *L. loa* DNA in blood are now available in specialized laboratories and are highly sensitive and specific. In practice, the diagnosis must often be based on a characteristic history and clinical presentation, blood eosinophilia, and elevated levels of antifilarial antibodies, particularly in travelers to an endemic region, who are usually amicrofilaremic. Other clinical findings in the latter individuals include hypergammaglobulinemia, elevated levels of serum IgE, and elevated leukocyte and eosinophil counts.

TREATMENT

DEC(8 to 10 mg/kg per day for 21 days) is effective against both the adult and the microfilarial forms of *L. loa*, but multiple courses are frequently necessary before the disease resolves completely. In cases of heavy microfilaremia, allergic or other inflammatory reactions can take place during treatment, including central nervous system involvement with coma and encephalitis. Heavy infections can be treated initially with apheresis to remove the microfilariae and with glucocorticoids (40 to 60 mg of prednisone per day) followed by doses of DEC (0.5 mg/kg per day). If antifilarial treatment has no adverse effects, the prednisone dose can be rapidly tapered and the dose of DEC gradually increased to 8 to 10 mg/kg per day.

Albendazole and ivermectin (although not approved by theFDA) have been shown to be effective in reducing microfilarial loads.DEC (300 mg weekly) is an effective prophylactic regimen for loiasis.

STREPTOCERCIASIS

Mansonella streptocerca, found mainly in the tropical forest belt of Africa from Ghana to Zaire, is transmitted by biting midges. The major clinical manifestations involve the skin and include pruritus, papular rashes, and pigmentation changes. Many infected individuals have inguinal adenopathy, although most are asymptomatic. The diagnosis is made by detection of the characteristic microfilariae in skin snips.DEC (6 mg/kg per day in divided doses for 14 to 21 days) is effective in killing both microfilariae and adult worms. As in onchocerciasis, treatment is sometimes accompanied by urticaria, arthralgias, myalgias, headaches, and abdominal discomfort. Ivermectin at a single dose of 150 ug/kg leads to sustained suppression of microfilariae in the skin and is likely to assume primacy in the treatment of streptocerciasis.

MANSONELLA PERSTANS INFECTION

Mansonella perstans, distributed across the center of Africa and in northeastern South America, is transmitted by midges. Adult worms reside in serous cavities -- pericardial, pleural, and peritoneal -- as well as in the mesentery and the perirenal and retroperitoneal tissues. Microfilariae circulate in the blood without periodicity. The clinical and pathologic features of the infection are poorly defined. Most patients appear to be asymptomatic, but manifestations may include transient angioedema and pruritus of the arms, face, or other parts of the body (analogous to the Calabar swellings of loiasis); fever; headache; arthralgias; and right upper quadrant pain. Occasionally, pericarditis

and hepatitis occur. The diagnosis is based on the demonstration of microfilariae in blood or serosal effusions. Perstans filariasis is often associated with peripheral blood eosinophilia and antifilarial antibody elevations. AlthoughDEC (8 to 10 mg/kg per day for 21 days) is the standard therapeutic agent, there is little evidence that it is effective. Cure is indicated by the disappearance of symptoms and eosinophilia; multiple courses of therapy are usually required. Both mebendazole (100 mg twice daily for 30 days) and albendazole (400 mg twice daily for 10 days) have been reported to be effective.

MANSONELLA OZZARDI INFECTION

The distribution of *Mansonella ozzardi* is restricted to Central and South America and certain Caribbean islands. Adult worms are rarely recovered from humans. Microfilariae circulate in the blood without periodicity. Although this organism has often been considered nonpathogenic, headache, articular pain, fever, pulmonary symptoms, adenopathy, hepatomegaly, pruritus, and eosinophilia have been ascribed to *M. ozzardi* infection. Diagnosis is made by the detection of microfilariae in peripheral blood. Ivermectin (a single dose of 6 mg) has been shown to be effective in treating this infection.

DRACUNCULIASIS (GUINEA WORM INFECTION)

ETIOLOGY AND EPIDEMIOLOGY

Dracunculiasis, caused by *Dracunculus medinensis*, is a parasitic infection whose incidence has declined dramatically because of global eradication efforts. Current estimates suggest that there are only 78,000 cases worldwide, the majority in Sudan. Humans acquire this infection when they ingest water containing infective larvae derived from *Cyclops*, a crustacean that is the intermediate host. Larvae penetrate the stomach or intestinal wall, mate, and mature. The adult male probably dies; the female *Dracunculus* develops over a year and migrates to subcutaneous tissues, usually in the lower extremity. As the thin female *Dracunculus*, ranging in length from 300 cm to 1 m, approaches the skin, a blister forms that, over days, breaks down and forms an ulcer. When the blister opens, large numbers of motile, rhabditiform larvae can be released into stagnant water; ingestion by *Cyclops* completes the life cycle.

CLINICAL FEATURES

Few or no clinical manifestations of dracunculiasis are evident until just before the blister forms, when there is an onset of fever and generalized allergic symptoms, including periorbital edema, wheezing, and urticaria. The emergence of the worm is associated with local pain and swelling. When the blister ruptures (usually as a result of immersion in water), the adult worm releases larva-rich fluid, and this release is associated with a relief of symptoms. The shallow ulcer surrounding the emerging adult worm heals over weeks to months. Such ulcers, however, can become secondarily infected, the result being cellulitis, local inflammation, abscess formation, or (uncommonly) tetanus. Occasionally, the adult worm does not emerge but becomes encapsulated and calcified.

DIAGNOSIS

The diagnosis is based on the findings developing with the emergence of the adult worm, as described above.

TREATMENT

Gradual extraction of the worm by winding of a few centimeters on a stick each day remains the common and effective practice. Worms may be excised surgically. The administration of thiabendazole (25 mg/kg twice daily for 3 days) or metronidazole (250 mg three times daily for 10 days) may relieve symptoms but has no proven activity against the worm.

PREVENTION

Prevention, which remains the only real control measure, depends on the provision of safe drinking water.

ZOONOTIC FILARIAL INFECTIONS

Dirofilariae that affect primarily dogs, cats, and raccoons and *Brugia* parasites that affect small mammals occasionally infect humans incidentally. Because humans are an abnormal host, the parasites never develop fully. Pulmonary dirofilarial infection caused by the canine heartworm *Dirofilaria immitis* generally presents in humans as a solitary pulmonary nodule. Chest pain, hemoptysis, and cough are uncommon. Infections with *D. repens* (from dogs) or *D. tenuis* (from raccoons) can cause local subcutaneous nodules in humans. Zoonotic *Brugia* infection can produce isolated lymph node enlargement. Eosinophilia levels and antifilarial antibody titers are not commonly elevated. Excisional biopsy is both diagnostic and curative; these infections usually do not respond to chemotherapy.

222. SCHISTOSOMIASIS AND OTHER TREMATODE INFECTIONS - *Adel A.F. Mahmoud*

Trematodes, or flatworms, are a group of morphologically and biologically heterogeneous parasitic helminths that belong to the phylum Platyhelminthes. Human infection with trematodes occurs in many geographic areas and can cause considerable morbidity and mortality. For clinical purposes, the significant trematode infections of humans may be divided according to the tissues invaded by adult flukes: blood, biliary tree, intestines, and lungs (Table 222-1).

Trematodes share some common morphologic features, including macroscopic size (from 1 cm to several cm); dorsoventral, flattened, bilaterally symmetric bodies (adult worms); and the prominence of two suckers. Except for the schistosomes, all trematodes that parasitize humans are hermaphroditic. The life cycle of trematodes involves a definitive host (mammalian/human), in which adult worms initiate sexual reproduction, and an intermediate host (snails, fish, etc.), in which asexual multiplication of the larval forms occurs. More than one intermediate host may be necessary for some species of trematodes. Human infection is initiated either by direct penetration of intact skin or by ingestion. Upon maturation within the human host, adult flukes initiate sexual reproduction that results in egg production. Helminth ova leave the definitive host in excreta or sputum and, upon reaching suitable environmental conditions, they hatch, releasing free-living miracidia that must find a specific snail intermediate host. After asexual reproduction, cercariae are released from infected snails; these organisms either infect humans (schistosomes) or must find another intermediate host to allow encystment into metacercariae.

The host-parasite relationship in trematode infections is a product of the biologic features of these organisms: they are multicellular, undergo several developmental changes within the host, and usually result in chronic infections. In general, the distribution of worm infections in human populations is overdispersed; i.e., it follows a negative binomial mathematical relationship in which most infected individuals harbor low worm burdens while a small percentage are heavily infected. It is the heavily infected minority who are particularly prone to disease sequelae and who represent an epidemiologically significant reservoir of infection in endemic areas. It is important to appreciate that worms do not multiply within the definitive host and that they have a relatively long life span, ranging from a few months to a few years. Morbidity and mortality due to trematode infections reflect a multifactorial process that results from the tipping of a delicate balance based on the intensity of infection and the host reactions that initiate and modulate pathologic outcome. The genetics of the parasite and the human host contribute to the outcome of infection and disease. Furthermore, infections with trematodes that migrate through or reside in host tissues are associated with a moderate to high degree of peripheral blood eosinophilia; this association is of significance in protective and immunopathologic sequelae and is a useful clinical indicator of infection.

Approach to the Patient

The approach to individuals with suspected trematode infection begins with the question: Where have you been? Details of geographic history, exposure to freshwater

bodies, and indulgence in local eating habits without ensuring safety of food and drink are all essential elements in the history. The workup plan must include a detailed physical examination and tests appropriate for the suspected infection. Diagnosis is based either on detection of the relevant stage of the parasite in excreta, sputum, or (rarely) tissue samples or on sensitive and specific serologic tests. Consultation with physicians familiar with these infections or with the U.S. Centers for Disease Control and Prevention (CDC) is helpful in guiding diagnosis and selecting therapy.

BLOOD FLUKES: SCHISTOSOMIASIS

Human schistosomiasis is caused by five species of this parasitic trematode belonging to the subclass Digenea: the intestinal species *Schistosoma mansoni*, *S. japonicum*, *S. mekongi*, and *S. intercalatum* and the urinary species *S. haematobium*. Infection may cause considerable morbidity in the intestines, liver, and urinary tract, and a proportion of affected individuals die. Other schistosome species (e.g., avian species) may invade human skin but then die in subcutaneous tissue, producing only self-limiting cutaneous manifestations.

Information on the prevalence and geographic distribution of human schistosomiasis is inexact. The five species are estimated to infect 200 to 300 million people in South America, the Caribbean, Africa, the Middle East, and Southeast Asia. The total population living under conditions favoring transmission approximates double or triple that number -- a fact reflecting the public health significance of schistosomiasis.

ETIOLOGY

Human infection is initiated by penetration of intact skin with infective cercariae. These organisms are released from infected snails in freshwater bodies; they measure ~2 mm in length and possess an anterior and a ventral sucker that attaches to the skin surface and facilitates penetration. Once in the subcutaneous tissue, the organism transforms into the next stage: the schistosomula. This transformation involves morphologic, membrane, and immunologic changes, prominent among which is the transformation of the cercarial outer membrane from a trilaminar to a heptalaminar structure that is then maintained throughout the life span of the worms in humans. The transformation to a heptalaminar structure is thought to be the schistosome's main adaptive mechanism for survival in humans. Schistosomula begin their migration within 2 to 4 days via venous or lymphatic vessels, reaching the lungs and finally the liver parenchyma. Sexually mature worms descend in pairs into the venous system at specific anatomic locations: intestinal veins (*S. mansoni*, *S. japonicum*, *S. mekongi*, and *S. intercalatum*) and vesical veins (*S. haematobium*). Adult gravid females then travel against venous blood flow to small tributaries, where they deposit their ova intravascularly. Schistosome ova have specific morphologic features that can be used to differentiate species. Aided by enzymatic secretions through minipores in eggshells, ova move through the venous wall, traversing host tissues to reach the lumen of the intestinal or urinary tract, and are voided with stools or urine. Approximately 50% of ova, however, fail in their attempt to be transported to the outside environment and are either retained in host tissues locally (intestines or urinary tract) or carried by venous blood flow to the liver and other organs. Schistosome ova that reach freshwater bodies hatch, releasing free-living miracidia that seek the snail intermediate host to undergo several asexual multiplication cycles.

Finally, infective cercariae are shed from snails.

Adult schistosome worms measure ~1 to 2 cm in length. The male is slightly shorter, with a flattened body; its edges curve anteriorly to form the gynecophoral canal, in which mature adult females are usually held. The females are longer, slender, and rounded in cross-section. The precise nature of biochemical and reproductive exchanges between the two sexes is unknown, as are the regulatory mechanisms for pairing. Adult schistosomes parasitize specific sites in the host venous system. What guides adult intestinal schistosomes to branches of the superior or inferior mesenteric veins or adult *S. haematobium* worms to the vesical plexus is unknown. In addition, the evasion mechanisms by which adult worms inhibit the coagulation cascade and the effector arms of the host immune responses are not fully understood.

A systematic examination of schistosomal molecular phylogeny as well as gene structure and organization has begun. Analysis of the sequence of nuclear ribosome and internal transcribed spacer 2 and mitochondrial 16 sRNA indicates that human schistosomes may be divided into three monophyletic groups: the *S. haematobium* group, including *S. haematobium* and *S. intercalatum*; the *S. mansoni* group, including *S. mansoni* and *S. rodhaini*; and a group containing the two Asian schistosomes, *S. japonicum* and *S. mekongi*. These molecular groupings coincide with results of previous attempts to use morphologic or nucleic acid data to produce a taxonomic framework. In other studies, the schistosome genome was determined to be made up of 16 chromosomes; sexual differentiation is related to the presence of ZW chromosomes in females and ZZ chromosomes in males.

EPIDEMIOLOGY

The distribution of schistosome infection and related disease syndromes in human populations is dependent on both parasite and host factors. In endemic areas, the rate of yearly onset of new infection, or incidence, is low. Prevalence, on the other hand, starts to be appreciable by the age of 3 to 4 years and builds to a maximum that varies by endemic region (up to 100%) in the 15- to 20-year age group. Prevalence then stabilizes or decreases slightly in older age groups (>40 years). Intensity of infection (as measured by fecal or urinary egg counts, which correlate with adult worm burdens in most circumstances) follows the increase in prevalence up to the age of 15 to 20 years and then declines markedly in older age groups. This decline may reflect acquisition of resistance, or it may be due to changes in water contact patterns, since older people are exposed less. Furthermore, the unique distribution of schistosomes in human populations, which fits a negative binomial pattern (see above), may be due to heterogeneity of worm populations, with some more invasive than others; alternatively, it may be due to differences in the genetic susceptibility of host populations.

Disease due to schistosomiasis is the outcome of parasitologic, host, and additional infectious, nutritional, and environmental factors. Most of the disease syndromes relate to the presence of one or more of the parasite stages in the human host. The distribution of disease manifestations in the populations of endemic areas correlates with the intensity and duration of infection as well as with the age and genetic susceptibility of the host. Overall, disease manifestations are clinically relevant in only a small proportion of persons infected with any of the intestinal schistosomes. In contrast,

urinary schistosomiasis manifests clinically in most infected individuals.

Patients with both HIV infection and schistosomiasis have been found to excrete far fewer eggs in their stools than those infected with *S. mansoni* alone. The two groups have responded equally to treatment with praziquantel.

PATHOGENESIS AND IMMUNITY

During the invasive stage, cercaria-associated dermatitis reflects dermal and subdermal inflammatory responses -- both humoral and cell-mediated. As the parasites approach sexual maturity and the commencement of oviposition, acute schistosomiasis or Katayama fever (a serum sickness-like illness; see "Clinical Features," below) may occur. The associated antigen excess results in the formation of soluble immune complexes, which may be deposited in several tissues, initiating the sequence of pathologic events. In chronic schistosomiasis, most disease manifestations are due to eggs retained in host tissue. The granulomatous response around these ova is cell-mediated and is regulated both positively and negatively by a cascade of cytokine, cellular, and humoral responses. Granuloma formation begins with recruitment of a host of inflammatory cells in response to antigens secreted by the living organism within the ova. Cells recruited initially include phagocytes, antigen-specific T cells, and eosinophils. Fibroblasts, giant cells, and B lymphocytes predominate later. Once activated, T cells produce cytokines [such as tumor necrosis factora (TNF-a), interleukin (IL) 2, IL-4, and IL-5, which in turn activate endothelial cells] and produce specific chemokines such as monocyte chemotactic protein 1 (MCP-1). The result is recruitment of the cellular elements that organize in the form of granulomas around parasite eggs. These lesions reach a size many times that of the eggs, thus inducing organomegaly and obstruction. Immunomodulation or downregulation of host responses to schistosome eggs plays a significant role in limiting the extent of the granulomatous lesions -- and consequently disease -- in chronically infected experimental animals or humans. The underlying mechanisms involve another cascade of regulatory cytokines (IL-10, IL-12) and idiotypic antibodies. Subsequent to the granulomatous response, fibrosis sets in, resulting in more permanent disease sequelae. Because schistosomiasis is a chronic infection, the accumulation of antigen-antibody complexes results in deposits in renal glomeruli and may cause significant kidney disease.

The better-studied pathologic sequelae in schistosomiasis are those observed in liver disease. Ova that are carried by portal blood embolize to the liver. Because of their size (~150´ 60 um in the case of *S. mansoni*), they lodge at presinusoidal sites, where granulomas are formed. The granulomas contribute to the liver enlargement observed in infected individuals. Schistosomal hepatomegaly is also associated with certain class I and class II HLA markers; its genetic basis appears to be multigenic. Presinusoidal portal blockage causes several hemodynamic changes, including portal hypertension and associated development of portosystemic collaterals at the esophagogastric junction and other sites. Esophageal varices are most likely to break and cause repeated episodes of hematemesis. Because changes in liver hemodynamics in schistosomiasis are slow, compensatory arterialization of blood flow through the liver is established. While this compensatory mechanism may be associated with certain metabolic side effects, the retention of hepatocyte perfusion may permit the maintenance of normal liver function for several years.

After granuloma formation, the second most significant pathologic change in the liver relates to the onset of fibrosis. It is characteristically periportal (Symmers' clay-pipe stem fibrosis) but may be diffuse. Fibrosis, when diffuse, may be seen in areas of egg deposition and granuloma formation, but it is also seen in distant locations such as portal tracts. Schistosomiasis alone results in pure fibrotic lesions in the liver; cirrhosis occurs when other nutritional or infectious agents (e.g., hepatitis B or C virus) are involved. In recent years, it has been recognized that deposition of fibrotic tissue in the extracellular matrix results from the interaction of T lymphocytes with cells of the fibroblast series; several cytokines, such asIL-2, IL-4, IL-1, and transforming growth factor b(TGF-b), are known to stimulate fibrogenesis. The process may be dependent on the genetic constitution of the host. Furthermore, regulatory cytokines that can suppress fibrogenesis, such as interferong (IFN-g) or IL-12, may play a role in modulating the response.

While the above description focuses on granuloma formation and fibrosis of the liver, similar processes occur in urinary schistosomiasis. Granuloma formation at the lower end of the ureters obstructs urinary flow, with subsequent development of hydroureter and hydronephrosis. Similar lesions in the urinary bladder cause the protrusion of papillomatous structures into its cavity; these may ulcerate and/or bleed. The chronic stage of infection is associated with scarring and deposition of calcium in the bladder wall.

Immunomodulation is an essential mechanism in shaping the clinical and pathologic outcome of schistosomiasis. While most detailed immunologic analyses have been performed in experimental animals, enough evidence exists from studies in humans to delineate the suppression of T cell responses in association with active infections and a regulatory role forIL-10.

Studies on immunity to schistosomiasis, whether innate or acquired, have expanded our knowledge of the components of these responses and the target antigens. The concept of innate immunity is illustrated by the inability of avian schistosomes, which cause swimmers' itch, to reach maturity in humans. The critical question, however, is whether humans acquire immunity to schistosomes. Epidemiologic evidence suggests the onset of acquired immunity during the course of infection in young adults. Curative treatment of infection divides populations in endemic areas into those who acquire reinfection rapidly (susceptible) and those who follow a protracted course (resistant). This difference may be explained by differences in transmission, immunologic response, or genetic susceptibility. The mechanism of acquired immunity involves antibodies, complement, and several effector cells, particularly eosinophils. Furthermore, the intensity of schistosome infection has been correlated with a region in chromosome 5. In other studies, several protective schistosome antigens have been identified as vaccine candidates.

CLINICAL FEATURES

In general, disease manifestations of schistosomiasis occur in three stages, which vary not only by species but also by intensity of infection and other host factors, such as age and genetics. During the phase of cercarial invasion, a form of dermatitis may be

observed. This so-called swimmers' itch (Fig. 222-CD1) occurs most often with *S. mansoni* and *S. japonicum* infections, manifesting 2 or 3 days after invasion as an itchy maculopapular rash on the affected areas of the skin. The condition is particularly severe when humans are exposed to avian schistosomes. This form of cercarial dermatitis is seen around the freshwater lakes in the northern United States, particularly in the spring. Cercarial dermatitis is a self-limiting clinical entity. During worm maturation and at the beginning of oviposition (i.e., 4 to 8 weeks after skin invasion), acute schistosomiasis or Katayama fever -- a serum sickness-like syndrome with fever, generalized lymphadenopathy, and hepatosplenomegaly -- may develop. Individuals suffering from acute schistosomiasis show a high degree of peripheral blood eosinophilia. Parasite-specific antibodies may be detected before schistosome eggs are identified in excreta. Acute schistosomiasis has become an important clinical entity worldwide because of increased travel to endemic areas. Travelers are exposed to the parasite while swimming or wading in freshwater bodies and upon their return present with the acute manifestations of the disease. The course of acute schistosomiasis is generally benign, but deaths are occasionally reported in association with heavy exposure to schistosomes.

The main clinical manifestations of chronic schistosomiasis are species-dependent. Intestinal species (*S. mansoni*, *S. japonicum*, *S. mekongi*, and *S. intercalatum*) cause intestinal and hepatosplenic disease as well as several manifestations associated with portal hypertension. During the intestinal phase, which may begin a few months after infection and may last for years, symptomatic patients characteristically have colicky abdominal pain and bloody diarrhea. Patients may also report fatigue and an inability to perform daily routine functions and may show evidence of growth retardation. The severity of intestinal schistosomiasis is often related to the intensity of the worm burden. The disease runs a chronic course but rarely progresses to a functional level (e.g., malabsorption) or to anatomic lesions of the gut. The exception is colonic polyposis, which has been seen in some endemic areas, such as Egypt.

The hepatosplenic phase of disease manifests early (during the first year of infection, particularly in children) with enlargement of the liver due to parasite-induced granulomatous lesions. Hepatomegaly is seen in ~15 to 20% of infected individuals when whole communities in endemic areas are studied. It correlates roughly with the intensity of infection, occurs more often in children than in adults, and may be related to specific HLA haplotypes. In subsequent phases of infection, presinusoidal blockage of blood flow leads to portal hypertension and splenomegaly. Moreover, portal hypertension may lead to varices at the lower end of the esophagus and at other sites. Patients with schistosomal liver disease may have right-upper-quadrant "dragging" pain during the hepatomegaly phase, and this pain may move to the left upper quadrant as splenomegaly progresses. Bleeding from esophageal varices may, however, be the first clinical manifestation of this phase. Patients may experience repeated bleeding but seem to tolerate its impact, since an adequate total hepatic blood flow permits normal liver function for a considerable period in schistosomal hepatomegaly. In late-stage disease, typical fibrotic changes occur along with liver function deterioration and the onset of ascites, hypoalbuminemia, and defects in coagulation. Intercurrent viral infections of the liver or nutritional deficiencies may well accelerate or exacerbate the deterioration of hepatic function.

The extent and severity of intestinal and hepatic disease in schistosomiasis mansoni and japonica have been well described. While it was originally thought that *S. japonicum* might induce more severe disease manifestations because the adult worms can produce ten times more eggs than *S. mansoni*, subsequent field studies have not supported this claim. Clinical observations of individuals infected with *S. mekongi* or *S. intercalatum* have been less detailed, partly because of the far more limited geographic distribution of these organisms.

The clinical manifestations of *S. haematobium* infection occur relatively early and involve a relatively high percentage of individuals. Up to 80% of children infected with *S. haematobium* have dysuria, frequency, and hematuria, which may be terminal. Urine examination reveals blood and albumin as well as an unusually high frequency of bacterial urinary tract infection. These manifestations correlate with intense infection, the presence of urinary bladder granulomas, and subsequent ulceration. Along with the local effects of granuloma formation in the urinary bladder, obstruction of the lower end of the ureters results in hydroureter and hydronephrosis, which can be seen in 25 to 50% of infected children. As infection progresses, bladder granulomas undergo fibrosis; the result is the presence of typical sandy patches visible on cystoscopy. In many endemic areas, an association between squamous cell carcinoma of the bladder and *S. haematobium* infection has been observed. Such malignancy is detected in a younger age group than transitional cell carcinoma. In fact, *S. haematobium* has now been classified as a human carcinogen.

Significant disease may occur in other organs during chronic schistosomiasis. Most important is disease in the lungs and central nervous system; other locations, such as the skin and the genital organs, are far less frequently affected. In pulmonary schistosomiasis, embolized eggs lodge in small arterioles, producing acute necrotizing arteriolitis and granuloma formation. During *S. mansoni* and *S. japonicum* infection, schistosome eggs reach the lungs after the development of portosystemic collateral circulation; in *S. haematobium* infection, ova may reach the lungs directly via connections between the vesical and systemic circulation. After the development of arteriolitis and granuloma formation, fibrous tissue deposition is detected and leads to endarteritis obliterans, pulmonary hypertension, and cor pulmonale. This clinical entity is an uncommon presentation during chronic schistosomiasis. The most frequent symptoms are cough, fever, and dyspnea; ascites and hemoptysis are less frequently encountered. Cor pulmonale may be diagnosed radiologically on the basis of prominent right side of the heart and dilation of the pulmonary artery. Frank evidence of right-sided heart failure may be seen in late cases.

Central nervous system schistosomiasis is important but less frequent than pulmonary schistosomiasis. It characteristically occurs as cerebral disease due to *S. japonicum* infection. Migratory worms deposit eggs in the brain and induce a granulomatous response. The frequency of this manifestation among infected individuals in some endemic areas (e.g., the Philippines) is calculated at 2 to 4%. Jacksonian epilepsy due to *S. japonicum* infection is the second most common cause of epilepsy in these areas. *S. mansoni* and *S. haematobium* infections have been associated with transverse myelitis. This syndrome is thought to be due to eggs traveling to the venous plexus around the spinal cord. In schistosomiasis mansoni, transverse myelitis is usually seen in the chronic stage after the development of portal hypertension and portosystemic

shunts, which allow ova to travel to the spinal cord veins. This proposed sequence of events has been challenged because of a few reports of transverse myelitis occurring early in the course of *S. mansoni* infection. More information is needed to confirm these observations. During schistosomiasis haematobia, ova may travel through communication between vesical and systemic veins, resulting in spinal cord disease that may be detected at any stage of infection. Pathologic study of lesions in schistosomal transverse myelitis may reveal eggs along with necrotic or granulomatous lesions. Patients usually present with acute or rapidly progressing lower-leg weakness accompanied by sphincter dysfunction.

DIAGNOSIS

Physicians in areas not endemic for schistosomiasis face considerable diagnostic challenges. In the most common clinical presentation, a returning traveler exhibits symptoms and signs of any of the acute syndromes of schistosomiasis -- namely, cercarial dermatitis or Katayama fever. Central to correct diagnosis is a thorough inquiry into travel history and exposure to freshwater bodies, whether slow or fast running. Differential diagnosis of fever in returned travelers includes a spectrum of infections whose etiologies are viral (e.g., Dengue fever), bacterial (e.g., enteric fever, leptospirosis), rickettsial, or protozoal (e.g., malaria). In cases of Katayama fever, prompt diagnosis is essential and is based on clinical presentation, high-level peripheral blood eosinophilia, and a positive serologic assay for schistosomal antibodies. Two tests are available at theCDC: the Falcon assay screening test/enzyme-linked immunosorbent assay (FAST-ELISA) and the confirmatory enzyme-linked immunoelectrotransfer blot (EITB). Both tests are highly sensitive and ~96% specific. In some instances, examination of stool or urine for ova may yield positive results.

Individuals with established infection are diagnosed by a combination of geographic history, characteristic clinical presentation, and presence of schistosome ova in excreta. The diagnosis may also be established with the serologic assays mentioned above or with those that detect circulating schistosome antigens. These assays can be applied either to blood or to other body fluids (e.g., cerebrospinal fluid). For stool examination, the Kato thick smear or any other concentration method generally identifies all but the most lightly infected individuals. Urine may be examined by microscopy of sediment or by filtration of a known volume through Nuclepore filters. Kato thick smear and Nuclepore filtration provide quantitative data on the intensity of infection, which is of value in assessing the degree of tissue damage and in monitoring the effect of chemotherapy. Finally, schistosome infection may be diagnosed by examination of tissue samples, typically rectal biopsies; other biopsy procedures (e.g., liver biopsy) are not needed, except in special circumstances.

Differential diagnosis of schistosomal hepatomegaly must include viral hepatitis of all etiologies, miliary tuberculosis, malaria, visceral leishmaniasis, ethanol abuse, and causes of hepatic and portal vein obstruction. Of patients with these conditions, only a few may present with organomegaly and relatively intact liver function. The differential diagnosis of hematuria in *S. haematobium* infection includes bacterial cystitis, tuberculosis, urinary stones, and malignancy.

TREATMENT

Treatment of schistosomiasis depends on the stage of infection and the clinical presentation. Other than topical dermatologic applications for relief of itching, no specific treatment is indicated for cercarial dermatitis caused by avian schistosomes. Therapy for acute schistosomiasis or Katayama fever needs to be adjusted appropriately for each case. While antischistosomal chemotherapy is indicated, it does not address immediate pathologic changes. In severe acute schistosomiasis, management in an acute-care setting is necessary, with supportive measures and consideration of glucocorticoid treatment. Once the acute critical phase is over, specific chemotherapy is indicated. For all individuals with infection established by either the demonstration of schistosome eggs or positive serology, treatment to eradicate the parasite should be administered. The drug of choice is praziquantel, which -- depending on the infecting species (Table 222-2) -- is administered orally as 40 or 60 mg/kg in two or three doses over a single day. Praziquantel treatment results in parasitologic cure in ~85% of cases and reduces egg counts by >90%. Few side effects have been encountered, and those that do develop usually do not interfere with completion of treatment. Other antischistosomal chemotherapeutic agents are currently considered only as alternatives when praziquantel is unavailable. The effect of antischistosomal treatment on disease manifestations varies by stage. Early hepatomegaly and bladder lesions are known to resolve following chemotherapy, but the late established manifestations, such as fibrosis, do not change. Additional management modalities are needed for individuals with other manifestations, such as hepatocellular failure or recurrent hematemesis. The use of these interventions is guided by general medical and surgical principles.

PREVENTION AND CONTROL

Since transmission of schistosomiasis is dependent on human behavior, it is theoretically possible to devise an effective preventive strategy. The geographic distribution of infections in endemic regions of the world is not clearly demarcated. It is therefore prudent for travelers to avoid contact with all freshwater bodies, irrespective of the speed of water flow or unsubstantiated claims of safety. Some topical agents, when applied to the skin, may conceivably inhibit cercarial penetration, but none of these agents is currently available. If exposure occurs, a follow-up visit with a health care provider is strongly recommended. Prevention of infection in inhabitants of endemic areas is a significant challenge. People of these regions use freshwater bodies for sanitary, domestic, recreational, and agricultural purposes. In the absence of adequate alternatives, several control measures have been used, including application of molluscicides, provision of sanitary water and means for sewage disposal, chemotherapy, and health education. Current recommendations to countries endemic for schistosomiasis emphasize the use of multiple approaches. Particularly with the advent of a single-oral-dose, safe, and effective antischistosomal agent, chemotherapy has been most successful in reducing the intensity of infection and reversing disease. The duration of this positive impact depends on transmission dynamics in a specific endemic region. The ultimate goal of research on prevention and control is the development of a vaccine. Although there are a few promising leads, this goal is probably not within reach during the next decade or so.

LIVER (BILIARY) FLUKES

Several species of biliary fluke infecting humans are particularly common in Southeast Asia and Russia. Other species are transmitted in Europe, Africa, and the Americas. On the basis of their migratory pathway in humans, these infections may be divided into the *Clonorchis* and *Fasciola* groups.

CLONORCHIASIS AND OPISTHORCHIASIS

Infection with *C. sinensis*, the Chinese or oriental fluke, is endemic among fish-eating mammals in Southeast Asia. Humans are an incidental host; the prevalence of human infection is highest in China, Vietnam, and Korea. Infection with *Opisthorchis viverrini* and *O. felineus* is zoonotic in cats and dogs. Transmission to humans occurs occasionally, particularly in Thailand (*O. viverrini*) and in Southeast Asia and eastern Europe (*O. felineus*). Data on the exact geographic distribution of these infectious agents in human populations are rudimentary.

Infection with any of these three species is established by ingestion of raw or inadequately cooked freshwater fish harboring metacercariae. These organisms excyst in the duodenum, releasing larvae that travel through the ampulla of Vater and mature into adult worms in the bile canaliculi. Mature flukes are flat and elongated, measuring 1 to 2 cm in length. The hermaphroditic worms reproduce by releasing small operculated eggs, which pass with bile into the intestines and are voided with stools. The life cycle is completed in the environment in specific freshwater snails (the first intermediate host) and encystment of metacercariae in freshwater fish.

Except for late sequelae, the exact clinical syndromes caused by clonorchiasis and opisthorchiasis are not well defined. Since most infected individuals harbor a low worm burden, many are asymptomatic. Moderate to heavy infection may be associated with vague right-upper-quadrant pain. In contrast, chronic or repeated infection is associated with manifestations such as cholangitis, cholangiohepatitis, and biliary obstruction. Cholangiocarcinoma is epidemiologically related to *C. sinensis* infection in China and to *O. viverrini* infection in northeastern Thailand. This association has resulted in the classification of these infectious agents as human carcinogens.

FASCIOLIASIS

Infections with *F. hepatica* and *F. gigantica* are worldwide zoonoses that are particularly endemic in sheep-raising countries. Human cases have been reported in South America, Europe, Africa, Australia, and the Far East. Recent estimates indicate a worldwide prevalence of 17 million cases. High endemicity has been reported in certain areas of Peru and Bolivia. In most endemic areas the predominant species is *F. hepatica*, but in Asia and Africa a varying degree of overlap with *F. gigantica* has been observed.

Humans acquire fascioliasis by ingestion of metacercariae attached to certain aquatic plants, such as watercress. Infection may also be acquired by consumption of contaminated water or ingestion of food items washed with such water. Acquisition of human infection through consumption of freshly prepared raw liver containing immature flukes has been reported. Infection is initiated when metacercariae excyst, penetrate the gut wall, and travel through the peritoneal cavity to invade the liver capsule. Adult

worms finally reach the bile ducts, where they produce large operculated eggs, which are voided in the bile and through the gastrointestinal tract to the outside environment. The flukes' life cycle is completed in specific snails (the first intermediate host) and encystment on aquatic plants.

The clinical features of fascioliasis relate to the intensity of infection, but even more to the stage of infection. Acute disease develops during the parasites' migration (1 to 2 weeks after infection) and includes fever, right-upper-quadrant pain, hepatomegaly, and eosinophilia. Computed tomography of the liver may show migratory tracks. Symptoms and signs usually subside as the parasites reach their final habitat. In individuals with chronic infection, bile duct obstruction and biliary cirrhosis are infrequently demonstrated. No relation to hepatic malignancy has been ascribed to fascioliasis.

DIAGNOSIS

The diagnosis of infection with any of the biliary flukes depends on a high degree of suspicion, the elicitation of an appropriate geographic history, and stool examination for the characteristically shaped parasite ova. Additional evidence may be obtained by documenting peripheral blood eosinophilia or imaging the liver. Serologic testing is helpful, particularly in lightly infected individuals.

TREATMENT

Drug therapy (praziquantel or triclabendazole) is summarized inTable 222-2. Patients with anatomic lesions in the biliary tract or malignancy are managed according to general medical guidelines.

INTESTINAL FLUKES

Two species of intestinal flukes cause human infection in defined geographic areas worldwide. The large *Fasciolopsis buski* (adults measure 2 by 7 cm) is endemic in Southeast Asia, while the smaller *Heterophyes heterophyes* is found in the Nile Delta of Egypt and in the Far East. Infection is initiated by ingestion of metacercariae attached to aquatic plants (*F. buski*) or encysted in freshwater or brackish-water fish (*H. heterophyes*). Flukes mature in human intestines, and eggs are passed with stools. Most individuals infected with intestinal flukes are asymptomatic. In heavy *F. buski* infection, diarrhea, abdominal pain, and malabsorption may be encountered. Heavy infection with *H. heterophyes* may be associated with abdominal pain and mucous diarrhea. The diagnosis is established by detection of the characteristically shaped ova in stool samples. The drug of choice for treatment is praziquantel (Table 222-2).

LUNG FLUKES

Infection with the lung fluke *Paragonimus westermani* and related species (e.g., *P. africanus*) is endemic in many parts of the world, excluding North America and Europe. Endemicity is particularly noticeable in West Africa, Central and South America, and Asia. In nature, the reservoir hosts of *P. westermani* are wild and domestic felines. In Africa, *P. africanus* has been found in other species, such as dogs. Adult lung flukes, which are 7 to 12 mm in length, are found encapsulated in the lungs of infected persons.

In rare circumstances, flukes are found encysted in the central nervous system (cerebral paragonimiasis) or abdominal cavity. Humans acquire lung fluke infection by ingesting infective metacercariae encysted in the muscles and viscera of crayfish and freshwater crabs. In endemic areas, these crustaceans are consumed either raw or pickled. Once the organisms reach the duodenum, they excyst, penetrate the gut wall, and travel through the peritoneal cavity, diaphragm, and pleural space to reach the lungs. Mature flukes are found in the bronchioles surrounded by cystic lesions. Parasite eggs are either expectorated with sputum or swallowed and passed to the outside environment with feces. The life cycle is completed in snails and freshwater crustacea.

When maturing flukes lodge in lung tissues, they cause hemorrhage and necrosis, resulting in cyst formation. The adjacent lung parenchyma shows evidence of inflammatory infiltration, predominantly by eosinophils. Cysts usually measure 1 to 2 cm in diameter and may contain 1 or 2 worms each. With the onset of oviposition, cysts usually rupture in adjacent bronchioles -- an event allowing ova to exit from the human host. Older cysts develop thickened walls, which may undergo calcification. During the active phase of paragonimiasis, lung tissues surrounding parasite cysts may contain evidence of pneumonia, bronchitis, bronchiectasis, and fibrosis.

Pulmonary paragonimiasis is particularly symptomatic in persons with moderate to heavy infection. Productive cough with brownish sputum or frank hemoptysis associated with peripheral blood eosinophilia is usually the presenting feature. Chest examination may reveal signs of pleurisy. In chronic cases, bronchitis or bronchiectasis may predominate, but these conditions rarely proceed to lung abscess. Imaging of the lungs demonstrates characteristic features, including patchy densities, cavities, pleural effusion, and ring shadows. Cerebral paragonimiasis presents as either space-occupying lesions or epilepsy. Pulmonary paragonimiasis is diagnosed by the detection of parasite ova in sputum and/or stools. Serology is of considerable help in egg-negative cases and in cerebral paragonimiasis. The drug of choice for treatment is praziquantel (Table 222-2). Other medical or surgical management may be needed for pulmonary or cerebral lesions.

CONTROL AND PREVENTION OF TISSUE FLUKES

For residents of nonendemic areas who are visiting an endemic region, the only effective preventive measure is to avoid ingestion of local plants, fish, or crustaceans; if their ingestion is necessary, they should be washed or cooked thoroughly. Instruction on water and food preparation and consumption should be included in physicians' advice to travelers (Chap. 123). Interruption of transmission among residents of endemic areas depends on avoiding ingestion of the infective stage of the helminths and appropriate disposal of feces and sputum to prevent the hatching of eggs in the environment. These two approaches rely greatly on socioeconomic development and health education. In countries where economic progress has resulted in financial and social improvements, transmission has decreased. The third approach to control in endemic communities entails selective use of chemotherapy for individuals posing the highest risk of transmission -- i.e., those with heavy infections. The availability of praziquantel -- a broad-spectrum, safe, and effective antihelminthic agent -- provides a means for reducing the reservoirs of infection in human populations. However, the existence of most of these helminths as zoonoses in several animal species complicates control

efforts.

223. CESTODES - *A. Clinton White, Jr.*, *Peter F. Weller*

Cestodes, or tapeworms, are segmented worms. The adults reside in the gastrointestinal tract, but the larvae can be found in almost any organ. Human tapeworm infections can be divided into two major clinical groups. In one group, humans are the definitive hosts, and the adult tapeworms live in the gastrointestinal tract (*Taenia saginata*, *Diphyllobothrium*, *Hymenolepis*, and *Dipylidium caninum*). In the other, humans are intermediate hosts, and larval-stage parasites are present in the tissues. Diseases in this category include echinococcosis, sparganosis, and coenurosis. For *T. solium*, the human may be either the definitive or the intermediate host.

The ribbon-shaped tapeworm attaches to the intestinal mucosa by means of sucking cups or grooves located on the head (scolex). Behind the scolex is a short, narrow neck from which proglottids (segments) form. As each proglottid matures, it is displaced further back from the neck by the formation of new, less mature segments. The progressively elongating chain of attached proglottids, called the *strobila*, constitutes the bulk of the tapeworm. The length varies among species. In some, the tapeworm may consist of more than 1000 proglottids and may be several meters long. As each proglottid becomes gravid, eggs are released. Since eggs of the different *Taenia* species are morphologically identical, differences in the morphology of the scolex or proglottids provide the basis for diagnostic identification to the species level. Most human tapeworms require at least one intermediate host for complete larval development. After ingestion by an intermediate host, an egg releases the larval oncosphere, which penetrates the intestinal mucosa. The oncosphere migrates to tissues and develops into an encysted form known as a *cysticercus* (single scolex), a *coenurus* (multiple scolices), or a *hydatid* (cyst with daughter cysts, each containing several protoscolices). Ingestion by the definitive host of tissues containing a cyst enables a scolex to develop into a tapeworm.

TAENIASIS SAGINATA

The beef tapeworm *T. saginata* occurs in all countries where raw or undercooked beef is eaten. It is most prevalent in sub-Saharan African and Middle Eastern countries.

Etiology and Pathogenesis Humans are the only definitive host for the adult stage of *T. saginata*. This tapeworm, which can reach 8 m in length, inhabits the upper jejunum and has a scolex with four prominent suckers and 1000 to 2000 proglottids. Each gravid segment has 15 to 30 uterine branches (in contrast to 8 to 12 for *T. solium*). The eggs are indistinguishable from those of *T. solium*; each measures 30 to 40 um and has a thick brown striated shell containing the embryo. Eggs deposited on vegetation can live for months to years until they are ingested by cattle or other herbivores. The embryo released after ingestion invades the intestinal wall and is carried to striated muscle, where it transforms into a cysticercus. When ingested in raw or undercooked beef, this form can infect humans. After the cysticercus is ingested, it takes about 2 months for an adult worm to develop.

Clinical Manifestations Patients become aware of the infection most commonly by noting passage of proglottids in their feces. The proglottids are often motile, and patients may experience perianal discomfort when proglottids are discharged. Mild

abdominal pain or discomfort, nausea, change in appetite, weakness, and weight loss can occur with *T. saginata* infection.

Diagnosis The diagnosis is made by the detection of eggs or proglottids in the stool. Eggs may also be present in the perianal area; thus, if proglottids or eggs are not found in the stool, the perianal region should be examined with use of a cellophane-tape swab (as in pinworm infection). Distinguishing *T. saginata* from *T. solium* requires examination of mature proglottids or the scolex. Serologic tests are not helpful diagnostically. Eosinophilia and elevated levels of serum IgE may be detected.

TREATMENT

A single dose of praziquantel (5 to 10 mg/kg) is highly effective.

Prevention The major method of preventing infection is the adequate cooking of beef; exposure to temperatures as low as 56°C for 5 min will destroy cysticerci. Refrigeration or salting for long periods or freezing at-10°C for 9 days also kills cysticerci in beef. General preventive measures include inspection of beef and proper disposal of human feces.

TAENIASIS SOLIUM AND CYSTICERCOSIS

The pork tapeworm *T. solium* can cause two distinct forms of infection. The form that develops depends on whether humans are infected with adult tapeworms in the intestine or with larval forms in the tissues (cysticercosis). Humans are the only definitive hosts for *T. solium*; pigs are the usual intermediate hosts, although dogs, cats, and sheep may harbor the larval forms. *T. solium* exists worldwide but is most prevalent in Latin America, Africa, South and Southeast Asia, and eastern Europe. Cysticercosis occurs in industrialized nations largely as a result of the immigration of infected persons from endemic areas.

Etiology and Pathogenesis The adult tapeworm generally resides in the upper jejunum. Its globular scolex attaches by both sucking disks and two rows of hooklets. Often only one adult worm is present, but that worm may live for years. The tapeworm, usually about 3 m in length, may have as many as 1000 proglottids, each of which produces up to 50,000 eggs. Groups of three to five proglottids are generally released and excreted into the feces, and the eggs in these proglottids are infective for both humans and animals. The eggs may survive in the environment for several months. After ingestion by the intermediate host, eggs embryonate, penetrate the intestinal wall, and are carried to many tissues, with a predilection for striated muscle of the neck, tongue, and trunk. Within 60 to 90 days, the encysted larval stage develops. These cysticerci can survive for long periods. Humans acquire infections that lead to intestinal tapeworms by ingesting undercooked pork containing cysticerci. Infections that cause human cysticercosis follow the ingestion of *T. solium* eggs, usually from fecally contaminated food. Autoinfection may occur if an individual with an egg-producing tapeworm ingests eggs derived from his or her own feces.

Clinical Manifestations Intestinal infections with *T. solium* may be asymptomatic. Epigastric discomfort, nausea, a sensation of hunger, weight loss, and diarrhea are

infrequent. Fecal passage of proglottids may be noted by patients.

In cysticercosis, the clinical manifestations are entirely different. Cysticerci can be found anywhere in the body, most commonly in the brain and the skeletal muscle. The clinical presentation of cysticercosis depends on the number and location of cysticerci as well as the extent of associated inflammatory responses or scarring. Neurologic manifestations are the most common. When inflammation surrounds cysticerci in the brain parenchyma, seizures are frequent. These seizures may be generalized, focal, or Jacksonian. Hydrocephalus results from obstruction of cerebrospinal fluid (CSF) flow by cysticerci and accompanying inflammation or by CSF outflow obstruction from arachnoiditis. Signs of increased intracranial pressure, including headache, nausea, vomiting, changes in vision, dizziness, ataxia, or confusion, are often evident. Patients with hydrocephalus may develop papilledema or display altered mental status. When cysticerci develop at the base of the brain or in the subarachnoid space, they cause chronic meningitis or arachnoiditis, communicating hydrocephalus, or strokes.

Diagnosis The diagnosis of intestinal *T. solium* infection is made by the detection of eggs or proglottids, as described for *T. saginata*. In cysticercosis, diagnosis can be difficult. A consensus conference has proposed absolute, major, minor, and epidemiologic criteria for diagnosis (Table 223-1). Diagnostic certainty is possible only with definite demonstration of the parasite (absolute criteria). This task can be accomplished by histologic observation of the parasite in excised tissue, by funduscopic visualization of the parasite in the eye (in the anterior chamber, vitreous, or subretinal spaces), or by neuroimaging studies demonstrating cystic lesions containing a scolex. In most cases, diagnostic certainty is not possible. Instead, a clinical diagnosis is made on the basis of a combination of clinical presentation, radiographic studies, serologic tests, and exposure history.

Neuroimaging findings suggestive of neurocysticercosis constitute the primary major diagnostic criterion. These findings include cystic lesions with or without enhancement (e.g., ring enhancement), one or more calcifications (which may also have associated enhancement), or focal enhancing lesions. Cysticerci in the brain parenchyma are usually 5 to 10 mm in diameter and rounded. Cystic lesions in the subarachnoid space or fissures may enlarge up to 5 cm in diameter and may be lobulated. For cysticerci within the subarachnoid space or ventricles, the walls may be very thin and the cyst fluid is often isodense withCSF. Thus, obstructive hydrocephalus or enhancement of the basilar meninges may be the only finding on computed tomography (CT) in neurocysticercosis. Cysticerci in the ventricles or subarachnoid space are usually visible to an experienced neuroradiologist on magnetic resonance imaging (MRI) or with intraventricular contrast injection. CT is more sensitive than MRI in identifying calcified lesions, whereas MRI is better for identifying cystic lesions and enhancement. Typical cigar-shaped calcifications in muscle are a second major diagnostic criterion.

The third major diagnostic criterion is detection of specific antibodies to cysticerci. While most tests employing unfractionated antigen have high rates of false-positive and -negative results, this problem can be overcome by using the more specific immunoblot assay. An immunoblot assay using lentil-lectin purified glycoproteins has>99% specificity and is highly sensitive. However, patients with single intracranial lesions or with calcifications may be seronegative. With this assay, serum samples provide greater

diagnostic sensitivity thanCSF. However, CSF may be useful when only unfractionated antigens are used.

Minor diagnostic criteria include the presence of subcutaneous nodules, punctate soft tissue or intracranial calcifications, clinical manifestations suggestive of neurocysticercosis (such as seizures, hydrocephalus, or altered mental status), or disappearance of lesions in conjunction with anticysticercal drug therapy. Epidemiologic criteria include current or prior residence in an endemic area, frequent travel to an endemic area, or exposure to a tapeworm carrier or household member infected with *T. solium*. Diagnosis is confirmed in patients with a combination of either two major criteria or one major criterion with two minor criteria and one epidemiologic criterion. The fulfillment of one major criterion and two other criteria or of three minor criteria with epidemiologic exposure supports a probable diagnosis. While theCSF is usually abnormal in neurocysticercosis, CSF abnormalities are not pathognomonic. Patients may have CSF pleocytosis with a predominance of lymphocytes, neutrophils, or eosinophils. The protein level in CSF may be elevated; the glucose concentration is usually normal but may be depressed.

TREATMENT

Intestinal *T. solium* infection is treated with a single dose of praziquantel (5 to 10 mg/kg). However, praziquantel can evoke an inflammatory response in the central nervous system if concomitant cryptic cysticercosis is present.

The management of neurocysticercosis focuses primarily on symptomatic treatment of seizures or hydrocephalus. Seizures can usually be controlled with anticonvulsants. If parenchymal lesions resolve without development of calcifications and patients remain free of seizures, anticonvulsant therapy can usually be discontinued after 2 years. Four placebo-controlled trials failed to identify any clinical advantage of antiparasitic drugs for parenchymal neurocysticercosis. However, trends toward faster resolution of neuroradiologic abnormalities were observed. Thus, some authorities favor use of antiparasitic drugs, including praziquantel (50 to 60 mg/kg daily in three divided doses for 15 days or 100 mg/kg in three doses given over a single day) or albendazole (15 mg/kg per day for 8 to 28 days). Both agents may exacerbate the inflammatory response around the dying parasite, exacerbating seizures or hydrocephalus. Thus, patients receiving these drugs should be carefully monitored. High-dose glucocorticoids can be used during treatment or if symptoms worsen. Since glucocorticoids induce first-pass metabolism of praziquantel and may decrease its antiparasitic effect, cimetidine should be coadministered to inhibit praziquantel metabolism.

For patients with hydrocephalus, the emergent reduction of intracranial pressure is the mainstay of therapy. In the case of obstructive hydrocephalus, this task requires either a diverting procedure, such as ventriculoperitoneal shunting, or removal of the cysticerci by craniotomy or via ventriculoscopy. Historically, shunts have usually failed. However, low failure rates have been attained with treatment with antiparasitic drugs or chronic glucocorticoids or with use of flow-sensitive shunts. In patients with subarachnoid cysts, glucocorticoids are needed to reduce arachnoiditis and accompanying vasculitis. Patients may benefit from prolonged courses of antiparasitic drugs and shunting for hydrocephalus. In patients with elevated intracranial pressure due to multiple inflamed

lesions, glucocorticoids are the mainstay of therapy, and antiparasitic drugs should be avoided until the elevated pressure resolves. For ocular and spinal medullary lesions, drug-induced inflammation may cause irreversible damage. Most patients should be managed surgically, although case reports have described cures with medical therapy.

Prevention Measures for the prevention of intestinal *T. solium* infection consist of the application to pork of precautions similar to those described above for beef with regard to *T. saginata* infection. The prevention of cysticercosis involves minimizing the opportunities for ingestion of fecally derived eggs by means of good personal hygiene, effective fecal disposal, and treatment and prevention of human intestinal infections.

ECHINOCOCCOSIS

Echinococcosis is an infection of humans caused by the larval stage of *Echinococcus granulosus*, *E. multilocularis*, or *E. vogeli*. *E. granulosus*, which produces unilocular cystic lesions, is prevalent in areas where livestock is raised in association with dogs. This tapeworm species is found in Australia, Argentina, Chile, Africa, eastern Europe, the Middle East, New Zealand, and the Mediterranean region, particularly Lebanon and Greece. *E. multilocularis*, which causes multilocular alveolar lesions that are locally invasive, is found in Alpine, sub-Arctic, or Arctic regions, including Canada, the United States, and central and northern Europe and Asia. *E. vogeli* causes polycystic hydatid disease and is found only in Central and South America. Like other cestodes, echinococcal species have both intermediate and definitive hosts. The definitive hosts are dogs that pass eggs in their feces. Cysts develop in the intermediate hosts -- sheep, cattle, humans, goats, camels, and horses for *E. granulosus* and mice and other rodents for *E. multilocularis* -- after the ingestion of eggs. When a dog ingests beef or lamb containing cysts, the life cycle is completed.

Etiology The small (5 mm long) adult *E. granulosus* worm, which lives for 5 to 20 months in the jejunum of dogs, has only three proglottids -- one immature, one mature, and one gravid. The gravid segment splits to release eggs that are morphologically similar to *Taenia* eggs and are extremely hardy. After humans ingest the eggs, embryos escape from the eggs, penetrate the intestinal mucosa, enter the portal circulation, and are carried to various organs, most commonly the liver and lungs. Larvae develop into fluid-filled unilocular hydatid cysts that consist of an external membrane and an inner germinal layer. Daughter cysts develop from the inner aspect of the germinal layer, as do germinating cystic structures called *brood capsules*. New larvae, called *protoscolices*, develop in large numbers within the brood capsule. The cysts expand slowly over a period of years.

The life cycle of *E. multilocularis* is similar except that small rodents serve as the intermediate hosts. The cyst of *E. multilocularis*, however, is quite different in that the larval form remains in the proliferative phase, the hydatid cyst is always multilocular, and vesicles progressively invade the host tissue by peripheral extension of processes from the germinal layer.

Clinical Manifestations Slowly enlarging echinococcal cysts generally remain asymptomatic until their expanding size or their space-occupying effect in an involved organ elicits symptoms. The liver and the lungs are the most common sites of these

cysts. Since a period of years elapses before cysts enlarge sufficiently to cause symptoms, they may be discovered incidentally on a routine x-ray or ultrasound study.

Patients with hepatic echinococcosis who are symptomatic most often present with abdominal pain or a palpable mass in the right upper quadrant. Compression of a bile duct or leakage of cyst fluid into the biliary tree may mimic recurrent cholelithiasis, and biliary obstruction can result in jaundice. Rupture of or episodic leakage from a hydatid cyst may produce fever, pruritus, urticaria, eosinophilia, or anaphylaxis. Pulmonary hydatid cysts may rupture into the bronchial tree or peritoneal cavity and produce cough, chest pain, or hemoptysis. Rupture of hydatid cysts may lead to multifocal dissemination of protoscolices, which can form additional cysts. Rupture can occur spontaneously or at surgery. Other presentations are due to the involvement of bone (invasion of the medullary cavity with slow bone erosion producing pathologic fractures), the central nervous system (space-occupying lesions), and the heart (conduction defects, pericarditis).

The cysts of *E. multilocularis* characteristically present as a slowly growing hepatic tumor, with progressive destruction of the liver and extension into vital structures. Patients commonly complain of upper quadrant and epigastric pain, and obstructive jaundice may be apparent. A minority of patients experience the metastasis of lesions to the lung and brain.

Diagnosis Radiographic and related imaging studies are important in detecting and evaluating echinococcal cysts. Plain films will define pulmonary cysts -- usually as rounded irregular masses of uniform density -- but may miss cysts in other organs unless there is cyst wall calcification (as occurs in the liver).MRI,CT, and ultrasound reveal well-defined cysts with thick or thin walls. When older cysts contain a layer of hydatid sand that is rich in accumulated scolices, these imaging methods may detect this fluid layer of different density. However, the most pathognomonic finding, if demonstrable, is that of daughter cysts within the larger cyst. This finding, like eggshell or mural calcification on CT, is indicative of *E. granulosus* infection and helps to distinguish the cyst from carcinomas, bacterial or amebic liver abscesses, or hemangiomas. CT of alveolar hydatid cysts reveals indistinct solid masses with central necrosis and plaquelike calcifications.

A specific diagnosis can be made by the examination of aspirated fluids for scoliceal hooklets, but diagnostic aspiration is not usually recommended because of the risk of fluid leakage resulting in either dissemination of infection or anaphylactic reactions. Serodiagnostic assays can be useful, although a negative test does not exclude the diagnosis of echinococcosis. Cysts in the liver elicit positive antibody responses in ~90% of cases, whereas up to 50% of individuals with cysts in the lungs are seronegative. Detection of antibody to specific echinococcal antigens by immunoblotting has the highest degree of specificity.

TREATMENT

Therapy for echinococcosis is based on considerations of the size, location, and manifestations of cysts and the overall health of the patient. Surgery has traditionally been the principal definitive method of treatment; *E. granulosus* cysts are excised, or

tissue containing *E. multilocularis* cysts is resected. Risks at surgery from leakage of fluid include anaphylaxis and dissemination of infectious scolices. The latter complication has been minimized by the instillation of scolicidal solutions such as hypertonic saline or ethanol, which may cause hypernatremia, intoxication, or sclerosing cholangitis. Albendazole, which is active against *Echinococcus*, should be administered adjunctively, beginning before resection and continuing for several weeks for *E. granulosus* and for up to 2 years for *E. multilocularis*. *P*ercutaneous *a*spiration, *i*nfusion of scolicidal agents, and *r*easpiration (PAIR) can be used instead of surgery in many cases of cystic echinococcosis. PAIR is contraindicated for superficially located cysts (because of the risk of rupture), for cysts with multiple thick internal septal divisions (honeycombing pattern), and for cysts communicating with the biliary tree. Therapy with albendazole (15 mg/kg daily in two divided doses) should be initiated at least 4 days before the procedure and continued for at least 4 weeks afterward. Ultrasound- orCT-guided aspiration allows confirmation of the diagnosis by demonstration of protoscolices in the aspirate. Either alcohol or hypertonic saline should then be infused. Daughter cysts within the primary cyst may need to be punctured separately. In experienced hands, this approach yields rates of cure and relapse equivalent to those following surgery, with less perioperative morbidity and shorter hospitalization. Medical therapy with albendazole alone for 12 weeks to 6 months results in cure in ~30% of cases and improvement in another 50%. Many of the failures are subsequently treated successfully with PAIR or additional courses of medical therapy. Response to treatment is best assessed by serial imaging studies with attention to cyst size and consistency.

Prevention In endemic areas, echinococcosis can be prevented by administering praziquantel to infected dogs, by denying dogs access to infected animals, or by vaccinating sheep. Limitation of the number of stray dogs is helpful in reducing the prevalence of infection among humans.

HYMENOLEPIASIS NANA

Infection with *Hymenolepis nana*, the dwarf tapeworm, is the most common of all the cestode infections. *H. nana* is endemic in both temperate and tropical regions of the world. Infection is spread by fecal/oral contamination and is common among institutionalized children.

Etiology and Pathogenesis *H. nana* is the only cestode of humans that does not require an intermediate host. Both the larval and adult phases take place in the human. The adult, the smallest tapeworm parasitizing humans, is about 2 cm long and dwells in the proximal ileum. Proglottids, which are quite small and are rarely seen in the stool, release spherical eggs 30 to 44 um in diameter, each of which contains an oncosphere with six hooklets. The eggs are immediately infective and are unable to survive in the external environment for more than 10 days. *H. nana* can also be acquired by the ingestion of infected insects (especially larval meal-worms and larval fleas). When the egg is ingested by a new host, the oncosphere is freed and penetrates the intestinal villi, becoming a cysticercoid larva. Larvae migrate back into the intestinal lumen, attach to the mucosa, and mature over 10 to 12 days into adult worms. Eggs may also hatch before passing into the stool, causing internal autoinfection with increasing numbers of intestinal worms. Although the life span of adult *H. nana* is only about 4 to 10 weeks, the autoinfection cycle perpetuates the infection.

Clinical Manifestations *H. nana* infection, even with many intestinal worms, is usually asymptomatic. When infection is intense, anorexia, abdominal pain, and diarrhea develop.

Diagnosis Infection is diagnosed by the finding of eggs in the stool.

TREATMENT

Praziquantel (25 mg/kg once) is the treatment of choice, since it acts against both the adult worms and the cysticercoids in the intestinal villi.

Prevention Good personal hygiene and improved sanitation can eradicate the disease. Epidemics have been controlled by mass chemotherapy coupled with improved hygiene.

HYMENOLEPIASIS DIMINUTA

Hymenolepis diminuta, a cestode of rodents, occasionally infects small children, who ingest the adult worm in uncooked cereal foods contaminated by fleas and other insects in which larvae develop. Infection is usually asymptomatic and is diagnosed by the detection of eggs in the stool. Treatment with praziquantel results in cure in most cases.

DIPHYLLOBOTHRIASIS

Diphyllobothrium latum and other *Diphyllobothrium* species are found in the lakes, rivers, and deltas of the northern hemisphere, Central Africa, and Chile.

Etiology and Pathogenesis The adult worm, the longest tapeworm (up to 25 m), attaches to the ileal and occasionally to the jejunal mucosa by its suckers, which are located on its elongated scolex. The adult worm has 3000 to 4000 proglottids, which release approximately 1 million eggs daily into the feces. If an egg reaches water, it hatches and releases a free-swimming embryo that can be eaten by small freshwater crustaceans (*Cyclops* or *Diaptomus* species). After an infected crustacean containing a developed procercoid is swallowed by a fish, the larva migrates into the fish's flesh and grows into a plerocercoid, or sparganum larva. Humans acquire the infection by ingesting infected raw fish. Within 3 to 5 weeks, the tapeworm matures into an adult in the human intestine.

Clinical Manifestations Most *D. latum* infections are asymptomatic, although manifestations may include transient abdominal discomfort, diarrhea, vomiting, weakness, and weight loss. Occasionally, infection can cause acute abdominal pain and intestinal obstruction; in rare cases cholangitis or cholecystitis may be produced by migrating proglottids. Because the tapeworm absorbs large quantities of vitamin B_{12} and interferes with ileal B_{12}absorption, vitamin B_{12}deficiency can develop. Up to 2% of infected patients, especially the elderly, have megaloblastic anemia resembling pernicious anemia and may exhibit neurologic sequelae of B_{12}deficiency.

Diagnosis The diagnosis is made readily by the detection of the characteristic eggs in

the stool. The eggs possess a single shell with an operculum at one end and a knob at the other. Mild to moderate eosinophilia may be detected.

TREATMENT

Praziquantel (5 to 10 mg/kg once) is highly effective. Parenteral vitamin B_{12}should be given if B_{12}deficiency is manifest.

Prevention Infection can be prevented by heating fish to 54°C for 5 min or by freezing it at-18°C for 24 h. Placing fish in brine with a high salt concentration for long periods kills the eggs.

DIPYLIDIASIS

Dipylidium caninum, a common tapeworm of dogs and cats, may accidentally infect humans. Dogs, cats, and occasionally humans become infected by ingesting fleas harboring cysticercoids. Children are more likely to become infected than adults. Most infections are asymptomatic, but abdominal pain, diarrhea, anal pruritus, urticaria, eosinophilia, or passage of segments in the stool may occur. The diagnosis is made by the detection of proglottids in the stool. As in *D. latum* infection, therapy consists of praziquantel. Prevention requires anthelmintic treatment and flea control for pet dogs or cats.

SPARGANOSIS

Humans can be infected by the sparganum, or plerocercoid larva, of a diphyllobothrid tapeworm of the genus *Spirometra*. Infection can be acquired by the consumption of water containing infected *Cyclops*; by the ingestion of infected snakes, birds, or mammals; or by the application of infected flesh as poultices. The worm migrates slowly in tissues, and infection commonly presents as a subcutaneous swelling. Periorbital tissues can be involved, and ocular sparganosis may destroy the eye. Surgical excision is used to treat localized sparganosis.

COENUROSIS

This rare infection of humans by the larval stage (coenurus) of the dog tapeworm *Taenia multiceps* or *T. serialis* results in a space-occupying cystic lesion. As in cysticercosis, involvement of the central nervous system and subcutaneous tissue is most common. Both definitive diagnosis and treatment require surgical excision of the lesion. Chemotherapeutic agents generally are not effective.

PART EIGHT -DISORDERS OF THE CARDIOVASCULAR SYSTEM

SECTION 1 -DIAGNOSIS

224. APPROACH TO THE PATIENT WITH HEART DISEASE - *Eugene Braunwald*

The symptoms caused by heart disease result most commonly from myocardial ischemia, from disturbance of the contraction and/or relaxation of the myocardium, from obstruction to blood flow, or from an abnormal cardiac rhythm or rate. Ischemia is manifest most frequently as chest discomfort, while reduction of the pumping ability of the heart commonly leads to weakness and fatigability or, when severe, produces cyanosis, hypotension, syncope, and elevated intravascular pressure behind a failing ventricle. The latter results in abnormal fluid accumulation, which in turn leads to dyspnea, orthopnea, and systemic or pulmonary edema. Obstruction to blood flow, as in valvular stenosis, can cause symptoms resembling those resulting from congestive heart failure. Cardiac arrhythmias often develop suddenly, and the resulting signs and symptoms -- palpitation, dyspnea, hypotension, presyncope and syncope -- generally occur abruptly and may disappear as rapidly as they develop. Ischemic heart disease, by far the most common form of heart disease in adults, may present with chest discomfort but also as heart failure, tachyarrhythmia, and sudden cardiac death.

Myocardial or coronary function that may be adequate at rest may be inadequate during exertion. Thus a history of chest discomfort and/or dyspnea that appears only during activity is characteristic of heart disease, while the opposite pattern, i.e., the appearance of these symptoms at rest and their remission during exertion, is rarely observed in patients with organic heart disease.

Many patients with cardiocirculatory disease also may be asymptomatic, both at rest and during exertion, but may present an abnormal physical finding, such as a heart murmur, elevated arterial pressure, or an abnormality of the electrocardiogram (ECG) or of the cardiac silhouette on the chest roentgenogram. Patients may exhibit asymptomatic ischemia on an exercise stress test. In some asymptomatic patients the first clinical event may be catastrophic -- sudden cardiac death, acute myocardial infarction, or stroke.

Diseases of the heart and circulation are so common and the laity is so well acquainted with the major symptoms resulting from these disorders that patients, and occasionally physicians, erroneously attribute many noncardiac complaints to cardiovascular disease. The combination of the widespread fear of heart disease with the deep-seated emotional connotations concerning this organ's function results in the frequent development of symptoms that mimic those of organic disease in persons with normal cardiovascular systems. The unraveling of symptoms and signs due to organic heart disease from those not directly related is an important and challenging task in such patients.

Patients in whom heart disease has been confirmed, especially those who have experienced a major cardiovascular event such as a myocardial infarction or a serious arrhythmia, are often frightened and anxious about hospital discharge and resuming normal activity, including sexual relations. Attention to these matters is vital in the care

of cardiac patients.

Dyspnea, one of the cardinal manifestations of heart failure, is not limited to patients with heart disease but is also observed in conditions as diverse as pulmonary disease, marked obesity, and anxiety (Chap. 32). Similarly, chest discomfort may result from a variety of causes other than myocardial ischemia (Chap. 13). Whether heart disease is responsible for these symptoms can frequently be determined by carrying out a careful clinical examination. Noninvasive testing using electrocardiography at rest and during exercise (Chap. 226), echocardiography (Chap. 227), roentgenography, and myocardial imaging usually provides important additional information to permit the correct interpretation of symptoms; more specialized invasive examinations (catheterization and angiography;Chap. 228) are occasionally necessary.

DIAGNOSIS

As outlined by the New York Heart Association, the elements of a complete cardiac diagnosis include consideration of the following:

1. *The underlying etiology*. Is the disease congenital, infectious, hypertensive, or ischemic in origin?

2. *The anatomic abnormalities*. Which chambers are involved? Are they hypertrophied, dilated, or both? Which valves are affected? Are they regurgitant and/or stenotic? Is there pericardial involvement? Has there been a myocardial infarction?

3. *The physiologic disturbances*. Is an arrhythmia present? Is there evidence of congestive heart failure or of myocardial ischemia?

One example may serve to illustrate the importance of establishing a complete diagnosis. The identification of myocardial ischemia as the etiology of a patient's exertional chest discomfort is of great clinical importance. However, the simple recognition of ischemia is insufficient to formulate a therapeutic strategy or prognosis until the underlying anatomic abnormalities responsible for the myocardial ischemia, e.g., coronary atherosclerosis or aortic stenosis, are identified and a judgment made as to whether other physiologic disturbances that cause an imbalance between myocardial oxygen supply and demand, such as severe anemia, thyrotoxicosis, or supraventricular tachycardia, play a contributory role.

The fourth element of the diagnosis involves an assessment of *functional disability*. How strenuous is the physical activity required to elicit symptoms? The functional classification provided by the New York Heart Association has been found to be useful (Table 224-1).

The establishment of a correct and complete cardiac diagnosis often commences with the history and physical examination (Chap. 225). Indeed the clinical examination remains the basis for the diagnosis of a wide variety of disorders (Table 224-2). The clinical examination may then be supplemented by four types of laboratory tests: (1)ECG(Chap. 226); (2) chest roentgenogram; (3) noninvasive graphic examinations [echocardiogram, radionuclide and imaging techniques] (Chap. 227); and occasionally

(4) specialized invasive examinations, i.e., cardiac catheterization, angiocardiography, and coronary angiography (Chap. 228).

In the diagnostic process, the results obtained from each of these several modalities should be analyzed independently of one another as well as together. Only in this way can one avoid overlooking a subtle, though important, finding. For example, anECGshould be obtained in every patient suspected of heart disease. It may provide the critical clue in establishing the correct diagnosis, e.g., the finding of a mild atrioventricular conduction disturbance in a patient with unexplained syncope, even when all other methods of examination reveal no abnormal findings, can be the clue that advanced heart block and asystole might be the cause and can dictate electrophysiologic testing. On the other hand, when combined intelligently with the results of other methods of examination, the ECG may provide essential confirmatory data. Thus, the knowledge that a patient has an apical diastolic rumbling murmur may direct particular attention to the P waves, and the recognition of electrocardiographic left atrial enlargement supports the suggestion that the murmur is caused by mitral stenosis. The diagnosis can then be confirmed by echocardiography, a technique that can also determine the severity of the obstruction and its effects on pulmonary artery pressure and on right and left ventricular function.

Family History In eliciting the history of a patient with known or suspected cardiovascular disease, particular attention should be directed to the family history. Familial clustering is common in many forms of heart disease. Mendelian transmission of single-gene defects may occur, as in hypertrophic cardiomyopathy (Chap. 238), the Marfan syndrome (Chap. 351), and sudden death associated with a prolonged QT syndrome (Chap. 230). Essential hypertension or coronary atherosclerosis are often polygenic disorders. While familial transmission may be less obvious than in the single-gene disorders, it is also helpful in assessing risk and prognosis. Familial clustering of cardiovascular diseases may occur not only on a genetic basis but also may be related to familial dietary or behavior patterns, such as excessive ingestion of salt or calories or cigarette smoking.

Assessment of Functional Impairment When an attempt is made to determine the severity of functional impairment in a patient with heart disease, it is helpful to ascertain with as much precision as possible the level of activity and the rate at which it is performed before symptoms develop. Thus, breathlessness that occurs after running up two long flights of stairs denotes far less functional impairment than similar symptoms occurring after taking a few steps on the level. Also, the degree of customary physical activity at work and during recreation should be considered. The development of two-flight dyspnea in a marathon runner may be far more significant than the development of one-flight dyspnea in a previously sedentary person. Similarly, the history must include a detailed consideration of the patient's therapeutic regimen. For example, the persistence or development of edema, breathlessness, and other manifestations of heart failure in a patient whose diet is rigidly restricted in sodium content and who is receiving optimal doses of diuretics is far more grave than are similar manifestations in the absence of these measures. In an effort to determine the rate of progression of symptoms, and thereby of the severity of the underlying illness, it may be useful to ascertain what, if any, specific tasks the patient could carry out 1 year earlier that he or she cannot carry out at present.

Electrocardiogram (See also Chap. 226) Although an ECG should be recorded in every patient with known or suspected heart disease, with the exception of the identification of arrhythmias and of acute myocardial infarction, it rarely permits establishment of a specific diagnosis. In the absence of other abnormal findings, electrocardiographic changes must not be overinterpreted. The range of normal electrocardiographic findings is wide, and the tracing can be affected significantly by many noncardiac factors, such as age, body habitus, and serum electrolyte concentrations.

Natural History The natural history of cardiovascular disease must be appreciated. Cardiovascular disorders often present acutely, as in a previously asymptomatic patient with extensive coronary atherosclerosis who develops an acute myocardial infarction or the previously asymptomatic patient with hypertrophic cardiomyopathy whose first clinical manifestation is syncope or even sudden death. However, in both instances, the alert physician may recognize the patient at risk of these complications long before they occur and can often take measures to prevent their occurrence. For example, the patient with acute myocardial infarction may well have had risk factors for atherosclerosis for many years. Had these been recognized, their elimination or reduction might have delayed or even prevented the infarction. Similarly, the patient with hypertrophic cardiomyopathy may have had a heart murmur for years, and a positive family history might have led to an echocardiographic examination and the recognition of the condition and appropriate therapy long before the acute manifestations.

PITFALLS IN CARDIOVASCULAR MEDICINE

Increasing subspecialization in internal medicine and the perfection of advanced diagnostic techniques in cardiology can lead to several undesirable consequences. Examples include:

1. Failure by the *noncardiologist* to recognize important cardiac manifestations of systemic illnesses. Examples of the latter are (a) stroke (atrial fibrillation, mitral stenosis); (b) skeletal muscular dystrophies (associated with cardiomyopathy); (c) hemochromatosis (associated with myocardial infiltration and restrictive cardiomyopathy); (d) congenital deafness (associated with prolonged QT interval and serious cardiac arrhythmias); (e) Raynaud's disease (associated with primary pulmonary hypertension and coronary vasospasm); (f) connective tissue disorders, e.g., the Marfan syndrome, (aortic dilatation and aneurysm, prolapsed mitral valve); (g) hyperthyroidism (heart failure, atrial fibrillation); (h) hypothyroidism (pericardial effusion, coronary artery disease); (i) rheumatoid arthritis (pericarditis, aortic valve disease); (j) scleroderma (cor pulmonale, myocardial fibrosis, pericarditis); (k) systemic lupus erythematosus (valvulitis, myocarditis, pericarditis); and (l) sarcoidosis (arrhythmias, cardiomyopathy). In patients with these and other systemic disorders a cardiovascular examination should be carried out to identify and estimate the severity of cardiovascular involvement.

2. Failure by the cardiologist to recognize underlying systemic disorders, such as those listed above, in patients with a cardiac disorder. Patients with heart disease should be assessed for the frequent *noncardiac* manifestations of systemic disorders with cardiovascular manifestations. For example, Lyme disease should be considered in patients with unexplained fluctuating atrioventricular block. A cardiovascular abnormality

may provide the clue critical to the recognition of some systemic disorders. For instance, unexplained atrial fibrillation may provide the first clue to the diagnosis of thyrotoxicosis.

3. Overreliance on and overutilization of laboratory tests, particularly invasive techniques for the examination of the cardiovascular system. Cardiac catheterization and coronary arteriography (Chap. 228) provide precise diagnostic information under many circumstances. For example, they aid in establishing a specific anatomic diagnosis, which, in turn, may be critical to developing a therapeutic plan in patients with known or suspected ischemic heart disease. Although a great deal of attention has been lavished on these expensive examinations, it should be recognized that they serve to *supplement*, not *supplant*, a careful examination carried out by clinical and noninvasive techniques. A coronary arteriogram should not be carried out in lieu of a careful history in patients with chest pain suspected of having ischemic heart disease. Although coronary arteriography may establish whether the coronary arteries are obstructed, the results often do not provide a definite answer to the question of whether a patient's complaint of chest pain is attributable to coronary arteriosclerosis. Catheterization of the left side of the heart is all too frequently employed to assess patients with valvular heart disease when echocardiographic examination would actually provide more useful information.

Despite the enormous value of these invasive tests in certain circumstances, they entail some small risk to the patient, involve discomfort and substantial cost, and place a strain on existing medical facilities. Therefore, they should be carried out only if, after clinical examination and assessment by noninvasive tests, the results of the invasive examination can be expected to modify the patient's management.

TREATMENT

After a complete diagnosis has been established, a number of therapeutic options are usually available. Several examples may be used to demonstrate some of the principles of cardiovascular therapeutics:

1. In the absence of evidence of heart disease, a clear, definitive statement to that effect should be made and the patient should *not* be asked to return at intervals for repeated examinations. If there is no evidence for disease, such continued attention may lead to the patient developing inappropriate anxiety and fixation on the heart.

2. If there is no evidence of cardiovascular disease but the patient has one or more risk factors for the development of ischemic heart disease (Chap. 242), a plan for their reduction should be developed and the patient should be retested at intervals to assess that he or she is complying and that these risk factors are in fact being reduced.

3. Asymptomatic or mildly symptomatic patients with valvular heart disease that is anatomically severe should be evaluated periodically, every 6 to 12 months, by clinical and noninvasive examinations. Early signs of deterioration of ventricular function can be detected in this manner and in appropriate patients may signify the need for surgical treatment before the development of disabling symptoms, irreversible myocardial damage, and excessive risk of surgical treatment (Chap. 236).

4. It is critical to establish clear criteria for deciding on the form of treatment (medical, percutaneous coronary intervention, or surgical revascularization) in patients with ischemic heart disease (Chap. 244). Mechanical revascularization, i.e., the latter two modalities, represents a major therapeutic advance in the treatment of this most common form of heart disease in developed nations, but these techniques are probably being employed too frequently in the United States; the mere presence of angina pectoris and/or the demonstration of critical coronary arterial narrowing at angiography should not reflexly evoke a decision to treat the patient surgically or by percutaneous coronary intervention. Instead, coronary revascularization should be limited to those patients with ischemic heart disease who have not responded adequately to medical treatment (e.g., intractable angina) or in whom the procedure has been shown to improve the natural history (e.g., three-vessel coronary artery disease with left ventricular dysfunction.)

225. PHYSICAL EXAMINATION OF THE CARDIOVASCULAR SYSTEM - *Robert A. O'Rourke, Eugene Braunwald*

A meticulous physical examination is an often inadequately utilized low-cost method for assessing the cardiovascular system and frequently provides important information for the appropriate selection of additional tests. First, the general physical appearance should be evaluated. The patient may appear tired because of a chronic low cardiac output; the respiratory rate may be rapid in cases of pulmonary venous congestion. Central cyanosis, often associated with clubbing of the fingers and toes, indicates right-to-left cardiac or extracardiac shunting or inadequate oxygenation of blood by the lungs. Cyanosis in the distal extremities, cool skin, and increased sweating result from vasoconstriction in patients with severe heart failure (Chap. 36). Noncardiovascular details can be equally important. For example, infective endocarditis is the likely diagnosis in patients with petechiae, Osler's nodes, and Janeway lesions (Chap. 126).

The blood pressure should be taken in both arms and with the patient supine and upright; the heart rate should be timed for 30 s. Orthostatic hypotension and tachycardia may indicate a reduced blood volume, while resting tachycardia may be due to heart failure.

Careful examination of the optic fundi is essential (Chap. 246), and the retinal vessels may show evidence of systemic hypertension, arteriosclerosis, or embolism. The latter may result from atherosclerosis in larger arteries (e.g., the carotid) or may represent a complication of valvular heart disease (e.g., endocarditis).

Palpation of the peripheral arterial pulses in the upper and lower extremities is necessary to define the adequacy of systemic blood flow and to detect the presence of occlusive arterial lesions. It is also important to examine both legs for evidence of edema, varicose veins, or thrombophlebitis (Chap. 248). The cardiovascular examination includes careful evaluation of both the carotid arterial and the jugular venous pulses, as well as deliberate precordial palpation and attentive cardiac auscultation.

ARTERIAL PRESSURE PULSE

The normal central aortic pulse wave is characterized by a fairly rapid rise to a somewhat rounded peak (Fig. 225-1). The anacrotic shoulder, present on the ascending limb, occurs at the time of peak rate of aortic flow just before maximum pressure is reached. The less steep descending limb is interrupted by a sharp downward deflection, coincident with aortic valve closure, called the *incisura*. As the pulse wave is transmitted peripherally, the initial upstroke becomes steeper, the anacrotic shoulder becomes less apparent, and the incisura is replaced by the smoother dicrotic notch. Accordingly, palpation of a peripheral arterial pulse (e.g., the radial pulse) frequently gives less information than examination of a more central pulse (e.g., the carotid pulse) regarding alterations in left ventricular ejection or aortic valve function. However, certain findings, such as the bisferiens pulse of aortic regurgitation or pulsus alternans, are more evident in peripheral arteries (Fig. 225-2). The carotid pulse is best examined with the sternocleidomastoid muscle relaxed and with the head rotated slightly toward the examiner. In palpating the brachial arterial pulse, the examiner can support the subject's

relaxed elbow with the right arm while compressing the brachial pulse with the thumb. The usual technique is to compress the artery with the thumb or forefinger until the maximum pulse is sensed. Varying degrees of pressure should then be applied while concentrating on the separate phases of the pulse wave. This method, known as *trisection*, is useful for assessing the sharpness of the upstroke, systolic peak, and diastolic slope of the arterial pulse. In most normal persons, a dicrotic wave is not palpable.

A small weak pulse, *pulsus parvus*, is common in conditions with a diminished left ventricular stroke volume, a narrow pulse pressure, and increased peripheral vascular resistance (Fig. 225-2). A *hypokinetic* pulse may be due to hypovolemia, to left ventricular failure, to restrictive pericardial disease, or to mitral valve stenosis. In aortic valve stenosis, the delayed systolic peak, *pulsus tardus*, results from obstruction to left ventricular ejection. In contrast, a large, bounding (*hyperkinetic*) pulse is usually associated with an increased left ventricular stroke volume, a wide pulse pressure, and a decrease in peripheral vascular resistance. This pattern occurs characteristically in patients with an elevated stroke volume, as in complete heart block; with hyperkinetic circulation due to anxiety, anemia, exercise, or fever; or with a rapid runoff of blood from the arterial system (as caused by a patent ductus arteriosus or peripheral arteriovenous fistula). Patients with mitral regurgitation or a ventricular septal defect may also have a bounding pulse, since vigorous left ventricular ejection produces a rapid upstroke in the arterial pulse, even though the duration of systole and the forward stroke volume may be reduced. In aortic regurgitation, the rapidly rising, bounding arterial pulse results from an increased left ventricular stroke volume and an increased rate of ventricular ejection.

The *bisferiens pulse*, which has two systolic peaks, is characteristic of aortic regurgitation (with or without accompanying stenosis) and of hypertrophic cardiomyopathy (Chap. 238). In the latter condition, the pulse wave upstroke rises rapidly and forcefully, producing the first systolic peak ("percussion wave"). A brief decline in pressure follows because of the sudden midsystolic decrease in the rate of left ventricular ejection, when severe obstruction often develops. This pressure trough is followed by a smaller and more slowly rising positive pulse wave ("tidal wave") produced by continued ventricular ejection and by reflected waves from the periphery. The *dicrotic pulse* has two palpable waves, one in systole and one in diastole. It usually denotes a very low stroke volume, particularly in patients with dilated cardiomyopathy.

Pulsus alternans is a pattern in which there is regular alteration of the pressure pulse amplitude, despite a regular rhythm (Fig. 225-2). It is due to alternating left ventricular contractile force, usually indicates severe impairment of left ventricular function, and commonly occurs in patients who also have a loud third heart sound. Pulsus alternans may also occur during or following paroxysmal tachycardia or for several beats following a premature beat in patients without heart disease. In *pulsus bigeminus*, there is also a regular alteration of pressure pulse amplitude, but it is caused by a premature ventricular contraction that follows each regular beat. In *pulsus paradoxus*, the decrease in systolic arterial pressure that normally accompanies the reduction in arterial pulse amplitude during inspiration is accentuated. In patients with pericardial tamponade (Chap. 239), airway obstruction, or superior vena cava obstruction, the decrease in systolic arterial pressure frequently exceeds the normal decrease of 10 mmHg and the peripheral pulse may disappear completely during inspiration.

Simultaneous palpation of the radial and femoral arterial pulses, which normally are virtually coincident, is important to rule out aortic coarctation, in which the latter pulse is weakened and delayed (Chap. 234).

JUGULAR VENOUS PULSE (JVP)

The two main objectives of the examination of the neck veins are inspection of their waveform and estimation of the central venous pressure (CVP). In most patients, the right internal jugular vein is best for both purposes. Usually, the pulsation of the internal jugular vein is greatest when the trunk is inclined by less than 30°. In patients with elevated venous pressure, it may be necessary to elevate the trunk further, sometimes to as much as 90°. When the neck muscles are relaxed, shining a beam of light tangentially across the skin overlying the vein exposes the pulsations of the internal jugular vein. Simultaneous palpation of the left carotid artery aids the examiner in deciding which pulsations are venous and in relating the venous pulsations to their timing in the cardiac cycle.

The normalJVPreflects phasic pressure changes in the right atrium and consists of two or sometimes three positive waves and two negative troughs (Fig. 225-1). The positive presystolic *a* wave is produced by venous distention due to right atrial contraction and is the dominant wave in the JVP, particularly during inspiration. Large *a* waves indicate that the right atrium is contracting against an increased resistance (Fig. 225-3), such as occurs with tricuspid stenosis or more commonly with increased resistance to right ventricular filling (pulmonary hypertension or pulmonic stenosis). Large *a* waves also occur during arrhythmias whenever the right atrium contracts while the tricuspid valve is closed by right ventricular systole. Such "cannon" *a* waves may occur regularly (as during junctional rhythm) or irregularly (as in atrioventricular dissociation with ventricular tachycardia or complete heart block). The *a* wave is absent in patients with atrial fibrillation, and there is an increased delay between the *a* wave and the carotid arterial pulse in patients with first-degree atrioventricular block.

The *c* wave, often observed in theJVP, is a positive wave produced by the bulging of the tricuspid valve into the right atrium during right ventricular isovolumetric systole and by the impact of the carotid artery adjacent to the jugular vein. The *x* descent is due both to atrial relaxation and to the downward displacement of the tricuspid valve during ventricular systole. The *x* descent wave during systole is often accentuated in patients with constrictive pericarditis (Fig. 225-3), but the nadir of this wave is reduced with right ventricular dilation and is often reversed in tricuspid regurgitation. The positive, late systolic *v* wave results from the increasing volume of blood in the right atrium during ventricular systole when the tricuspid valve is closed. Tricuspid regurgitation causes the *v* wave to be more prominent; when tricuspid regurgitation becomes severe, the combination of a prominent *v* wave and obliteration of the *x* descent results in a single large positive systolic wave. After the *v* wave peaks, the right atrial pressure falls because of the decreased bulging of the tricuspid valve into the right atrium as right ventricular pressure declines and the tricuspid valve opens (Fig. 225-3).

This negative descending limb -- the *y* descent of theJVP -- is produced mainly by the opening of the tricuspid valve and the subsequent rapid inflow of blood into the right

ventricle. A rapid, deep *y* descent in early diastole occurs with severe tricuspid regurgitation. A venous pulse characterized by a sharp *y* descent, a deep *y* trough, and a rapid ascent to the baseline is seen in patients with constrictive pericarditis or with severe right-sided heart failure and a high venous pressure. A slow *y* descent in the JVP suggests an obstruction to right ventricular filling, as occurs with tricuspid stenosis or right atrial myxoma.

The right internal jugular is the best vein to use for accurate estimation of theCVP. The sternal angle is used as the reference point, because the center of the right atrium lies approximately 5 cm below the sternal angle in the average patient, regardless of body position. The patient is examined at the optimal degree of trunk elevation for visualization of venous pulsations. The vertical distance between the top of the oscillating venous column and the level of the sternal angle is determined; generally it is less than 3 cm (3 cm + 5 cm= 8 cm blood). The most common cause of a high venous pressure is an elevated right ventricular diastolic pressure. In patients suspected of having right ventricular failure who have a normal CVP at rest, the abdominojugular reflux test may be helpful. The palm of the examiner's hand is placed over the abdomen, and firm pressure is applied for 10 s or more. In normal persons, this maneuver does not alter the jugular venous pressure significantly, but when right heart function is impaired, the upper level of venous pulsation usually increases. A positive abdominojugular test is best defined as an increase inJVPduring 10 s of firm midabdominal compression followed by a rapid drop in pressure of 4 cm blood on release of the compression. The most common cause of a positive test is right-sided heart failure secondary to elevated left heart filling pressures. Also, abdominal compression may elicit the JVP pattern typical of tricuspid regurgitation when the resting pulse wave is normal. *Kussmaul's sign* -- an increase rather than the normal decrease in the CVP during inspiration -- is most often caused by severe right-sided heart failure; it is a frequent finding in patients with constrictive pericarditis or right ventricular infarction.

PRECORDIAL PALPATION

The location, amplitude, duration, and direction of the cardiac impulse usually can be best appreciated with the fingertips. The normal left ventricular apex impulse is located at or medial to the left midclavicular line in the fourth or fifth intercostal space and is a tapping, early systolic outward thrust localized to a point usually less than 2.5 cm in diameter. It is due primarily to recoil of the heart as blood is ejected and should be evaluated with the patient supine and in the left lateral position. Left ventricular hypertrophy results in exaggeration of the amplitude, duration, and often size of the normal left ventricular thrust. The impulse may be displaced laterally and downward into the sixth or seventh interspace, particularly in patients with a left ventricular volume load such as occurs in cases of aortic regurgitation or dilated cardiomyopathy.

Additional abnormal features that are detectable at the left ventricular apex include marked presystolic distention of the left ventricle, which is often accompanied by a fourth heart sound in patients with an excessive left ventricular pressure load or myocardial ischemia/infarction, and a prominent early diastolic rapid-filling wave, which is often accompanied by a third heart sound in patients with left ventricular failure or mitral valve regurgitation (Fig. 225-1). A double systolic apical impulse is often palpable

in patients with hypertrophic cardiomyopathy.

Right ventricular hypertrophy often results in a sustained systolic lift at the lower left parasternal area, which starts in early systole and is synchronous with the left ventricular apical impulse.

Abnormal precordial pulsations occur during systole in patients with left ventricular dyssynergy due to ischemic heart disease or to diffuse myocardial disease from some other cause. These pulsations often occur in patients with a recent myocardial infarction and may be present in some patients only during episodes of angina. They are most commonly felt in the left midprecordium one or two interspaces above and/or 1 to 2 cm medial to the left ventricular apex. A systolic bulge occurring in the region of the apex is difficult to distinguish from the impulse of left ventricular hypertrophy.

A left parasternal lift is frequently present in patients with severe mitral regurgitation. This pulsation occurs distinctly later than the left ventricular apical impulse, is synchronous with the *v* wave in the left atrial pressure curve, and is due to anterior displacement of the right ventricle by an enlarged, expanding left atrium. A similar impulse occurs to the right of the sternum in some patients with severe tricuspid regurgitation and a giant right atrium. Pulsation of the right sternoclavicular joint may indicate a right-sided aortic arch or aneurysmal dilation of the ascending aorta. Pulmonary artery pulsation is often visible and palpable in the second left intercostal space. While it may be normal in children or thin young adults, this pulsation usually denotes pulmonary hypertension, increased pulmonary blood flow, or poststenotic pulmonary artery dilation.

Thrills are palpable, low-frequency vibrations associated with heart murmurs. The systolic murmur of mitral regurgitation may be palpated at the cardiac apex. When the palm of the hand is placed over the precordium, the thrill of aortic stenosis crosses the palm toward the right side of the neck, while the thrill of pulmonic stenosis radiates more often to the left side of the neck. The thrill due to a ventricular septal defect is usually located in the third and fourth intercostal spaces near the left sternal border.

Percussion should be performed in each patient to identify normal or abnormal position of the heart, stomach, and liver. However, in patients with a normal cardiac situs, percussion adds little to careful inspection and palpation in the recognition of cardiac enlargement.

CARDIAC AUSCULTATION

To obtain the most information from cardiac auscultation, the observer should keep in mind several principles: (1) Auscultation should be performed in a quiet room to avoid the distracting noises of normal activity. (2) For optimal auscultation, attention must be focused on the phase of the cardiac cycle during which the auscultatory event is expected to occur. (3) The timing of a heart sound or murmur can be determined accurately from its relation to other observable events in the cardiac cycle -- the carotid arterial pulse, the apical impulse, or theJVP. (4) To define the significance of a cardiac sound or murmur, it is often necessary to observe alterations in its timing or intensity during various physiologic and/or pharmacologic interventions (Table 225-1).

HEART SOUNDS

The major components of heart sounds are vibrations associated with the abrupt acceleration or deceleration of blood in the cardiovascular system. Studies using simultaneous echocardiographic-phonocardiographic recordings indicate that the first and second heart sounds are produced primarily by the closure of the atrioventricular (AV) and semilunar valves and the events that accompany these closures. The intensity of the *first heart sound* (S_1) is influenced by (1) the position of the mitral leaflets at the onset of ventricular systole; (2) the rate of rise of the left ventricular pressure pulse; (3) the presence or absence of structural disease of the mitral valve; and (4) the amount of tissue, air, or fluid between the heart and the stethoscope. S_1 is louder if diastole is shortened because of tachycardia, if atrioventricular flow is increased because of high cardiac output or prolonged because of mitral stenosis, or if atrial contraction precedes ventricular contraction by an unusually short interval, reflected in a short PR interval. The loud S_1 in mitral stenosis usually signifies that the valve is pliable and that it remains open at the onset of isovolumetric contraction because of the elevated left atrial pressure. A soft S_1 may be due to poor conduction of sound through the chest wall, a slow rise of the left ventricular pressure pulse, a long PR interval, or imperfect closure due to reduced valve substance, as in mitral regurgitation. S_1 is also soft when the anterior mitral leaflet is immobile because of rigidity and calcification, even in the presence of predominant mitral stenosis.

Splitting of the two high-pitched components of S_1 by 10 to 30 ms is a normal phenomenon (Fig. 225-1). The first component of S_1 is attributed to mitral valve closure, and the second to tricuspid valve closure. Widening of the S_1 is due most often to complete right bundle branch block and the resulting delay in onset of the right ventricular pressure pulse. Reversed splitting of the S_1, in which the mitral component follows the tricuspid component, may be present in patients with severe mitral stenosis, left atrial myxoma, and left bundle branch block.

Splitting of the *second heart sound* (S_2) into audibly distinct aortic (A_2) and pulmonic (P_2) components occurs normally during inspiration, when the augmented inflow into the right ventricle increases its stroke volume and ejection period and thus delays closure of the pulmonic valve. P_2 is coincident with the incisura of the pulmonary artery pressure curve, which is separated from the right ventricular pressure tracing by an interval termed the "hangout time." The absolute value of this interval reflects the resistance to pulmonary blood flow and the impedance characteristics of the pulmonary vascular bed. This interval is prolonged, and physiologic splitting of S_2 is accentuated, in conditions associated with right ventricular volume overload and a distensible pulmonary vascular bed. However, in patients with an increase in pulmonary vascular resistance, the hangout time is markedly reduced, and narrow splitting of S_2 is present. Splitting that persists with expiration (heard best at the pulmonic area or left sternal border) is usually abnormal when the patient is in the upright position. Such splitting may be due to many causes: delayed activation of the right ventricle (right bundle branch block); left ventricular ectopic beats; a left ventricular pacemaker; prolongation of right ventricular contraction with an increased right ventricular pressure load (pulmonary embolism or pulmonic stenosis); or delayed pulmonic valve closure because of right ventricular volume overload associated with right ventricular failure or diminished impedance of the

pulmonary vascular bed and a prolonged hangout time (atrial septal defect).

In pulmonary hypertension, P_2 is loud, and splitting of the second heart sound may be diminished, normal, or accentuated, depending on the cause of the pulmonary hypertension, the pulmonary vascular resistance, and the presence or absence of right ventricular decompensation. Early aortic valve closure, occurring with mitral regurgitation or a ventricular septal defect, may also produce splitting that persists during expiration. It may also occur with constrictive pericarditis. In patients with an atrial septal defect, the proportion of right atrial filling contributed by the left atrium and the venae cavae varies reciprocally during the respiratory cycle, so that right atrial inflow remains relatively constant. Therefore, the volume and duration of right ventricular ejection are not significantly increased by inspiration, and there is little inspiratory exaggeration of the splitting of S_2. This phenomenon, termed *fixed splitting* of the second heart sound, is of considerable diagnostic value.

A delay in aortic valve closure causing P_2 to precede A_2results in so-called reversed (paradoxic) splitting of S_2. Splitting is then maximal in expiration and decreases during inspiration with the normal delay of pulmonic valve closure. The most common causes of reversed splitting of S_2 are left bundle branch block and delayed excitation of the left ventricle from a right ventricular ectopic beat. Mechanical prolongation of left ventricular systole, resulting in reversed splitting of S_2, may also be caused by severe aortic outflow obstruction, a large aorta-to-pulmonary artery shunt, systolic hypertension, and ischemic heart disease or cardiomyopathy with left ventricular failure. P_2 is normally softer than A_2 in the second left intercostal space; a P_2 that is greater than A_2 in this area suggests pulmonary hypertension, except in patients with atrial septal defect.

The *third heart sound* (S_3) is a low-pitched sound produced in the ventricle 0.14 to 0.16 s after A_2, at the termination of rapid filling. This sound is frequent in normal children and in patients with high cardiac output. However, in patients over 40 years old, an S_3usually indicates impairment of ventricular function,AV valve regurgitation, or other conditions that increase the rate or volume of ventricular filling. The left-sided S_3 is best heard with the bell piece of the stethoscope at the left ventricular apex during expiration and with the patient in the left lateral position. The right-sided S_3 is best heard at the left sternal border or just beneath the xiphoid and is usually louder with inspiration. Often it is accompanied by the systolic murmur of functional tricuspid regurgitation. Third heart sounds often disappear with treatment of heart failure.

An S_3 that is earlier (0.10 to 0.12 s after A_2) and higher-pitched than normal (a pericardial knock) often occurs in patients with constrictive pericarditis (Chap. 239); its presence depends on the restrictive effect of the adherent pericardium, which halts diastolic filling abruptly.

The *opening snap* (OS) is a brief, high-pitched, early diastolic sound, which is usually due to stenosis of an AVvalve, most often the mitral valve. It is generally heard best at the lower left sternal border and radiates well to the base of the heart. The A_2-OS interval is inversely related to the height of the mean left atrial pressure and ranges from 0.04 to 0.12 s. In the second intercostal space, an OS is often confused with P_2. However, careful auscultation will reveal both components of S_2, followed by the OS. The OS of tricuspid stenosis occurs later in diastole than the mitral OS and is often

overlooked in patients with more prominent mitral valve disease.

The *fourth heart sound* (S_4) is a low-pitched, presystolic sound produced in the ventricle during ventricular filling; it is associated with an effective atrial contraction and is best heard with the bell piece of the stethoscope. The sound is absent in patients with atrial fibrillation. The S_4occurs when diminished ventricular compliance increases the resistance to ventricular filling, and it is frequently present in patients with systemic hypertension, aortic stenosis, hypertrophic cardiomyopathy, ischemic heart disease, and acute mitral regurgitation. Most patients with an acute myocardial infarction and sinus rhythm have an audible S_4. The fourth heart sound is frequently accompanied by visible and palpable presystolic distention of the left ventricle. It is loudest at the left ventricular apex when the patient is in the left lateral position and is accentuated by mild isotonic or isometric exercise in the supine position. The right-sided S_4 is present in patients with right ventricular hypertrophy secondary to either pulmonic stenosis or pulmonary hypertension and frequently accompanies a prominent presystolic *a* wave in theJVP.

An S_4frequently accompanies delayedAVconduction even in the absence of clinically detectable heart disease. The incidence of an audible S_4increases with increasing age. Whether an audible S_4 in adults without other evidence of cardiac disease is abnormal remains controversial.

The *ejection sound* is a sharp, high-pitched event occurring in early systole and closely following the first heart sound. Ejection sounds occur in the presence of semilunar valve stenosis and in conditions associated with dilation of the aorta or pulmonary artery. The aortic ejection sound is usually heard best at the left ventricular apex and the second right intercostal space; the pulmonary ejection sound is loudest at the upper left sternal border. The latter, unlike most other right-sided acoustical events, is heard better during expiration.

Nonejection or *midsystolic clicks*, occurring with or without a late systolic murmur, often denote prolapse of one or both leaflets of the mitral valve (Chap. 236). They also may be caused by tricuspid valve prolapse. They probably result from chordae tendineae that are functionally unequal in length on either or bothAVvalves and are heard best along the lower left sternal border and at the left ventricular apex. Systolic clicks may be single or multiple, and they may occur at any time in systole but are usually later than the systolic ejection sound.

HEART MURMURS (See alsoChap. 34)

Cardiac murmurs result from vibrations set up in the bloodstream and the surrounding heart and great vessels as a result of turbulent blood flow, the formation of eddies, and cavitation (bubble formation as a result of sudden decrease in pressure).

The intensity (loudness) of murmurs may be graded from I to VI. A grade I murmur is so faint that it can be heard only with special effort; a grade IV murmur is commonly accompanied by a thrill; and a grade VI murmur is audible with the stethoscope removed from contact with the chest. The configuration of a murmur may be crescendo, decrescendo, crescendo-decrescendo (diamond-shaped), or plateau. The precise time of onset and time of cessation of a murmur depend on the instant in the cardiac cycle at

which an adequate pressure difference between two chambers arises and disappears (Fig. 225-4).

The location on the chest wall where the murmur is best heard and the areas to which it radiates can aid in identifying the cardiac structure from which the murmur originates. For example, the murmur of aortic valve stenosis is usually loudest in the second right intercostal space and radiates to the carotid arteries. By contrast, the murmur of mitral regurgitation is most often loudest at the cardiac apex. It may radiate to the left sternal border and base of the heart when the posterior mitral leaflet is predominantly involved or to the axilla and back when the anterior leaflet is more severely affected. In the latter case, the regurgitant blood is directed toward the posterior left atrial wall.

It is often difficult to classify a cardiac murmur with certainty on the basis of its timing, configuration, location, radiation, pitch, or intensity. However, by noting changes in the characteristics of the murmur during maneuvers that alter cardiac hemodynamics, the auscultator can often identify its correct origin and significance (Table 225-1).

Accentuation of a murmur during inspiration (a maneuver that augments systemic venous return) implies that it originates on the right side of the circulation; expiratory exaggeration has less significance. Prolonged expiratory pressure against a closed glottis (i.e., the Valsalva maneuver) reduces the intensity of most murmurs by diminishing both right and left ventricular filling (i.e., ventricular preload). The systolic murmur associated with *hypertrophic cardiomyopathy* and the late systolic murmur due to *mitral valve prolapse* are exceptions and may be paradoxically accentuated during the Valsalva maneuver. Murmurs due to flow across a normal or obstructed semilunar valve increase in intensity in the cycle following a premature ventricular beat or a long RR interval in atrial fibrillation. In contrast, murmurs due toAV valve regurgitation or a ventricular septal defect do not change appreciably during the beat following a prolonged diastole. Standing, which decreases left ventricular volume, accentuates the murmur of hypertrophic cardiomyopathy and occasionally the murmur due to mitral valve prolapse. Squatting, which increases both venous return and systemic arterial resistance and thus ventricular afterload, increases most murmurs, except those due to hypertrophic cardiomyopathy and mitral regurgitation due to a prolapsed mitral valve, which often decrease. Sustained handgrip exercise, which increases systemic arterial pressure and heart rate, often accentuates the murmurs of mitral regurgitation, aortic regurgitation, and mitral stenosis but usually diminishes those due to aortic stenosis or hypertrophic cardiomyopathy. Pharmacologic interventions include inhalation of amyl nitrite, which reduces systemic arterial pressure and increases blood flow, thereby increasing the intensity of murmurs due to valvular stenosis while diminishing those due to aortic or mitral regurgitation (Table 225-1). Transient external arterial occlusion by the inflation of bilateral arm cuffs to 20 mmHg (2.66 kPa) above systolic blood pressure for 5 s usually intensifies murmurs due to left-sided regurgitant lesions; this method is applicable to almost all patients and does not require administration of any drug.

Systolic Murmurs *Holosystolic (pansystolic) murmurs* are generated when there is flow between two chambers that have widely different pressures throughout systole, such as the left ventricle and either the left atrium or the right ventricle (Fig. 225-4). The pressure gradient occurs early in contraction and lasts until relaxation is almost complete. Therefore, holosystolic murmurs begin before aortic ejection, and at the area of maximal

intensity they begin with S_1 and end after S_2. Holosystolic murmurs accompany mitral or tricuspid regurgitation, ventricular septal defect, and, under certain circumstances, aortopulmonary shunts. Although the typical high-pitched murmur of mitral regurgitation usually continues throughout systole, the shape of the murmur may vary considerably. The holosystolic murmurs of mitral regurgitation and ventricular septal defect are augmented by transient exercise and are diminished by lowering the left ventricular systolic pressure by inhalation of amyl nitrite. The murmur of tricuspid regurgitation associated with pulmonary hypertension is holosystolic and frequently increases during inspiration. Not all patients with mitral or tricuspid regurgitation or ventricular septal defect have holosystolic murmurs (Chap. 236). Often, a mild valvular regurgitant jet, detected by color flow Doppler techniques, is not associated with an audible murmur despite optimal auscultation. Such regurgitant jets usually do not indicate clinical heart disease. Trivial mitral regurgitation can be detected by Doppler in up to 45% of normal individuals; tricuspid regurgitation in up to 70%; and pulmonic regurgitation in up to 88%. Normal aortic regurgitation is encountered much less frequently, and its incidence increases with advancing age (Fig. 225-5).

Midsystolic murmurs, also called *systolic ejection murmurs*, which are often crescendo-decrescendo in shape, occur when blood is ejected across the aortic or pulmonic outflow tracts (Fig. 225-4). The murmur starts shortly after S_1, when the ventricular pressure becomes high enough to open the semilunar valve. As the velocity of ejection increases, the murmur gets louder; as ejection declines, it diminishes. The murmur ends before the ventricular pressure falls enough to permit closure of the aortic or pulmonic leaflets. When the semilunar valves are normal, an increased flow rate (as occurs in states of elevated cardiac output), ejection into a dilated vessel beyond the valve, or increased transmission of sound through a thin chest wall may be responsible for this murmur. Most benign, functional murmurs are midsystolic and originate from the pulmonary outflow tract. Valvular or subvalvular obstruction of either ventricle may also cause such a midsystolic murmur, the intensity being related to the flow rate.

The murmur of aortic stenosis is the prototype of the left-sided midsystolic murmur. The location and radiation of this murmur are influenced by the direction of the high-velocity jet within the aortic root. In *valvular aortic stenosis*, the murmur is usually maximal in the second right intercostal space, with radiation into the neck. In *supravalvular aortic stenosis*, the murmur is occasionally loudest even higher, with disproportionate radiation into the right carotid artery. In hypertrophic cardiomyopathy, the midsystolic murmur originates in the left ventricular cavity and is usually maximal at the lower left sternal edge and apex, with relatively little radiation to the carotids. When the aortic valve is immobile (calcified), the aortic closure sound (A_2) may be soft and inaudible so that the length and configuration of the murmur are difficult to determine. Midsystolic murmurs also occur in patients with mitral regurgitation or, less frequently, tricuspid regurgitation resulting from papillary muscle dysfunction. Such murmurs due to mitral regurgitation are often confused with those originating in the aorta, particularly in elderly patients.

The patient's age and the area of maximal intensity aid in determining the significance of midsystolic murmurs. Thus, in a young adult with a thin chest and a high velocity of blood flow, a faint or moderate midsystolic murmur heard only in the pulmonic area is usually without clinical significance, while a somewhat louder murmur in the aortic area may indicate congenital aortic stenosis. In elderly patients, pulmonic flow murmurs are

rare, while aortic systolic murmurs are common and may be due to aortic dilation, to a significant degree of valvular aortic stenosis, or to nonstenotic thickening of the aortic valve leaflets. Midsystolic aortic and pulmonic murmurs are intensified after amyl nitrite inhalation and during the cardiac cycle following a premature ventricular beat, while those due to mitral regurgitation are unchanged or softer. Aortic systolic murmurs are diminished by interventions that increase aortic impedance, such as transient arterial occlusion. Echocardiography or cardiac catheterization may be necessary to separate a prominent and exaggerated functional murmur from one due to congenital or acquired semilunar valve stenosis.

Early systolic murmurs begin with the first heart sound and end in midsystole. In *large ventricular septal defects with pulmonary hypertension*, the shunting at the end of systole may be small or absent, resulting in an early systolic murmur. A similar murmur may occur with very *small muscular ventricular septal defects*, the shunt being interrupted in late systole. An early systolic murmur is a feature of *tricuspid regurgitation occurring in the absence of pulmonary hypertension*. This lesion is common in narcotics abusers with infective endocarditis, in whom a tall regurgitant right atrial *v* wave reaches the level of the normal right ventricular pressure in late systole, confining the murmur to early systole. Patients with acute mitral regurgitation into a noncompliant left atrium and a large *v* wave often have a loud early systolic murmur that diminishes as the pressure gradient between the left ventricle and left atrium decreases in late systole (Chap. 236).

Late systolic murmurs are faint or moderately loud, high-pitched apical murmurs that start well after ejection and do not mask either heart sound. They are probably related to papillary muscle dysfunction caused by infarction or ischemia of these muscles or to their distortion by left ventricular dilation. They may appear only during angina but are common in patients with myocardial infarction or diffuse myocardial disease. Late systolic murmurs following midsystolic clicks are due to late systolic mitral regurgitation caused by prolapse of the mitral valve into the left atrium (Chap. 236).

Diastolic Murmurs *Early diastolic murmurs* (Fig. 225-4) begin with or shortly after S_2, as soon as the corresponding ventricular pressure falls enough below that in the aorta or pulmonary artery. The high-pitched murmurs of aortic regurgitation or of pulmonic regurgitation due to pulmonary hypertension are generally decrescendo, since there is a progressive decline in the volume or rate of regurgitation during diastole. Faint, high-pitched murmurs of aortic regurgitation are difficult to hear unless they are specifically sought by applying firm pressure with the diaphragm over the left midsternal border while the patient sits leaning forward and holds a breath in full expiration. The diastolic murmur of aortic regurgitation is enhanced by an acute elevation of the arterial pressure, such as occurs with handgrip exercise; it diminishes with a decrease in arterial pressure, as with amyl nitrite inhalation. The diastolic murmur of congenital pulmonic regurgitation without pulmonary hypertension is low- to medium-pitched. The onset of this murmur is delayed because the regurgitant flow is minimal at the onset of pulmonic valve closure when the reverse pressure gradient responsible for the regurgitation is negligible.

Middiastolic murmurs usually arise from the mitral or tricuspid valves (Fig. 225-4), occur during early ventricular filling, and are due to disproportion between valve orifice size and flow rate. Such murmurs may be quite loud (grade III), despite only slightAV valve

stenosis, when there is normal or increased blood flow. Conversely, the murmurs may be soft or even absent despite severe obstruction if the cardiac output is markedly reduced. When stenosis is marked, the diastolic murmur is prolonged, and the duration of the murmur is more reliable than its intensity as an index of the severity of valve obstruction.

The low-pitched, middiastolic murmur of mitral stenosis characteristically follows the OS. It should be specifically sought by placing the bell of the stethoscope at the site of the left ventricular impulse, which is best localized with the patient on the left side. Frequently, the murmur of mitral stenosis is present only at the left ventricular apex, and it may be increased in intensity by mild supine exercise or by inhalation of amyl nitrite. In tricuspid stenosis, the middiastolic murmur is localized to a relatively limited area along the left sternal edge and may be louder during inspiration.

Middiastolic murmurs may be generated across the mitral valve in cases of mitral regurgitation, patent ductus arteriosus, or ventricular septal defect, and across the tricuspid valve in cases of tricuspid regurgitation or atrial septal defect. These murmurs are related to the torrential flow across anAVvalve, usually follow an S_3, and tend to occur with large left-to-right shunts or severe AV valve regurgitation. A soft middiastolic murmur may sometimes be heard in patients with acute rheumatic fever (Carey-Coombs murmur). It has been attributed to inflammation of the mitral valve cusps or excessive left atrial blood flow as a consequence of mitral regurgitation.

In acute, severe aortic regurgitation, the left ventricular diastolic pressure may exceed the left atrial pressure, resulting in a middiastolic murmur due to "diastolic mitral regurgitation." In severe, chronic aortic regurgitation, a murmur is frequently present that may be either middiastolic or presystolic (Austin-Flint murmur). This murmur appears to originate at the anterior mitral valve leaflet when blood enters the left ventricle simultaneously from both the aortic root and the left atrium.

Presystolic murmurs begin during the period of ventricular filling that follows atrial contraction and therefore occur in sinus rhythm. They are usually due toAV valve stenosis and have the same quality as the middiastolic filling rumble, but they are usually crescendo, reaching peak intensity at the time of a loud S_1. The presystolic murmur corresponds to the AV valve gradient, which may be minimal until the moment of right or left atrial contraction. It is the presystolic murmur that is most characteristic of tricuspid stenosis and sinus rhythm. A right or left *atrial myxoma* may occasionally cause either middiastolic or presystolic murmurs that resemble the murmurs of mitral or tricuspid stenosis.

Continuous Murmurs These begin in systole, peak near S_2, and continue into all or part of diastole. These murmurs result from continuous flow due to a communication between high- and low-pressure areas that persists through the end of systole and the beginning of diastole. A *patent ductus arteriosus* causes a continuous murmur as long as the pressure in the pulmonary artery is much below that in the aorta. The murmur is intensified by elevation of the systemic arterial pressure and is reduced by amyl nitrite inhalation. When pulmonary hypertension is present, the diastolic portion may disappear, leaving the murmur confined to systole. A continuous murmur is uncommon in cases of aortopulmonary septal defect, which usually is associated with severe

pulmonary hypertension. Surgically produced connections and the subclavian-pulmonary artery anastomosis result in murmurs similar to that of a patent ductus.

Continuous murmurs may result from congenital or acquired *systemic arteriovenous fistula*, *coronary arteriovenous fistula*, anomalous origin of the left coronary artery from the pulmonary artery, and communications between the *sinus of Valsalva and the right side of the heart*. Continuous murmurs may also occur in patients with a small atrial septal defect with a high left atrial pressure. Murmurs associated with *pulmonary arteriovenous fistulas* may be continuous but are usually only systolic. Continuous murmurs may also be due to disturbances of flow pattern in constricted systemic (e.g., renal) or pulmonary arteries when marked pressure differences between the two sides of the narrow segment persist; a continuous murmur in the back may be present in *coarctation of the aorta*; *pulmonary embolism* may cause continuous murmurs in partially occluded vessels.

In nonconstricted arteries, continuous murmurs may be due to rapid flow through a tortuous bed. Such murmurs typically occur within the bronchial arterial collateral circulation in cyanotic patients with severe pulmonary outflow obstruction. The "mammary souffle," an innocent murmur heard over the breasts during late pregnancy and in the early postpartum period, may be systolic or continuous. The innocent cervical venous hum is a continuous murmur usually audible over the medial aspect of the right supraclavicular fossa with the patient upright. The hum is usually louder during diastole and can be abolished instantaneously by digital compression of the ipsilateral internal jugular vein. Transmission of a loud venous hum to the area below the clavicles may result in a mistaken diagnosis of patent ductus arteriosus.

Pericardial Friction Rub These adventitious sounds may have presystolic, systolic, and early diastolic scratchy components, may be confused with a murmur or extracardiac sound when heard only in systole. It is best appreciated with the patient upright and leaning forward and may be accentuated during inspiration.

The evaluation of the patient with a heart murmur may vary greatly depending on many of the considerations discussed above. These include the intensity of the cardiac murmur, its timing in the cardiac cycle, its location and radiation, and its response to various physiologic maneuvers. Also of importance are the presence or absence of cardiac and noncardiac symptoms and whether other cardiac or noncardiac physical findings suggest that the cardiac murmur is clinically significant. The skill and confidence of the cardiac auscultator, the relative costs of various diagnostic approaches, and the accuracy and reliability of additional tests in the laboratory where they are performed are also important factors. One systematic approach to the patient with a heart murmur is depicted inFig. 34-3. This algorithm is particularly applicable to children and adults under age 40.

226. ELECTROCARDIOGRAPHY - *Ary L. Goldberger*

The electrocardiogram (ECG or EKG) is a graphic recording of electric potentials generated by the heart. The signals are detected by means of metal electrodes attached to the extremities and chest wall and are then amplified and recorded by the electrocardiograph. ECG *leads* actually display the instantaneous *differences* in potential between these electrodes.

The clinical utility of theECGderives from its immediate availability as a noninvasive, inexpensive, and highly versatile test. In addition to its use in detecting arrhythmias, conduction disturbances, and myocardial ischemia, electrocardiography may reveal other findings related to life-threatening metabolic disturbances (e.g., hyperkalemia) or increased susceptibility to sudden cardiac death (e.g., QT prolongation syndromes). The advent of coronary thrombolysis or angioplasty in the early therapy of acute myocardial infarction (Chap. 243) has refocused particular attention on the sensitivity and specificity of ECG signs of myocardial ischemia.

ELECTROPHYSIOLOGY (See alsoChaps. 229 and230)

Depolarization of the heart is the initiating event for cardiac contraction. The electric currents that spread through the heart are produced by three components: cardiac pacemaker cells, specialized conduction tissue, and the heart muscle itself. TheECG, however, records only the depolarization (stimulation) and repolarization (recovery) potentials generated by the atrial and ventricular myocardium. Under resting conditions, myocardial cells are *polarized*; that is, they carry an electric charge on their surface due to transmembrane ion concentration differences. The charge measured across atrial and ventricular cell membranes is about 90 mV, with the inside negative relative to the outside. When these cells are stimulated above a critical threshold potential, they rapidly depolarize and transiently reverse their membrane polarity. This depolarization process spreads in a wavelike manner through the atria and ventricles. The return of myocardial fibers to their original resting state occurs during repolarization.

The depolarization stimulus for the normal heartbeat originates in the sinoatrial (SA) *node* (Fig. 226-1) or *sinus node*, a collection of *pacemaker* cells. These cells fire spontaneously; that is, they exhibit *automaticity*. The first phase of cardiac electrical activation is the spread of the depolarization wave through the right and left atria, followed by atrial contraction. Next, the impulse stimulates pacemaker and specialized conduction tissues in the atrioventricular (AV) nodal and His-bundle areas; together, these two regions constitute the AV junction. The bundle of His bifurcates into two main branches, the right and left bundles, which rapidly transmit depolarization wavefronts to the right and left ventricular myocardium by way of Purkinje fibers. The main left bundle bifurcates into two primary subdivisions, a left anterior fascicle and a left posterior fascicle. The depolarization wavefronts then spread through the ventricular wall, from endocardium to epicardium, triggering ventricular contraction.

Since the cardiac depolarization and repolarization waves have direction and magnitude, they can be represented by vectors. *Vectorcardiograms* that measure and display these instantaneous potentials are no longer used much in clinical practice. However, the general principles of vector analysis remain fundamental to understanding

the genesis of normal and pathologicECGwaveforms. Vector analysis illustrates a central concept of electrocardiography -- that the ECG records the complex spatial and temporal summation of electrical potentials from multiple myocardial fibers conducted to the surface of the body. This principle accounts for inherent limitations in both ECG *sensitivity* (activity from certain cardiac regions may be canceled out or may be too weak to be recorded) and *specificity* (the same vectorial sum can result from either a selective gain or a loss of forces in opposite directions).

ECG WAVEFORMS AND INTERVALS

TheECGwaveforms are labeled alphabetically, beginning with the P wave, which represents atrial depolarization (Fig. 226-2). The QRS complex represents ventricular depolarization, and the ST-T-U complex (ST segment, T wave, and U wave) represents ventricular repolarization. The J point is the junction between the end of the QRS complex and the beginning of the ST segment. Atrial repolarization is usually too low in amplitude to be detected, but it may become apparent in such conditions as acute pericarditis or atrial infarction.

The QRS-T waveforms of the surface (extracellular)ECGcorrespond in a general way with the different phases of simultaneously obtained ventricular *action potentials*, the intracellular recordings from single myocardial fibers (Fig. 226-3) (Chap. 229). The rapid upstroke (phase 0) of the action potential corresponds to the onset of QRS. The plateau (phase 2) corresponds to the isoelectric ST segment, and active repolarization (phase 3) to the inscription of the T wave. Factors that decrease the slope of phase 0 by impairing the influx of Na^+(e.g., drugs such as quinidine or procainamide, or hyperkalemia) tend to increase QRS duration. Conditions that prolong phase 2 (amiodarone, hypocalcemia) increase the QT interval. In contrast, shortening of ventricular repolarization (phase 2), as by digitalis or hypercalcemia, abbreviates the ST segment.

The electrocardiogram is ordinarily recorded on special graph paper which is divided into 1-mm^2gridlike boxes (Fig. 226-4). Since theECGpaper speed is generally 25 mm/s, the smallest (1 mm) horizontal divisions correspond to 0.04 s (40 ms), with heavier lines at intervals of 0.20 s (200 ms). Vertically, the ECG graph measures the amplitude of a given wave or deflection (1 mV = 10 mm with standard calibration; the voltage criteria for hypertrophy mentioned below are given in millimeters). There are four major ECG intervals: R-R, PR, QRS, and QT (Fig. 226-2). The heart rate (beats per minute) can be readily computed from the interbeat (R-R) interval by dividing the number of large (0.20 s) time units between consecutive R waves into 300 or the number of small (0.04 s) units into 1500. The PR interval measures the time (normally 120 to 200 ms) between atrial and ventricular depolarization, which includes the physiologic delay imposed by stimulation of cells in theAVjunction area. The QRS interval (normally 100 ms or less) reflects the duration of ventricular depolarization. The QT interval includes both ventricular depolarization and repolarization times and varies inversely with the heart rate. A rate-related ("corrected") QT interval, QT_c, can be calculated as and normally is£0.44s.

The QRS complex is subdivided into specific deflections or waves. If the initial QRS deflection in a given lead is negative, it is termed a *Q wave*; the first positive deflection

is termed an *R wave*. A negative deflection after an R wave is an *S wave*. Subsequent positive or negative waves are labeled R¢ and S¢, respectively. Lowercase letters (qrs) are used for waves of relatively small amplitude. An entirely negative QRS complex is termed a *QS wave*.

ECG LEADS

The 12 conventionalECGleads record the difference in potential between electrodes placed on the surface of the body. These leads are divided into two groups: six extremity (limb) leads and six chest (precordial) leads. The extremity leads record potentials transmitted onto the *frontal plane* (Fig. 226-5*A*), and the chest leads record potentials transmitted onto the *horizontal plane* (Fig. 226-5*B*). The six extremity leads are further subdivided into three *bipolar* leads (I, II, and III) and three *unipolar* leads (aVR, aVL, and aVF). Each bipolar lead measures the difference in potential between electrodes at two extremities: lead I= left arm-right arm voltages, lead II= left leg-right arm, and lead III= left leg-left arm. The unipolar leads measure the voltage (V) at one locus relative to an electrode (called the *central terminal* or *indifferent electrode*) that has approximately zero potential. Thus, aVR = right arm, aVL= left arm, and aVF = left leg (foot). The lowercase *a* indicates that these unipolar potentials are electrically augmented by 50 percent. The right leg electrode functions as a ground. The spatial orientation and polarity of the six frontal plane leads is represented on the hexaxial diagram (Fig. 226-6).

The six chest leads (Fig. 226-7) are unipolar recordings obtained by electrodes in the following positions: lead V_1, fourth intercostal space, just to the right of the sternum; lead V_2, fourth intercostal space, just to the left of the sternum; lead V_3, midway between V_2 and V_4; lead V_4, midclavicular line, fifth intercostal space; lead V_5, anterior axillary line, same level as V_4; and lead V_6, midaxillary line, same level as V_4 and V_5.

Together, the frontal and horizontal plane electrodes provide a three-dimensional representation of cardiac electrical activity. Each lead can be likened to a different camera angle "looking" at the same events -- atrial and ventricular depolarization and repolarization -- from different spatial orientations. The conventional 12-leadECG can be supplemented with additional leads under special circumstances. For example, right precordial leads V_3R, V_4R, etc. are useful in detecting evidence of acute right ventricular ischemia. Esophageal leads may reveal atrial activity not detectable on the surface ECG. Bedside telemetry units and ambulatory ECG (Holter) recordings usually employ only one or two modified leads, respectively.**Intracardiac electrocardiography and electrophysiologic testing are discussed in Chaps. 229 and 230.*

TheECGleads are configured so that a positive (upright) deflection is recorded in a lead if a wave of depolarization spreads toward the positive pole of that lead, and a negative deflection if the wave spreads toward the negative pole. If the mean orientation of the depolarization vector is at right angles to a given lead axis, a biphasic (equally positive and negative) deflection will be recorded.

GENESIS OF THE NORMAL ECG

P WAVE

The normal atrial depolarization vector is oriented downward and toward the subject's left, reflecting the spread of depolarization from the sinus node to the right and then the left atrial myocardium. Since this vector points toward the positive pole of lead II and toward the negative pole of lead aVR, the normal P wave will be positive in lead II and negative in lead aVR. By contrast, activation of the atria from an ectopic pacemaker in the lower part of either atrium or in theAVjunction region may produce retrograde P waves (negative in lead II, positive in lead aVR).

QRS COMPLEX

Normal ventricular depolarization proceeds as a rapid, continuous spread of activation wavefronts. This complex process can be divided into two major, sequential phases, and each phase can be represented by a mean vector (Fig. 226-8). The first phase is depolarization of the interventricular septum from the left to the right (vector 1). The second results from the simultaneous depolarization of the main mass of the right and left ventricles; it is normally dominated by the more massive left ventricle, so that vector 2 points leftward and posteriorly. Therefore, a right precordial lead (V_1) will record this biphasic depolarization process with a small positive deflection (septal r wave) followed by a larger negative deflection (S wave). A left precordial lead, e.g., V_6, will record the same sequence with a small negative deflection (septal q wave) followed by a relatively tall positive deflection (R wave). Intermediate leads show a relative increase in R-wave amplitude (normal R-wave progression) and a decrease in S-wave amplitude progressing across the chest from the right to left. The precordial lead where the R and S waves are of approximately equal amplitude is referred to as the *transition zone* (usually V_3 or V_4) (Fig. 226-9).

The QRS pattern in the extremity leads may vary considerably from one normal subject to another depending on the *electrical axis* of the QRS, which describes the mean orientation of the QRS vector with reference to the six frontal plane leads. Normally, the QRS axis ranges from -30° to + 100°(Fig. 226-6). An axis more negative than- 30° is referred to as *left axis deviation*, while an axis more positive than + 100° is referred to as *right axis deviation*. Left axis deviation may occur as a normal variant but is more commonly associated with left ventricular hypertrophy, a block in the anterior fascicle of the left bundle system (left anterior fascicular block or hemiblock), or inferior myocardial infarction. Right axis deviation also may occur as a normal variant (particularly in children and young adults), as a spurious finding due to reversal of the left and right arm electrodes, or in conditions such as right ventricular overload (acute or chronic), infarction of the lateral wall of the left ventricle, dextrocardia, left pneumothorax, or left posterior fascicular block.

T WAVE AND U WAVE

Normally, the mean T-wave vector is oriented roughly concordant with the mean QRS vector. Since depolarization and repolarization are electrically opposite processes, this normal QRS-T-wave vector concordance indicates that repolarization must normally proceed in the reverse direction from depolarization (i.e., from ventricular epicardium to endocardium). The normal U wave is a small, rounded deflection (£1 mm) that follows the T wave and usually has the same polarity as the T wave. An abnormal increase in

U-wave amplitude is most commonly due to drugs (e.g., quinidine, procainamide, disopyramide) or hypokalemia. Very prominent U waves are a marker of increased susceptibility to the *torsades de pointes* type of ventricular tachycardia (Chap. 230). Inversion of the U wave in the precordial leads is abnormal and may be a subtle sign of ischemia.

MAJOR ECG ABNORMALITIES

CARDIAC ENLARGEMENT AND HYPERTROPHY

Right atrial overload (acute or chronic) may lead to an increase in P-wave amplitude (³2.5 mm) (Fig. 226-10). Left atrial overload typically produces a biphasic P wave in V_1 with a broad negative component or a broad (³120 ms), often notched P wave in one or more limb leads (Fig. 226-10). This pattern also may occur with left atrial conduction delays in the absence of actual atrial enlargement, leading to the more general designation of *left atrial abnormality*.

Right ventricular hypertrophy due to a pressure load (as from pulmonic valve stenosis or pulmonary artery hypertension) is characterized by a relatively tall R wave in lead V_1 (R³ S wave), usually with right axis deviation (Fig. 226-11); alternatively, there may be a qR pattern in V_1 or V_3R. ST depression and T-wave inversion in the right to midprecordial leads are also often present. This so-called ventricular strain pattern is attributed to repolarization abnormalities in hypertrophied muscle. Right ventricular hypertrophy due to ostium secundum-type atrial septal defects, with the accompanying right ventricular volume overload, is commonly associated with an incomplete or complete right bundle branch block pattern with a rightward QRS axis.

Acute cor pulmonale due to pulmonary embolism (Chap. 261) for example, may be associated with a normalECG or a variety of abnormalities. Sinus tachycardia is the most common arrhythmia, although other tachyarrhythmias, such as atrial fibrillation or flutter, may occur. The QRS axis may shift to the right, sometimes in concert with the so-called $S_1Q_3T_3$pattern (prominence of the S wave in lead I, Q wave in lead III, with T-wave inversion in lead III). Acute right ventricular dilation also may be associated with poor R-wave progression and T-wave inversions in V_1 to V_4(right ventricular "strain") simulating acute anterior infarction. A right ventricular conduction disturbance may appear.

Chronic cor pulmonale due to obstructive lung disease (Chap. 237) usually does not produce the classicECGpatterns of right ventricular hypertrophy noted above. Instead of tall right precordial R waves, chronic lung disease more typically is associated with small R waves in right to midprecordial leads (poor R-wave progression) due in part to downward displacement of the diaphragm and the heart. Low-voltage complexes are commonly present, owing to hyperaeration of the lungs.

A number of different voltage criteria for *left ventricular hypertrophy* (Fig. 226-11) have been proposed on the basis of the presence of tall left precordial R waves and deep right precordial S waves [e.g., SV_1 + (RV_5 or RV_6)³ 35 mm; or (RV_5 or RV_6)³ 25 mm]. Repolarization abnormalities (ST depression with T-wave inversions) also may appear (left ventricular "strain" pattern) in leads with prominent R waves. However, prominent

precordial voltages may occur as a normal variant, especially in athletic or thin-chested individuals. Left ventricular hypertrophy may increase limb lead voltage (e.g., RaVL ³ 11 to 13 mm, RaVF³ 20 mm; R_I + S_{III}³ 25 mm) with or without increased precordial voltage. The presence of left atrial abnormality increases the likelihood of underlying left ventricular hypertrophy in cases with borderline voltage criteria. Left ventricular hypertrophy often progresses to incomplete or complete left bundle branch block. The sensitivity of conventional voltage criteria for left ventricular hypertrophy is decreased in obese persons and in women.ECGevidence for left ventricular hypertrophy is a major noninvasive marker of increased risk of cardiovascular morbidity and mortality, including sudden cardiac death. However, because of false-positive and false-negative diagnoses, the ECG is of limited utility in diagnosing atrial or ventricular enlargement. More definitive information is provided by echocardiography (Chap. 227).

BUNDLE BRANCH BLOCKS

Intrinsic impairment of conduction in either the right or left bundle system (intraventricular conduction disturbances) leads to prolongation of the QRS interval. With complete bundle branch blocks the QRS interval is³ 120 ms in duration; with incomplete blocks the QRS interval is between 100 and 120 ms. The QRS vector is usually oriented in the direction of the myocardial region where depolarization is delayed (Fig. 226-12). Thus, with right bundle branch block, the terminal QRS vector is oriented anteriorly and to the right (rSR¢ in V_1 and qRS in V_6, typically). Left bundle branch block alters both early and later phases of ventricular depolarization. The major QRS vector is directed to the left and posteriorly. In addition, the normal early left-to-right pattern of septal activation is disrupted such that septal depolarization proceeds from right to left as well. As a result, left bundle branch block generates wide, predominantly negative (QS) complexes in lead V_1 and entirely positive (R) complexes in lead V_6. A pattern identical to that of left bundle branch block, preceded by a sharp spike, is seen in most cases of electronic right ventricular pacing because of the relative delay in left ventricular activation.

Bundle branch block may occur in a variety of conditions. In subjects without structural heart disease, right bundle branch block is seen more commonly than left bundle branch block. Right bundle branch block also occurs with heart disease, both congenital (e.g., atrial septal defect) and acquired (e.g., valvular, ischemic). Left bundle branch block is often a marker of one of four underlying conditions: ischemic heart disease, long-standing hypertension, severe aortic valve disease, and cardiomyopathy. Bundle branch blocks may be chronic or intermittent. A bundle branch block may be rate-related; for example, often it occurs when the heart rate exceeds some critical value.

Bundle branch blocks and depolarization abnormalities secondary to artificial pacemakers not only affect ventricular depolarization (QRS) but are also characteristically associated with *secondary repolarization* (ST-T) abnormalities. With bundle branch blocks, the T-wave is typically opposite in polarity to the last deflection of the QRS (Fig. 226-12). This discordance of the QRS-T-wave vectors is caused by the altered sequence of repolarization that occurs secondary to altered depolarization. In contrast, *primary repolarization* abnormalities are independent of QRS changes and are related instead to actual alterations in the electrical properties of the myocardial fibers

themselves (for example, in the resting membrane potential or action potential duration), not just to changes in the sequence of repolarization. Ischemia, electrolyte imbalance, and drugs such as digitalis all cause such primary ST-T-wave changes. Primary and secondary T-wave changes may coexist. For example, T-wave inversions in the right precordial leads with left bundle branch block or in the left precordial leads with right bundle branch block may be important markers of underlying ischemia or other abnormalities.

Partial blocks ("hemiblocks") in the left bundle system (left anterior or posterior fascicular blocks) generally do not prolong the QRS duration substantially but instead are associated with shifts in the frontal plane QRS axis (leftward or rightward, respectively). More complex combinations of fascicular and bundle branch blocks may occur involving the left and right bundle system. Examples of *bifascicular block* include right bundle branch block and left posterior fascicular block, right bundle branch block with left anterior fascicular block, and complete left bundle branch block. Chronic bifascicular block in an asymptomatic individual is associated with a relatively low risk of progression to high-degreeAV heart block. In contrast, new bifascicular block with acute anterior myocardial infarction carries a much greater risk of complete heart block. Alternation of right and left bundle branch block is a sign of *trifascicular disease*. However, the presence of a prolonged PR interval and bifascicular block does not necessarily indicate trifascicular involvement, since this combination may arise with AV node disease and bifascicular block. Intraventricular conduction delays also can be caused by extrinsic (toxic) factors that slow ventricular conduction, particularly hyperkalemia or drugs (type 1 antiarrhythmic agents, tricyclic antidepressants, phenothiazines).

Prolongation of QRS duration does not necessarily indicate a conduction delay but may be due to *preexcitation* of the ventricles via a bypass tract, as in the Wolff-Parkinson-White (WPW) syndrome (Chap. 230) and related variants. The diagnostic triad of WPW consists of a wide QRS complex associated with a relatively short PR interval and slurring of the initial part of the QRS (delta wave), the latter effect due to aberrant activation of ventricular myocardium. The presence of a bypass tract predisposes to reentrant supraventricular tachyarrhythmias (Chap. 230).

MYOCARDIAL ISCHEMIA AND INFARCTION (See alsoChap. 243)

TheECG is a cornerstone in the diagnosis of acute and chronic ischemic heart disease. The findings depend on several key factors: the nature of the process [reversible (i.e., ischemia) versus irreversible (i.e., infarction)], the duration (acute versus chronic), extent (transmural versus subendocardial), and localization (anterior versus inferoposterior), as well as the presence of other underlying abnormalities (ventricular hypertrophy, conduction defects).

Ischemia exerts complex time-dependent effects on the electrical properties of myocardial cells. Severe, acute ischemia lowers the resting membrane potential and shortens the duration of the action potential. Such changes cause a voltage gradient between normal and ischemic zones. As a consequence, current flows between these regions. These so-called currents of injury are represented on the surfaceECG by deviation of the ST segment (Fig. 226-13). When the acute ischemia is *transmural*, the

ST vector is usually shifted in the direction of the outer (epicardial) layers, producing ST elevations and sometimes, in the earliest stages of ischemia, tall, positive so-called hyperacute T waves over the ischemic zone. With ischemia confined primarily to the *subendocardium*, the ST vector typically shifts toward the subendocardium and ventricular cavity, so that overlying (e.g., anterior precordial) leads show ST-segment depression (with ST elevation in lead aVR). Multiple factors affect the amplitude of acute ischemic ST deviations. Profound ST elevation or depression in multiple leads usually indicates very severe ischemia. From a clinical viewpoint, the division of acute myocardial infarction into ST segment elevation and non-ST elevation (NSTEMI) types is useful since the efficacy of acute reperfusion therapy is limited to the former group (Chap. 243).

TheECGleads are more helpful in localizing regions of ST elevation than non-ST elevation ischemia. For example, acute transmural anterior wall ischemia is reflected by ST elevations or increased T-wave positivity (Fig. 226-14) in one or more of the precordial leads (V_1 to V_6) and leads I and aVL. Anteroseptal ischemia produces these changes in leads V_1 to V_3, apical or lateral ischemia in leads V_4 to V_6. Transmural inferior wall ischemia produces changes in leads II, III, and aVF. Posterior wall ischemia may be indirectly recognized by *reciprocal* ST depressions in leads V_1 to V_3. Prominent reciprocal ST depressions in these leads also occur with certain inferior wall infarcts, particularly those with posterior or lateral wall extension. Right ventricular ischemia usually produces ST elevations in right-sided chest leads (Fig. 226-7). When ischemic ST elevations occur as the earliest sign of acute infarction, they are typically followed within a period ranging from hours to days by evolving T-wave inversions and often by Q waves occurring in the same lead distribution. (T-wave inversions due to evolving or chronic ischemia correlate with prolongation of repolarization and are often associated with QT lengthening.) Reversible transmural ischemia, for example, due to coronary vasospasm (Prinzmetal's variant angina), may cause transient ST-segment elevations without development of Q waves. Depending on the severity and duration of such ischemia, the ST elevations may either resolve completely in minutes or be followed by T-wave inversions that persist for hours or even days. Patients with ischemic chest pain who present with deep T-wave inversions in multiple precordial leads (e.g., V_1 to V_4) with or without cardiac enzyme elevations typically have severe obstruction in the left anterior descending coronary artery system (Fig. 226-15). In contrast, patients whose baseline ECG already shows abnormal T-wave inversions may develop T-wave normalization (pseudonormalization) during episodes of acute transmural ischemia.

With infarction, depolarization (QRS) changes often accompany repolarization (ST-T) abnormalities. Necrosis of sufficient myocardial tissue may lead to decreased R-wave amplitude or frank abnormal Q waves in the anterior or inferior leads (Fig. 226-16). Previously, abnormal Q waves were considered to be markers of transmural myocardial infarction, while subendocardial infarcts were thought not to produce Q waves. However, carefulECG-pathology correlative studies have indicated that transmural infarcts may occur without Q waves and that subendocardial (nontransmural) infarcts may sometimes be associated with Q waves. Therefore, infarcts are more appropriately classified as "Q-wave" or "non-Q-wave." The major acute ECG changes in syndromes of ischemic heart disease are schematically summarized inFig. 226-17. Loss of depolarization forces due to posterior or lateral infarction may cause reciprocal increases in R-wave amplitude in leads V_1 and V_2without diagnostic Q waves in any of

the conventional leads. Atrial infarction may be associated with PR-segment deviations due to an atrial current of injury, changes in P-wave morphology, or atrial arrhythmias. In the weeks and months following infarction, these ECG changes may persist or begin to resolve. Complete normalization of the ECG following Q-wave infarction is uncommon but may occur, particularly with smaller infarcts. In contrast, ST-segment elevations that persist for several weeks or more after a Q-wave infarct usually correlate with a severe underlying wall motion disorder (akinetic or dyskinetic zone), although not necessarily a frank ventricular aneurysm.

ECGchanges due to ischemia may occur spontaneously or may be provoked by various exercise protocols (stress electrocardiography) (Chap. 244). In patients with severe ischemic heart disease, exercise testing is most likely to elicit signs of subendocardial ischemia (horizontal or downsloping ST depression in multiple leads). ST-segment elevation during exercise is most often observed after a Q-wave infarct. This repolarization change does not necessarily indicate active ischemia but correlates strongly with the presence of an underlying ventricular wall motion abnormality. However, in patients *without* prior infarction, transient ST-segment elevation with exercise is a reliable sign of transmural ischemia.

TheECG has important limitations in both sensitivity and specificity in the diagnosis of ischemic heart disease. Although a single normal ECG does not exclude ischemia or even acute infarction, a normal ECG *throughout* the course of an acute infarct is distinctly uncommon. Prolonged chest pain without diagnostic ECG changes, therefore, should always prompt a careful search for other noncoronary causes of chest pain (Chap. 13). Furthermore, the diagnostic changes of acute or evolving ischemia are often masked by the presence of left bundle branch block, electronic ventricular pacemaker patterns, andWPWpreexcitation. On the other hand, clinicians may overdiagnose ischemia or infarction based on the presence of ST-segment elevations or depressions, T-wave inversions, tall positive T waves, or Q waves *not* related to ischemic heart disease (pseudoinfarct patterns). For example, ST-segment elevations simulating ischemia may occur with acute pericarditis (Fig. 226-18) or myocarditis, or as a normal variant ("early repolarization" pattern). Similarly, tall, positive T waves do not invariably represent hyperacute ischemic changes but also may be caused by normal variants, hyperkalemia, cerebrovascular injury, and left ventricular volume overload due to mitral or aortic regurgitation, among other causes. ST-segment elevations and tall, positive T waves are common findings in leads V_1 and V_2 in left bundle branch block or left ventricular hypertrophy in the absence of ischemia. The differential diagnosis of Q waves (Table 226-1) includes physiologic or positional variants, ventricular hypertrophy, acute or chronic noncoronary myocardial injury, hypertrophic cardiomyopathy, and ventricular conduction disorders. Digitalis, ventricular hypertrophy, hypokalemia, and a variety of other factors may cause ST-segment depression mimicking subendocardial ischemia. Prominent T-wave inversion may occur with ventricular hypertrophy, cardiomyopathy, myocarditis, and cerebrovascular injury (particularly intracranial bleeds;Fig. 226-19), among many other conditions.

METABOLIC FACTORS AND DRUG EFFECTS

A variety of metabolic and pharmacologic agents alter theECG and, in particular, cause changes in repolarization (ST-T-U) and sometimes QRS prolongation. Certain

life-threatening electrolyte disturbances may be diagnosed initially and monitored from the ECG. *Hyperkalemia* produces a sequence of changes usually beginning with narrowing and peaking (tenting) of the T waves. Further elevation of extracellular K^+ leads to AVconduction disturbances, diminution in P-wave amplitude, and widening of the QRS interval. Severe hyperkalemia eventually causes cardiac arrest with a slow sinusoidal type of mechanism ("sine-wave" pattern) followed by asystole. *Hypokalemia* (Fig. 226-19) prolongs ventricular repolarization, often with prominent U waves. Prolongation of the QT interval (Fig. 226-19) is also seen with drugs that increase the duration of the ventricular action potential -- type 1A antiarrhythmic agents and related drugs (e.g., quinidine, disopyramide, procainamide, tricyclic antidepressants, phenothiazines) and type III agents (amiodarone, sotalol). Marked QT prolongation, sometimes with deep, wide T-wave inversions, may occur with intracranial bleeds, particularly subarachnoid hemorrhage ("CVA T-wave" pattern) (Fig. 226-19). Systemic *hypothermia* (Fig. 226-19) also prolongs repolarization, usually with a distinctive convex elevation of the J point (Osborn wave). *Hypocalcemia* typically prolongs the QT interval (ST portion), while *hypercalcemia* shortens it (Fig. 226-20). Digitalis glycosides also shorten the QT interval, often with a characteristic "scooping" of the ST-T-wave complex (*digitalis effect*).

Many other factors are associated withECGchanges, particularly alterations in ventricular repolarization. T-wave flattening, minimal T-wave inversions or slight ST-segment depression ("nonspecific ST-T-wave changes") may occur with a variety of electrolyte and acid-base disturbances, a variety of infectious processes, central nervous system disorders, endocrine abnormalities, many drugs, ischemia, hypoxia, and virtually any type of cardiopulmonary abnormality. While subtle ST-T-wave changes may be markers of ischemia, transient nonspecific repolarization changes also may occur following a meal or with postural (orthostatic) change, hyperventilation, or exercise in healthy individuals.

ELECTRICAL ALTERNANS

Electrical alternans -- a beat-to-beat alternation in one or more components of theECGsignal -- is a common type of nonlinear cardiovascular response to a variety of perturbations. For example, total electrical alternans (P-QRS-T) with sinus tachycardia is a relatively specific sign of pericardial effusion, often with cardiac tamponade. The mechanism relates to a periodic swinging motion of the heart in the effusion at a frequency exactly one-half the heart rate. ST-T alternans is a sign of electrical instability and may precede ventricular fibrillation.

CLINICAL INTERPRETATION OF THE ECG

Accurate analysis ofECGs requires thoroughness and care. The patient's age, gender, and clinical status should always be taken into account. For example, T-wave inversions in leads V_1 to V_3 are more likely to represent a normal variant in a healthy young adult woman ("persistent juvenile T-wave pattern") than in an elderly man with chest discomfort. Similarly, the likelihood that ST-segment depression during exercise testing represents ischemia depends partly on the prior probability of coronary artery disease.

Many mistakes inECGinterpretation are errors of omission. Therefore, a systematic

approach is desirable. The following 14 points should be analyzed carefully in every ECG: (1) standardization (calibration) and technical features (including lead placement and artifacts); (2) heart rate; (3) rhythm; (4) PR interval; (5) QRS interval; (6) QT interval; (7) P waves; (8) QRS voltages; (9) mean QRS electrical axis; (10) precordial R-wave progression; (11) abnormal Q waves; (12) ST segments; (13) T waves; (14) U waves.

Only after analyzing all these points should the interpretation be formulated. Where appropriate, important clinical correlates or inferences should be mentioned. For example, prolonged ventricular repolarization with prominent U waves should suggest hypokalemia or drug toxicity (e.g., due to quinidine or procainamide) (Fig. 226-19). The combination of left atrial abnormality (enlargement) and signs of right ventricular hypertrophy suggests mitral stenosis. Low voltage with sinus tachycardia raises the possibility of pericardial tamponade or chronic obstructive lung disease. Sinus tachycardia with QRS and QT (U) prolongation suggests tricyclic antidepressant overdose (Fig. 226-19). Comparison with previousECGs is essential.**The diagnosis and management of specific cardiac arrhythmias and conduction disturbances are discussed in Chaps. 229 and 230.*

COMPUTERIZED ELECTROCARDIOGRAPHY

ComputerizedECGsystems are increasingly used. Digital systems provide for convenient storage and immediate retrieval of thousands of ECG records. In recent years, computer programs for ECG analysis have become more reliable. However, despite these advances, computer interpretation of ECGs has important limitations. Incomplete or inaccurate readings are most likely with arrhythmias and complex abnormalities. Therefore, computerized interpretation (including measurements of basic ECG intervals) should not be accepted without careful physician review.

227. NONINVASIVE CARDIAC IMAGING: ECHOCARDIOGRAPHY AND NUCLEAR CARDIOLOGY - *Rick A. Nishimura*, *Raymond J. Gibbons*, *A. Jamil Tajik*

Cardiovascular imaging has significantly enhanced the practice of cardiology over the past few decades. Two-dimensional echocardiography is able to visualize the heart directly in real time using ultrasound, providing instantaneous assessment of the myocardium, valves, pericardium, and great vessels. Doppler echocardiography measures the velocity of moving red blood cells and has become a noninvasive alternative to cardiac catheterization for assessment of hemodynamics. Transesophageal echocardiography has provided a new window for high-resolution imaging of posterior structures of the heart, particularly the left atrium, mitral valve, and aorta. Nuclear cardiology uses isotopes to assess myocardial perfusion and function and has contributed greatly to the evaluation of patients with ischemic heart disease. This**chapter**provides an overview of the basic concepts of both echocardiography and nuclear cardiology and the clinical indications for each procedure.

ECHOCARDIOGRAPHY

TWO-DIMENSIONAL ECHOCARDIOGRAPHY

Basic Principles Two-dimensional echocardiography uses the principle of ultrasound reflection off cardiac structures to produce images of the heart (Table 227-1). The imaging is performed from multiple acoustic windows with different transducer rotations so that the entire heart and great vessels can be displayed in real time and in various two-dimensional planes. Most information from a study is obtained from a visual analysis of the two-dimensional images. Some laboratories use a concomitant M-mode study (one-dimensional echocardiogram) derived from the two-dimensional image for objective measurements of chamber size and function. For a transthoracic echocardiogram, the imaging is performed with a hand-held transducer placed directly on the chest wall. In selected patients, a transesophageal echocardiogram may be performed, in which an ultrasound transducer is mounted on the tip of an endoscope placed in the esophagus and directed towards the cardiac structures, so that high-resolution images of the posterior structures are obtained.

The frequency of the ultrasound used in clinical practice is usually between 2.5 and 5.0 MHz. The images produced depend on the acoustic reflection of the ultrasound off the various structures. Ultrasound passes readily through liquid, such as blood or pericardial fluid, and these are displayed as black on the two-dimensional image. When ultrasound is reflected off more solid structures, such as the myocardium and valves, there is a gray scale display. Structures such as calcium produce intense acoustic reflection and are displayed as bright white on the two-dimensional image. In a standard echocardiographic examination, the images are obtained from parasternal, apical, subcostal, and suprasternal windows. Multiple transducer rotations and angulations from each window are used to ensure that all parts of the cardiac structures are imaged. Most echocardiographic studies are recorded on videotape for off-line analysis, but direct digital acquisition units are enhancing the ability for storage and retrieval of images.

Current echocardiographic machines are portable, which allows them to be wheeled

directly to the patient's bedside. Thus, a major advantage of echocardiography over other imaging modalities is the ability to obtain instantaneous images of the cardiac structures for immediate interpretation, even in emergency or trauma units or in critical care settings.

A limitation of a two-dimensional echocardiogram performed via a transthoracic approach is the inability to obtain high-quality images in all patients, especially those with a thick chest wall or severe lung disease. Ultrasound waves are poorly transmitted through lung parenchyma. In patients with inadequate transthoracic echocardiographic images, transesophageal echocardiography can be performed.

The diagnostic accuracy of an echocardiogram is highly dependent upon both the operator of the echocardiographic equipment and the interpreter of the study. There are many important technical aspects to obtaining and interpreting the two-dimensional images, requiring training, experience, and expertise.

Chamber Size and Function Two-dimensional echocardiography is an ideal imaging modality for assessing left ventricular size and function (Fig. 227-1). A qualitative assessment of the cavity size of the ventricle and systolic function can be made directly from the two-dimensional image by experienced observers (Fig. 227-2). Quantitative assessment of left ventricular size and function can be made by M-mode echocardiography (measuring systolic and diastolic dimensions of the short axis of the left ventricle) or quantitative two-dimensional echocardiography. With quantitative two-dimensional echocardiography, endocardial outlines of the left ventricular cavity are traced in systole and diastole and the left ventricular cavity areas are then fitted to computer models of the left ventricle to obtain systolic and diastolic volumes, making it more cumbersome and less reproducible than the M-mode method. However, the M-mode method can be used only in patients with symmetrically contracting ventricles, as the M-mode samples only the septum and free wall at the mid-ventricle level. The presence or absence of regional wall motion abnormalities can be visually assessed by examining endocardial motion as well as wall thickening. M-mode and two-dimensional echocardiography are useful in the diagnosis of left ventricular hypertrophy, seen as an increase in wall thickness. Other chamber sizes are assessed by visual analysis, including the left atrium and right-sided chambers. There is no method for quantitative analysis of right ventricular size and function by two-dimensional echocardiography, due to the complex geometry of the right ventricle.

Valve Abnormalities (See also Chap. 236) Valve morphology and motion can be visualized by two-dimensional echocardiography (Figs. 227-1 and 227-2). Leaflet thickness and mobility, valve calcification, and the appearance of subvalvular and supravalvular structures can be assessed. Valve stenosis is reliably diagnosed by the thickening and decreased mobility of the valve. Two-dimensional echocardiography is the "gold standard" for the diagnosis of mitral stenosis, which produces typical tethering and diastolic doming. The severity of the stenosis can be obtained from a direct planimeter measurement of the mitral valve orifice from the short axis view. The presence and etiology of stenosis of the semilunar valves can be made by two-dimensional echocardiography (Plate I-1). Estimating the severity of the stenosis by two-dimensional echocardiography alone is less reliable and requires Doppler echocardiography. The diagnosis of valvular regurgitation must be made by Doppler

echocardiography, but two-dimensional echocardiography is valuable for determining the etiology of the regurgitation. Annular dilatation, prolapse, flail leaflets, vegetation, and rheumatic involvement can be diagnosed and the left ventricular response to volume overload can be assessed by two-dimensional echocardiography.

Pericardial Disease (See also Chap. 239) Two-dimensional echocardiography is the imaging modality of choice for the detection of pericardial effusion, which is easily visualized as a black echo-lucent ovoid structure surrounding the heart. In the hemodynamically unstable patient with pericardial tamponade, typical echo findings of right ventricular collapse, right atrial collapse, and a dilated inferior vena cava are seen (seeFig. 239-1). In patients with subclinical tamponade, these two-dimensional echocardiographic features may not be present, but the diagnosis of elevated pericardial pressure can be made by Doppler findings of variations of inflow velocities with respiration (seeFigs. 239-2 and239-4). Echocardiographically guided pericardiocentesis has now become a standard of care. A two-dimensional echocardiogram can directly visualize the location of the pericardial fluid in relationship to the entry point, and this technique has led to a low complication rate. Increased thickness of the pericardium is difficult to assess by two-dimensional echocardiography. Subtle clues to pericardial constriction can be seen on two-dimensional echocardiography from enhanced ventricular interaction, but Doppler imaging is required for confirmation of this diagnosis.

Intracardiac Masses (See also Chap. 240) Intracardiac masses can be visualized on two-dimensional echocardiography, provided that image quality is adequate. Solid masses appear as echo-dense structures, which can be located inside the cardiac chambers or infiltrating into the myocardium or pericardium (see Fig. 240-1). Although an echocardiographic examination cannot provide pathologic confirmation of the etiology of a mass, there are several instances in which the diagnosis of the mass can be suspected from its appearance, mobility, and the concomitant abnormalities seen. *Left ventricular thrombus* appears as an echo-dense structure, usually in the apical region associated with regional wall motion abnormalities. The appearance and mobility of the thrombus are predictive of embolic events. *Atrial myxoma* can be diagnosed by the appearance of a well-circumscribed mobile mass with attachments to the atrial septum. Prominent benign structures, such as *lipomatous infiltration of the atrial septum* and a *calcified mitral annulus*, may appear as cardiac masses. The high-resolution images provided by transesophageal echocardiography may be required for further delineation of myocardial masses.

Aortic Disease (See alsoChap. 247) Two-dimensional echocardiography can provide information on diseases of the aorta. The proximal ascending aorta, the arch, and the distal descending aorta can usually be visualized via the transthoracic approach. For patients in whom a dilated aorta is well visualized, two-dimensional echocardiography can be used for serial follow-up. Aortic dissection can be diagnosed when an intimal flap is visualized on a transthoracic echocardiogram. However, the definitive diagnosis of an aortic dissection usually requires a transesophageal echocardiogram (Plate I-2).

DOPPLER ECHOCARDIOGRAPHY

Basic Principles Doppler echocardiography uses ultrasound reflecting off moving red

blood cells to measure the velocity of blood flow across valves, within cardiac chambers, and through the great vessels. Normal and abnormal blood flow patterns can be assessed noninvasively. Color flow Doppler imaging (Plates I-1 and I-2) displays the blood velocities in real time superimposed upon a two-dimensional echocardiographic image. The different colors indicate the direction of blood flow (blue towards and red away from the transducer), with green color superimposed when there is turbulent flow. Thus regurgitant lesions and shunts may be assessed by color flow Doppler. Pulsed-wave Doppler measures the blood flow velocity in a specific location on the two-dimensional echocardiographic image and displays the velocities in a spectral pattern using time as the *x*-axis. Continuous-wave Doppler echocardiography can measure high velocities of blood flow directed along the line of the Doppler beam, such as occur in the presence of valve stenosis, valve regurgitation, or intracardiac shunts. These high velocities can be used to determine intracardiac pressure gradients by a modified Bernoulli equation:

In this equation, the contribution from viscous friction and flow acceleration to the change in pressure is assumed to be negligible. The derived pressure gradient can be used to determine intracardiac pressures and stenosis severity.

Valve Gradients (See also Chap. 236) In the presence of valvular stenosis, there is an increase in the velocity of blood flow across the stenotic valve. A continuous-wave Doppler beam can be placed into this jet of blood, and the measured velocity used to determine an instantaneous gradient across the valve by applying the modified Bernoulli equation. Integration of this velocity over time provides an accurate measurement of the mean gradient across the valve. If the Doppler beam is directed parallel to the jet, the Doppler-derived valve gradient is accurate and reproducible and correlates with that obtained from cardiac catheterization. Since the valve gradient is dependent upon transvalvular flow, a valve area should be derived noninvasively. An accurate assessment of the mean gradient and valve area can be obtained in most patients, provided that the Doppler beam is parallel to the stenotic jet. The Doppler examination is highly operator-dependent, especially in patients with aortic stenosis. If the Doppler beam is not parallel to the stenotic jet, there may be a significant underestimation of the valve gradient. In patients with mitral stenosis, it is technically easier to align the Doppler beam with the stenotic jet; thus the mean transmitral gradient is usually accurate and reproducible. A Doppler-derived transmitral gradient may be more reliable than that obtained by conventional cardiac catheterization, given the inherent errors that may occur with a pulmonary artery wedge pressure measurement.

Valvular Regurgitation (See also Chap. 236) Valvular regurgitation is diagnosed by Doppler echocardiography when there is an abnormal retrograde flow across the valve. Color flow imaging is the Doppler method used most frequently to detect valve regurgitation by visualization of a high-velocity turbulent jet in the chamber proximal to the regurgitant valve. The sensitivity of Doppler echocardiography for the detection of regurgitant lesions is high, and even trivial or mild regurgitation in the absence of clinical auscultatory evidence of a regurgitant murmur may be detected. The size and extent of the color flow jet into the receiving cardiac chamber provide a qualitative estimate of the severity of regurgitation, but there are many limitations to using color jet size alone.

Indirect clues for the severity of valvular regurgitation are available from other Doppler interrogation sites (e.g., intensity of a continuous-wave signal, volume of forward flow across a regurgitant valve). Methods for quantitation of regurgitation severity are now available, such as the measurement of the proximal isovelocity surface area, and these may be employed for determining effective orifice area and regurgitant volumes. As with other quantitative Doppler measurements, these methods are operator-dependent, and reliable data require an experienced high-volume laboratory.

Intracardiac Pressures These can be calculated from the peak continuous-wave Doppler signal of a regurgitant lesion. The Bernoulli equation is applied to the peak velocity to obtain the pressure gradient between two cardiac chambers. This is commonly applied to a tricuspid regurgitant jet, from which the systolic pressure gradient between the right atrium and right ventricle can be calculated. Adding an assumed right atrial pressure to this gradient will give a derived right ventricular systolic pressure. Change in pressure over time during isovolumic contraction can be derived from a mitral regurgitation signal. This measurement provides an index of systolic contractility.

Cardiac Output Volume flow rates can be reliably measured noninvasively from Doppler echocardiography. Using the hydrodynamic principle of flow through a rigid tube, the volume of flow can be calculated from the area of an orifice through which blood flows multiplied by the time of the velocity. The most accurate site for this measurement is through the left ventricular outflow tract. The product of the outflow area and velocity provides a beat-to-beat measurement of stroke volume, which, when multiplied by heart rate, provides a measurement of cardiac output.

Diastolic Filling (See also Chap. 231) Doppler echocardiography allows noninvasive evaluation of ventricular diastolic filling. The transmitral velocity curves reflect the relative pressure gradients between the left atrium and left ventricle throughout the diastolic filling period. They are influenced by the rate of ventricular relaxation, the driving force across the valve, and the compliance of the left ventricle. There is a progression of diastolic dysfunction in disease states, which can be assessed by Doppler flow velocity curves (Fig. 227-3). In the early phase of diastolic dysfunction there is primarily an abnormality of relaxation, with decreased early transmitral flow and a compensatory increase in flow during atrial contraction. As disease progresses, there is a higher left atrial pressure and reduced compliance of the left ventricle, resulting in a higher early transmitral velocity and shortening of the deceleration of flow in early diastole, termed *restriction to filling*. These transmitral flow curves can be used to estimate ventricular filling pressures and to determine prognosis in certain disease entities. The addition of Doppler interrogation of pulmonary venous flow as well as right-sided chamber flow provides further information concerning the diastolic properties.

Congenital Heart Disease (See also Chap. 234) Doppler echocardiography has been useful in the evaluation of patients with congenital heart disease. Congenital stenotic or regurgitant valve lesions can be assessed. The detection and semiquantitation of intracardiac shunts is possible by Doppler echocardiography. Patency of surgical shunts and conduits can be determined.

STRESS ECHOCARDIOGRAPHY (See also Chap. 244)

Two-dimensional and Doppler echocardiography are usually performed in the resting state. Further information can be obtained by reimaging during either exercise or pharmacologic stress. The primary indications for stress echocardiography are to confirm the suspicion of coronary artery disease and estimate its severity. Doppler stress testing provides additional information for the patient with valvular heart disease.

The response of the myocardium to ischemia consists of a cascade of events. A decrease in systolic contraction of the ischemic area, termed a *regional wall motion abnormality*, occurs before symptoms or electrocardiographic changes. During a stress echocardiogram, two-dimensional echocardiographic images at rest and during stress are digitized and displayed in a side-by-side format so that induced regional wall motion abnormalities may be detected. Changes in overall systolic function as well as end-systolic volume are also assessed. New regional wall motion abnormalities, a decline in ejection fraction, and an increase in end-systolic volume with stress are all indicators of myocardial ischemia (Fig. 227-4).

Stress testing is usually done with exercise protocols using either upright treadmill or bicycle exercise. The echocardiographic imaging is done at baseline and then immediately after exercise. In patients who are not able to exercise, pharmacologic testing can be performed by infusing dobutamine, which increases myocardial oxygen demand. Dobutamine echocardiography has also been used to assess myocardial viability in patients with poor systolic function and concomitant coronary artery disease. In this type of study, dobutamine is given at a low dose of 5 to 10 ug/kg per minute. In the presence of viable myocardium, an increase in the systolic contraction of the myocardium is evident.

There are limitations to stress echocardiography. It is important that the images be obtained as soon as possible after exercise is stopped since regional wall motion abnormalities may dissipate rapidly with time. Optimal image quality is essential for proper interpretation, and this depends on not only patient habitus but also the ability of the sonographer to obtain the image. Interpretation of the images is highly operator-dependent, and thus this technique requires an experienced echocardiographer.

Doppler echocardiography can be used at rest and during exercise in patients with valvular heart disease to determine the hemodynamic response to stress. Gradients across stenotic valves can be measured at rest and immediately after exercise, which provides information previously obtained by right heart catheterization during exercise. Pulmonary pressures can be obtained from the tricuspid regurgitation velocities at rest and during exercise.

TRANSESOPHAGEAL ECHOCARDIOGRAPHY

This technique has provided a new window on the heart. Because of the close proximity of the esophagus to the heart, high-resolution images of posterior structures are consistently obtained. Transesophageal echocardiography should be performed when further information is required after comprehensive two-dimensional and Doppler

transthoracic echocardiograms. Diseases of the aorta, such as aortic dissection, can be readily diagnosed and quantitated by transesophageal echocardiography (Plate I-2;Chap. 247). Defining the source of embolism is a common indication for transesophageal echocardiography, as abnormalities such as atrial thrombi, patent foramen ovale, and aortic debris can be detected. Other masses, particularly those in the atria, can be visualized. The presence of vegetations for the diagnosis of infective endocarditis and its complications can be assessed by transesophageal echocardiography (Chap. 126). The evaluation of suspected abnormalities of a mitral prosthesis is an indication for transesophageal echocardiography, as the posterior imaging window will avoid the problems of acoustic reflection caused by the prosthetic valve seen with transthoracic echocardiography. Transesophageal echocardiography can be used during cardiac surgery to guide various operations, such as mitral valve repair and septal myectomy. When limited information is obtained from a transthoracic echocardiogram due to poor imaging windows, transesophageal echocardiography can be useful.

ADVANCES IN ECHOCARDIOGRAPHY

There are several areas of technological advances in the field of echocardiography. Digital conversion of images allows zoom functions and endless loop playback and facilitates storage and retrieval. Harmonic imaging is a technologic advance that may significantly improve image quality, particularly in patients with poor acoustic windows. Echo contrast agents containing microbubbles cause reflection of ultrasound waves and produce bright echo-dense images. Newer contrast agents have been developed that traverse the pulmonary circulation, entering the left-sided chambers from an intravenous injection. Two-dimensional echocardiographic imaging during the appearance of echo contrast in the left ventricle enhances definition of the endocardial border. The appearance of contrast directly in the myocardium may be useful for examining myocardial blood flow. Three-dimensional reconstruction of ultrasound images is an exciting new area of investigation that will add further to the utility of echocardiography.

NUCLEAR CARDIOLOGY

BASIC PRINCIPLES OF NUCLEAR CARDIOLOGY

All nuclear cardiology studies depend upon the injection into the patient of an isotope that emits photons, generally gamma rays generated during radioactive decay when the nucleus of an isotope changes from one energy level to a lower one. Radionuclide imaging uses a special camera that images these photons. A common problem with all nuclear studies is that photons are emitted in all directions from the point of origin, and scattering, attenuation, and absorption of the photons can occur. The higher the energy of the isotope, the less chance for scatter or absorption.

The two most commonly used isotopes are technetium 99m (^{99m}Tc) and thallium 201 (^{201}Tl). Technetium is used in both myocardial perfusion studies and radionuclide angiography and is formed on site from molybdenum 99 (^{99}Mo). The parent compound has a half-life of 66 h and thus is easily transported.^{99m}Tc, which is a metastable compound, is constantly formed from^{99}Mo in the on-site generator. During the decay of^{99m}Tc to^{99}Tc, photons are emitted with a characteristic 140-keV photopeak and a

half-life of 6 h.^{201}Tl, on the other hand, needs to be generated in a cyclotron facility and transported as a finished product, with a half-life of 73 h. The thallium isotope decay process is more complex than that of technetium, with most photons in the 80-keV range. Due to its higher energy and shorter half-life, technetium is a more desirable imaging agent.

ASSESSMENT OF VENTRICULAR FUNCTION

Equilibrium radionuclide angiography, also known as *multiple-gated blood pool imaging*, is useful for the noninvasive assessment of ventricular function. It involves the imaging of^{99m}Tc-labeled albumin or red cells that are uniformly distributed throughout the blood volume. Resting images of the blood pool of isotopes within the cardiac chambers are obtained by electrocardiographic gating through multiple cycles, so that sufficient counts can be detected to obtain an image. This requires that the heart rate be reasonably constant without significant arrhythmia. Resting images are usually obtained in the anterior, lateral, and left anterior oblique views. Each image lasts approximately 2 to 4 min.

Ejection fraction is determined by a count-based program from equilibrium radionuclide angiography; this does not require any assumptions regarding the geometry of the ventricle. It provides an accurate, reproducible method for assessment of left ventricular function. Regional wall motion analysis can be done by visual qualitative assessment, although there are programs for quantitative analysis. Left ventricular volume can also be assessed by a count-based method, using a regression equation. Other clinical variables that can be obtained include size and function of the right ventricle, size of atrial chambers and great vessels, and diastolic filling parameters. The severity of valvular regurgitant lesions can be assessed by measurement of a regurgitant fraction, which compares right ventricular stroke volume with left ventricular stroke volume.

First-pass radionuclide angiography is an alternative method for the noninvasive assessment of ventricular function. In contrast to equilibrium radionuclide angiography, first-pass radionuclide angiography involves the recording of the movement of a bolus of radionuclide during its "first pass" through the central circulation. This does not require labeling of red blood cells.^{99m}Tc is utilized because of its low cost and short half-life. During this testing, the passage of the radioisotope through the right atrium, right ventricle, pulmonary circulation, left atrium, left ventricle, and aorta is recorded with a high count (usually multicrystal) camera. The high count rates allow temporal definition of the passage of the bolus. The change in counts of a sample placed over a ventricle reflects its function. One major advantage of first-pass angiography is the short acquisition time required, as an injected bolus will complete its passage within 30 s. In contrast to equilibrium radionuclide angiography, the right and left sides of the heart can be scanned separately. The disadvantage of first-pass radionuclide angiography compared to equilibrium testing is its poorer resolution of ventricular wall motion. It is also inaccurate in instances where the injected bolus becomes delayed in its transit, such as with severe tricuspid regurgitation or pulmonary hypertension.

Ejection fraction and regional wall motion may also be assessed using gating of single-photon emission computed tomographic (SPECT) myocardial perfusion images using technetium-labeled perfusion agents (see below).

ASSESSMENT OF MYOCARDIAL PERFUSION

Myocardial perfusion imaging by nuclear techniques is now widely applied for the evaluation of ischemic heart disease. Injection of radioisotopes at rest and during stress is performed to produce images of myocardial regional uptake proportional to regional blood flow. With maximal exercise, myocardial blood flow is increased up to fivefold above the resting condition. In the presence of a fixed coronary stenosis, there is an inability to increase myocardial perfusion in the territory supplied by the stenosis, creating a flow differential and inhomogeneous distribution of the isotope (see Fig. 244-2). In patients who are unable to exercise, pharmacologic agents are used to increase blood flow and create similar inhomogeneities. The preferred pharmacologic agents are adenosine or dipyridamole, which increase blood flow to a similar degree as exercise. In patients with bronchospastic lung disease, which is a contraindication to the use of adenosine or dipyridamole, dobutamine may be used as an alternative, although it does not increase blood flow to the same extent.

^{201}Tl is a potassium analogue and is avidly taken up by viable myocardial cells. The degree of uptake is related directly to the coronary blood flow. An initial injection is usually performed at peak exercise, and hypoperfused myocardium will have less thallium uptake than a region of normal perfusion (see Fig. 244-2). Over the next several hours, a complex process occurs that is known as "redistribution." There is a continuous input of thallium into the myocardium from a large reservoir of thallium in the blood pool. At the same time, thallium continuously washes out of portions of the myocardium at a rate that is dependent on local myocardial perfusion. The final result is that a region of ischemia that initially appears as an area of reduced uptake becomes apparently normal over time; this redistribution is seen on delayed imaging. In regions of fibrosis (infarction), there will be no redistribution on delayed imaging. A "reinjection" of an additional small amount of thallium before acquisition of the delayed images enhances the detection of ischemia. The presence of redistribution in areas of hypokinesia has been associated with recovery of left ventricular function after revascularization.

Other findings on thallium imaging may be of considerable clinical importance. Increased lung uptake of thallium may be seen immediately after stress and assessed either quantitatively or qualitatively. This finding reflects increased pulmonary capillary wedge pressure during stress. It occurs in the presence of severe coronary artery disease and/or left ventricular dysfunction. It provides important adverse prognostic information that is incremental to other clinical, stress, and coronary angiographic variables. Thallium images may also show evidence of transient poststress left ventricular dilatation. This finding is also associated with severe coronary artery disease and/or left ventricular dysfunction as well as with an adverse prognosis.

^{99m}Tc-labeled compounds have a higher photon energy and shorter half-life than ^{201}Tl, permitting the injection of larger doses. As a result, these compounds generally provide higher quality scans with fewer artifacts. Three technetium-labeled agents have been approved for general use: teboroxime, tetrofosmin, and sestamibi. The latter is the best studied of these agents and is currently used most frequently. Like thallium, sestamibi distributes to the myocardium in relation to blood flow, and its uptake requires a viable myocardial cell and an intact cell membrane. It is transported through the cytoplasm and

bound to the mitochondria in a nearly irreversible fashion. Compared to thallium, there is far less redistribution. As a result, the agent must generally be injected twice -- once at rest and once during stress.

Myocardial Perfusion Imaging Protocols (Plate I-1) The use of ^{201}Tl usually involves one of three protocols. The first protocol (stress-redistribution-delayed imaging) involves stress imaging, followed by redistribution imaging 3 or 4 h later (see Fig. 244-2). If fixed defects are present, delayed imaging is performed at a later time (usually 24 h) to detect additional redistribution. The second protocol (stress-redistribution-reinjection) also involves stress images and redistribution images 3 or 4 h later. In those patients with fixed defects on redistribution imaging, reinjection of a small amount of thallium is then performed. Repeat imaging is performed approximately 30 min later to identify a difference in myocardial uptake consistent with ischemia. In the third protocol (stress-reinjection-delayed imaging) patients are reinjected with a small amount of thallium before performing delayed imaging at 3 or 4 h. In those patients who have fixed defects on these reinjection images, more delayed imaging is then performed (usually at 24 h) in order to detect redistribution of both the initial stress dose as well as the reinjection dose. All three protocols therefore involve the use of stress images and delayed images in all patients, with a third set of images in a small subset of patients in order to improve the detection of thallium redistribution.

Stress imaging with sestamibi may utilize a 2-day protocol with different days for the injections of sestamibi at rest and during stress. Either the stress image or the rest image may be performed first. The protocol may also be carried out in one day. When the rest study is performed first a low dose is used, followed by a stress study using a larger injected dose. Alternatively, the order of these two studies may be reversed.

COMPARISON OF THALLIUM AND SESTAMIBI

Both ^{201}Tl and ^{99m}Tc sestamibi provide clinically useful myocardial perfusion images in the majority of patients. The choice between the two is often dictated by local experience and economics. However, in selected patients, there may be factors that suggest a clear advantage for one or the other. The relative advantages of both agents are listed in Table 227-2.

NUCLEAR CARDIOLOGY IN CLINICAL DECISION MAKING

Stress-myocardial-perfusion imaging with either ^{201}Tl or ^{99m}Tc sestamibi plays a pivotal role in both the diagnosis and risk stratification of patients with established or suspected coronary artery disease.

For the diagnosis of coronary artery disease, stress-myocardial-perfusion imaging is an appropriate initial test (as opposed to a treadmill exercise electrocardiogram) in patients with left bundle branch block, an electronically paced ventricular rhythm,>1 mm of ST segment depression at rest, or prior coronary artery revascularization, or in patients who are unable to exercise to a level high enough to give meaningful results. Stress-myocardial-perfusion imaging is also performed as a second test to clarify the significance of an equivocal treadmill exercise electrocardiogram.

For risk stratification, stress perfusion imaging can identify the extent, severity, and location of ischemia. These findings are often pivotal in defining the need for coronary angiography and coronary revascularization. Normal stress-myocardial-perfusion scans are highly predictive of both the absence of significant coronary artery disease and a low risk of cardiac death (less than 1% per year); coronary angiography is usually not required. Patients with markedly abnormal myocardial perfusion scans (large stress-induced defects, multiple stress-induced defects of moderate size, large fixed defect with left ventricular dilatation or increased ^{201}Tl lung uptake) are at high risk (>3 percent annual mortality rate). In such patients, coronary angiography and possible revascularization are appropriate.

POSITRON EMISSION TOMOGRAPHY (PET)

The underlying physics of PET scanning is quite different from that involved in the standard radionuclide techniques described above. The annihilation of the positron leads to the simultaneous emission of two very high energy (511 keV) photons in opposite directions. These can then be imaged by a series of detectors placed in a ring around the patient. The very high energy of the photons results in far less scatter and attenuation than with conventional nuclear cardiology techniques. The sophistication of the required equipment and the associated expense have generally limited the availability of this technique. PET cameras are considerably more expensive than conventional nuclear cardiology cameras. The radiopharmaceuticals involved require a cyclotron for production and generally have half-lives that are so short that transportation beyond the immediate local region is not feasible.

Positron emitters can be employed to study both myocardial blood flow and myocardial metabolism. Nitrogen-13 ammonia, oxygen-15 water, and rubidium-82 have all been employed to assess myocardial blood flow. They permit measurement of absolute regional blood flows, in contrast to the relative blood flows that are assessed with ^{201}Tl or ^{99m}Tc sestamibi. This advantage has been utilized for research purposes but has not yet been exploited clinically. Myocardial metabolism is most often assessed using fluorine-18 deoxyglucose. This agent permits the detection and quantification of exogenous glucose utilization in areas of hypoperfused myocardium.

The clinical application of PET scanning that has been most well studied is the assessment of myocardial viability. The pattern of enhanced fluorodeoxyglucose uptake in regions of decreased perfusion (termed *glucose/blood flow "mismatch"*) indicates the presence of ischemic myocardium that has preferentially shifted its metabolic substrate towards glucose rather than fatty acid or lactate. This pattern identifies regions of ischemic or hibernating myocardium that are likely to improve in function after revascularization (Chap. 244).

Careful studies have consistently shown the ability of PET to identify ischemic or hibernating myocardium in 10 to 20% of regions that would be classified as fibrotic (infarcted) by ^{201}Tl or ^{99m}Tc sestamibi. For that reason, this technique is generally regarded as the "gold standard" for the assessment of myocardial viability. However, because of its greater cost, national clinical practice guidelines have suggested that its usage be restricted to the specific situations where it is most beneficial.

Within the past few years, specially modified conventional gamma cameras have been employed to image fluorodeoxyglucose in an attempt to avoid the expense related to cameras dedicated toPET. The limited evidence available suggests that this approach is inferior to standard PET.

228. DIAGNOSTIC CARDIAC CATHETERIZATION AND ANGIOGRAPHY - *Donald S. Baim, William Grossman*

Despite progressive improvements in noninvasive techniques, cardiac catheterization remains a key clinical tool for assessing the anatomy and physiology of the heart and its associated vasculature. It involves the insertion of small (diameter, 2 to 3 mm), hollow plastic tubes or catheters into a peripheral artery or vein under local anesthesia, and passage of their tips into the heart for pressure measurement or for the injection of a liquid radiographic contrast agent. The findings characterize the extent and severity of cardiac disease and thereby help in deciding on the most appropriate plan for medical, surgical, or catheter-based treatment. While most patients with coronary artery disease (CAD) or valvular disease can be managed using only clinical and noninvasive test data, more than 1.5 million cardiac catheterization and angiographic procedures are performed each year for diagnostic or interventional purposes, or both. This**chapter**focuses on the uses of cardiac catheterization as a diagnostic tool.**For further discussion of catheter-based interventions, see Chap. 245.*

INDICATIONS, CONTRAINDICATIONS, AND COMPLICATIONS

Indications Given the expense and small, but real, risks of cardiac catheterization, it is not performed routinely whenever cardiac disease is diagnosed or suspected. Instead, cardiac catheterization is recommended only when there is a need to confirm the presence of a clinically suspected condition, define its anatomic and physiologic severity, and determine whether important associated conditions are present. This need most commonly arises when a patient is experiencing limiting or escalating symptoms of cardiac dysfunction (Chap. 232) or myocardial ischemia (Chap. 244) or when objective measures (such as exercise testing or echocardiography) suggest that the patient has a high risk of progressing to rapid functional deterioration, myocardial infarction, or other adverse events. Under these circumstances, catheterization is often a prelude to treatment by cardiac surgery or a catheter-based intervention. In the past, cardiac catheterization was considered mandatory in *all* patients being considered for cardiac surgery. Today, many patients with congenital or valvular heart disease can undergo surgical correction based solely on clinical and noninvasive test data; however, cardiac catheterization and coronary arteriography remain the only techniques that can define coronary anatomy with sufficient precision to support decisions regarding coronary surgery or catheter-based interventions in patients withCAD. In patients with other forms of heart disease (e.g., dilated cardiomyopathy, valvular heart disease), cardiac catheterization can provide hemodynamic characterization essential for the design of an appropriate medical regimen as well as for an assessment of prognosis.

Contraindications When there is a clinical "need to know," there are very few absolute contraindications in a patient who understands and accepts the associated risks. Some relative contraindications to cardiac catheterization, however, are listed inTable 228-1. Most center on factors that increase the risk of the procedure above the baseline mortality risk of roughly 1 in 1000 for clinically stable patients. This risk is increased more than tenfold in patients with severe symptoms, certain types of coronary anatomy, valve disease, left ventricular dysfunction, or severe noncardiac disease, as outlined inTable 228-2.

Complications Beyond the mortality risk, cardiac catheterization carries a 1 in 1000 risk of stroke or myocardial infarction. Other problems, such as transient tachy- or bradyarrhythmias or bruising or bleeding at the catheter insertion site, occur in fewer than 1% of patients and respond to drug therapy, countershock, or vascular surgical repair, without long-term sequelae. Although serious, problems such as cardiac perforation or arterial dissection are very rare in the modern era of cardiac catheterization.

Some patients, however, are intolerant of the iodinated contrast agents used for angiography, which may produce transient deterioration in renal function (particularly in patients with baseline renal dysfunction or proteinuria who are not adequately prehydrated) or *allergic reactions* ranging from urticaria to frank anaphylaxis in sensitive patients. These allergic reactions can be suppressed by pretreatment with glucocorticoids (prednisone, 20 to 40 mg every 6 h), conventional antihistamines (e.g., diphenhydramine, 25 mg every 6 h), and H_2antagonists (cimetidine, 300 mg every 6 h), starting 18 to 24 h prior to the procedure. Despite these precautions, occasional individuals still develop anaphylactic reactions during radiographic contrast angiography, and intravenous epinephrine must be at hand to treat such instances. Alternatively, one of the newer nonionic contrast agents may be used with less risk of a severe allergic reaction. Unlike the original high-osmolar agents, the newer low-osmolar contrast agents (including true nonionic contrast agents and the ionic dimer ioxaglate) have a lesser myocardial depressant effect and produce fewer side effects (hypotension, nausea, bradycardia, or a sensation of marked warmth following injection) than earlier high-osmolar agents. They are, however, somewhat more expensive than traditional high-osmolar ionic agents, so that many catheterization laboratories reserve their use for patients who are at higher risk for contrast-related problems.

TECHNIQUES

Cardiac catheterization is performed with the patient in the fasting state and awake but sedated. Although cardiac catheterization used to be performed exclusively as an inpatient procedure, current practice is to perform most elective procedures on an outpatient basis, with the patient discharged 4 to 6 h after the procedure is completed. Typical preprocedure sedatives include diazepam (Valium, 5 to 10 mg orally) or midazolam (Versed, 1 mg intravenously). It is also customary to give the antihistamine diphenhydramine (Benadryl, 25 to 50 mg orally) before the procedure in the hope of suppressing minor allergic reactions to iodinated contrast. Since cardiac catheterization is a sterile procedure, prophylactic antibiotics are not necessary. To minimize the risks of bleeding at the local catheter insertion site, patients who have been anticoagulated chronically with warfarin should have this agent discontinued at least 48 h prior to the procedure, so that the INR falls below 2.

Most (>95%) cardiac catheterizations are performed by the percutaneous femoral technique, in which a needle puncture is performed in the femoral artery (for left heart catheterization) and the femoral vein (for right heart catheterization). A flexible guidewire is inserted through this needle, allowing placement of a vascular access sheath through which the desired catheters can be advanced. This percutaneous technique has been modified for other sites, including the brachial and even the radial artery. The brachial or radial approach has an advantage in the patient with peripheral vascular disease

involving the abdominal aorta and iliac or femoral arteries or in whom immediate postprocedure ambulation is desired, but it involves some limitations in the range of devices that can be used if the diagnostic procedure evolves into a catheter-based intervention. With these alternatives, the original cut-down, or Sones, technique of cardiac catheterization by direct exposure of the brachial artery and vein in the antecubital fossa is rarely used.

Cardiac catheterization may include a variety of different measurements of pressure and flow (hemodynamics) as well as a variety of different contrast injections recorded as x-ray movies (angiography). The exact types of testing performed in any given procedure depend on the nature of the clinical problem being evaluated. In patients withCAD, the procedure may include only left ventriculography and coronary angiography, while in patients with valvular heart disease, full left and right heart hemodynamic studies may be performed.

RIGHT HEART CATHETERIZATION

Measurement of the pressures in the right side of the heart was once a routine part of each cardiac catheterization, but it is now used in fewer than 25% of procedures because it adds little to the evaluation of the patient withCAD. It is still useful, however, when significant left and/or right ventricular dysfunction, valve disease, myopericardial disease, or intracardiac shunting is suspected. The right heart catheterization procedure is similar to the placement of a Swan-Ganz catheter at the bedside in the intensive care unit, except that it is performed under fluoroscopic guidance. A balloon flotation catheter is advanced from a suitable vein (femoral, brachial, subclavian, or internal jugular) into the superior vena cava, where blood is sampled for oximetry. The catheter is then positioned in the right atrium, where pressure is measured. The balloon is inflated with air (or carbon dioxide, if intracardiac shunting is supected) and advanced sequentially into the right ventricle, pulmonary artery, and pulmonary artery wedge position. Pressure is recorded at each of these locations, with normal values for pressures measured during cardiac catheterization summarized in Table 228-3. After the pulmonary wedge pressure (which approximates left atrial pressure) is recorded, the balloon is deflated so that pulmonary artery pressure can be monitored and blood samples obtained for oximetry. Comparison of oxygen saturations in the superior and inferior vena cava, the chambers of the right heart, and pulmonary artery permits assessment of the presence of a left-to-right shunt at the atrial, ventricular, or pulmonary artery level, which will be manifested as an increase ("step-up") in oxygen saturation of blood as it traverses these vessels and chambers.

Measurement of Cardiac Output Measurements of the pulmonary artery and aortic oxygen content and oxygen consumption allow calculation of the cardiac output by the Fick principle, which states that

In order to compare individuals of different body weights and sizes, O_2consumption and cardiac output (Q) are commonly divided by body surface area. Normal values for O_2consumption and cardiac output are given inTable 228-3. What is calculated by dividing O_2consumption by the arteriovenous O_2difference across the lungs (estimated

pulmonary venous- pulmonary arterial O_2content) is actually the pulmonary blood flow (Q_p). In patients with left-to-right shunt at the atrial, ventricular, or pulmonary artery levels, pulmonary blood flow will exceed systemic blood flow. In such cases, systemic blood flow (Q_s) is calculated by dividing O_2consumption by the systemic arteriovenous O_2difference. The latter is calculated as the systemic arterial blood O_2content minus the mixed venous blood O_2content as estimated using blood from the chamber immediately proximal to the level of the shunt. The Fick method is most dependable when the cardiac output is low and the arteriovenous oxygen difference is large.

Another approach to the measurement of cardiac output during right heart catheterization is the thermodilution technique, in which a thermistor is mounted on the tip of a balloon flotation catheter and positioned in the pulmonary artery. Cold dextrose solution or saline is injected via a proximal port on the catheter into the vena cava or right atrium, and the change in temperature monitored at the thermistor is integrated electronically. This integral is inversely proportional to the volume flow rate past the thermistor, and if the temperatures of the injectate and pulmonary artery blood are measured, cardiac output (actually, pulmonary blood flow) can be calculated. In contrast to the Fick method, the indicator-dilution method is least reliable when the cardiac output is low.

LEFT HEART CATHETERIZATION

Whether performed using the femoral, brachial, or radial approach, the left heart catheter is advanced under fluoroscopic guidance into the central aorta, where pressure is measured and recorded. Next, the catheter is advanced in retrograde fashion across the aortic valve into the left ventricle, where pressure is measured. If a right heart catheter is in place, this is an appropriate time for simultaneous measurement and recording of left heart, right heart, and peripheral arterial pressures together with a determination of cardiac output by either thermodilution or the Fick principle. These measures allow assessment of possible pressure gradients across the mitral and aortic valves, and catheter pullback on the right side permits assessment of possible gradients across the pulmonic and tricuspid valves. Simultaneous measurement of pressures and cardiac output provides the data for calculation of systemic and pulmonary vascular resistances. The resistance to blood flow through the systemic vascular bed is

where *SVR* is systemic vascular resistance [(dyn×s)/cm_5], *MAP* and *RA* are mean aortic and right atrial pressures (mmHg), 80 is a constant for converting to metric units, and *SBF* is systemic blood flow (L/min). Resistance to blood flow through the pulmonary vascular bed is

where *PVR* is pulmonary vascular resistance [(dyn×s)/cm_5]; *PA*, *PCW*, and *LA* are pulmonary artery, pulmonary capillary wedge, and left atrial mean pressures, respectively (mmHg); and *PBF* is pulmonary blood flow (L/min). Normal values for pulmonary and systemic vascular resistances are given in Table 228-3.

When valvular stenosis is present, the measurements of the upstream and downstream pressures and flow allow calculation of the valve orifice using the Gorlin formula.

where *A* is the valve orifice area (cm^2), *flow* is the blood flow (mL/s) across the stenotic valve;D*P* is the mean pressure gradient (mmHg) during the period of blood flow; and *K* is a constant (44.3 for the aortic valve and 37.7 for the mitral valve).

As seen inFig. 228-1, normal left ventricular and aortic pressures are essentially equal during systole, while normal left atrial (pulmonary capillary wedge) and left ventricular pressures are equal during diastole in the normal heart. The presence of a systolic pressure gradient between the left ventricle and aorta indicates obstruction at the level of the aortic valve (e.g., calcific *aortic stenosis*) or at subaortic level (e.g., *hypertrophic obstructive cardiomyopathy*). Similarly, the presence of a diastolic pressure gradient between the left atrium (or pulmonary capillary wedge pressure) and the left ventricle generally indicates *mitral stenosis*, although it may also be seen in rare conditions such as cor triatriatum and left atrial myoxoma. An example of a large diastolic pressure gradient in a patient with mitral stenosis is seen inFig. 228-2. As seen inFig. 228-3, patients with significant mitral regurgitation may have a prominent *v* wave in the pulmonary capillary wedge pressure, which often increases substantially during modest exercise. Severe *aortic regurgitation* produces a widening of the aortic pulse pressure, with equilibration of aortic and left ventricular pressures in diastole (Fig. 228-4). Right-sided pressures exhibit a characteristic deformity in the presence of valvular heart disease affecting the tricuspid or pulmonic valves. In patients with severe *tricuspid regurgitation*, the right atrial pressure resembles the right ventricular pressure closely in appearance. Mean right atrial pressure and right ventricular end-diastolic pressure are both elevated in tricuspid regurgitation. In *tricuspid stenosis*, there is a pressure gradient between the right atrium and ventricle during diastole.

Abnormalities in pressure waveforms may also be suggestive of conditions such as *cardiac tamponade* or *pericardial constriction* (Chap. 239). In both conditions there is equalization of left and right ventricular diastolic pressures. However, in constrictive pericarditis, nearly all ventricular filling occurs shortly after mitral and tricuspid valve opening; after this period of rapid filling, ventricular volumes cannot increase further owing to the constricting pericardium. This abnormality produces an abrupt early ventricular diastolic pressure rise with a mid- and late-ventricular pressure plateau, giving the so-called square root sign (Fig. 228-5). In contrast, in tamponade there is equalization of diastolic pressures with a gradual increase throughout diastole.

Congestive heart failure due to myocardial contractile dysfunction is associated with characteristic alterations in the ventricular pressure waveforms seen at cardiac catheterization. Neither the rise nor the decline in isovolumic pressure is as steep as in the normal heart. The reduced slopes of pressure rise and decline are associated with an abbreviated ejection period, giving the left ventricular pressure tracing a triangular appearance (Fig. 228-6). Also, the pressure decline does not continue to zero, so the minimal left ventricular pressure may be elevated. This hemodynamic finding correlates with an increased ventricular end-systolic volume, which is a sign of depressed contractile function of the left ventricular myocardium.

CARDIAC ANGIOGRAPHY

LEFT VENTRICULOGRAPHY

Following the measurement of cardiac pressures, the angiographic portion of the cardiac catheterization usually begins with left ventriculography -- the injection of radiographic contrast material directly into the left ventricular cavity. A power injector is used to inject 30 to 45 mL of radiographic contrast material into the left ventricular chamber at a rate of 10 to 12 mL/s. The resulting radiographic images are recorded, and the left ventricular silhouette is defined at end-diastole and end-systole. This permits calculation of the left ventricular chamber volumes and ejection fraction, as well as qualitative assessment of regional wall motion abnormalities. The normal left ventricle ejects 50 to 80% of its end-diastolic volume with each beat; i.e., its *ejection fraction* is 0.50 to 0.80. In adults, normal values for left ventricular volumes are, for end-diastolic volume, 72± 15 mL/m^2(mean ± standard deviation) and, for end-systolic volume, 20 ± 8 mL/m^2. Regional abnormalities of wall motion are illustrated inFig. 228-7 and include diminished inward motion of a myocardial segment (*hypokinesis*), absence of inward movement of a myocardial segment (*akinesis*), and paradoxical systolic expansion of a regional myocardial segment (*dyskinesis*).

Left ventriculography is usually performed in the right anterior oblique projection, which allows assessment of the mitral and aortic valves. Mitral regurgitation is easily visualized as the leakage of radiographic contrast material back into the left atrium during left ventricular systole. Its severity can be estimated qualitatively using a grading system of 1+ (mild; radiographic contrast material clears with each beat and never opacifies the entire left atrium) to 4+ (severe; opacification of the entire left atrium occurs within one beat, and contrast material can be seen refluxing into the pulmonary veins).

Left ventriculography performed in the *left* anterior oblique projection permits detection of abnormal communications, such as a ventricular septal defect (Chap. 234). In the most common form of hypertrophic cardiomyopathy (idiopathic hypertrophic subaortic stenosis;Chap. 238), left ventriculography in this projection shows anterior motion of the anterior leaflet of the mitral valve during systole and bulging of the interventricular septum into the left ventricular cavity, especially in the subaortic region. Mural thrombi within the left ventricular chamber may be well visualized during left ventriculography; they occur most commonly in the left ventricular apex.

AORTOGRAPHY

Rapid injection of radiographic contrast material into the ascending aorta allows detection of abnormalities that involve the aorta and aortic valve. When suspected clinically, aortography permits detection and qualitative assessment of the severity of abnormalities such as aortic regurgitation, which is graded using a 1+ to 4+ scale, as for mitral regurgitation. Abnormal communications between the aorta and right side of the heart, such as a patent ductus arteriosus or ruptured aneurysm of a sinus of Valsalva, may be visualized. Aortography can permit identification of aortic aneurysm and of aortic dissection (Chap. 247) by visualizing an intimal flap within the aortic lumen.

CORONARY ANGIOGRAPHY

This common procedure involves the selective injection of a radiographic contrast agent into the coronary arteries. Placement of the catheter tip into the right and left coronary arteries is carried out under fluoroscopic guidance, and contrast agent is injected by hand during recording of the radiographic image. Each coronary artery is usually viewed in several projections to permit assessment of the severity of stenosis and to minimize the overlap of adjacent vessels. In addition to the detection of coronary artery stenoses, coronary angiography is useful for the detection of congenital abnormalities of the coronary circulation, coronary arteriovenous fistulas, and patency of coronary artery bypass grafts. Examples of normal and abnormal coronary anatomy are shown in Figs. 228-8 and 228-9. The location, severity, and morphology of the stenotic lesions can be analyzed in great detail, and the resulting information is essential to planning either bypass surgery or catheter-based intervention (Fig. 228-10). This is usually done by visual estimation of percent diameter stenosis of each lesion relative to the "uninvolved" adjacent reference segment, with stenosis > 50% taken as being hemodynamically significant (interfering with maximal increases in perfusion of the subserved myocardial territory during stress).

POSTPROCEDURE CARE

The average cardiac catheterization procedure takes between 30 and 45 min. Intravenous heparin (2000 to 3000 IU) may or may not be given at the time of catheter insertion. At the completion of the procedure, heparin may be reversed with intravenous protamine or allowed to wear off until the activated clotting time falls below 160 s. At that time, the vascular sheaths are removed and hemostasis is achieved by applying local pressure over the puncture site for 10 to 15 min. Patients then remain at bed rest for 4 to 6 h before ambulating and being discharged to home. A variety of devices for sealing the arterial puncture site can allow a shorter period of bed rest and earlier ambulation. Patients with suitable anatomy may return at a later date for either catheter-based intervention or bypass surgery, although it is now common practice to perform a catheter-based intervention during the same procedure as the diagnostic cardiac catheterization, if appropriate.

SECTION 2 -DISORDERS OF RHYTHM

229. THE BRADYARRHYTHMIAS: DISORDERS OF SINUS NODE FUNCTION AND AV CONDUCTION DISTURBANCES - *Mark E. Josephson, Peter Zimetbaum*

ANATOMY OF THE CONDUCTING SYSTEM

Under normal conditions, the pacemaker function of the heart resides in the sinoatrial (SA) node, which lies at the junction of the right atrium and superior vena cava. The SA node is approximately 1.5 cm long and 2 to 3 mm wide and is supplied by the sinus node artery, which arises from either the right coronary artery (60%) or the left circumflex coronary artery (40%). Once the impulse exits the sinus node and perinodal tissue, it traverses the atrium until it reaches the atrioventricular (AV) node. The blood supply of the AV node is derived from the posterior descending coronary artery (90%). The AV node lies at the base of the interatrial septum just above the tricuspid annulus and anterior to the coronary sinus. The electrophysiologic properties of the AV node result in slow conduction, which is responsible for the normal delay in AV conduction, i.e., the PR interval.

The bundle of His emerges from the AVnode, enters the fibrous skeleton of the heart, and courses anteriorly across the membranous interventricular septum. It has a dual blood supply from the AV nodal artery and a branch of the anterior descending coronary artery. The branching (distal) portion of the bundle of His gives rise to a broad sheet of fibers that course over the left side of the interventricular septum to form the left bundle branch and a narrow cable-like structure on the right side that forms the right bundle branch. The arborization of both the right and left bundle branches gives rise to the distal His-Purkinje system, which ultimately extends throughout the endocardium of the right and left ventricles.

TheSA node, atrium, andAV node are significantly influenced by autonomic tone. Vagal influences depress automaticity of the SA node, depress conduction, and prolong refractoriness in the tissue surrounding the SA node; inhomogeneously decrease atrial refractoriness and slow atrial conduction; and prolong AV nodal conduction and refractoriness. Sympathetic influences exert the opposite effect.

ELECTROPHYSIOLOGIC PRINCIPLES

In the resting state, the interior of most cardiac cells, with the exception of theSA andAVnodes, is approximately -80 to-90 mV, negative with respect to a reference extracellular electrode. The resting membrane potential is determined primarily by the concentration gradient of potassium across the cell membrane. Activation of cardiac cells results from movement of ions across the cell membrane, causing a transient depolarization known as the *action potential*. The ionic species responsible for the action potential varies among the cardiac tissues, and the configuration of the action potential is therefore unique to each tissue (Fig. 229-1).

The action potential of the His-Purkinje system and ventricular myocardium has five phases (Fig. 229-2). The rapid depolarizing current (phase 0) is mainly determined by an influx of sodium into myocardial cells followed by a secondary (slower) influx of

calcium, which produces a slow inward current. The repolarization phases of the action potential (phases 1 to 3) are primarily related to outward flux of potassium. The resting membrane potential is phase 4.

The bradyarrhythmias result from abnormalities either of impulse formation, i.e., automaticity, or of conduction. *Automaticity*, which is normally observed in the sinus node, the specialized fibers of the His-Purkinje system, and some specialized atrial fibers, is the property of a cardiac cell that causes it to depolarize spontaneously during phase 4 of the action potential, leading to the generation of an impulse. To exhibit automaticity, the resting membrane potential must decrease spontaneously until threshold potential is reached and an all-or-none regenerative response occurs. The ionic currents producing spontaneous diastolic depolarization appear to involve the inward current of either sodium or calcium and a decreasing outward potassium current. The velocity of *conduction*, i.e., impulse propagation through cardiac tissues, depends on the magnitude of inward current, which is directly related to the rate of rise and amplitude of phase 0 of the action potential. The more positive the threshold potential and the slower the rate of depolarization toward threshold, the slower is the rate of rise of phase 0 of the action potential and the slower is the conduction velocity. Disease states or drugs may result in lower rates of rise of phase 0 at any given membrane potential. Passive membrane properties (e.g., intracellular resistance and intercellular coupling) can also affect impulse propagation. Propagation is more rapid parallel to fiber orientation than transverse to it, a property termed *anisotropic conduction*.

Refractoriness is a property of cardiac cells that defines the period of recovery that cells require after being discharged before they can be reexcited by a stimulus. The *absolute refractory period* is defined by that portion of the action potential during which no stimulus, regardless of its strength, can evoke another response. The *effective refractory period* is that part of the action potential during which a stimulus can evoke only a local, nonpropagated response. The *relative refractory period* extends from the end of the effective refractory period to the time that the tissue is fully recovered. During this time, a stimulus of greater than threshold strength is required to evoke a response, which is propagated more slowly than normal. In the normal His-Purkinje system or ventricular myocytes, excitability is recovered following completion of the action potential, and evoked responses have characteristics similar to the spontaneous normal response. In theAV node, recovery of excitability occurs well after completion of the action potential.

INTRACARDIAC RECORDINGS OF THE SPECIALIZED CONDUCTING SYSTEM

Electrode catheters allow the recording of activation of portions of the specialized conducting system, including the bundle of His. To obtain a recording from the bundle of His, the electrode catheter is positioned across the tricuspid valve (Fig. 229-3). The interval from local atrial depolarization in the His bundle recording to the onset of depolarization of the His bundle deflection is called the *AH interval* (normal= 60 to 125 ms) and represents an indirect method of assessingAV nodal conduction time. The interval from the beginning of the His bundle deflection to the earliest onset of ventricular activation, as measured from any of multiple-surface electrocardiogram (ECG) leads or the intracardiac ventricular electrogram, is called the *HV interval* (normal= 35 to 55 ms) and represents conduction time through the His-Purkinje system.

Electrode catheters can be positioned in the area of the sinus node to record high right atrial activity. Left atrial activity may be recorded directly via a catheter placed across a patent foramen ovale or indirectly using a catheter inserted into the coronary sinus. The atrial activation sequence may be "mapped," and sites of intra- and interatrial conduction abnormalities may be ascertained.

SINUS NODE DYSFUNCTION

TheSA node is normally the dominant cardiac pacemaker because its intrinsic discharge rate is the highest of all potential cardiac pacemakers. Its responsiveness to alterations in autonomic nervous system tone is responsible for the normal acceleration of heart rate during exercise and the slowing that occurs during rest and sleep. Increases in sinus rate normally result from an increase in sympathetic tone acting via b-adrenergic receptors and/or a decrease in parasympathetic tone acting via muscarinic receptors. Slowing of the heart rate is normally due to opposite alterations. In adults, the normal sinus rate under basal conditions is 60 to 100 beats per minute. *Sinus bradycardia* is said to exist when the sinus rate is less than 60 beats per minute, and *sinus tachycardia* when it exceeds 100 beats per minute. However, there is wide variation among individuals, and rates less than 60 beats per minute do not necessarily indicate pathologic states. For example, trained athletes often exhibit resting rates under 50 beats per minute due to increases in vagal tone. Normal elderly individuals may also show marked sinus bradycardia at rest.

ETIOLOGY

SAnode dysfunction is most often found in the elderly as an isolated phenomenon. Although interruption of the blood supply to the SA node may produce dysfunction, the correlation between obstruction of the sinus node artery and clinical evidence of SA node dysfunction is poor. Specific disease states associated with SA node dysfunction include senile amyloidosis and other conditions associated with infiltration of the atrial myocardium. Sinus bradycardia is associated with hypothyroidism, advanced liver disease, hypothermia, typhoid fever, and brucellosis; it occurs during episodes of hypervagotonia (vasovagal syncope), severe hypoxia, hypercapnia, acidemia, and acute hypertension. However, most cases of SA node dysfunction are due to idiopathic degeneration or are secondary to pharmacologic agents.

MANIFESTATIONS

Although marked (£50 beats per minute) sinus bradycardia may cause fatigue and other symptoms due to inadequate cardiac output, more commonly sinus node dysfunction is manifest as paroxysmal dizziness, presyncope, or syncope. These symptoms usually result from abrupt, prolonged sinus pauses caused by failure of sinus impulse formation (sinus arrest) or block of conduction of sinus impulses to the surrounding atrial tissue (sinus exit block). In either case, theECGmanifestation is a prolonged period (>3 s) of atrial asystole. In some patients,SA node dysfunction is accompanied by abnormalities inAVconduction. In addition to the absence of atrial activity, lower pacemakers fail to emerge during the sinus pauses, resulting in periods of ventricular asystole and syncope. Occasionally, SA node dysfunction is manifested by an inadequate acceleration in sinus rate in response to a stress such as exercise or fever. In some

patients, SA node dysfunction may become manifest only in the presence of certain cardioactive drugs: cardiac glycosides,b-adrenergic blocking drugs, calcium channel blockers, amiodarone, and other antiarrhythmic agents. These agents, which do not usually cause sinus node dysfunction in normal people, may unmask evidence of sinus node dysfunction in susceptible individuals.

The *sick sinus syndrome* refers to a combination of symptoms (dizziness, confusion, fatigue, syncope, and congestive heart failure) caused bySA node dysfunction and manifested by marked sinus bradycardia, sinoatrial block, or sinus arrest. Because these symptoms are nonspecific, and becauseECGmanifestations of sinus node dysfunction are often intermittent, it may be difficult to prove that such symptoms are actually caused by SA node dysfunction.

Atrial tachyarrhythmias such as atrial fibrillation, atrial flutter, or atrial tachycardia may be accompanied bySA node dysfunction. The *bradycardia-tachycardia syndrome* refers to paroxysmal atrial arrhythmia that upon termination is followed by prolonged sinus pauses (Fig. 229-4) or in which there are alternating periods of tachyarrhythmia and bradyarrhythmia. Syncope or presyncope may result from failure of the sinus node to recover function following suppression of automaticity by atrial tachyarrhythmia.

DIAGNOSIS

First-degree sinoatrial exit block denotes a prolonged conduction time from theSA node to the surrounding atrial tissue. It cannot be recognized on a standard (surface)ECG but requires invasive intracardiac recordings, which can detect this condition indirectly, by measuring the sinus response to atrial premature beats, or directly, by recording SA node electrograms. *Second-degree sinoatrial exit block* denotes the intermittent failure of conduction of sinus impulses to the surrounding atrial tissue; it is manifested as the intermittent absence of P waves (Fig. 229-5). *Third-degree*, or *complete, sinoatrial block* is characterized by a lack of atrial activity or by the presence of an ectopic subsidiary atrial pacemaker. On the standard ECG it cannot be distinguished from sinus arrest, but direct intracardiac recordings of SA node activity permit this distinction. The *bradycardia-tachycardia syndrome* is manifested on the standard ECG as tachyarrhythmias (Fig. 229-4). Most often these are atrial flutter or fibrillation, although any tachycardia during which the atria are activated may cause overdrive suppression of the sinus node resulting in clinical appearance of this syndrome.

The most important step in the diagnosis is to correlate symptoms withECGevidence ofSA node dysfunction. While ambulatory ECG (Holter) monitoring remains a mainstay in evaluating sinus node function, most episodes of syncope are paroxysmal and unpredictable. Single and even multiple 24-h Holter monitor recordings may fail to include a symptomatic episode.

Caution must be taken in interpreting the Holter monitor results. For instance, a pause during sleep is often a normal finding associated with heightened vagal tone. This should not be interpreted as sinus node dysfunction requiring pacemaker implantation.

Continuous-loop event records represent a more specific diagnostic tool. These devices may be worn for prolonged periods of time and allow close correlation between

electrocardiographic findings and symptoms. They do require the patient's ability to activate the monitor at the time of symptoms. More recently, an implantable event recorder, which can be interrogated like a pacemaker, has been developed for patients with rare events.

The response to carotid sinus pressure and pharmacologic autonomic "denervation" of the heart may be helpful. Carotid sinus pressure can be particularly useful in patients in whom paroxysmal dizziness or syncope is compatible with the hypersensitive carotid sinus syndrome (Chap. 21). In such patients, the response can be dramatic, and sinus pauses in excess of 5 s may occur. Although pauses in excess of 3 s are considered abnormal, in elderly patients such pauses are common and do not necessarily signify a diagnostic response. This is a major limitation of the use of carotid sinus pressure as a diagnostic test in the elderly. The other noninvasive test ofSA node function involves the use of pharmacologic agents to manipulate the autonomic nervous system and assess the balance of parasympathetic and sympathetic activity on the sinus node. Physiologic or pharmacologic maneuvers that are vagomimetic (Valsalva maneuver or phenylephrine-induced hypertension), vagolytic (atropine), sympathomimetic (isoproterenol or hypotension by nitroprusside), or sympatholytic (b-adrenergic blocking agents) can be utilized, singly and in combination. These studies are designed to test the response of the sinus node to autonomic stimulation and inhibition and thereby characterize the status of autonomic regulation of the sinus node. Abnormalities of the autonomic control of sinus function are particularly common in patients in whom asymptomatic sinus bradycardia is documented.

Intrinsic Heart Rate This is a manifestation of the primary activity of theSA node, and its determination requires chemical autonomic blockade of the heart with a combination of atropine and a beta blocker. Normal values of intrinsic heart rate (in beats per minute) are calculated by the formula 118.1- (0.57 ´ age). The use of autonomic blockade can separate patients with asymptomatic sinus bradycardia into a group with primary sinus node dysfunction (slow intrinsic heart rate) and a group with autonomic imbalance (normal intrinsic heart rate). Autonomic blockade is particularly useful when combined with invasive assessment of sinus node function. Autonomic blockade may depress conduction in patients with intrinsic disease of the conduction system and should be carried out only in a setting where arrhythmias can be monitored and treated rapidly.

EVALUATION

The invasive electrophysiologic investigation ofSA node dysfunction should be undertaken in patients who have had symptoms compatible with SA node dysfunction and in whom no documentation of the arrhythmia responsible for these symptoms has been obtained by prolonged Holter monitoring. Asymptomatic patients with sinus bradycardia need *not* be tested, since no therapy is indicated. Similarly, symptomatic patients withECGdocumentation of asystole, sinoatrial block or arrest, or the bradycardia-tachycardia syndrome do not require electrophysiologic tests for diagnosis. However, in symptomatic patients without documentation of an arrhythmia, electrophysiologic assessment of SA node function can yield information that may be used to guide appropriate therapy.

The results of electrophysiologic tests of sinus node function must be interpreted with

caution.SA node dysfunction coexists frequently with other disorders such asAVconduction disturbances, which may cause symptoms such as syncope. Electrophysiologic evaluation of patients with symptoms such as undiagnosed syncope must not stop with the demonstration of abnormalities of SA node dysfunction or carotid sinus hypersensitivity. Instead, complete evaluation, including His bundle recordings and programmed atrial and ventricular stimulation (Chap. 230), is necessary to search for additional electrophysiologic abnormalities that could be responsible for symptoms.

TREATMENT

Permanent pacemakers (p. 1290) are the mainstay of therapy for patients with symptomaticSA node dysfunction. Patients with intermittent paroxysms of bradycardia or sinus arrest and with the cardioinhibitory form of the hypersensitive carotid sinus syndrome are usually adequately treated by demand ventricular pacemakers. These devices are reliable, relatively inexpensive, and suffice to prevent episodic symptoms due to abrupt bradycardia. Whether dual-chamber pacing offers any advantages to ventricular pacing in such circumstances remains uncertain. Patients with symptomatic chronic sinus bradycardia or frequent prolonged episodes of sinus node dysfunction do better with dual-chamber pacemakers that preserve the normalAVactivation sequence. Although theoretically an atrial demand pacemaker should be adequate for patients with SA node dysfunction, the frequent accompaniment of dysfunction in other portions of the cardiac conduction system usually mandates placement of a pacemaker capable of ventricular pacing. Recent studies suggest that AV sequential pacing may also be useful in preventing atrial fibrillation, an important component of the bradycardia-tachycardia syndrome.

AV CONDUCTION DISTURBANCES

The specialized cardiac conducting system normally ensures synchronous conduction of each sinus impulse from the atria to the ventricles. Abnormalities of conduction of the sinus impulse to the ventricles may portend the development of heart block, which can ultimately lead to syncope or cardiac arrest. In order to evaluate the clinical significance of conduction abnormalities, the physician must assess (1) the site of conduction disturbance, (2) the risk of progression to complete block, and (3) the probability that a subsidiary escape rhythm arising distal to the site of block will be electrophysiologically and hemodynamically stable. This latter point is perhaps the most important, since the rate and stability of the escape pacemaker determine what symptoms result from heart block. The escape pacemaker followingAV nodal block is usually in the His bundle, which generally has a stable rate of 40 to 60 beats per minute and is associated with a QRS complex of normal duration (in the absence of a preexisting intraventricular conduction defect). This contrasts with escape rhythms arising in the distal His-Purkinje system, which have lower intrinsic rates (25 to 45 beats per minute), manifest wide QRS complexes with prolonged duration, and are unstable. Thus, the most important issue is to assess the risk of infra- or intra-His block (which always mandates a pacemaker) or AV nodal block in which the frequency of the escape pacemaker is not sufficient to meet hemodynamic requirements (Table 229-1). Although prolonged QRS complexes are invariable when the distal His-Purkinje pacemakers form the escape mechanism, wide QRS complexes can also coexist with AV nodal block and a His bundle rhythm. Therefore, QRS morphology alone may not be adequate to identify the site of block.

ETIOLOGY

TheAV node is supplied by the parasympathetic and sympathetic nervous systems and is sensitive to variations in autonomic tone. Chronic slowing of AV nodal conduction may be seen in highly trained athletes who have hypervagotonia at rest. A variety of diseases and drugs can also influence AV nodal conduction. These include acute processes such as myocardial infarction (particularly inferior), coronary spasm (usually of the right coronary artery), digitalis intoxication, excesses of beta and/or calcium blockers, acute infections such as viral myocarditis, acute rheumatic fever, infectious mononucleosis, and miscellaneous disorders such as Lyme disease, sarcoidosis, amyloidosis, and neoplasms, particularly cardiac mesotheliomas. AV nodal block may also be congenital.

Two degenerative diseases are commonly responsible for damage to the specialized conducting system and produceAV block usually associated with bundle branch block (Chap. 226). In *Lev's disease*, there is calcification and sclerosis of the fibrous cardiac skeleton, which frequently involves the aortic and mitral valves, the central fibrous body, and the summit of the ventricular septum. *Lenegre's disease* appears to be a primary sclerodegenerative disease within the conducting system itself with no involvement of the myocardium or the fibrous skeleton of the heart. These two diseases are probably the most common causes of isolated chronic heart block in adults. Hypertension and aortic and/or mitral stenosis are specific disorders that either accelerate the degeneration of the conducting system or have a direct effect by calcification and fibrosis involving the conducting system.

First-degree AV block, more properly termed *prolonged AV conduction*, is classically characterized by a PR interval >0.20 s, but use of this value may be misleading in terms of clinical significance. Since the PR interval is determined by atrial,AVnodal, and His-Purkinje activation, delay in any one or more of these structures can contribute to a prolonged PR interval. In the presence of a QRS complex of normal duration, a PR interval >0.24 s almost invariably is due to a delay within the AV node. If the QRS is prolonged, delays may be present at any of the levels mentioned above. Delay within the His-Purkinje system is always accompanied by a prolonged QRS duration but can occur with a relatively normal PR interval (Fig. 229-6). However, as indicated below, it is only with intracardiac recordings that the exact site of delay can be determined.

Second-degree heart block (intermittentAVblock) is present when some atrial impulses fail to conduct to the ventricles. Mobitz type I second-degree AV block (AV Wenckebach block) is characterized by progressive PR interval prolongation prior to block of an atrial impulse (Fig. 229-7*A*). The pause that follows is less than fully compensatory (i.e., is less than two normal sinus intervals), and the PR interval of the first conducted impulse is shorter than the last conducted atrial impulse prior to the blocked P wave. Usually the difference between the longest and shortest PR intervals exceeds 100 ms. This type of block is almost always localized to the AV node and associated with a normal QRS duration, although bundle branch block may be present. It is seen most often as a transient abnormality with inferior wall infarction or with drug intoxication, particularly digitalis, beta blockers, and occasionally calcium channel antagonists. This type of block can also be observed in normal individuals with heightened vagal tone. Although Mobitz

type I block can progress to complete heart block, this is uncommon, except in the setting of acute inferior wall myocardial infarction. Even when it does, however, the heart block is usually well tolerated because the escape pacemaker usually arises in the proximal His bundle and provides a stable rhythm. As a result, the presence of Mobitz type I second-degree AV block rarely mandates aggressive therapy. Therapeutic decisions depend on the ventricular response and the symptoms of the patient. If the ventricular rate is adequate and the patient is asymptomatic, observation is sufficient.

In Mobitz type II second-degreeAVblock, conduction fails suddenly and unexpectedly without a preceding change in PR intervals (Fig. 229-7*B*). It is generally due to disease of the His-Purkinje system and is most often associated with a prolonged QRS duration. When Mobitz type II block occurs with a normal QRS duration, an intra-His site of block should be expected (Fig. 229-7*C*). It is important to recognize this type of block because it has a high incidence of progression to complete heart block with an unstable, slow, lower escape pacemaker. Therefore, pacemaker implantation is necessary in this condition. Mobitz type II block may occur in the setting of anteroseptal infarction or in the primary or secondary sclerodegenerative or calcific disorders of the fibrous skeleton of the heart. In so-called high-degree AV block there are periods of two or more consecutively blocked P waves, but intermittent conduction can be demonstrated. Block is usually in the His-Purkinje system, but simultaneous block in the AV node may also be present. Regardless of the site of origin of the escape rhythm, if it is slow and the patient is symptomatic, a cardiac pacemaker is mandatory.

Third-degree AV block is present when no atrial impulse propagates to the ventricles. If the QRS complex of the escape rhythm is of normal duration, occurs at a rate of 40 to 55 beats per minute, and increases with atropine or exercise,AV nodal block is probable. Congenital complete AV block is usually localized to the AV node. If the block is within the His bundle, the escape pacemaker is usually less responsive to these perturbations. If the escape rhythm of the QRS is wide and associated with rates £40 beats per minute, block is usually localized in, or distal to, the His bundle and mandates a pacemaker, since the escape rhythm in this setting is unreliable (Fig. 229-8). Some patients with infra-His bundle block are capable of retrograde conduction. In such patients, a "pacemaker syndrome" (see below) may develop if a simple ventricular pacemaker is used. Dual-chamber pacemakers eliminate this potential problem.

AV DISSOCIATION

AV dissociation exists whenever the atria and ventricles are under the control of two separate pacemakers and, while present in complete AV block, can occur in the absence of a primary conduction disturbance. AV dissociation unrelated to heart block may occur under two circumstances: First, it may develop with an AV junctional rhythm in response to severe sinus bradycardia. When the sinus rate and the escape rate are similar and the P waves occur just before, in, or following the QRS complex, *isorhythmic AV dissociation* is said to be present. Treatment usually consists of removal of the offending cause of sinus bradycardia (i.e., discontinuation of digitalis, beta blockers, or calcium antagonists), accelerating the sinus node by vagolytic agents, or insertion of a pacemaker if the escape rhythm is slow and results in symptoms. Second, AV dissociation can be caused by an enhanced lower (junctional or ventricular) pacemaker that competes with normal sinus rhythm and frequently exceeds it. This has been called

interference AV dissociation because the rapid lower pacemaker results in bombardment of the AV node in a retrograde fashion, rendering it refractory to the normal sinus impulses. Thus failure of antegrade conduction is a physiologic response in this circumstance. Interference dissociation commonly occurs during ventricular tachycardia, accelerated junctional or ventricular rhythms seen with digitalis intoxication, myocardial ischemia and/or infarction, or local irritation following cardiac surgery. The accelerated rhythm should be treated with either antiarrhythmic drugs (Chap. 230), removal of an offending drug, or correction of the metabolic abnormality or ischemia.

INTRACARDIAC ELECTROCARDIOGRAPHIC RECORDINGS IN DIAGNOSIS AND MANAGEMENT

The main therapeutic decision in patients withAVconduction disturbance is whether or not a permanent pacemaker is required, and a number of circumstances exist in which His bundle electrocardiography can be a useful diagnostic tool upon which to base this decision. It is unquestionable that patients with *symptomatic* second- or third-degree AV block should be paced, and therefore, these patients do not require electrophysiologic study. However, intracardiacECGrecordings can be useful in at least the following four groups of patients:

1. *Patients with syncope and bundle branch or bifascicular block without documentation ofAVblock*. In such patients, the demonstration of marked infra-His bundle conduction disturbances, i.e., a prolonged HV interval (>100 ms), may usually be taken as an indication of the need for the insertion of the permanent pacemaker. Complete electrophysiologic evaluation, including atrial and ventricular programmed stimulation, is indicated to help identify other possible cardiac etiologies for the syncope. Since the incidence of significant advanced AV block is low in *asymptomatic* patients who have bifascicular block, electrophysiologic evaluation or permanent pacemakers are not cost-effective. In this group, observation appears most reasonable.

2. *Patients with 2:1 AV conduction*. Intracardiac recordings are necessary to ascertain the site of the conduction disturbance because the typicalECGfeatures of Mobitz type I or Mobitz type II block cannot be discerned during a 2:1 pattern ofAVconduction on the surface ECG. Intracardiac recordings may demonstrate that AV nodal block, intra-His bundle block, infra-His bundle block, or combinations of block may be responsible (Figs. 229-7 and229-8). A surface ECG finding that suggests an infra-His bundle lesion is the presence of alternating bundle branch block associated with changing PR intervals. Intracardiac recordings in such patients confirm that the block is almost always in the His-Purkinje system. Increasing block with exercise or following atropine suggests intra- or infra-His block (Table 229-2). The finding of infra- or intra-His bundle block in patients with asymptomatic second-degree AV block mandates pacemaker therapy because of the high likelihood of the development of symptomatic high-grade AV block and syncope.

3. *Patients with Wenckebach block in the presence of bundle branch block*. This situation, particularly when the maximal change in PR interval is£ 50 ms, can suggest intra- or infra-His Wenckebach block, in which case a pacemaker is mandated. Intracardiac recordings are necessary to make this diagnosis.

4. *Asymptomatic patients with third-degreeAVblock*. In such patients, electrophysiologic studies may be useful in assessing the stability of the junctional pacemaker. Pacing is indicated when the His bundle escape pacemaker is shown to be unstable by an inadequate response to exercise, atropine, or isoproterenol or by a prolonged junctional recovery time following ventricular pacing.

GENETIC CONSIDERATIONS

A number of congenital and familial syndromes involving the cardiac conduction system have been described. An example of a congenital condition that is transmitted but not genetic is congenital complete heart block associated with material systemic lupus erythematosus. This disorder is associated with maternal IgG autoantibodies to several ribonucleoproteins that are transplacentally transmitted to the fetus and damage the fetalAV node. The fetal conduction disease is generally clinically evident by the second trimester and is associated with significant fetal mortality and neonatal requirement of cardiac pacing.

The embryonic development of the cardiac septa and conduction system occur together, and clinical disorders have been described, including the Holt-Oram syndrome, an autosomal dominant disorder including upper limb dysplasia and atrial septal defect, often with conduction disturbances in theAV node. Studies of families with a high incidence of congenital heart disease, including ostium secundum atrial septal defect and conduction disorders in the AV node, have identified the gene NKX2-5 on chromosome 5q35 as important in the regulation of septation and in the development and function of the AV node. A familial syndrome of progressive complete heart block has also long been recognized. The gene for this disorder has been mapped to a region on chromosome 19q13. Familial disorders ofSA node function have also been described, but specific details of abnormal genetic sites are not available.

TREATMENT

Pharmacologic Therapy Pharmacologic therapy is usually reserved for acute situations. Atropine (0.5 to 2.0 mg intravenously) and isoproterenol (1 to 4 ug/min intravenously) are useful in increasing heart rate and decreasing symptoms in patients with sinus bradycardia orAV block localized to the AV node. They have an insignificant effect on lower pacemakers. In patients with neurovascular syncope, beta blockers and disopyramide have been suggested as methods to depress left ventricular function and decrease mechanoreceptor-related reflexes. Mineralocorticoids, ephedrine, and theophylline have also been reported to be of benefit to occasional patients. Unfortunately, no controlled study has shown that any of these pharmacologic modalities works in a predictable fashion in all patients. Further work on delineating different mechanisms in different patient groups may allow us to apply pharmacologic agents more appropriately. Long-term therapy of bradyarrhythmias is best accomplished by pacemakers.

Pacemakers External energy sources can be used to stimulate the heart when disorders in impulse formation and/or transmission lead to symptomatic bradyarrhythmias (Fig. 229-CD1). Pacer stimuli can be applied to the atria and/or ventricles. Indications for pacemaker insertion are listed in theGuidelines.

Temporary Pacing This is usually instituted to provide immediate stabilization prior to permanent pacemaker placement or to provide pacemaker support when a bradycardia is precipitated by what is presumed to be a transient event such as ischemia or drug toxicity. Temporary pacing is usually achieved by the transvenous insertion of an electrode catheter with the catheter positioned in the right ventricular apex and attached to an external generator. This procedure is associated with a small risk of cardiac perforation, infection at the insertion site, and thromboembolism; the risk of the latter two complications increases markedly if the pacing wire is left in place for more than 48 h. The development of an entirely external transthoracic cardiac pacing system may preclude the need for transvenous pacing in selected patients. However, occasional failure of ventricular capture and significant discomfort related to the large current required for effective transthoracic ventricular stimulation preclude the uniform use of this approach.

Permanent Pacing This mode of pacing is instituted for persistent or intermittent symptomatic bradycardia not related to a self-limiting precipitating factor or for documented infranodal second- or third-degreeAVblock. Permanent pacing leads are usually inserted transvenously through the subclavian or cephalic vein with the leads positioned in the right atrial appendage for atrial pacing and the right ventricular apex for ventricular pacing. The leads are then attached to the pulse generator, which is inserted into a subcutaneous pocket below the clavicle. Epicardial lead placement is used when (1) transvenous access cannot be obtained; (2) the chest is already open, i.e., in the course of a cardiac operation; and (3) adequate endocardial lead placement cannot be achieved. Most pacemaker generators are powered by lithium batteries. The life expectancy of the generator is related to (1) voltage output required for capture, (2) requirement for incessant or intermittent pacing, and (3) number of cardiac chambers paced. Life expectancy of the simple ventricular demand pacemaker can exceed 10 years.

Pacing Code A code consisting of three to five letters has been developed for describing pacemaker type and function (Table 229-3). The first letter indicates the chamber(s) paced and is designated *V* for ventricular pacing, *A* for atrial pacing, or *D* for dual-chamber (both atrial and ventricular) pacing. The second letter indicates the chamber in which electrical activity is sensed and is also indicated by *A*, *V*, or *D*. An additional designation, *O*, has been used when pacemaker discharge is not dependent on a sensed electrical activity. The third letter refers to the response to a sensed electric signal. The letter *O* represents no response to an underlying electric signal, usually related to the absence of associated sensing function; *I* represents inhibition of pacing function; *T* represents triggering of pacing function; and *D* indicates a dual response, i.e., spontaneous atrial and ventricular activity inhibiting atrial and ventricular pacing and atrial activity triggering a ventricular response. Additional fourth and fifth letters of the pacing code have been recommended to indicate whether the pacemaker is programmable and has rate modulation (fourth) and whether special antitachycardia functions are available (i.e., antitachycardia pacing, *T*, and delivery of high- or low-energy shocks). In the fourth category, *M* represents multiprogrammability and *R* represents rate response ("physiologic") pacing. It follows from the described code that the standard VVIR (ventricular demand pacemaker) paces the ventricle, senses the ventricle, is inhibited by sensed spontaneous ventricular activity, and has rate

modulation, while the DDDR pulse generator is capable of sensing and pacing both the atria and ventricles and has a dual response to the sensed atrial and ventricular activity as described above (Fig. 229-9). Both pacemakers have rate modulation (*R*). "Physiologic" pacemakers use sensors (muscular activity, respiratory rate, temperature, O_2saturation, QT interval, etc.) as methods to allow the pacemaker to increase the heart rate in response to physiologic demands, i.e., exercise. These pacemakers are essential when chronotropic incompetence is present and an increase in heart rate is required to enhance physiologic performance. Studies have shown that such "physiologic" pacemakers improve exercise tolerance and relieve symptoms to a greater degree than fixed-rate pacemakers.

Selection of the appropriate pacemaker and pacing mode depends on the clinical condition and the type of bradyarrhythmia being treated. The two most common pacing mode selections are DDD and VVI. DDD providesAVsequential pacing, which is ideally suited for the relatively young and active patient who has intact sinus node function or intermittent dysfunction and high-grade persistent or intermittent AV block. The DDD mode will allow for physiologic atrial sensed and ventricular paced rates and improve exercise tolerance. AV synchrony and dual-chamber pacing may also be desirable in patients with borderline hemodynamic reserve who are dependent on atrial contribution to cardiac output and in those patients who develop the pacemaker syndrome (see below) in response to ventricular demand pacing.

Rate-responsive DDD (i.e., DDDR) pacing is indicated when chronotropic incompetence is present in a patient who requiresAVsynchrony. The DDD pacing mode is contraindicated in chronic atrial fibrillation or flutter, because rapid and irregular ventricular pacing will occur to the upper rate limit. In some cases this will produce a more rapid ventricular rate than the patient's own rate in the absence of a pacemaker. DDD pacemakers must either automatically switch (i.e., mode-switching function) or be reprogrammed to the VVI mode. Almost all such pacemakers are now combined with some form of rate responsiveness so that when the device functions in the VVI mode, it also will respond to physiologic demands (VVIR).

Chronotropic insufficiency (i.e., the inability of the sinus rate to accelerate) is a contraindication for a DDD pacemaker, since such a pacemaker will act as a "fixed-rate" pacemaker at the programmed lower rate. In these situations, a rate-adaptive or "physiologic" pacemaker is indicated (VVIR or DDDR). In patients with impaired sinus node function or chronic atrial fibrillation, a sensor-driven, rate-adaptive pacemaker must be implanted. As mentioned earlier, these pacemakers automatically adjust ventricular pacing rates to a sensed indicator of exertion. The DDD pacing mode may also be contraindicated in patients with intermittent or persistent ventriculoatrial conduction, who may develop pacemaker-mediated tachycardia (see below).

Programmability of Pacemakers This allows for modification of pacing function after implantation and for adaptation to changes in clinical needs. Pacemaker programming is accomplished by activation of the programming head positioned over the implanted pulse generator after making the desired changes in programmable parameters (Table 229-3). A radio frequency system is routinely used to communicate the program to the pacemaker. A high degree of sophistication is required to recognize the presence and causes of pacemaker malfunction and their treatment.

Complications Adverse effects of permanent pacing are usually associated with failure or malfunction of the pacing system. These problems are usually secondary to over- or undersensing, output failure, and/or lead fracture or displacement. Two other problems may occur. The *pacemaker syndrome* consists of fatigue, dizziness, syncope, and distressing pulsations in the neck and chest and can be associated with adverse hemodynamic effects. The pathophysiologic contributors to the pacemaker syndrome include (1) loss of atrial contribution to ventricular systole; (2) vasodepressor reflex initiated by cannon *a* waves, which are caused by atrial contractions against a closed tricuspid valve and observed in the jugular venous pulse (Chap. 225); and (3) systemic and pulmonary venous regurgitation due to atrial contraction against a closedAVvalve. The symptoms associated with the pacemaker syndrome can be prevented by maintaining AV synchrony by dual-chamber pacing or, in the case of a ventricular demand pacemaker, by programming an escape rate 15 to 20 beats per minute below that of the paced rate (i.e., hysteresis). As a result of this programming, sinus activity and thus atrial contraction will be less likely to occur at the same time as ventricular pacing and ventricular contraction. The second major problem peculiar to dual-chamber pacemakers is the development of *pacemaker-mediated tachycardia*. In this instance, retrograde depolarization of the atria, resulting from a premature ventricular depolarization or a paced ventricular complex, is sensed and leads to subsequent triggering of ventricular pacing. This, in turn, can result in repetition of the phenomenon of ventriculoatrial conduction with the development of an endless-loop, pacemaker-mediated tachycardia. It may be corrected by reprogramming the atrial refractory period.

230. THE TACHYARRHYTHMIAS - *Mark E. Josephson, Peter Zimetbaum*

MECHANISMS OF TACHYARRHYTHMIAS

Tachyarrhythmias may be divided into disorders of impulse propagation and disorders of impulse formation.

REENTRY

Disorders of impulse propagation (reentry) are generally considered to be the most common mechanism of sustained paroxysmal tachyarrhythmia. The requirements for initiating reentry include (1) electrophysiologic inhomogeneity (i.e., differences in conduction and/or refractoriness) in two or more regions of the heart connected with each other to form a potentially closed loop; (2) unidirectional block in one pathway; (3) slow conduction over an alternative pathway, allowing time for the initially blocked pathway to recover excitability; and (4) reexcitation of the initially blocked pathway to complete a loop of activation (Fig. 230-1). Repetitive circulation of the impulse over this loop can produce a sustained tachyarrhythmia. While anatomic obstacles may underlie reentry and provide an inexcitable center around which the impulse can circulate, they are not essential. Reentrant arrhythmias can be reproducibly initiated and terminated by premature complexes and rapid stimulation. The response of these arrhythmias to stimulation can help distinguish them from arrhythmias caused by triggered activity.

ENHANCED AUTOMATICITY

Disorders of impulse formation can be subdivided into tachyarrhythmias caused by enhanced automaticity and those caused by triggered activity. In addition to the sinus node, automatic pacemaker activity can be observed in specialized atrial fibers, fibers of the atrioventricular (AV) junction, and Purkinje fibers (Chap. 229). Myocardial cells do not normally possess pacemaker activity. Enhancement of normal automaticity in latent pacemaker fibers or the development of abnormal automaticity due to partial depolarization of the resting membrane occurs as a consequence of a variety of pathophysiologic states, which include (1) increased endogenous or exogenous catecholamines, (2) electrolyte disturbances (e.g., hyperkalemia), (3) hypoxia or ischemia, (4) mechanical effects (e.g., stretch), and (5) drugs (e.g., digitalis). Tachycardia caused by automaticity cannot be started or stopped by pacing.

TRIGGERED ACTIVITY

Rhythms due to triggered activity are events that do not occur spontaneously but require a change in cardiac electrical frequency as a trigger. Triggered activity may be caused by early afterdepolarizations, which occur during phases 2 and 3 of the action potential, or delayed afterdepolarizations, which occur following completion of phase 3 of the action potential (Fig. 229-2). Triggered activity has been observed in atrial, ventricular, and His-Purkinje tissue under conditions such as increased local catecholamine concentration, hyperkalemia, hypercalcemia, and digitalis intoxication (delayed afterdepolarizations) or during bradycardia, hypokalemia, or other situations prolonging action potential duration (early afterdepolarizations). All of these conditions produce an accumulation of intracellular calcium. With increasing amplitude of the

afterdepolarizations, threshold can be reached and repetitive activity produced. The exact role of triggered activity in spontaneous clinical arrhythmias is unknown, but tachyarrhythmias associated with digitalis intoxication, accelerated idioventricular rhythm in acute infarction and/or reperfusion, and exercise-induced ventricular tachycardia (VT) are believed to be caused by triggered activity due to delayed afterdepolarizations. *Torsade de pointes* ("twisting of the points"; polymorphic VT associated with long QT intervals) may be caused by triggered activity due to early afterdepolarizations, although reentry may also be operative.

The use of electrophysiologic studies, i.e., intracardiac recordings and programmed stimulation, has greatly expanded the understanding of the mechanisms of tachyarrhythmias. In addition to helping diagnose arrhythmias, these techniques may be of value in determining the most appropriate types of therapy because they allow the physician to observe the hemodynamic and symptomatic consequences of the arrhythmia in the presence or absence of therapy. Electrophysiologic studies of tachycardias require the positioning of multiple electrode catheters at critical areas within the heart. These electrodes must be capable of both stimulating and recording from multiple sites in the atria and/or ventricles.

PREMATURE COMPLEXES

ATRIAL PREMATURE COMPLEXES (APC)

APCscan be found on 24-h Holter monitoring in over 60% of normal adults. APCs are usually asymptomatic and benign, although at times they may be associated with palpitations. In susceptible patients, they can initiate paroxysmal supraventricular tachycardias. APCs may originate from any location in either atrium, and they are recognized on the electrocardiogram (ECG) as early P waves with a morphology that differs from the sinus P wave (Fig. 230-2). While APCs usually conduct to the ventricles when they occur late in the cardiac cycle, early APCs may reach theAVconduction system while it is still in its relative refractory period, resulting in a conduction delay manifested by prolonged PR interval following the premature P wave (Fig. 230-2). Very early APCs may even block in the AV node if this structure is encountered during its effective refractory period. APCs, whether conducted or not, are usually followed by a pause before a return to sinus activity. Most commonly, an APC enters and resets the sinus node, so the sum of the pre- and postextrasystolic PP intervals is less than the sum of two sinus PP intervals (Fig. 230-2). In this case, the pause is said to be less than fully compensatory. The QRS complex following most APCs is normal, although early APCs may be followed by aberrantly conducted QRS complexes due to the premature complex falling within the relative refractory period of the His-Purkinje system.

Since mostAPCs are asymptomatic, treatment is not required. When they cause palpitations or trigger paroxysmal supraventricular tachycardias (see below), treatment may be useful. Factors that precipitate APCs, such as alcohol, tobacco, or adrenergic stimulants, should be identified and eliminated; in their absence, mild sedation or the use of a beta blocker may be tried.

AVJUNCTIONAL COMPLEXES

The site of origin of these complexes is thought to be in the bundle of His, since the normal AV node in vivo possesses no automaticity. AV junctional complexes are less common than either atrial or ventricular premature complexes and are more often associated with cardiac disease or digitalis intoxication. Junctional premature impulses can conduct both antegradely to the ventricles and retrogradely to the atrium and, on rare occasions, may fail to conduct in either direction. Premature AV junctional complexes can be recognized by normal-appearing QRS complexes that are not preceded by a P wave. Retrograde P waves (inverted in leads II, III, and aVF) may be observed after the QRS complex.

While often asymptomatic, junctional premature complexes may be associated with palpitations and cause cannon *a* waves, which may result in distressing pulsations in the neck. When symptomatic, they should be treated likeAPCs.

VENTRICULAR PREMATURE COMPLEXES (VPCS)

These are among the most common arrhythmias and occur in patients with and without heart disease. Of adult males, ³60% will exhibit VPCs during a 24-h Holter monitoring. In patients without heart disease, VPCs have not been shown to be associated with any increased incidence in mortality or morbidity. VPCs may occur in up to 80% of patients with previous myocardial infarction, and in this setting, if frequent (>10 per hour) and/or complex (occurring in couplets), they have been associated with increased mortality. However, cardiac mortality in such patients usually occurs in association with significantly impaired ventricular function. While frequent and complex ventricular ectopy is an independent risk factor, it is not as strong a risk factor as is impaired ventricular function. Moreover, even though ventricular tachycardia and/or fibrillation may be the basis for the sudden death in these patients, this does not a priori establish a cause-and-effect relation between spontaneous ectopy and life-threatening ventricular tachycardia or fibrillation. Very early cycle (R-on-T) VPCs have been stated by some to increase the risk of sudden death. Although this has been observed during acute ischemia and in the setting of QT prolongation, frequently,VT or fibrillation is precipitated by VPCs that occur after the T wave of the prior beat.

VPCsare recognized by wide (usually >0.14 s), bizarre QRS complexes that are not preceded by P waves (Fig. 230-3*A*). They may bear a relatively fixed relationship to the preceding sinus complex (i.e., fixed coupled VPCs). When fixed coupling is not present and the interval between VPCs has a common denominator, *ventricular parasystole* is said to be present (Fig. 230-4). Under these circumstances, the VPCs are a manifestation of abnormal automaticity of a protected ventricular focus. Because this focus is not penetrated by sinus impulses, it is not reset by them, and the interectopic intervals remain relatively fixed (£120 ms variation of mean RR cycle length).

VPCsmay occur singly; in patterns of bigeminy, in which every sinus beat is followed by a VPC; in trigeminy, in which two sinus beats are followed by a VPC; in quadrigeminy, etc. Two successive VPCs are termed *pairs* or *couplets*, while three or more consecutive VPCs are termed *ventricular tachycardia* when the rate exceeds 100 beats per minute (Fig. 230-3*B*). VPCs may have similar morphologies (monomorphic, or uniform) or different morphologies (polymorphic, or multiformed).

Most commonly,VPCs are not conducted retrogradely to the atrium to reset the sinoatrial node. Thus they produce a fully compensatory pause; i.e., the interval between conducted sinus beats that bracket the VPC equals two basic RR intervals. Ventricular impulses may also manifest retrograde conduction to the atrium and cause inverted P waves in leads II, III, and aVF. This retrograde atrial activation can reset the sinus node, and the pause that results may therefore be less than compensatory. In many instances, the VPC will not be associated with retrograde ventriculoatrial (VA) conduction but may block retrogradely in theAV node. This renders the AV node refractory to the subsequent sinus beat and causes slowed conduction (i.e., prolonged PR interval) or block of the next sinus P wave. This prolonged PR interval is said to be a manifestation of concealed retrograde conduction of the ventricular impulse into the AV node. A VPC that does not produce any manifestation of retrograde concealed conduction and fails to influence the oncoming sinus impulse is termed an *interpolated VPC*.

VPCscan cause palpitations or neck pulsations secondary to either the occurrence of cannon *a* waves or the increased force of contraction due to postextrasystolic potentiation of ventricular contractility. Patients with frequent VPCs or bigeminy may rarely develop syncope or lightheadedness because the VPCs do not result in an adequate stroke volume and the cardiac output is reduced by the "halving" of the heart rate.

TREATMENT

In the absence of cardiac disease, isolated asymptomaticVPCs, regardless of configuration and frequency, need no treatment. When arrhythmias are symptomatic, the symptoms should first be addressed by either allaying the patient's anxiety or, if this is not successful, reducing the frequency of the VPCs with antiarrhythmic agents. b-Adrenergic blockers may be successful in managing VPCs that occur primarily in the daytime or under stressful situations and in specific settings such as mitral valve prolapse and thyrotoxicosis. While other antiarrhythmic agents may be tried should this be unsuccessful, their risk may outweigh any benefits. In patients with cardiac disease, frequent VPCs are associated with an increased risk of sudden and nonsudden cardiac death, and many physicians have attempted to eliminate or reduce the frequency of these VPCs in an attempt to reduce this risk. However, the cause-and-effect relationship of the VPCs to fatal events has never been established. The ability of pharmacologic antiarrhythmic therapy guided by continuousECGmonitoring to reduce the risk of sudden death in postmyocardial infarction patients with frequent (³6 per minute) VPCs was tested by the Cardiac Arrhythmia Suppression Trial (CAST). This study compared mortality in patients whose ectopy was suppressed by one of three agents (encainide, flecainide, or moricizine) and then randomized to treat with either the "effective" drug or placebo. After a mean follow-up of 2 years, the study was discontinued because both the sudden death and overall mortality rate were significantly increased in patients receiving antiarrhythmic agents. This study has shown that in patients having the characteristics of the study population, abolition of ventricular ectopy by pharmacologic therapy cannot be used as a marker to define reduction of the risk of sudden death after myocardial infarction and, in fact, may increase mortality. Recent studies have evaluated the use of electrophysiologic testing and implantable cardioverter/defibrillator (ICD) placement in the management of patients at high risk for sudden death (i.e., those

with left ventricular ejection fractions<40% and nonsustainedVT). These studies have found that induction of a sustained ventricular arrhythmia through programmed electrical stimulation selects a group of these patients whose prognosis is improved with implantation of a defibrillator. These studies have found no correlation between the rate, morphology, or duration of nonsustained episodes of VT and the likelihood of having a sustained ventricular arrhythmia.

Antiarrhythmic agents can also produce the lethal arrhythmias that they are given to prevent (proarrhythmic effects). Thus therapy directed towardVPCs in the setting of chronic cardiac disease may result in an inappropriate and costly use of agents without proven efficacy and with potential side effects in many patients. The high incidence of side effects and the frequent exacerbation of arrhythmias caused by all antiarrhythmic drugs make it mandatory to monitor patients being treated with such agents.

In acute myocardial infarction, the greatest incidence of primary ventricular fibrillation occurs within the first 24 h (Chap. 243). Temporary prophylactic antiarrhythmic therapy with lidocaine or procainamide was formerly recommended for all patients with acute infarction, regardless of the presence or degree of spontaneous ectopy. However, failure to improve overall survival and drug toxicity have led most physicians to recommend prophylactic antiarrhythmic therapy only to young patients with complicated infarctions, where a favorable risk-benefit ratio may be obtained. Other studies have shown that intravenous beta blockers may also reduce the incidence of primary ventricular fibrillation.

TACHYCARDIAS

Tachycardias refer to arrhythmias with three or more complexes at rates exceeding 100 beats per minute; they occur more often in structurally diseased than in normal hearts. Those paroxysmal tachycardias that are initiated byAPCs orVPCs are considered to be due to reentry, except some of the digitalis-induced tachyarrhythmias, which are probably due to triggered activity (see below).

If the patient is hemodynamically stable, an attempt should be made to determine the mechanism and origin of the tachycardia, since this will usually lead to an appropriate therapeutic decision. Information to be obtained from theECGincludes (1) the presence, frequency, morphology, and regularity of P waves and QRS complexes; (2) the relationship between atrial and ventricular activity; (3) a comparison of the QRS morphology during sinus rhythm and during the tachycardia; and (4) the response to carotid sinus massage or other vagal maneuvers. It is useful first to compare a 12-lead ECG during the tachycardia with one recorded during sinus rhythm. One can also utilize the electrodes situated at the end of a flexible pacing catheter inserted into the esophagus behind the left atrium to record atrial activity.

Observation of the jugular venous pulse can provide clues to the presence of atrial activity and its relationship to ventricular ectopy. Intermittent cannon *a* waves suggestAVdissociation, while persistent cannon a waves suggest 1:1VAconduction. Flutter waves may be seen or no atrial activity may be apparent, as in the presence of atrial flutter and fibrillation, respectively. The arterial pulse may also manifest AV dissociation or atrial fibrillation by demonstrating variations in amplitude. A first heart

sound of variable intensity during a regular rhythm also suggests AV dissociation or atrial fibrillation (AF).

Carotid sinus pressure should only be applied while the patient is electrocardiographically monitored with resuscitative equipment available to manage the rare episode of asystole and/or ventricular fibrillation associated with this procedure. Carotid sinus massage should not be performed in patients with carotid arterial bruits. The patient should be positioned flat with the neck extended. Massage of one carotid bulb at a time should be performed by applying firm pressure just underneath the angle of the jaw for up to 5 s. Alternative vagomimetic maneuvers include the Valsalva maneuver, immersion of the face in cold water, and administration of 5 to 10 mg edrophonium.

SINUS TACHYCARDIA

In the adult, sinus tachycardia is said to be present when the heart rate exceeds 100 beats per minute (bpm): sinus tachycardia rarely exceeds 200 bpm and is not a primary arrhythmia; instead, it represents a physiologic response to a variety of stresses, such as fever, volume depletion, anxiety, exercise, thyrotoxicosis, hypoxemia, hypotension, or congestive heart failure. Sinus tachycardia has a gradual onset and offset. TheECGdemonstrates P waves with sinus contour preceding each QRS complex. Carotid sinus pressure usually produces modest slowing with a gradual return to the previous rate upon cessation. This contrasts with the response of paroxysmal supraventricular tachycardias, which may slow slightly and terminate abruptly.

TREATMENT

Sinus tachycardia should not be treated as a primary arrhythmia, since it is almost always a physiologic response to a demand placed on the heart. As such, the therapy should be directed to the primary disorder. This may involve institution of digitalis and/or diuretics for heart failure and oxygen for hypoxemia, treatment of thyrotoxicosis, volume repletion, aspirin for fever, or tranquilizers for emotional upset.

ATRIAL FIBRILLATION

AFis a common arrhythmia that may occur in paroxysmal and persistent forms. It may be seen in normal subjects, particularly during emotional stress or following surgery, exercise, acute alcoholic intoxication, or a prominent surge of vagal tone (i.e., vasovagal response). It may also occur in patients with heart or lung disease who develop acute hypoxia, hypercapnia, or metabolic or hemodynamic derangements. Persistent AF usually occurs in patients with cardiovascular disease, most commonly rheumatic heart disease, nonrheumatic mitral valve disease, hypertensive cardiovascular disease, chronic lung disease, atrial septal defect, and a variety of miscellaneous cardiac abnormalities. AF may be the presenting finding in thyrotoxicosis. So-called lone AF, which occurs in patients without underlying heart disease, often represents the tachycardia phase of the tachycardia-bradycardia syndrome.

The morbidity associated withAF is related to (1) excessive ventricular rate, which in turn may lead to hypotension, pulmonary congestion, or angina pectoris in susceptible

individuals; (2) the pause following cessation of AF, which can cause syncope; (3) systemic embolization, which occurs most commonly in patients with rheumatic heart disease (Table 230-1); (4) loss of the contribution of atrial contraction to cardiac output, which may cause fatigue; and (5) anxiety secondary to palpitations. In patients with severe cardiac dysfunction, particularly those with hypertrophied, noncompliant ventricles, the combination of the loss of the atrial contribution to ventricular filling and the abbreviated filling period due to the rapid ventricular rate in AF can produce marked hemodynamic instability, resulting in hypotension, syncope, or heart failure. In patients with mitral stenosis, in whom ventricular filling time is critical, development of AF with a rapid ventricular rate may precipitate pulmonary edema (Chap. 236). AF may also cause a cardiomyopathy related to persistent rapid rates (so-called tachycardia-induced cardiomyopathy).

AFis characterized by disorganized atrial activity without discrete P waves on the surfaceECG(Fig. 230-5*A*). Atrial activation is manifested by an undulating baseline or by more sharply inscribed atrial deflections of varying amplitude and frequency ranging from 350 to 600 beats per minute. The ventricular response is irregularly irregular. This results from the large number of atrial impulses that penetrate theAV node, making it partially refractory to subsequent impulses. This effect of nonconducted atrial impulses to influence the response to subsequent atrial impulses is termed *concealed conduction*. As a result, the ventricular response is relatively slow, considering the actual atrial rate. AF may convert to atrial flutter, especially in response to antiarrhythmic drugs like quinidine or flecainide. If AF converts to atrial flutter, which has a slower atrial rate, the effect of concealed conduction may be diminished, and a paradoxic increase in the ventricular response may occur. The main factor determining the rate of the ventricular response is the functional refractory period of the AV node or the most rapid paced rate at which 1:1 conduction through the AV node can be observed.

If, in the presence ofAF, the ventricular rhythm becomes regular and slow (e.g., 30 to 60 bpm), complete heart block is suggested, and if the ventricular rhythm is regular and rapid (e.g.,^{3}100 bpm), a tachycardia arising in theAVjunction or ventricle should be suspected. Digitalis intoxication is a common cause of both phenomena.

Patients withAFexhibit a loss of *a* waves in the jugular venous pulse and variable pulse pressures in the carotid arterial pulse. The first heart sound usually varies in intensity. On echocardiography, the left atrium is frequently enlarged, and in patients in whom the left atrial diameter exceeds 4.5 cm, it may be difficult to convert AF to sinus rhythm and/or maintain the latter, despite therapy.

TREATMENT

In acuteAF, a precipitating factor such as fever, pneumonia, alcoholic intoxication, thyrotoxicosis, pulmonary emboli, congestive heart failure, or pericarditis should be sought. When such a factor is present, therapy should be directed toward the primary abnormality. If the patient's clinical status is severely compromised, electrical cardioversion is the treatment of choice. In the absence of severe cardiovascular compromise, slowing of ventricular rate becomes the initial therapeutic goal. This may be most rapidly accomplished withb-adrenergic blockers and/or calcium channel antagonists. Both prolong the refractory period of theAV node and slow conduction

within it. When catecholamine levels or sympathetic nervous system tone is likely to be elevated, beta blockers may be favored. Digitalis preparations are less effective, take longer to act, and are associated with more toxicity. Conversion to sinus rhythm may then be attempted. Prior to cardioversion, precautions must be taken to reduce the risk of systemic embolization. Patients should be anticoagulated to an INR of at least 1.8 for the prior 3 consecutive weeks or have had AF for<48 h. Alternatively, for those patients with AF for >48 h who are not anticoagulated, a transesophageal echocardiogram can exclude the presence of left atrial thrombus and allow safe cardioversion. Following cardioversion, anticoagulation must be maintained for at least 4 weeks until atrial mechanical function returns to normal.

Antiarrhythmic medications in either oral or intravenous form may be employed but are only modestly effective in restoring sinus rhythm. When antiarrhythmic agents such as the quinidine-like drugs (type 1A) or the flecainide-like agents (type 1C) are used (Table 230-2), it is important to increaseAV node refractoriness prior to administering such drugs because their vagolytic effect and/or their ability to convertAF to atrial flutter may reduce the concealed conduction in the AV node and lead to an excessively rapid ventricular response. b-Adrenergic blockers are especially useful in this regard.

Direct-current electrical cardioversion is a highly effective method to restore sinus rhythm, either as a primary method of therapy or following the failure of antiarrhythmic medications. Electrical cardioversion is accomplished through the delivery of at least 200 W× s of energy between electrodes placed to the right of the sternum and the cardiac apex or to the left of the scapula. If external cardioversion is unsuccessful, internal cardioversion with energy delivered between two catheters inside the heart or one inside and a patch outside the heart may prove effective.

It is unlikely that patients with chronicAF will convert to and remain in sinus rhythm in the presence of long-standing rheumatic heart disease and/or when the atria are markedly enlarged. It is also unlikely for patients with recurrent, paroxysmal lone AF to be converted to and maintained in sinus rhythm.

The goal of therapy in patients in whomAFcannot be converted to sinus rhythm is control of the ventricular response. This can usually be accomplished by digitalis, beta blockers, or calcium channel blockers singly or in combination. In occasional patients, the ventricular response cannot be controlled by pharmacologic therapy alone. In such patients, the creation of complete heart block by radiofrequency catheter ablation of theAVjunction followed by permanent pacemaker implantation is appropriate. Surgical or direct-current catheter ablation of the AV junction is rarely required to achieve AV block.

If sinus rhythm is restored electrically or pharmacologically, quinidine or related agents as well as the class IC agents (e.g., flecainide), sotalol, or amiodarone may be used to prevent recurrence. In patients in whom cardioversion is unsuccessful or in whomAF has recurred or is likely to recur despite antiarrhythmic therapy, it is probably wisest to allow the patient to remain inAF and to control the ventricular response with calcium antagonists,b-adrenergic blockers, or digitalis glycosides. Since such patients are always at risk of systemic embolization, particularly in the presence of organic heart disease, chronic anticoagulation must be considered (Table 230-3). Chronic

anticoagulation is particularly important in the elderly, where the attributable risk of AF for stroke approaches 30%. Several studies have now demonstrated conclusively that the incidence of embolization in patients with AF not associated with valvular heart disease is reduced by chronic anticoagulation with warfarin-like agents. Aspirin also may be effective for this purpose in patients who are not at high risk for stroke. Although anticoagulation may be associated with hemorrhagic complications, the risk is largely associated with INRs above the recommended range of 1.8 to 3.0. Recommendations for the selection of antiarrhythmic medications to prevent the recurrence of AF are shown inFig. 230-6.

Ablation therapy for cure ofAF is an active area of investigation. This therapy is particularly attractive for the small subset of patients who have a focal atrial tachycardia that degenerates into AF. These automatic foci are often located in the pulmonary veins, and a targeted ablation in these areas may be curative. While ablation of these foci is possible, the procedure can result in pulmonary vein stenosis, pulmonary hypertension, and stroke. Further technologic advances are necessary before this procedure can be more widely and safely performed. A more morbid approach involves making multiple lesions in the right and left atria (MAZE procedure) to compartmentalize the electrical conductance of these chambers and disallow the propagation of fibrillatory waves. The morbidity, mortality, and success rate of such catheter-based procedures renders them experimental at this time.

ATRIAL FLUTTER

This arrhythmia occurs most often in patients with organic heart disease. Flutter may be paroxysmal, in which case there is usually a precipitating factor, such as pericarditis or acute respiratory failure, or it may be persistent. Atrial flutter (as well asAF) is very common during the first week following open-heart surgery. Atrial flutter is usually less long-lived than is AF, although on occasion it may persist for months to years. Most commonly, if it lasts for more than a week, atrial flutter will convert to AF. Systemic embolization is less common in atrial flutter than in AF.

Atrial flutter is characterized by an atrial rate between 250 and 350 bpm. Typically, the ventricular rate is half the atrial rate, i.e., approximately 150 bpm. If the atrial rate is slowed to<220 beats per minute by antiarrhythmic agents such as quinidine, which also possess vagolytic properties, the ventricular rate may rise suddenly because of the development of 1:1AVconduction. Classically, flutter waves are seen as regular sawtooth-like atrial activity, most prominent in the inferior leads (Fig. 230-5*B*). When the ventricular response is regular and not a simple fraction of the atrial rate, complete AV block is present, which may be a manifestation of digitalis toxicity. Activation mapping suggests that atrial flutter is a form of atrial reentry localized to the right atrium.

TREATMENT

The most effective treatment of atrial flutter is direct-current cardioversion, which can be accomplished at low energy (25 to 50 W× s) under mild sedation. Higher energies (100 to 200 W × s) are often used because they are less likely to causeAF, which not infrequently occurs following lower energy delivery. Although atrial flutter is associated with a slightly lower risk of embolization than AF, the same precautions should be

followed in regard to anticoagulation as are used with AF. In patients who develop atrial flutter following open-heart surgery or recurrent flutter in the setting of acute myocardial infarction, particularly if they are being treated with digitalis, atrial pacing (using temporary pacing wires implanted at the time of operation or a pacing lead inserted into the atrium pervenously) at rates of 115 to 130% of the atrial flutter rate can usually convert the atrial flutter to sinus rhythm. Atrial pacing may also result in the conversion of atrial flutter to AF, which allows for easier control of the ventricular response. If immediate conversion of atrial flutter is not mandated by the patient's clinical status, the ventricular response should first be slowed by blocking theAV node with a beta blocker, calcium antagonist, or digitalis. Digitalis is the least effective and occasionally converts atrial flutter into AF. Once AV nodal conduction is slowed with any of these drugs, an attempt to convert flutter to sinus rhythm using a class I (A or C) agent or amiodarone should be made. Increasing doses of the drug selected are administered until the rhythm converts or side effects occur. Ibutilide is a new antiarrhythmic agent that is administered intravenously and appears to be particularly effective for conversion of atrial flutter to sinus rhythm.

Quinidine, other Class IA drugs, flecainide, propafenone, sotalol, and amiodarone (Table 230-4) may be useful in preventing recurrences of atrial flutter. Radiofrequency ablation is a highly effective treatment for patients with the most typical forms of atrial flutter, which are due to reentry around the tricuspid valve in a counterclockwise or clockwise fashion. The coronary sinus and inferior vena cava cause the wavefront of activation to pass between them and the tricuspid valve. Ablation of the narrowed isthmus using radiofrequency energy can cure flutter in >85% of cases.

PAROXYSMAL SUPRAVENTRICULAR TACHYCARDIAS (PSVT)

In most cases, functional differences in conduction and refractoriness in theAV node or the presence of an AV bypass tract provide the substrate for the development of PSVT (previously termed *paroxysmal atrial tachycardia*). Electrophysiologic studies have demonstrated that reentry is responsible for the vast majority of cases of PSVT (Fig. 230-7). Reentry has been localized to the sinus node, atrium, AV node, or a macroreentrant circuit involving conduction in the antegrade direction through the AV node and retrograde through an AV bypass tract. Such a bypass tract may also conduct antegradely, in which case the Wolff-Parkinson-White (WPW) syndrome is said to be present. When the bypass tract manifests only retrograde conduction, it is termed a *concealed bypass tract* (Fig. 230-7*B*). In these cases, the QRS complex during sinus rhythm is normal. In the absence of the WPW syndrome, reentry through the AV node or through a concealed bypass tract makes up more than 90% of all PSVTs.

AV NODAL REENTRANT TACHYCARDIA

There is no age or disease predisposition for the development of AV nodal reentrant tachycardia, the most common cause of supraventricular tachycardia. It is, however, more commonly observed in women. It usually presents as a regular narrow QRS complex tachycardia at rates of 120 to 250 bpm.APCsthat initiate the arrhythmia are almost always associated with a prolonged PR interval. Retrograde P waves may be absent, buried in the QRS complex, or appear as distortions at the terminal parts of the QRS complex (Fig. 230-7*A*).

AVnodal reentrantPSVT(Fig. 230-8) can be reproducibly initiated and terminated by appropriately timed atrial premature stimuli. The onset of the tachycardia is almost always associated with prolongation of the PR interval due to marked AV nodal conduction delay (prolonged AH interval) following theAPC that is critical for the genesis of the arrhythmia. The sudden prolongation of the AH interval is consistent with the concept of dual AV nodal pathways: a *fast pathway*, which exhibits rapid conduction and a long refractory period, and a *slow pathway*, which has a short refractory period but conducts slowly. During sinus rhythm, only conduction over the fast pathway is manifest, resulting in a normal PR interval (Fig. 230-8). Atrial extrastimuli at a critical coupling interval are blocked in the fast pathway because of its longer refractory period and are conducted slowly through the slow pathway. If conduction down the slow pathway is slow enough to allow the previously refractory fast pathway time to recover excitability, a single atrial (echo) reentrant beat or sustained tachycardia ensues. A critical balance between conduction velocity and refractoriness within the node is required to sustain AV nodal reentry. Retrograde atrial and antegrade ventricular activation occur simultaneously, explaining why P waves may not be apparent on the surfaceECG.

Clinical Features AV nodal reentry may produce palpitations, syncope, and heart failure depending on the rate and duration of the arrhythmia and the presence and severity of any underlying heart disease. Hypotension and syncope may occur because of the sudden loss of the atrial contribution to ventricular filling; this can also lead to a marked increase in atrial pressure, acute pulmonary edema, and a reduction in ventricular filling. Simultaneous atrial and ventricular contraction produces cannon *a* waves with each heartbeat.

TREATMENT

In patients without hypotension, vagal maneuvers, particularly carotid sinus massage, can terminate the arrhythmia in 80% of cases. If hypotension is present, raising the blood pressure by the cautious use of intravenous phenylephrine in 0.1-mg increments may terminate the arrhythmia alone or in combination with carotid sinus pressure. If these maneuvers are unsuccessful, verapamil (2.5 to 10 mg intravenously) or adenosine (6 to 12 mg intravenously) is the agent of choice. We prefer to use adenosine because of its extremely short half-life, lessening the consequences of any side effects. Beta blockers may also be used to slow or terminate the tachycardia but are agents of second choice. Digitalis glycosides have a slower onset of action and should *not* be used for acute therapy. When these drugs fail to terminate the tachycardia, or when the tachycardia is recurrent, atrial or ventricular pacing via a temporary pacemaker inserted pervenously may be used to terminate the arrhythmia. However, if severe ischemia and/or hypotension is caused by the tachycardia, dc cardioversion should be considered.

AVnodal reentry can usually be prevented by the use of drugs that act primarily on the antegrade slow pathway (such as digitalis, beta blockers, or calcium channel antagonists) or on the fast pathway (class IA or IC;Table 230-4;Fig. 230-CD1). We favor initial therapy with beta blockers, calcium channel antagonists, or digoxin because the risk-benefit ratio associated with treatment with these agents is more favorable than that

of IA or IC agents. Drugs most likely to avert recurrences prevent induction of the arrhythmias by programmed stimulation. This technique utilizes temporary pacemaker catheters connected to a physiologic stimulator capable of variable rate pacing and stimulation with one or more precisely timed premature impulses. In symptomatic patients who require chronic therapy, radiofrequency catheter modification of the AV node (Fig. 230-CD2) should be considered. This technique can cure AV nodal reentry in >90% of cases and has been proven to be safe, although a 1 to 2% risk of AV block requiring a permanent pacemaker exists.

AV REENTRANT TACHYCARDIA

PSVTdue to AV reentry incorporates a concealed AV bypass tract as part of the tachycardia circuit. Thus the impulse passes antegradely from the atria through the AV node and His-Purkinje system to the ventricles and then retrogradely through the (concealed) bypass tract back to the atrium. Patients with this disorder manifest the same type of PSVT as do patients with theWPWsyndrome (see below), but the bypass tract cannot conduct in an antegrade direction during sinus rhythm or other atrial tachyarrhythmias.

AVreentrant tachycardia can be initiated and terminated by eitherAPCs orVPCs. Initiation ofPSVT by a VPC is virtually diagnostic of AV reentry. Alternation of the QRS complexes occurs in approximately one-third of such tachycardias. Since atrial activation must follow ventricular activation during AV reentry, the P wave usually occurs after the QRS complex (Fig. 230-7*B*).

Atrial activation mapping is of major value in evaluating the origin of these tachycardias. Most concealed bypass tracts are left-sided. Thus, duringPSVT or during ventricular pacing, the earliest activation sequence is recorded in the left atrium, usually via a catheter in the coronary sinus. This eccentric atrial activation is quite distinct from the normal retrograde activation sequence in which the earliest activation of the atria is in the area of theAVjunction. The ability of a ventricular stimulus to conduct to the atrium at a time when the bundle of His is refractory and the termination of the tachycardia by a ventricular stimulus that does not reach the atrium are diagnostic of retrograde conduction over a concealed bypass tract.

TREATMENT

This is similar to the treatment forAV nodal reentry tachycardia. Although pharmacologic agents may be used, patients who require chronic therapy should be considered candidates for radiofrequency catheter ablation of the bypass tract. This requires detailed electrophysiologic study to exclude other arrhythmias that may be responsible for patients' symptoms and to determine the location of the bypass tract(s). The efficacy of this procedure exceeds 90%, with minimal risks. In the remaining small number of patients failing catheter ablation, surgical ablation or pharmacologic therapy can be used.

SINUS NODE REENTRY AND OTHER ATRIAL TACHYCARDIAS

Reentry in the region of the sinus node or within the atria is invariably initiated byAPCs.

These arrhythmias are less common thanAV nodal or AV reentry and are more often associated with underlying cardiac disease. During sinus node reentry, the P-wave morphology is identical to that occurring in sinus rhythm, but the PR interval is prolonged. This is in contrast to sinus tachycardia, in which the PR interval tends to shorten. With intraatrial reentry, the P-wave configuration differs from that during sinus rhythm, and the PR interval is prolonged (Fig. 230-7*C*).

TREATMENT

Sinus node and atrial reentrant arrhythmias are managed like other reentrantPSVTs, except that catheter ablation is less successful because multiple foci may be present.

NONREENTRANT ATRIAL TACHYCARDIAS

These may be a manifestation of digitalis intoxication or may be associated with severe pulmonary or cardiac disease, with hypokalemia, or with the administration of theophylline or adrenergic drugs. Multifocal atrial tachycardia (MAT) (Fig. 230-9) is particularly common following theophylline administration. By definition, MAT requires three or more consecutive P waves of different morphologies at rates greater than 100 beats per minute. MAT usually has an irregular ventricular rate because of varyingAVconduction. There is a high incidence of atrial fibrillation (50 to 70%) in patients with MAT. Treatment should be directed at the underlying disorder. The digitalis-induced arrhythmias are caused by triggered activity. In such atrial tachycardias with AV block secondary to digitalis intoxication, the atrial rate rarely exceeds 180 bpm, and typically 2:1 block is present. Atrial arrhythmias precipitated by digitalis can usually be treated by withdrawal of the drug.

Automatic atrial tachycardias not caused by digitalis are difficult to terminate, and in such cases the main goal of therapy should be to control the ventricular response, either by drugs that affect theAV node, such as digitalis, beta blockers, or calcium channel antagonists, or by ablation techniques. Catheter ablation and surgery have been employed to eradicate the arrhythmia's focus or create heart block for rate control.

PREEXCITATION (WPW) SYNDROME

The most frequently encountered type of ventricular preexcitation is that associated withAVbypass tracts (Fig. 230-CD3). These connections are composed of strands of atrial-like muscle which may occur almost anywhere around the AV rings. The term *Wolff-Parkinson-White syndrome* is applied to patients with both preexcitation on theECG and paroxysmal tachycardias. AV bypass tracts can be associated with certain congenital abnormalities, the most important of which is Ebstein's anomaly.

AVbypass tracts that conduct in an antegrade direction produce a typicalECGpattern of a short PR interval (<0.12 s), a slurred upstroke of the QRS complex (delta wave), and a wide QRS complex. This pattern results from a fusion of activation of the ventricles over both the bypass tract and the AV nodal His-Purkinje system (Fig. 230-10). The relative contribution of activation over each system determines the amount of preexcitation.

DuringPSVT inWPW, the impulse is usually conducted antegradely over the normalAVsystem and retrogradely through the bypass tract. The characteristics are identical to those described on p. 1299. Rarely (approximately 5%), tachycardias occurring in patients with WPW will exhibit a reverse pattern with antegrade conduction through the bypass tract and retrograde conduction through the normal AV system. This produces a tachycardia with a wide QRS complex in which the ventricles are totally activated by the bypass tract. Atrial flutter andAF also occur commonly in patients with WPW syndrome. Since the bypass tract does not have the same decremental conducting properties as the AV node, the ventricular responses during atrial flutter or fibrillation may be unusually rapid and may cause ventricular fibrillation (VF).

The goals of electrophysiologic evaluation in patients suspected of having theWPWsyndrome are (1) to confirm the diagnosis, (2) to localize the bypass tract and determine how many bypass tracts are present, (3) to demonstrate the role of the bypass tract in the genesis of the arrhythmias, (4) to determine the potential for the development of possibly life-threatening rates during atrial flutter or fibrillation, and (5) to evaluate therapeutic options.

TREATMENT

Pharmacologic therapy is aimed at altering the electrophysiologic properties (i.e., refractoriness or conduction velocity) of one or more components of the reentrant circuit. This is most often accomplished by agents such as beta blockers or calcium channel blockers that slow conduction and increase refractoriness of theAV node or by agents such as quinidine or flecainide that slow conduction and increase refractoriness primarily in the bypass tract. Some drugs may affect multiple sites (Fig. 230-11).

Acute management of episodes ofPSVT in patients withWPWsyndrome is similar to that of PSVT in patients with concealed bypass tracts.

In patients with theWPWsyndrome andAF, dc cardioversion should be carried out if there is a life-threatening, rapid ventricular response. In non-life-threatening situations, lidocaine (3 to 5 mg/kg) or procainamide (15 mg/kg) administered intravenously over 15 to 20 min will usually slow the ventricular response. More recently, ibutilide has become available as an alternative therapy for preexcitation tachycardia. Caution should be employed when using digitalis or intravenous verapamil in patients with the WPW syndrome and AF, since these drugs can shorten the refractory period of the accessory pathway and can increase the ventricular rate, thereby placing the patient at increased risk forVF. Chronic oral therapy with verapamil is not associated with this risk. In addition to these drugs, beta-blocking agents are of no utility in controlling the ventricular response during AF when conduction proceeds over the bypass tract. Although atrial or ventricular pacing can almost always terminatePSVT in patients with the WPW syndrome, they can induce AF. As such, chronic pacemaker therapy is to be discouraged.

While surgical ablation of bypass tracts offers a permanent cure of supraventricular tachycardia (SVT) and mostAFs associated with SVT, the advent of radiofrequency catheter ablation has virtually eliminated the need for surgery. Catheter ablation of bypass tracts is possible in >90% of patients and is the treatment of choice in patients

with symptomatic arrhythmias. It is safer, more cost-effective, and just as successful as surgery. Nevertheless, surgical ablation may be required in the occasional patient in whom catheter ablation fails.

NONPAROXYSMAL JUNCTIONAL TACHYCARDIA

This rhythm usually results from conditions that produce enhanced automaticity or triggered activity in theAVjunction and is most commonly due to digitalis intoxication, inferior wall myocardial infarction, myocarditis, endogenous or exogenous catecholamine excess, acute rheumatic fever, or valve surgery.

The onset of nonparoxysmal junctional tachycardia is usually gradual, with a "warm-up" period prior to stabilization of the rate, which can range from 70 to 150 bpm, faster rates usually being associated with digitalis intoxication. Nonparoxysmal junctional tachycardia is recognized by a QRS complex identical to that of sinus rhythm. The rate can be influenced by autonomic tone and can be increased by catecholamines, vagolytic agents, or exercise and slowed somewhat by carotid sinus pressure. When this rhythm is due to digitalis intoxication, it usually is associated withAV block and/or dissociation. Soon after cardiac surgery, retrograde conduction is more likely to be present because of the heightened sympathetic state.

TREATMENT

This is directed toward elimination of the underlying etiologic factors. Since digitalis is the most common cause of this rhythm, discontinuation of this drug is indicated. If the rhythm is associated with other serious manifestations of digitalis intoxication, such as ventricular or atrial irritability, active intervention with lidocaine or a beta blocker may be useful, and in some instances, use of digitalis antibodies (Fab fragments) should be considered. Cardioversion of this rhythm should not be attempted, particularly in the setting of digitalis intoxication. WhenAVconduction is intact, atrial pacing can capture and override the junctional focus and provide the AV synchrony necessary to maximize cardiac output. Nonparoxysmal junctional tachycardia is usually not a chronic, recurrent problem, and attention to the acute precipitating events can often resolve the tachycardia.

VENTRICULAR TACHYCARDIA

Sustained ventricular tachycardia is defined asVT that persists for more than 30 s or requires termination because of hemodynamic collapse. VT generally accompanies some form of structural heart disease, most commonly chronic ischemic heart disease associated with a prior myocardial infarction. Sustained VT may also be associated with nonischemic cardiomyopathies, metabolic disorders, drug toxicity, or prolonged QT syndrome, and it occurs occasionally in the absence of heart disease or other predisposing factors. Nonsustained VT (three beats to 30 s) is also associated with cardiac disease but occurs in its absence more often than the sustained arrhythmia. While nonsustained VT usually does not produce symptoms, sustained VT is almost always symptomatic and is often associated with marked hemodynamic compromise and/or the development of myocardial ischemia. A fixed anatomic substrate, not acute ischemia, is responsible for most recurrent episodes of sustained uniform VT. Acute

ischemia appears to have little role in the genesis of sustained uniform VT associated with chronic infarction but may play a role in the degeneration of stable VT intoVF or initiation of polymorphic VT. Most episodes of VF begin with VT.

TheECGdiagnosis ofVT is suggested by a wide-complex QRS tachycardia at a rate exceeding 100 bpm. The QRS configuration during any episode of VT may be uniform (monomorphic), or it may vary from beat to beat (polymorphic). *Bidirectional tachycardia* refers to VT that shows an alternation in QRS amplitude and axis. Typically this appears as a QRS with a right bundle branch block pattern with alternating superior (leftward) and inferior axes (rightward). While the rhythm is usually quite regular, slight irregularity may exist. Atrial activity may be dissociated from ventricular activity, or the atria may be depolarized retrogradely. The onset of the tachycardia is generally abrupt, but in nonparoxysmal tachycardias it can be gradual. Paroxysmal VT is usually initiated by aVPC.

It is important to distinguishSVT with aberration of intraventricular conduction fromVTbecause the clinical implications and management of these two arrhythmias are totally different. The most important clinical predictor of VT is the presence of structural heart disease. The observation of intermittent cannon *a* waves and varying first heart sounds suggestsAVdissociation and is diagnostic of VT. In a majority of cases, the diagnosis can and should be made by close examination of the 12-leadECG. Pharmacologic maneuvers, such as administration of intravenous verapamil or adenosine, can be hazardous and should be avoided. It is always useful to have a 12-lead ECG recorded during sinus rhythm for comparison with that during tachycardia. When the tracing obtained during sinus rhythm demonstrates the same morphologic features as those during the tachycardia, the diagnosis ofPSVTwith aberration is favored. An infarction pattern on the sinus rhythm tracing suggests the potential presence of the anatomic substrate necessary for VT. Characteristics of the 12-lead ECG during the tachycardia that suggest a ventricular origin for the arrhythmia are (1) a QRS complex>0.14 s in the absence of antiarrhythmic therapy, (2) AV dissociation (with or without fusion or captured beats) or variable retrograde conduction (Fig. 230-12), (3) a superior QRS axis in the presence of a right bundle branch block pattern, (4) concordance of the QRS pattern in all precordial leads (i.e., all positive or all negative deflections), and (5) other QRS patterns (morphology) with prolonged duration that are inconsistent with typical right or left bundle branch block patterns. (SeeTable 230-5 for a detailed synopsis of ECG criteria that favor the diagnosis of VT over SVT for wide complex tachycardia.) A wide, complex, bizarre tachycardia that is very irregular suggestsAF with conduction over an AV bypass tract. Similarly, a QRS complex in excess of 0.20 s is uncommon during VT in the absence of drug therapy and is more common with preexcitation. Intravenous verapamil will stop most recalcitrant SVTs involving the AV junction, but it is rarely effective for VT. Because of this property, verapamil has been utilized to attempt to differentiate SVT with aberrant conduction from VT. However, this is extremely hazardous, since intravenous verapamil can precipitate cardiac arrest in patients with VT.

It has been possible to replicate sustained uniformVT in more than 95% of patients with this arrhythmia using programmed electrical stimulation. In most patients the tachycardia is initiated with ventricular premature stimuli. A sustained monomorphic VT with a morphology identical to that of the spontaneous arrhythmia is the rule. The

clinical significance of polymorphic VT initiated by programmed stimulation is not clear, since more aggressive stimulation (i.e., the use of three or four extrastimuli) can induce polymorphic VT and evenVF in some normal subjects and in patients who have never had a clinical arrhythmia.

Sustained uniformVT can be terminated by programmed stimulation or rapid pacing in at least 75% of patients; the remainder require cardioversion. The ability to reproducibly initiate and terminate a sustained, uniform VT permits assessment of pharmacologic and electrical therapy of these arrhythmias.

The reproducible termination ofVT by programmed stimulation permits evaluation of the effectiveness of antitachycardia pacemakers for long-term therapy of paroxysmal episodes of arrhythmia. Unfortunately, rapid pacing, the most effective form of therapy, can accelerate the tachycardia and/or produceVF. Therefore, antitachycardia pacing is a viable form of therapy only when the pacing device includes backup defibrillation capabilities.

Clinical Features Symptoms resulting fromVTdepend on the ventricular rate, duration of the tachycardia, and presence and extent of underlying cardiac disease. When the tachycardia is rapid and associated with severe myocardial dysfunction and cerebrovascular disease, hypotension and syncope are common. However, the presence of hemodynamic stability does not preclude a diagnosis of VT. The rate, loss of the atrial contribution to ventricular filling, and abnormal sequence of ventricular activation are important factors producing a decreased cardiac output during VT.

The *prognosis* ofVTdepends on the underlying disease state. If sustained VT develops within the first 6 weeks following acute myocardial infarction, the prognosis is poor, with a 75% mortality rate at 1 year. Patients with nonsustained VT following myocardial infarction have a threefold greater risk of death than a comparable group of patients without this arrhythmia. However, a cause-and-effect relationship between the nonsustained tachycardia and subsequent sudden death has not been established. Patients without heart disease who have uniform VT have a good prognosis and an extremely low risk of sudden death.

TREATMENT

The risk-benefit ratio of treating each specific type ofVTshould be considered before beginning therapy. This is important because antiarrhythmic agents can produce or exacerbate the very arrhythmias that they are given to prevent. In general, patients with VT but without organic heart disease have a benign course; such patients with asymptomatic, nonsustained VT need not be treated because their prognosis will not be affected. An exception is the patient with congenital long QT syndrome. Such patients have recurrent polymorphic VT and a high mortality from sudden death if untreated. Patients with sustained VT in the absence of heart disease usually require therapy because the arrhythmia causes symptoms. These tachycardias may respond to beta blockers; verapamil; class IA, IC, or III agents (Fig. 230-CD4); or amiodarone. In patients with VT and organic heart disease, if marked hemodynamic compromise is present or if there is evidence of ischemia, congestive heart failure, or central nervous system hypoperfusion, the rhythm should be promptly terminated by dc cardioversion

(see below). If the patient with organic heart disease tolerates the VT well, pharmacologic therapy may be tried. Procainamide is probably the most effective agent for acute therapy. It may or may not terminate the tachycardia but almost always slows the rate. In stable patients in whom these drugs do not terminate the arrhythmia, a pacing catheter can be inserted pervenously into the right ventricular apex, and the tachycardia can be terminated by overdrive pacing.

Programmed stimulation is probably the most effective way to select the appropriate antiarrhythmic agent to prevent recurrent, sustainedVT. After demonstrating that the tachycardia can be initiated reproducibly in the absence of antiarrhythmic agents, drugs can be studied serially, and the drug that prevents initiation of the tachycardia can be selected; long-term (>2 years) successful prevention of the arrhythmia can then be expected in 80% of patients if a complete stimulation protocol is used following drug administration. Failure to perform a complete protocol will lead to recurrences, which are often blamed on the lack of utility of programmed stimulation as a method of evaluating drug efficacy. Drug levels demonstrated to be successful in the laboratory need to be maintained chronically. Unfortunately, prevention of inducible VT is expected in only 50% of cases. Use of Holter monitor for guided therapy, although advocated by some, is of less value.

Antitachycardia pacing has been used as a means to terminate tachycardias that have been reproducibly terminated by pacing in the electrophysiology laboratory. Automatic antitachycardia pacing devices are not used alone because pacing duringVT may accelerate tachycardia, converting a stable arrhythmia into an unstable one and resulting in severe hemodynamic compromise. However, devices combining antitachycardia pacing with anICD (see below) afford a "backup" means of terminating unstable arrhythmias.

The advent of endocardial catheter and intraoperative mapping led to the development of surgical techniques for the management ofVT. Activation mapping permits localization of the site of origin of the arrhythmia. In centers in which expertise in mapping is available, operation has been successfully employed to cure tachycardias in the majority of patients in whom it has been undertaken. Even though most patients with VT and ischemic heart disease have markedly impaired left ventricular function and multivessel coronary artery disease, the operative mortality rate has ranged between 8 and 15%. Following operation, >90% of survivors are controlled either off (two-thirds of patients) or on (one-third) antiarrhythmic agents that were previously ineffective in controlling these rhythms. With the development of radiofrequency ablation and refinement of mapping criteria to locate critical sites of the VT circuit, precisely, catheter ablation can be performed as a curative procedure in selected patients. In experienced centers cure of VT in these *selected* patients approaches 75%.

Specific Types of VT *Torsade de pointes* (Fig. 230-13) refers toVTcharacterized by polymorphic QRS complexes that change in amplitude and cycle length, giving the appearance of oscillations around the baseline. This rhythm is, by definition, associated with QT prolongation. The latter may result from electrolyte disturbances (particularly hypokalemia and hypomagnesemia), use of a variety of antiarrhythmic drugs (especially quinidine), phenothiazines and tricyclic antidepressants, liquid protein diets, intracranial events, and bradyarrhythmias, particularly third-degree AV block. It also may occur as a

congenital anomaly that most often presents with torsade de pointes (syncope or sudden death) at a young age.

The electrocardiographic hallmark is polymorphicVTpreceded by marked QT prolongation, often in excess of 0.60 s. These patients often have multiple episodes of nonsustained polymorphic VT associated with recurrent syncope, but they also may developVF and sudden cardiac death.

Therapy should be directed at removing the precipitating factors, i.e., correcting metabolic abnormalities and removing drugs that have induced the prolonged QT interval. In the setting of drug-induced torsade de pointes, atrial or ventricular overdrive pacing and the administration of magnesium have also been useful in terminating and preventing the arrhythmia. For patients with the congenital prolonged QT interval syndrome, b-adrenergic blocking agents have been the mainstay of therapy; agents that shorten the QT interval may also be useful (e.g., phenytoin). Cervicothoracic sympathectomy has been proposed as a form of therapy for congenital prolonged QT syndrome, but it is not often effective as the sole therapy. Pacing in combination with beta blockers and sympathectomy has been used by some investigators when beta blockers fail, but it is not uniformly successful and results in a Horner's syndrome. More recently,ICDswith dual chambered pacing capability and beta blockers have become the treatment of choice for patients with recurrent episodes despite beta blockers.

Polymorphic tachycardias associated with normal QT intervals in patients with ischemic heart disease that are initiated by "R-on-T"VPCs are probably caused by reentry, and their treatment is totally different. This is not true torsade de pointes. In such cases, class I or III agents may be the most effective form of therapy and should be administered in full antiarrhythmic doses. However, these arrhythmias may also result from acute, severe ischemia and will only respond to abolition of the ischemia, usually by revascularization.

Accelerated idioventricular rhythm, also termed *slow VT*, with a rate that ranges from 60 to 120 bpm, usually occurs in acute myocardial infarction, often during reperfusion. It may also be seen following cardiac operations; in patients with cardiomyopathy, rheumatic fever, or digitalis intoxication; and in patients with no evidence of heart disease. The rhythm is usually transient and rarely causes significant hemodynamic compromise or symptoms.

Treatment is rarely necessary and should usually be considered only if symptoms arise due to impaired hemodynamics, most commonly due toAVdissociation. In most cases, atropine can accelerate the sinus rate to overdrive the ventricular rhythm.

VENTRICULAR FLUTTER AND VENTRICULAR FIBRILLATION (Fig. 230-14; See alsoChap. 39)

These arrhythmias occur most often in patients with ischemic heart disease. They also occur following administration of antiarrhythmic drugs, particularly those that induce prolonged QT intervals and torsade de pointes (see above), in patients with severe hypoxia or ischemia, and in those withWPW who developAF with an extremely rapid ventricular response (p. 1299). Electrical accidents frequently cause cardiac arrest due

to the development ofVF. The onset of these arrhythmias is rapidly followed by loss of consciousness and, if untreated, death. Episodes of cardiac arrest recorded during Holter monitoring reveal that approximately three-fourths of the sudden deaths are due toVT or VF.

In patients with nonischemicVF, the onset usually begins with a short run of rapidVT, which is initiated by a relatively late coupledVPC. In patients with acute myocardial infarction or ischemia, however, VF is usually precipitated by a single early ventricular complex beat falling on the T wave (the vulnerable period), which produces a rapid VT that degenerates into VF (Fig. 230-14).

The clinical setting in whichVFoccurs is important. Most patients who have primary VF within the first 48 h of the onset of acute infarction have a good long-term prognosis, with a very low rate of recurrence or sudden cardiac death. Their short-term mortality may, however, be slightly increased. In contrast, patients who experience VF unassociated with the development of acute myocardial infarction have a recurrence rate of 20 to 30% in the year following the event (Chap. 39).

Ventricular flutter usually appears as a sine wave with a rate between 150 and 300 bpm. These oscillations make it impossible to assign a specific morphology to the arrhythmia and in some cases to distinguish it from rapidVT.VF is recognized by grossly irregular undulations of varying amplitudes, contours, and rates (Fig. 230-14). Electrophysiologic studies have demonstrated that regardless of the apparent gross irregularity on the surfaceECG, VF usually starts out with a rapid repetitive sequence of VT that ultimately breaks down into multiple wavelets of reentry.

Electrophysiologic studies have been useful in patients who have been resuscitated from cardiac arrest. In approximately 70% of patients with prior infarction, programmed stimulation can reproducibly initiate a sustainedVT. Ablation may be possible in some of these patients, particularly if the VT can be slowed so that it can be mapped. Several recent secondary prevention trials have demonstrated superior survival (3 years) in patients treated withICDsversus amiodarone (Table 230-6). However, in patients with ejection fractions >35% or<20%, survival was comparable. Further subgroup analysis is necessary to identify those patients most likely to be benefited by ICDs.

GENETIC CONSIDERATIONS

Many advances have been made in the identification of genes responsible for syndromes associated with ventricular tachycardias and sudden cardiac death. Four specific examples include the congenital long QT syndrome (LQTS), hypertrophic obstructive cardiomyopathy (Chap. 238), arrhythmogenic right ventricular dysplasia, and the Brugada syndrome. The latter is a recently described disorder characterized by the electrocardiographic profile of a pseudo bundle branch block pattern with ST elevation and terminal T-wave inversion in leads V_1-V_3(Fig. 230-15). The clinical presentation isVF in patients with structurally normal hearts. A mutation in the cardiac sodium channel, SCN 5A, is believed to be responsible. While the same gene is responsible for the LQTS, the mutation is different in the two syndromes.

TREATMENT

Pharmacologic Antiarrhythmic Therapy Prior to initiation of pharmacologic antiarrhythmic therapy, potential aggravating factors such as transient metabolic abnormalities, congestive heart failure, or acute ischemia must be corrected; in some cases this may suffice to control arrhythmias. In addition, the potential role of drugs as a cause or exacerbating factor in the development of the arrhythmia must be considered. It must be recognized that we do not have a good understanding of the effects of antiarrhythmic agents on the spontaneous onset of tachyarrhythmias. In some cases, they may facilitate the onset.

Antiarrhythmic drugs are used in three principal situations: (1) to terminate an acute arrhythmia; (2) to prevent recurrence of an arrhythmia; and (3) to prevent a life-threatening arrhythmia for which the patient is perceived to be at risk but which has never occurred.

Most currently available antiarrhythmic agents (Table 230-4) have a relatively low toxic/therapeutic ratio; all can exert proarrhythmic effects (Table 230-7), and therefore they may exacerbate underlying arrhythmias. Serum levels can be determined for most currently available antiarrhythmic agents. Standards for therapeutic and toxic levels can serve only as a rough guide for selecting the appropriate dose in any individual patient. In the final analysis, the therapeutic level in a given patient is the concentration that achieves the desired antiarrhythmic effect, and the toxic level for each patient is the concentration at which undesirable side effects occur. Since many adverse effects are directly related to drug concentrations, the lowest serum level that achieves an effective antiarrhythmic response should be chosen.

In order to determine the therapeutic level for a patient, one must have a standard to judge drug efficacy. For a patient with an incessant arrhythmia, antiarrhythmic drugs may be administered empirically until the arrhythmia is suppressed. If a reproducible precipitating factor such as exercise can be identified, serial drug testing during such a provocative maneuver may be performed. Unfortunately, most arrhythmias are sporadic and occur unpredictably without identifiable precipitating factors. In these cases, if one waits to observe spontaneous recurrences on each antiarrhythmic drug, assessment of drug efficacy may require months. This type of assessment of efficacy may be adequate for arrhythmias that are not life-threatening. However, this mode of assessment is inadequate for arrhythmias that compromise hemodynamic stability, result in syncope, or cause cardiac arrest. In such cases, two methods for determination of arrhythmic drug efficacy have been utilized. The first, which consists of continuousECGmonitoring in the control state and then in the presence of antiarrhythmic drugs, has been used in order to determine the effect that each drug has on spontaneous atrial or ventricular ectopy. This method presupposes that the mechanism responsible for sustained arrhythmias is the same as that causing isolated premature depolarizations (which may or may not be true) and that therefore eradication of isolated ectopy will correlate with prevention of sustained arrhythmias. This method has a number of limitations. First, patients frequently show marked degrees of spontaneous variation in frequency of ectopy, which may mimic antiarrhythmic drug effects. Second, 25 to 30% of patients with sustained ventricular arrhythmias such asVT orVFdemonstrate only rare spontaneous ectopy. Finally, many patients demonstrate a dissociation between the effects of antiarrhythmic agents on spontaneous ectopy and the effects of the same

agent on sustained arrhythmias.

An alternative method to assess drug efficacy is programmed stimulation. Numerous studies have demonstrated that most clinically occurring supraventricular and ventricular tachyarrhythmias may be reproducibly initiated and terminated safely using this technique. Studies are performed initially in a baseline state in the absence of antiarrhythmic drugs. If the patient's clinical arrhythmia can be reproducibly initiated, then the ability of individual antiarrhythmic drugs to prevent reinduction of the arrhythmia can be assessed either after the drug is administered intravenously or after several days of oral loading in order to achieve a steady-state serum concentration. Use of this method assumes that (1) the induced and spontaneous arrhythmias are identical, and (2) prevention of induction of arrhythmias will correlate with prevention of recurrent spontaneous tachycardias on the same drug regimen. This technique has been validated in patients with a variety of reentrantPSVTs,VT, andVF. The technique is safe when carefully performed, the potential complications being those of any intravascular catheterization. Appropriate interpretation of the results of programmed stimulation is critically dependent on correlating the patient's spontaneous arrhythmias with those induced in the laboratory, with regard to rate and morphology, in order to be certain that the arrhythmia induced in the laboratory represents the same arrhythmia that occurred spontaneously and caused symptoms.

Classification of Antiarrhythmic Drugs A number of classifications of antiarrhythmic drugs have been proposed; the most frequently used is a modification of one proposed by Vaughan-Williams (Table 230-2). This classification is based in part on the ability of antiarrhythmic drugs to modify the cardiac cellular (1) excitatory currents (Na^+ or Ca^{2+}), (2) action potential duration, and (3) automaticity (phase 4 depolarization). These effects of the drugs on isolated cardiac cells are thought to account for some of the antiarrhythmic properties of the drugs. Thus depression of excitatory currents by class I and class IV antiarrhythmics results in slowing of conduction velocity and may interrupt arrhythmias by blocking conduction in areas of marginal excitability, where conduction velocity is already slow. Class III antiarrhythmics allegedly exert their action by increasing refractoriness through prolongation of the action potential duration. However, this classification has a number of limitations. The electrophysiologic effects of these drugs in vivo may differ from their effects on isolated cells. Also, the effects of heart rate and fiber geometry are not considered. Not all drugs (e.g., adenosine) fit into the classifications. Finally, some drugs (e.g., amiodarone) exhibit properties consistent with multiple classes. The uses, actions, and toxic actions of currently available antiarrhythmic drugs are summarized in Tables 230-4 and230-7.

Electrical Therapy of Tachyarrhythmias

Pacemakers Cardiac pacing can be used to terminate and in selected cases prevent recurrent supraventricular and ventricular arrhythmias. Because many tachyarrhythmias appear to be due to a reentrant mechanism with the impulse traveling in a circuit, a properly timed paced impulse can penetrate and prematurely depolarize part of the circuit, rendering it refractory to the next circulating wavefront and thereby interrupting the circus movement. Pacing therapy for arrhythmias is generally reserved for patients whose arrhythmias are refractory to drug therapy and who remain hemodynamically stable during the tachycardia. All forms of pacing therapy require repeated

demonstration of their effectiveness and reliability in terminating the arrhythmias during electrophysiologic testing prior to implantation of the pacing device.

The type of pacing device and modality selected for arrhythmia termination depends on (1) the rate of the tachycardia (rates >160 bpm are rarely terminated by a single premature stimulus), (2) the type of arrhythmia (atrial flutter andVT are rarely terminated by single extrastimuli), and (3) concomitant drug therapy.

Because many tachycardias cannot be terminated by single premature stimuli, pacemakers have been developed that allow for multiple extrastimuli (burst pacing) to be introduced. In the current era, antitachycardia pacing is almost exclusively for ventricular arrhythmias because of the success of radiofrequency ablative therapy for supraventricular arrhythmias.

Cardiac pacing has also been used to prevent ventricular tachyarrhythmias. PolymorphicVTassociated with a long QT interval and bradycardia (torsade de pointes, p. 1304) is most likely to respond. Pacing the atrium and/or ventricle at rates between 90 and 120 bpm appears to increase the homogeneity of electrical recovery and markedly reduces the propensity for a recurrence of arrhythmias.

Pacemakers may be self-contained or energized by an external radiofrequency source. The self-contained pacemaker may function automatically [i.e., it incorporates an arrhythmia recognition program (circuit)], or it may be activated by an external magnet. The major advantage of a fully automatic system is that there is no need for the patient to recognize the arrhythmia in order for termination to occur. The advantages of the externally activated system (rarely used today) include (1) the decreased risk of unnecessary treatment because of faulty sensing, and (2) the opportunity to initiate monitoring at the time of attempted termination of arrhythmia. This type of monitoring is frequently helpful if pacing techniques are employed to terminateVT, given the risk of acceleration of the arrhythmia by pacing.

The limitations of pacing therapy are primarily related to (1) the changes in the characteristics of the arrhythmia over time such that programmed pacing parameters no longer terminate the tachycardia, (2) the risk of acceleration of the tachycardia with the development ofAF when stimulating the atrium and the development of rapidVT andVF when stimulating the ventricles, and (3) inappropriate recognition of supraventricular tachyarrhythmias as ventricular tachycardias, leading to delivery of therapy unnecessarily, which can initiate VT or VF. Future pacing generators that can perform cardioversion and defibrillation will increase the applicability of pacing therapy for the treatment of arrhythmias (see below).

Cardioversion and Defibrillation Electrical cardioversion and defibrillation remain the most reliable methods for terminating arrhythmias. By depolarizing all or at least a large portion of excitable myocardium in a near homogeneous fashion, the electrical shock can interrupt reentrant arrhythmias. External cardioversion is routinely performed by placing two paddles 12 cm in diameter in firm contact with the chest wall, with one paddle usually located to the right of the sternum at the level of the second rib and the other in the left anterior axillary line in the fifth intercostal space. If the patient is conscious, a short-acting barbiturate to act as an anesthetic or an amnesic drug such as

diazepam or medazolam should be administered to prevent patient discomfort. A person skilled in maintaining an airway should be present.

Energy is delivered synchronously with the QRS complex for all arrhythmias except ventricular flutter andVF, since asynchronous shocks can produce VF. The amount of energy used will vary with the type of tachycardia being treated. With the exception ofAF,SVTs can frequently be terminated with energy levels in the range of 25 to 50 W× s, while AF usually requires³100 W × s for termination. For terminatingVT, energy levels ³100 W× s should probably be employed. While energies as low as 25 W × s may be used successfully, they also have a higher incidence of producing VF or AF. At least 200 W× s of energy should be used for initial attempts at terminating VF. If the initial shock fails, all repeated attempts at defibrillation should be with the maximum energy that the defibrillator is capable of delivering (320 to 400 W ×s).

Indications for cardioversion depend on the clinical setting and the patient's general condition. Any tachycardia (except sinus tachycardia) that produces hypotension, myocardial ischemia, or heart failure warrants consideration of prompt termination using external cardioversion. Arrhythmias that fail to terminate with pharmacologic therapy may also be terminated by electrical cardioversion. Transient bradycardias and supraventricular and ventricular irritability following cardioversion are common and usually do not warrant antiarrhythmic intervention.

Implanted Cardioverter/Defibrillator (Fig. 230-CD5) ICDdevices have been developed that will promptly recognize and terminate life-threatening ventricular arrhythmias. These devices can deliver<1 to 40 W × s, the amount of which can be programmed. Current devices have antitachycardia pacing capabilities such thatVT can be sensed and terminated without resorting to a painful shock. In such devices, high-energy shocks are reserved for hypotensive VT, acceleration of VT, or failure to terminate VT after a programmed duration (Fig. 230-16). ICDs now can be implanted transvenously, and some are small enough to be implanted in a manner similar to pacemakers. Clinical trials testing the function of these devices in patients with drug-refractory ventricular arrhythmias have demonstrated survival from sudden death at 1 year ranging between 92 and 100%. Currently, ICDs should be considered for patients with VT that is not hemodynamically tolerated. As mentioned earlier, recent randomized trials suggest that ICDs confer improved mortality over amiodarone in patients with hemodynamically untolerated VT and a cardiac arrest not due to reversible causes (Table 230-6). Finally, they are indicated for patients with depressed left ventricular function, prior myocardial infarction, nonsustained and sustained VT at electrophysiologic study (Table 230-8). Guidelines for their use are given inTable 230-9.

The most frequent problem with theICD has been its inappropriate discharge in the absence of sustained ventricular arrhythmias. Additional potential problems include an increase in defibrillation threshold and decrease in tachycardia rates below the rate cut-off of the device in response to many antiarrhythmic drugs. Permanently implanted ventricular pacemakers may interfere with the device's ability to senseVF. This can be avoided by using committed bipolar pacing systems that are better able to sense local ventricular activity. Diagnostic features of newer, all-in-one devices are able to identify the probable cause of an ICD discharge (e.g.,AF,SVT, fractured lead) and to adjust pharmacologic therapy or reprogram the device to avoid such inappropriate shocks.

These newer devices have the capability to take a "second look" prior to shock delivery and thus may abort delivery for self-terminating arrhythmias. In addition, the range of candidates suitable for implantation will be expanded because the newer devices have the capability of shock therapy for patients whose arrhythmias do not cause loss of consciousness.

Newer generations ofICDs are smaller and frequently allow placement of a second lead in the right atria. This lead senses atrial activity and provides enhanced discrimination of atrial from ventricular electrical activity. This enhanced discrimination ofSVT fromVTprevents inappropriate shocks for SVT that may be misinterpreted as VT and allows the device to switch from a dual-chamber to a single-chamber device should an SVT-likeAFdevelop. These dual-chamber devices also allowAVsequential pacing. Finally, ICDs are now available that have defibrillation coils in the right atrium as well as right ventricle. These devices are suited for patients with infrequent but highly symptomatic atrial fibrillation. Patients with these atrial defibrillators can activate the device themselves and terminate their atrial fibrillation without going to the hospital.

Ablative Therapy for Arrhythmias Catheter-based mapping techniques have provided a nonoperative approach to the identification and cure of a variety of arrhythmias. In fact, catheter ablation techniques are now the procedures of choice for symptomatic patients with (1) concealed or manifest (WPW) bypass tracts, (2)AV nodal reentrantSVT, (3) typical atrial flutter, and (4) poorly controlled ventricular responses to atrial arrhythmias, most commonlyAF. Successful ablation of bypass tracts and modifications of the AV node by radiofrequency energy are extremely successful and cost-effective and are the procedure of choice for patients with recurrent episodes. The creation of AV block with implantation of a pacemaker is the method of choice in managing patients with AF and poorly controlled ventricular response. IdiopathicVTs (Fig. 230-17) and some VTs that are associated with coronary artery disease are also amenable to ablation, but the result is less successful than for ablation of SVTs.

Surgical therapy is now relegated to cases of sustainedVTassociated with coronary artery disease when operative intervention is needed for coronary bypass surgery and/or aneurysmectomy or VT associated with specific structural abnormalities (e.g., idiopathic left ventricle aneurysm, s/p surgery for tetralogy of Fallot). It also may be undertaken for the unusual instances of failed catheter ablation forSVTs associated with bypass tracts.

SECTION 3 -DISORDERS OF THE HEART

231. NORMAL AND ABNORMAL MYOCARDIAL FUNCTION - *Eugene Braunwald*

CELLULAR BASIS OF CARDIAC CONTRACTION

THE CARDIAC ULTRASTRUCTURE

About three-fourths of the ventricular *myocardium* is composed of individual striated muscle cells (myocytes), normally 17 to 25 um in diameter and 60 to 140 um in length (Fig. 231-1*A*). Each fiber contains multiple, rodlike cross-banded strands (myofibrils) that run the length of the fiber and are, in turn, composed of serially repeating structures, the sarcomeres. The cytoplasm between the myofibrils contains other cell constituents (Fig. 231-1*B*), such as the single centrally located nucleus, numerous mitochondria, and intracellular membrane system, the sarcoplasmic reticulum.

The *sarcomere*, the structural and functional unit of contraction, is delimited by two adjacent dark lines, the Z lines (Fig. 231-1*C*). The distance between Z lines varies with the degree of contraction or stretch of the muscle and ranges between 1.6 and 2.2 um. Within the confines of the sarcomere are alternating light and dark bands, giving the myocardial fibers their striated appearance under the light microscope. At the center of the sarcomere is a dark band of constant length (1.5 um), the A band, which is flanked by two lighter bands, the I bands, which are of variable length. The sarcomere of heart muscle, like that of skeletal muscle, is made up of two sets of interdigitating myofilaments (Fig. 232-1*D*). Thicker filaments, composed principally of the protein myosin, traverse the A band. They are about 10 nm (100 A) in diameter, with tapered ends, and measure 1.5 to 1.6 um in length. Thinner filaments, composed primarily of actin, course from the Z line through the I band into the A band. They are approximately 5 nm (50 A) in diameter and 1.0 um in length. Thus there is overlapping of thick and thin filaments only within the A band, while the I band contains only thin filaments (Fig. 232-1*C*). On electron-microscopic examination, bridges may be seen to extend between the thick and thin filaments within the A band.

THE CONTRACTILE PROCESS

The sliding model for muscle rests on the fundamental observation that the thick and thin filaments are constant in overall length during both contraction and relaxation. With activation, the actin filaments are propelled further into the A band. In the process, the A band remains constant in length, whereas the I band shortens and the Z lines move toward one another.

The *myosin* molecule is a complex, asymmetric fibrous protein with a molecular weight of about 500,000; it has a rodlike portion that is about 150 nm (1500 A) in length with a globular portion at its end (Fig. 231-1*D*). This globular portion of the myosin is the site of ATPase activity and also forms the bridges between the myosin and actin.In forming the thick myofilament, which is composed of ~300 longitudinally stacked myosin molecules, the rodlike segments of the myosin molecules are laid down in an orderly, polarized manner, leaving the globular portions projecting outward so that they can interact with actin to generate force and shortening (Fig. 231-2). *Actin* has a molecular weight of

about 47,000. The thin filament is composed of a double helix of two chains of actin molecules wound about each other on a larger molecule, tropomyosin, which serves as a "backbone" to the thin filament. A group of these regulatory proteins, troponins C, I, and T, are spaced at regular intervals on this filament (Fig. 231-3). In contrast to myosin, actin has no intrinsic enzymatic activity, but it has the ability to combine reversibly with myosin in the presence of ATP and Ca^{2+}. The latter activates the myosin ATPase, which in turn breaks down ATP, the energy source for contraction. In relaxed muscle this interaction is inhibited by tropomyosin. *Titin* (Fig. 231-1*D*) is a large, flexible, myofibrillar protein that connects myosin to the Z line. Its stretching is believed to contribute to the elasticity of the heart.

During activation of the myocyte, Ca^{2+}becomes attached to troponin C, which results in a conformational change in the regulatory protein tropomyosin, which in turn exposes the actin cross-bridge interaction sites. Repetitive interaction between myosin heads and actin filaments is termed *cross-bridge cycling*, which results in sliding of the actin along the myosin filaments, ultimately causing muscle shortening and/or the development of tension. The splitting of ATP, which is synthesized in the mitochondria, then dissociates the myosin cross-bridge from the actin. In the presence of ATP (Fig. 231-2), linkages between actin and myosin filaments are made and broken cyclically as long as sufficient Ca^{2+} is present; these linkages cease when $[Ca^{2+}]$ falls below a critical level, and the troponin-tropomyosin complex once more prevents interactions between the myosin cross-bridges and the actin filaments. Intracytoplasmic Ca^{2+} is a principal mediator of the inotropic state of the heart; the fundamental action of most positive inotropic drugs, including the digitalis glycosides,b-adrenergic agonists, and phosphodiesterase inhibitors, is to raise the $[Ca^{2+}]$ in the vicinity of the myofilaments. Cyclic AMP enhances the phosphorylation of troponin I, a protein that accelerates cardiac relaxation.

The *sarcoplasmic reticulum* (SR) (Fig. 231-1*B*) is a complex network of anastomosing intracellular channels that invests the myofibrils. It is less profuse in cardiac than in skeletal muscle. Its longitudinally disposed membrane-lined tubules are closely applied to the surfaces of individual sarcomeres but have no direct continuity with the outside of the cell. However, closely related to the SR, both structurally and functionally, are the transverse tubules, or T system, formed by tubelike invaginations of the sarcolemma that extend into the myocardial fiber along the Z lines, i.e., the ends of the sarcomeres.

CARDIAC ACTIVATION

At rest, the cardiac cell is polarized, i.e., the interior has a negative charge relative to the outside of the cell, with a transmembrane potential of -80 to-100 mV (Chap. 229). The sarcolemma, which in the resting state is largely impermeable to Na^+, has a Na^+- and K^+-stimulating pump energized by ATP that extrudes Na^+ from the cell; the pump plays a critical role in establishing this resting potential. Thus, on the inside of the cell $[K^+]$ is relatively high and $[Na^+]$ is far lower, while in the extracellular milieu $[Na^+]$ is high and $[K^+]$ is low. At the same time, in the resting state, the extracellular $[Ca^{2+}]$ greatly exceeds the free intracellular $[Ca^{2+}]$.

During the plateau of the action potential (phase 2) there is a slow inward current through L-type Ca^{2+}channels in the sarcolemma (Fig. 231-4). The absolute quantity of

Ca^{2+}that crosses the surface membrane is relatively small and itself appears to be incapable of bringing about full activation of the contractile apparatus. The depolarizing current not only extends across the surface of the cell but penetrates deeply into the cell by way of the ramifying T system; this Ca^{2+}current triggers the release of much larger quantities of $Ca^{2+}$from theSR, a process termed *Ca^{2+}-induced Ca^{2+}release*.

The Ca^{2+}released from theSR then diffuses toward the sarcomere and, as already described, combines with troponin C. By repressing this inhibitor of contraction, Ca^{2+}activates the myofilaments to shorten. During repolarization the activity of the Ca^{2+}pump in the SR reaccumulates Ca^{2+}against a concentration gradient, and the Ca^{2+} is stored by its attachment to a protein *calsequestrin*. This is an energy-requiring process that lowers the [Ca^{2+}] in the vicinity of the myofibrils to a level that inhibits the actin-myosin interaction responsible for contraction and in this manner leads to relaxation. Also, there is an exchange of Ca^{2+} for Na^{+} at the sarcolemma, reducing the cytoplasmic [Ca^{2+}]. Thus, the combination of the cell membrane, transverse tubules, and SR, with their ability to transmit the action potential, to release, and then to reaccumulate Ca^{2+}, appears to play a fundamental role in the rhythmic contraction and relaxation of heart muscle.

The ATP formed from substrate oxidation is the principal source of energy for almost all of the mechanical work of contraction performed by the myocardial cell. The high-energy phosphate stores in ATP are in equilibrium with those in the form of creatine phosphate. The activity of myosin ATPase determines the rate of forming and breaking of the actin-myosin cross-bridges and ultimately the velocity of muscle contraction.

THE ROLE OF MUSCLE LENGTH

In all striated muscle, including cardiac muscle, the force of contraction depends on initial muscle length. The sarcomere length associated with the most forceful contraction is approximately 2.2 um. At this length the two sets of myofilaments of the sarcomere are configured so as to provide the greatest area for their interaction. The length of the sarcomere also regulates the extent of activation of the contractile system, i.e., its sensitivity to Ca^{2+}. According to this concept, termed *length-dependent activation*, at the optimal sarcomere length of 2.2 um, the myofilament sensitivity to Ca^{2+} is maximal.

The relation between the initial length of the muscle fibers and the developed force is of prime importance for the function of heart muscle. This forms the basis of the Frank-Starling relation (Starling's law of the heart), which states that, within limits, the force of ventricular contraction is a function of the end-diastolic length of the cardiac muscle, which in turn is closely related to the ventricular end-diastolic volume.

MYOCARDIAL MECHANICS

THE FORCE-VELOCITY CURVE

The mechanical activity of striated muscle, skeletal and cardiac, may be expressed externally in two ways: by shortening and by the development of tension. In both forms of striated muscle the velocity of shortening is inversely related to the tension

development, an expression of the so-called force-velocity relation (Fig. 231-5). Expressed simply, the greater the load the muscle is called upon to lift, the lower the velocity (and extent) of shortening, and vice versa. Skeletal muscle fibers have a single, essentially fixed, force-velocity curve; i.e., at any given muscle length, the inverse relation between force and velocity is fixed. The contractile activity of skeletal muscle is controlled by varying the frequency of nerve impulses stimulating the muscle, and thereby the number of contractions of each fiber per unit of time, as well as by the number of muscle fibers, i.e., motor units, that contact, while the contractile properties of each individual fiber remain constant. Although the muscle's resting length also influences the characteristics of contraction, this variable remains essentially fixed in vivo because of the muscles' skeletal attachments. In contrast to skeletal muscle, the number of myocardial cells and within them the myofibrils and sarcomeres that become activated during each contraction is constant. However, the contractile activity of the myocardium is readily altered under physiologic conditions by changes in resting fiber length and by changes in the inotropic state, i.e., the contractility, both of which shift the myocardial force-velocity curve. Many neurohumoral influences affect contractility, but the most important influence is the adrenergic nervous system operating via its neurotransmitter, norepinephrine.

VENTRICULAR EJECTION AND FILLING

Analysis of the heart as a pump has classically centered on the relation between the end-diastolic volume of the ventricle (which is related to the length of the muscle fibers) and its stroke volume (the Frank-Starling relation). The end-diastolic or "filling" pressure of the ventricle is sometimes used as a surrogate for the end-diastolic volume. In the heart-lung preparation the stroke volume varies directly with the diastolic fiber length (preload) and inversely with the arterial resistance (afterload), and as the heart fails it delivers a progressively smaller stroke volume from a normal or even elevated end-diastolic volume. The relation between the ventricular end-diastolic pressure and the stroke work of the ventricle (the ventricular function curve) provides a useful definition of the level of *myocardial contractility* (also termed the contractile, or inotropic, state of the ventricle). An increase in ventricular contractility is accompanied by a shift of the ventricular function curve upward and to the left [greater stroke work at any level of ventricular end-diastolic pressure (or volume), or lower end-diastolic pressure at any level of stroke work], while depression of contractility is characterized by a shift downward and to the right (Fig. 231-6).

During the adrenergic stimulation of the myocardium that accompanies exercise, relatively little change in ventricular end-diastolic volume occurs, while cardiac output, aortic flow velocity, stroke work, and the rate of ventricular pressure development are all augmented, reflecting an increase in myocardial contractility.

The important influence of the adrenergic neurotransmitter, norepinephrine (Chap. 72), on the mechanical properties of the myocardium has long been recognized. Direct stimulation of the cardiac adrenergic nerves augments ventricular function as a consequence of the release of norepinephrine from adrenergic nerve endings in the heart. Norepinephrine activates myocardial b receptors and through a series of G (guanine nucleotide binding) protein mediated changes activates the enzyme adenylate cyclase, which leads to the formation of cyclic AMP from ATP (Fig. 231-7). The latter, in

turn, activates protein kinase, which causes a more rapid, forceful contraction by phosphorylating the Ca^{2+}channel in the myocardial sarcolemma, thereby enhancing the influx of Ca^{2+}into the myocyte. Ca^{2+}acts on the contractile apparatus, as described on p. 1311. Cyclic AMP also phosphorylates theSRprotein phospholamban, which increases the uptake of Ca^{2+} by the SR, thereby enhancing the rate of relaxation. Adrenergic activation is evidenced by tachycardia, a reduction in cardiac dimensions, and increased rates of ejection and filling.

ASSESSMENT OF CARDIAC FUNCTION

Several techniques are available for defining impaired cardiac function in patients. With the patient at rest, and at a normal or elevated ventricular end-diastolic pressure, the cardiac output and stroke volume may be depressed in the presence of heart failure, but not uncommonly these variables are within normal limits. A more sensitive index is the ejection fraction, i.e., the ratio of stroke volume to end-diastolic volume (normal value = 67 ± 8%), which may be estimated by radiocontrast or radionuclide angiography or echocardiography, and it is frequently depressed in systolic heart failure even when the stroke volume itself is normal. Alternatively, the detection of abnormally elevated ventricular end-diastolic volumes (normal value = 70± 20 mL/m^2) in the presence of a normal stroke volume signifies impairment of left ventricular systolic function. A limitation of cardiac output, ejection fraction, and ventricular volume in the assessment of cardiac function is that these variables are influenced strongly by ventricular loading conditions. Thus, a depressed ejection fraction and lowered cardiac output may be observed in patients with normal ventricular function but reduced preload, as occurs in hypovolemia, or with increased afterload, as occurs in acutely elevated arterial pressure.

The end-systolic left ventricular pressure-volume relationship is a particularly useful index of ventricular performance since it is independent of both preload and afterload (Fig. 231-8). At any level of myocardial contractility, left ventricular end-systolic volume varies inversely with end-systolic pressure; as contractility declines, end-systolic volume (at any level of end-systolic pressure) rises. Noninvasive techniques, particularly echocardiography and radionuclide angiography (Chap. 227), are of great value in the clinical assessment of myocardial function. They provide measurements of end-systolic volume (or end-systolic dimension) that can be related to systolic arterial pressure. In addition, they provide convenient measurements of ejection fraction and systolic shortening rate and allow measurement of ventricular filling (see below).

Exercise A useful technique for evaluating ventricular performance involves the measurement of the circulatory changes occurring during exercise. Thus, left ventricular performance may be estimated accurately by measuring the left ventricular end-diastolic pressure, cardiac output, and total-body O_2consumption at rest and during exercise. In persons with normal cardiac function, the cardiac output rises by more than 500 mL/min for each 100-mL increase in O_2consumption per minute. The left ventricular end-diastolic pressure at rest is less than 12 mmHg and changes little during exercise, while cardiac output, and to a lesser extent stroke volume, rise, the latter especially when exercise is carried out in the upright position. The failing left ventricle, on the other hand, is characterized by an elevation of end-diastolic pressure during exercise to above 12 mmHg, accompanied by either no change or a fall in stroke volume and a

subnormal increase in cardiac output related to the increase in minute O_2consumption. The overall performance of the cardiopulmonary system in delivering oxygen to the metabolizing tissue can also be estimated by measuring the maximal O_2consumption achieved during escalating treadmill exercise ($_{max}O_2$). Normal values exceed 20 mL/min per kilogram, while values under 10 mL/min per kilogram represent severe impairment of function, usually seen in patients with severe heart failure and a poor prognosis.

The potential value of stressing the left ventricle in assessing its performance is emphasized by the fact that the normal range of left ventricular end-diastolic pressure, cardiac index, and ventricular stroke work in the resting state are wide, with values that frequently overlap those seen in patients with ventricular dysfunction.

DIASTOLIC FUNCTION (Fig. 231-9)

This important variable is best assessed by continuously measuring the flow velocity across the mitral valve using Doppler echocardiography. Normally, the velocity of inflow is more rapid in early diastole than during atrial systole; with impaired relaxation the rate of early diastolic filling declines, while the rate of presystolic filling rises. With severe impairment of filling the pattern is "pseudo-normalized" and early ventricular filling becomes more rapid as left atrial pressure upstream to the stiff left ventricle rises.

CONTROL OF CARDIAC PERFORMANCE AND OUTPUT

The extent of shortening of heart muscle and, therefore, the stroke volume of the intact ventricle are determined by three influences: (1) the length of the muscle at the onset of contraction, i.e., the preload; (2) the inotropic state of the muscle, i.e., the position of its force-velocity-length relation and its end-diastolic-shortening-relation; and (3) the tension that the muscle is called upon to develop during contraction, i.e., the afterload. Within wide limits, heart rate determines the cardiac output at any stroke volume as long as the other three influences remain constant. Ventricular filling is influenced by the extent and speed of myocardial relaxation, which in turn is determined by the rate of uptake of Ca^{2+} by the SR; the latter may be reduced by ischemia. Filling may be also impeded by the stiffness of the ventricular wall, which may be increased by ventricular hypertrophy and conditions that infiltrate the ventricle, such as amyloid, or by an extrinsic constraint (e.g., pericardial compression).

VENTRICULAR END-DIASTOLIC VOLUME (PRELOAD)

At any level of inotropic state and afterload, the performance of the myocardium is influenced profoundly by ventricular end-diastolic fiber length and therefore by diastolic ventricular volume, i.e., by operation of the Frank-Starling mechanism (Fig. 231-6). The following are the major determinants of ventricular preload in the intact organism:

Total Blood Volume When blood volume is depleted, as in hemorrhage or dehydration, venous return to the heart declines (Chap. 38) and ventricular end-diastolic volume (preload) falls, as does ventricular performance, as reflected in stroke volume and ventricular work.

Distribution of Blood Volume The ventricular end-diastolic volume is influenced by the

distribution of blood volume between the intra- and extrathoracic compartments. This distribution in turn is influenced by the following:

1. *Body position*. Gravitational forces pool blood in dependent portions of the body; upright posture augments extrathoracic at the expense of intrathoracic blood volume and reduces ventricular work.

2. *Intrathoracic pressure*. Normally, mean intrathoracic pressure is negative, which increases thoracic blood volume and ventricular end-diastolic volume and enhances the return of blood to the heart, particularly during inspiration, when this pressure becomes more negative. Elevation of intrathoracic pressure, as occurs during the Valsalva maneuver or prolonged bouts of coughing or with positive-pressure ventilation, has the opposite effect. It impedes venous return, diminishes intrathoracic blood volume, and reduces stroke volume and ventricular work.

3. *Intrapericardial pressure*. When this pressure is elevated, as in pericardial tamponade (Chap. 239), there is interference with cardiac filling, and the resultant reduction in ventricular diastolic volume reduces stroke volume and ventricular work.

4. *Venous tone*. The venous system is not a simple system of passive conduits between the systemic capillary bed and the right atrium. Instead, the smooth muscle in the walls of the venules and veins responds to a variety of neural and humoral stimuli. Venoconstriction occurs during muscular exercise, deep respiration, fright, or marked hypovolemic shock, reducing extrathoracic and augmenting intrathoracic and intraventricular blood volumes and ventricular performance.

5. *The pumping action of skeletal muscle*. During muscular exercise the contracting skeletal muscles squeeze blood out of the venous bed and, with the aid of the venous valves, displace it centrally, thereby increasing intrathoracic blood volume, ventricular end-diastolic volume, and ventricular work.

Atrial Contraction Vigorous, appropriately timed atrial contraction augments ventricular filling and end-diastolic volume. The atrial contribution to ventricular filling, the so-called atrial kick, is of particular importance in patients with concentric ventricular hypertrophy. In such patients, the loss of atrial systole (as occurs with the development of atrial fibrillation) reduces ventricular end-diastolic pressure and volume, ultimately lowering myocardial performance. The atrial contribution to ventricular filling may also be reduced by atrioventricular dissociation, prolongation or abbreviation of the P-R interval, and depression of atrial contractility.

INOTROPIC STATE (MYOCARDIAL CONTRACTILITY)

A number of factors determine the level of ventricular performance at any given ventricular end-diastolic volume, i.e., the position of the ventricular function curve (Fig. 231-6) as well as the position of the left ventricular pressure-volume plane (Fig. 231-8). These influences may be considered to operate by modifying myocardial force-velocity relations. In the final analysis, most of these influences act by altering the [Ca^{2+}] in the vicinity of the myofilaments, which in turn trigger cross-bridge cycling (p. 1293).

Adrenergic Nerve Activity (See also Chap. 72) The quantity of norepinephrine released by adrenergic nerve endings in the heart is determined by the adrenergic nerve impulse traffic; alterations in the frequency of these nerve impulses modify the quantity of norepinephrine released and acting on theb-adrenergic receptors in the myocardium. This mechanism is the most important one that acutely modifies myocardial contractility under physiologic conditions.

Circulating Catecholamines (See also Chap. 72) When it is stimulated by adrenergic nerve impulse, the adrenal medulla releases catecholamines, which, when they reach the heart, augment both heart rate and myocardial contractility.

The Force-Frequency Relation The position of the myocardial force-velocity curve is also influenced by the rate and rhythm of cardiac contraction; e.g., ventricular extrasystoles result in postextrasystolic potentiation, presumably by increasing the quantity of Ca^{2+}that enters the cardiac cell. The contractility of the normal (but not of the failing) heart is augmented by an increase in frequency of contraction.

Exogenously Administered Inotropic Agents Isoproterenol, dopamine, dobutamine, and other sympathomimetic agents, cardiac glycosides, Ca^{2+}, amrinone, milrinone, and other phosphodiesterase inhibitors all improve the myocardial force-velocity relation and therefore may be used to stimulate ventricular performance.

Physiologic Depressants Included among these are severe myocardial hypoxia, ischemia, and acidosis. Acting either singly or in combination, these influences depress the myocardial force-velocity curve and left ventricular work at any given ventricular end-diastolic volume.

Pharmacologic Depressants These include many antiarrhythmic drugs such as procainamide and disopyramide; calcium antagonists such as verapamil; beta blockers; and large doses of barbiturates, alcohol, and general anesthetics as well as many other drugs.

Loss of Myocytes When a sufficiently large portion of ventricular myocardium becomes nonfunctional or necrotic, as occurs transiently during ischemia (Chap. 244) and permanently in myocardial infarction (Chap. 243), total ventricular performance at any given level of end-diastolic volume becomes depressed. Programmed cell death (apoptosis) can also cause loss of myocytes and, when sufficiently widespread, can impair ventricular function and cause heart failure.

Intrinsic Myocardial Depression Although the fundamental mechanisms responsible for depression of myocardial contractility in most cases of chronic congestive heart failure secondary to prolonged ventricular overload or cardiomyopathy remain to be elucidated (p. 1316), it is now apparent that in this condition the inotropic state of individual surviving myocytes is depressed, and as a consequence the ventricular performance at any ventricular preload and afterload is lowered.

VENTRICULAR AFTERLOAD

The stroke volume is ultimately a function of the extent of ventricular fiber shortening. In

the intact heart, as in isolated cardiac muscle, the velocity and extent of shortening of ventricular muscle fibers at any level of preload and myocardial contractility are inversely related to the afterload, i.e., the load that opposes shortening. In the intact heart the afterload may be defined as the tension or stress developed in the ventricular wall during ejection. Therefore, the afterload is determined by the aortic pressure as well as the volume and thickness of the ventricular cavity. Laplace's law indicates that the tension of the myocardial fiber is a function of the product of the intracavitary ventricular pressure and ventricular radius divided by the wall thickness. Therefore, at any given level of aortic pressure, the afterload faced by a dilated left ventricle of normal thickness is higher than that encountered by a normal-sized ventricle. Conversely, at the same aortic pressure and ventricular diastolic volume, the afterload of a thick-walled ventricle is lower than of a thin-walled chamber. The aortic pressure, in turn, is determined by the peripheral vascular resistance, the physical characteristics of the arterial tree, and the volume of blood it contains at the onset of ejection.

The critical role played by the ventricular afterload in cardiovascular regulation is shown in Fig. 231-10. As already noted, increases in both preload and contractility increase myocardial fiber shortening, while increases in afterload reduce it. The extent of myocardial fiber shortening and left ventricular size are the determinants of stroke volume. Arterial pressure, in turn, is related to the product of cardiac output and systemic vascular resistance, while afterload is a function of left ventricular volume, wall thickness, and arterial pressure. An increase in arterial pressure induced by vasoconstriction, for example, augments afterload, which opposes myocardial fiber shortening, reducing stroke volume. This in turn tends to limit the increase in pressure.

When myocardial contractility becomes impaired and the ventricle dilates, afterload rises and becomes increasingly important in determining cardiac output. Increases in afterload may result from neural and humoral stimuli that occur in response to a fall in cardiac output. This increased afterload may reduce cardiac output further while myocardial oxygen requirements are increased. This can cause a vicious cycle. Treatment with vasodilators has the opposite effect; by reducing afterload, cardiac output rises (Chap. 232).

Under normal circumstances, the various influences acting on cardiac performance enumerated above interact in a complex fashion to maintain cardiac output at a level appropriate to the requirements of the metabolizing tissues, and interference with any one of these mechanisms may not influence the cardiac output. For example, a moderate reduction of blood volume *or* the loss of the atrial contribution to ventricular contraction can ordinarily be sustained without a reduction in the cardiac output at rest. Other factors, such as increases in the frequency of adrenergic nerve impulses to the heart and in heart rate, will, in a normal individual, serve as compensatory mechanisms, augment contractility, and sustain cardiac output.

EXERCISE

The hemodynamic changes that occur normally during exercise in the upright position are complex (Fig. 231-6). Hyperventilation, the pumping action of the exercising muscles, and the venoconstriction during exercise all augment venous return and hence ventricular filling and preload. Simultaneously, the increase in the adrenergic nerve

impulse traffic to the myocardium, the increased concentration of circulating catecholamines, and the tachycardia that occur during exercise combine to augment the contractile state of the myocardium (Fig. 231-6, curves 1 and 2) and lead to an elevation of stroke work and stroke volume, without change or even a reduction of end-diastolic pressure and volume (Fig. 231-6, points A and B). Vasodilatation occurs in the exercising muscles, thus tending to limit the increase in arterial pressure that would otherwise occur as cardiac output rises to levels as high as five times basal during maximal exercise. This vasodilatation ultimately allows the achievement of a greatly elevated cardiac output during exercise, at an arterial pressure only moderately higher than in the resting state.

THE FAILING HEART

Although heart failure may be readily described as a clinical syndrome, characterized by well-known symptoms and physical signs (Chap. 232), a precise physiologic or biochemical definition is far more difficult. However, from the clinical point of view, heart failure may be considered to be the condition in which *an abnormality of cardiac function is responsible for the inability of the heart to pump blood at a rate commensurate with the requirements of the metabolizing tissues and/or allows it to do so only from an abnormally elevated ventricular diastolic volume*. Abnormalities during systole and/or diastole may be present in heart failure (Fig. 231-9). In so-called *systolic heart failure* (p. 1320), an impairment of myocardial contractility causes weakened systolic contraction, which leads, ultimately, to a reduction in stroke volume and cardiac output, inadequate ventricular emptying, cardiac dilatation, and often elevation of ventricular diastolic pressure. Idiopathic dilated cardiomyopathy (Chap. 238) is the prototype of systolic heart failure. In *diastolic heart failure* (p. 1320), the principal abnormality is impaired relaxation and filling of the ventricle, which leads to an elevation of ventricular diastolic pressure at any given diastolic volume (Fig. 231-9). Failure of relaxation can be functional and transient, as during ischemia, which reduced the ATP required for theSR pump to lower cytoplasmic Ca^{2+}. Chronically impaired ventricular filling can be caused by a stiffened, thickened ventricle. Typical conditions in which diastolic failure occurs are restrictive cardiomyopathy secondary to infiltrative conditions, such as amyloidosis or hemochromatosis, as well as hypertrophic cardiomyopathy (Chap. 238). The concentric hypertrophy associated with chronic hypertension can also impair ventricular filling but rarely causes overt heart failure. In many patients with cardiac hypertrophy and dilatation, systolic and diastolic failure coexist; the left ventricle both empties and fills abnormally. There may be cardiac dilatation, but the ventricle's pressure-volume relation is shifted, raising the ventricular diastolic pressure at any given volume.

Although a defect in myocardial contraction is characteristic of systolic heart failure, many conditions may cause such a defect. These include a primary abnormality in the heart muscle, as occurs in cardiomyopathy, or an abnormality secondary to a chronic excessive work load as in hypertension or valvular heart disease. In ischemic heart disease, systolic heart failure results from a loss in the quantity of normally contracting cells (secondary to myocardial necrosis and apoptosis) and/or from transient loss of function in reversibly ischemic (hibernating) myocardium (Chap. 244).

Heart failure should be distinguished from conditions that resemble it, such as (1) states of circulatory insufficiency in which myocardial function is not primarily impaired, such as

cardiac tamponade or hemorrhagic shock; (2) conditions in which there is circulatory congestion because of abnormal salt and water retention but in which there is no serious disturbance of the heart's function, such as acute glomerulonephritis; and (3) conditions in which a normal myocardium is suddenly presented with a load that exceeds its capacity, such as accelerated hypertension or rupture of a valve cusp secondary to infective endocarditis.

ADAPTIVE MECHANISMS

A number of mechanisms aid the heart faced with an increased hemodynamic burden (such as pressure or volume overload) or that has sustained loss of myocardium or contractility. These mechanisms include the following:

1. The *Frank-Starling mechanism* operating through an increase in preload (p. 1314). As outlined above, an increase in the end-diastolic volume of the ventricle is associated with stretching of the sarcomeres, which increases the interaction between actin and myosin filaments and their sensitivity to Ca^{2+}. Ventricular dilatation may become maladaptive when it becomes excessive, as may occur in severe aortic or mitral regurgitation; this increases wall stress through the operation of LaPlace's law and reduces shortening.

2. *Increased afterload*, as occurs in aortic stenosis and hypertension, also augments wall tension, leading to concentric hypertrophy, which in turn restores elevated ventricular wall stress to normal (Figs. 231-CD1 and231-CD2). However, ventricular hypertrophy impairs ventricular filling, and if the hypertrophy is insufficient to restore wall stress to normal, the ventricle dilates and this increases wall stress further, leading to a vicious circle.

3. *Redistribution of a subnormal cardiac output* away from the skin, skeletal muscle, and kidneys with maintenance of blood flow to the brain and the heart.

4. *Neurohumoral adjustments*, which tend to maintain arterial pressure and are discussed inChap. 72. Like the other adaptive mechanisms, when neurohumoral adjustments are severe and chronic they impair cardiac function (see below).

BIOCHEMICAL ABNORMALITIES IN HEART FAILURE

There is no unifying theory providing a biochemical basis for heart failure. However, a number of abnormalities have been described.

Reduction in Cardiac Efficiency The common forms of low-output systolic heart failure, secondary to coronary atherosclerosis, hypertension, cardiomyopathy, and certain valvular and congenital lesions, are characterized by an absolute or a relative reduction in the external work delivered by the heart, while myocardial oxygen consumption remains normal or nearly so. Therefore, the external efficiency, i.e., the ratio of external work performed to energy consumed, is often depressed.

Alterations in Energy Metabolism When heart failure occurs in the presence of acute or chronic ischemia, it can be attributed to reduced myocardial energy supplies. Severe

ventricular hypertrophy and/or dilatation of any etiology can also cause relative ischemia, especially in the subendocardium, and this can impair both ventricular contraction and filling. In some forms of experimental and clinical heart failure without ischemia, myocardial energy stores in the form of creatine phosphate are decreased, as is the activity of the enzyme creatin kinase required for the shuttling of high-energy phosphate between creatine phosphate and adenosine diphosphate, suggesting that reductions in myocardial energy reserves may play a role.

Alterations in Regulatory Proteins Changes in the cardiac regulatory proteins frequently occur in chronic heart failure. These include a reduction of myosin ATPase activity, which may be caused by an alteration in the expression of troponin T and/or of myosin light chain kinase 2, alterations that could be responsible for lowering the rate of interaction between myosin and actin myofilaments, leading to systolic heart failure.

Abnormalities of Excitation-Contraction Coupling Substantial evidence supports the view that in many forms of heart failure the delivery of Ca^{2+} to the contractile sites is reduced, thereby impairing cardiac performance (Table 231-1). However, the molecular basis of this abnormality -- indeed of the subcellular structures involved, i.e., the sarcolemma, T tubules, and/orSR -- has yet to be defined. There is, however, evidence for a reduction in the activity of the Ca^{2+}release channel in the SR and of messenger RNAs of the proteins regulating Ca^{2+}movements. These include the sarcolemmal Ca^{2+}channels, the Ca^{2+}release channels, and the Ca^{2+}uptake pump, which play critical roles in the movement of Ca^{2+}between the SR and the cytoplasm. Impaired expression of the genes encoding these proteins can impair both myocardial contraction and relaxation and thereby contribute to the development of heart failure.

NEUROHUMORAL AND CYTOKINE ADJUSTMENTS

A reduction in cardiac performance evokes a series of neurohumoral adjustments, which, at different times, may be adaptive and maladaptive. Although they are useful because they maintain arterial perfusion pressure in the face of a sudden reduction of cardiac output, these neurohumoral adjustments increase the hemodynamic burden and oxygen requirements of the failing ventricle (Fig. 231-11).

The Adrenergic Nervous System In patients with heart failure the levels of circulating norepinephrine may be markedly elevated, reflecting the increased activity of the adrenergic nervous system; indeed the prognosis in patients with heart failure varies inversely with the concentration of plasma norepinephrine. This increased activity of the adrenergic neurons supports ventricular contractility in *acute* heart failure. Heart failure is intensified when large doses of b-adrenergic blocking agents are administered acutely, providing evidence for the protective action of adrenergic nervous activation. However, the *chronic* adrenergic stimulation that occurs in heart failure may increase afterload by raising vascular resistance, cause cardiac arrhythmias, and may damage myocytes further, perhaps by causing Ca^{2+}overload.

The density of adrenergic receptors, their coupling to G proteins, and the concentration of cardiac norepinephrine stores are all reduced in chronic, severe heart failure. These changes are accompanied by a reduction in the activity of adenylate cyclase, which may lower the intracellular concentration of cyclic AMP. The latter in turn reduces the

activation of protein kinase, the phosphorylation of Ca^{2+}channels, transarcolemmal Ca^{2+}entry, as well as the phosphorylation of phospholamban, a protein in the SR, which reduces the reuptake of Ca^{2+} by the latter (Fig. 231-7). Changes in the G proteins, which couple the b receptor to the catalytic adenylate cyclase (which is responsible for the production of cyclic AMP), may also occur in heart failure, with increased activity of the inhibitory subunit.

The Renin-Angiotensin-Aldosterone System When cardiac output declines, the renin-angiotensin-aldosterone system (Chap. 331;Fig. 231-CD3) is activated. Concentrations of both circulating angiotensin II and aldosterone are increased, the former contributing to excess vasoconstriction and the latter to the retention of salt and water and perhaps to cardiac fibrosis. The local (tissue) renin-angiotensin system is also activated in heart failure. Patients with heart failure are usually improved by blocking this system with angiotensin-converting enzyme inhibitors, angiotensin II receptor blockers, and aldosterone antagonists (Chap. 232).

Endothelin The concentration of circulatory endothelin, a polypeptide that is a very powerful vasoconstrictor, is increased in heart failure. A number of studies have shown that blockade of endothelin receptors improves left ventricular function in patients and experimental animals with heart failure.

Tumor Necrosis Factora The overexpression of a number of cytokines also appears to play a prominent role in the pathogenesis of heart failure. It has now been well established that patients exhibit elevated levels of tumor necrosis factor (TNF) a, both in the circulation and in cardiac muscle; the pathophysiologic significance of this finding is just unfolding. Transgenic mice with overexpressed cardiac TNF-a have systolic dysfunction, myocarditis, ventricular dilatation, heart failure, and shortened survival. The infusion of TNF-a impairs ventricular function, and this can be reversed with a TNF-aantagonist.

Vasodilator Peptides A number of vasodilator peptides are released by the dilated heart. Best known are the natriuretic peptides atrial natriuretic peptide (ANP) and brain natriuretic peptide (BNP). When stretch receptors in the atria (ANP and BNP) and ventricles (BNP) are activated, these hormones (or their prohormones) are released and act on specific natriuretic peptide receptors, which increase the concentrations of cyclic GMP in the kidney, adrenal glomerulose, vascular smooth muscle, and platelets. Urine volume and sodium excretion are augmented, vascular resistance is reduced, and the release of renin and the secretion of aldosterone are reduced. These effects, while beneficial, are not sufficiently powerful to oppose the sodium-retaining and vasoconstrictor influences of the other neurohumoral systems activated in heart failure. Elevated circulating concentrations of ANP and particularly BNP correlate with a poor prognosis in heart failure. Drugs that augment the concentrations of these compounds are under development.

Figure 231-11 illustrates current concepts of neurohumoral-cytokine activation in heart failure. The activation of the adrenergic nervous system and the renin-angiotensin-aldosterone system and the enhanced elaboration of endothelin and arginine vasopressin appear to be adaptive in *acute*, severe heart failure. However, they all appear to exert a maladaptive response in chronic heart failure. Inflammatory

cytokines and oxidative stress are emerging as potent noxious stimuli as well. Together they result in a vicious circle, causing myocyte hypertrophy, remodeling, and cell death, the latter often due to myocardial apoptosis, all resulting in further impairment of cardiac function and myocardial injury. Effective agents that interfere with the adverse effects of these stimuli on cardiac function, such as endothelin receptor blockers andTNF-aantagonists, are becoming available, and these neurohumoral and cytokine blockers appear capable of interrupting the vicious circle.

HEART FAILURE -- A DISTURBANCE OF THE MYOCARDIAL PUMP

In the final analysis, in systolic heart failure the basic problem is depression of the myocardial force-velocity relationship and of the length-active tension curve, reflecting reductions in the contractile state of the myocardium (Fig. 231-6, curves 1 to 3,Fig. 231-8, right). In diastolic failure there is upward displacement of the diastolic pressure-volume relation (Fig. 231-9). In many instances, cardiac output and external ventricular performance at rest are within normal limits but are maintained at these levels only by an increased end-diastolic fiber length and an elevated ventricular end-diastolic volume, i.e., through the operation of the Frank-Starling mechanism (Fig. 231-6, points A to D). The elevation of left ventricular preload is associated with increases in the pulmonary capillary pressure, contributing to the dyspnea experienced by patients with heart failure, while elevation of right ventricular preload raises systemic venous pressure and contributes to the development of edema. The improvement of contractility that normally accompanies augmented adrenergic activity during exercise is attenuated or even prevented by norepinephrine depletion and downregulation of myocardial b receptors, which occur in severe heart failure (Fig. 231-6, curves 3 and 3¢).

The factors that augment ventricular filling during exercise in the normal individual push the failing myocardium along its flattened length-active tension curve, and although the left ventricle may perform somewhat better at this higher diastolic volume, this occurs only as a consequence of an inordinate elevation of ventricular end-diastolic volume and pressure and, therefore, of the pulmonary capillary pressure. The latter intensifies dyspnea and therefore plays an important role in limiting the intensity of exercise that the patient can perform. Left ventricular failure becomes fatal when the myocardial length-active tension curve is depressed (Fig. 231-6, curve 4) to the point at which cardiac performance fails to satisfy the requirements of the peripheral tissues even at rest, and/or the left ventricular end-diastolic and pulmonary capillary pressures are elevated to levels that result in pulmonary edema (Fig. 231-6, point E).

232. HEART FAILURE - *Eugene Braunwald*

Heart failure (HF) is the pathophysiologic state in which an abnormality of *cardiac* function is responsible for the failure of the heart to pump blood at a rate commensurate with the requirements of the me tabolizing tissues *and/or* allows it to do so only from an abnormally elevated diastolic volume. HF is frequently, but not always, caused by a defect in myocardial contraction, and then the term *myocardial failure* is appropriate. The latter may result from a primary abnormality in heart muscle, as occurs in the cardiomyopathies, in viral myocarditis (Chap. 238), and with excessive programmed cell death (apoptosis). HF also results commonly from coronary atherosclerosis, which interferes with cardiac contraction by causing myocardial infarction and ischemia. HF may also occur in valvular and/or congenital heart disease in which the heart muscle is damaged by the long-standing excessive hemodynamic burden imposed by the valvular abnormality or cardiac malformation.

In other patients withHF, however, a similar clinical syndrome is present but without any detectable abnormality of *myocardial* function. In some of these patients the normal heart is suddenly presented with a mechanical load that exceeds its capacity, such as an acute hypertensive crisis, rupture of an aortic valve cusp, or massive pulmonary embolism. HF in the presence of normal myocardial function also occurs in chronic conditions in which there is impaired filling of the ventricles due to a mechanical abnormality such as tricuspid and/or mitral stenosis, constrictive pericarditis without myocardial involvement, endocardial fibrosis, and some forms of hypertrophic cardiomyopathy. In many patients with HF, particularly those with valvular or congenital heart disease, there is a combination of impaired myocardial function and hemodynamic overload.

Heart failure should be distinguished from (1) conditions in which there is circulatory congestion secondary to abnormal salt and water retention but in which there is no disturbance of cardiac function per se, as occurs in renal failure; and (2) noncardiac causes of inadequate cardiac output, such as hypovolemic shock (Chap. 38).

The ventricles respond to a chronically increased hemodynamic burden with the development of hypertrophy (Fig. 232-1). When the ventricle is called on to deliver an elevated cardiac output for prolonged periods, as in valvular regurgitation, it develops *eccentric hypertrophy*, i.e., cavity dilatation, with an increase in muscle mass so that the ratio between wall thickness and ventricular cavity size remains relatively constant early in the process. With chronic pressure overload, as in valvular aortic stenosis or untreated hypertension, *concentric ventricular hypertrophy* develops; in this condition the ratio between wall thickness and ventricular cavity size increases. In both eccentric and concentric hypertrophy, a stable hyperfunctioning state may exist for many years, but myocardial function may ultimately deteriorate, leading toHF. Often at this time, the ventricle dilates and the ratio between wall thickness and cavity size declines, leading to increased stress on each unit of myocardium, further dilatation, and a vicious circle.

Heart failure represents a major public health problem in industrialized nations. It appears to be the only common cardiovascular condition that is increasing in prevalence and incidence. In the United States,HF is responsible for almost 1 million hospital admissions and 40,000 deaths annually. Since HF is more common in the elderly, its

prevalence is likely to continue to increase as the population ages.

CAUSES OF HEART FAILURE

In evaluating patients withHF, it is important to identify not only the *underlying* but also the *precipitating cause*. The cardiac abnormality produced by a congenital or acquired lesion such as valvular aortic stenosis may exist for many years and cause no clinical disability. Frequently, however, clinical manifestations of HF are precipitated for the first time in the course of some acute disturbance that places an additional load on a myocardium that is chronically excessively burdened (see below). Such a heart may be compensated but have little additional reserve, and the additional load imposed by a precipitating cause results in further deterioration of cardiac function. Identification of such precipitating causes is of critical importance because their prompt alleviation may be lifesaving. In the absence of underlying heart disease, these acute disturbances do not by themselves lead to HF.

PRECIPITATING CAUSES

1. *Infection*. Patients with pulmonary vascular congestion due to left ventricular failure are more susceptible to pulmonary infection than are normal persons; any infection may precipitateHF. The resulting fever, tachycardia, and hypoxemia and the increased metabolic demands may place a further burden on an overloaded, but compensated, myocardium of a patient with chronic heart disease.

2. *Anemia*. In the presence of anemia, the oxygen needs of the metabolizing tissues can be met only by an increase in the cardiac output (Chap. 61). Although such an increase in cardiac output can be sustained by a normal heart, a diseased, overloaded, but otherwise compensated heart may be unable to augment sufficiently the volume of blood that it delivers to the periphery. In this manner, the combination of anemia and previously compensated heart disease can precipitateHF and lead to inadequate delivery of oxygen to the periphery.

3. *Thyrotoxicosis and pregnancy*. Similar to anemia and fever, thyrotoxicosis and pregnancy are also high cardiac output states. The development or intensification ofHF in a patient with previously compensated heart disease may actually be one of the first clinical manifestations of hyperthyroidism (Chap. 330). Similarly, HF not infrequently occurs for the first time during pregnancy in women with rheumatic valvular disease, in whom cardiac compensation may return following delivery (Chap. 7).

4. *Arrhythmias*. In patients with compensated heart disease, arrhythmias are among the most frequent precipitating causes ofHF. They exert a deleterious effect for a variety of reasons: (a) Tachyarrhythmias reduce the time period available for ventricular filling and in patients with ischemic heart disease they may also cause ischemic myocardial dysfunction. (b) The dissociation between atrial and ventricular contractions characteristic of many brady- and tachyarrhythmias results in the loss of the atrial booster pump mechanism, thereby raising atrial pressures. (c) Cardiac performance may become further impaired because of the loss of normally synchronized ventricular contraction in any arrhythmia associated with abnormal intraventricular conduction. (d) Marked bradycardia associated with complete atrioventricular block or other severe

bradyarrhythmias reduces cardiac output unless stroke volume rises reciprocally; this compensatory response cannot occur with serious myocardial dysfunction, even in the absence of HF (Chaps. 229 and230).

5. *Rheumatic, viral, and other forms of myocarditis*. Acute rheumatic fever and a variety of other inflammatory or infectious processes affecting the myocardium may precipitateHF in patients with or without preexisting heart disease (Chaps. 235 and238).

6. *Infective endocarditis*. The additional valvular damage, anemia, fever, and myocarditis that often occur as a consequence of infective endocarditis may, singly or in concert, frequently precipitateHF(Chap. 126).

7. *Physical, dietary, fluid, environmental, and emotional excesses*. The sudden augmentation of sodium intake as with a large meal, the inappropriate discontinuation of pharmaceuticals to treatHF, blood transfusions, physical overexertion, excessive environmental heat or humidity, and emotional crises all may precipitate HF in patients with heart disease who were previously compensated.

8. *Systemic hypertension*. Rapid elevation of arterial pressure, as may occur in some instances of hypertension of renal origin or upon discontinuation of antihypertensive medication in patients with essential hypertension, may result in cardiac decompensation (Chap. 246).

9. *Myocardial infarction*. In patients with chronic but compensated ischemic heart disease, a fresh infarct, sometimes otherwise silent clinically, may further impair ventricular function and precipitateHF(Chap. 243).

10. *Pulmonary embolism.* Physically inactive patients with low cardiac output are at increased risk of developing thrombi in the veins of the lower extremities or the pelvis. Pulmonary emboli may result in further elevation of pulmonary arterial pressure, which in turn may produce or intensify ventricular failure. In the presence of pulmonary vascular congestion, such emboli also may cause pulmonary infarction (Chap. 261).

A systematic search for these precipitating causes should be made in every patient with the new development or recent intensification ofHF. If properly recognized, the precipitating cause of HF usually can be treated more effectively than the underlying cause. Therefore, the prognosis in patients with HF in whom a precipitating cause can be identified, treated, and eliminated is more favorable than in patients in whom the underlying disease process has progressed to the point of producing HF without a precipitating cause.

FORMS OF HEART FAILURE

HFmay be described as *systolic* or *diastolic*, *high-output* or *low-output*, *acute* or *chronic*, *right-sided* or *left-sided*, and *forward* or *backward*. These descriptors are often useful in a clinical setting, particularly early in the patient's course, but late in the course of chronic HF the differences between them often become blurred.

SYSTOLIC VERSUS DIASTOLIC FAILURE

The distinction between these two forms ofHF, described in Fig. 231-9, relates to whether the principal abnormality is the inability of the ventricle to contract normally and expel sufficient blood (systolic failure) or to relax and/or fill normally (diastolic failure). The major clinical manifestations of systolic failure relate to an inadequate cardiac output with weakness, fatigue, reduced exercise tolerance, and other symptoms of hypoperfusion, while in diastolic HF the manifestations relate principally to the elevation of filling pressures. Many patients, particularly those who have both ventricular hypertrophy *and* dilatation, exhibit abnormalities both of contraction and relaxation coexist.

DiastolicHF may be caused by increased resistance to ventricular inflow and reduced ventricular diastolic capacity (constrictive pericarditis and restrictive, hypertensive, and hypertrophic cardiomyopathy), impaired ventricular relaxation (acute myocardial ischemia), and myocardial fibrosis and infiltration (restrictive cardiomyopathy).

HIGH-OUTPUT VERSUS LOW-OUTPUT HEART FAILURE

It is useful to classify patients withHF into those with a low cardiac output, i.e., *low-output HF*, and those with an elevated cardiac output, i.e., *high-output HF*. The former occurs secondary to ischemic heart disease, hypertension, dilated cardiomyopathy, and valvular and pericardial disease, while the latter is seen in patients with HF and hyperthyroidism, anemia, pregnancy, arteriovenous fistulas, beriberi, and Paget's disease. In clinical practice, however, low-output and high-output HF cannot always be readily distinguished. The normal range of cardiac output is wide [2.2 to 3.5 (L/min)/m_2]; in many patients with so-called low-output HF, the cardiac output may actually be just within the normal range at rest (although lower than it had been previously), but it fails to rise normally during exertion. On the other hand, in patients with so-called high-output HF, the output may not exceed the upper limits of normal (although it would have been elevated had it been measured before HF supervened); rather, it may have fallen to within normal limits. Regardless of the *absolute* level of the cardiac output, however, cardiac failure may be said to be present when the characteristic clinical manifestations described below are accompanied by a depression of the curve relating ventricular end-diastolic volume to cardiac performance (seeFig. 231-6).

An integral physiologic component of *systolic*HF is the delivery of an inadequate quantity of oxygen required by the metabolizing tissues. In the absence of peripheral shunting of blood, this is reflected in an abnormal widening of the normal arterial-mixed venous oxygen difference (35 to 50 mL/L in the basal state). In mild cases, such an abnormality may not be present at rest but becomes evident only during exertion or other hypermetabolic states. In patients with high cardiac output states, such as those associated with arteriovenous fistula or thyrotoxicosis, the arterial-mixed venous oxygen difference is normal or low. The mixed venous oxygen saturation is raised by the admixture of blood that has been diverted away from the metabolizing tissues, and it may be presumed that even in these patients the delivery of oxygen to the latter is reduced despite the normal or even elevated mixed venous oxygen saturation. When HF occurs in such patients, the arterial-mixed venous oxygen difference, regardless of the absolute value, still exceeds the level that existed prior to the development of HF.

Therefore, the cardiac output, though normal or even elevated, is lower than before HF supervened.

In most forms of high-outputHF, the heart is called on to pump abnormally large quantities of blood in order to deliver the oxygen required by the metabolizing tissues. The hemodynamic burden placed on the myocardium by the increased flow load resembles that produced by chronic aortic regurgitation. In addition, thyrotoxicosis and beriberi may also impair myocardial metabolism directly, while very severe anemia may interfere with myocardial function by producing myocardial anoxia, especially in the subendocardium and in the presence of underlying obstructive coronary artery disease.

ACUTE VERSUS CHRONIC HEART FAILURE

The prototype of *acute HF* is the sudden development of a large myocardial infarction or rupture of a cardiac valve in a patient who previously was entirely well. *Chronic HF* is typically observed in patients with dilated cardiomyopathy or multivalvular heart disease that develops or progresses slowly. AcuteHF is usually predominantly systolic, and the sudden reduction in cardiac output often results in systemic hypotension without peripheral edema. In contrast, in chronic HF, arterial pressure is ordinarily well maintained until very late in the course, but there is often accumulation of edema.

RIGHT-SIDED VERSUS LEFT-SIDED HEART FAILURE

Many of the clinical manifestations of HFresult from the accumulation of excess fluid behind either one or both ventricles (Chaps. 32 and37). This fluid usually localizes upstream to (behind) the ventricle that is initially affected. For example, patients in whom the left ventricle is hemodynamically overloaded (e.g., aortic stenosis) or weakened (e.g., postmyocardial infarction) develop dyspnea and orthopnea as a result of pulmonary congestion, a condition referred to as *left-sided HF*. In contrast, when the underlying abnormality affects the right ventricle primarily (e.g., congenital valvular pulmonic stenosis or pulmonary hypertension secondary to pulmonary thromboembolism), symptoms resulting from pulmonary congestion are uncommon, and edema, congestive hepatomegaly, and systemic venous distention, i.e., clinical manifestations of *right-sided HF*, are more prominent. When HF has existed for months or years, such localization of excess fluid behind the failing ventricle may no longer exist. For example, patients with long-standing aortic valve disease or systemic hypertension may develop ankle edema, congestive hepatomegaly, and systemic venous distention late in the course of their disease, even though the abnormal hemodynamic burden initially was placed on the left ventricle. This occurs in part because of the secondary pulmonary hypertension and resultant right-sided HF but also because of the retention of salt and water characteristic of HF (Chap. 37). The muscle bundles composing both ventricles are continuous, and both ventricles share a common wall, the interventricular septum. Also, biochemical changes that occur in HF and that may be involved in the impairment of myocardial function (Chap. 231), such as norepinephrine depletion and alterations in the activity of myosin ATPase, occur in the myocardium of *both* ventricles, regardless of the specific chamber on which the abnormal hemodynamic burden is placed initially.

BACKWARD VERSUS FORWARD HEART FAILURE

For many years a controversy has revolved around the question of the mechanism of the clinical manifestations resulting fromHF. The concept of *backward HF* contends that in HF, one or the other ventricle fails to discharge its contents or fails to fill normally. As a consequence, the pressures in the atrium and venous system behind the failing ventricle rise, and retention of sodium and water occurs as a consequence of the elevation of systemic venous and capillary pressures and the resultant transudation of fluid into the interstitial space (Chap. 37). In contrast, the proponents of the *forward HF* hypothesis maintain that the clinical manifestations of HF result directly from an inadequate discharge of blood into the arterial system. According to this concept, salt and water retention is a consequence of diminished renal perfusion and excessive proximal tubular sodium reabsorption and of excessive distal tubular reabsorption through activation of the renin-angiotensin-aldosterone (RAA) system.

A rigid distinction between *backward* and *forward*HF (like a rigid distinction between right and left HF) is artificial, since both mechanisms appear to operate to varying extents in most patients with HF. However, the rate of onset of HF often influences the clinical manifestations. For example, when a large portion of the left ventricle is suddenly destroyed, as in myocardial infarction, although stroke volume and blood pressure are suddenly reduced (both manifestations of forward failure), the patient may succumb to acute pulmonary edema, a manifestation of backward failure. If the patient survives the acute insult, clinical manifestations resulting from a chronically depressed cardiac output, including the abnormal retention of fluid within the systemic vascular bed, may develop. Similarly, in the case of massive pulmonary embolism, the right ventricle may dilate and the systemic venous pressure may rise to high levels (backward failure), or the patient may develop shock secondary to low cardiac output (forward failure), but this low-output state may have to be maintained for some days before sodium and water retention sufficient to produce peripheral edema occurs.

REDISTRIBUTION OF CARDIAC OUTPUT

InHF, systemic blood flow is redistributed so that the delivery of oxygen to vital organs, such as the brain and myocardium, is maintained at normal or near-normal levels, while flow to less critical areas, such as the cutaneous and muscular beds and the viscera, is reduced. This redistribution serves as an important compensatory mechanism when cardiac output is reduced. It is most marked when a patient with HF exercises, but as HF advances, redistribution occurs even in the basal state. Vasoconstriction mediated by the adrenergic nervous system is largely responsible for redistribution, which in turn may be responsible for many of the clinical manifestations of HF, such as fluid accumulation (reduction of renal blood flow), low-grade fever (reduction of cutaneous flow), and fatigue (reduction of muscle flow).

SALT AND WATER RETENTION (See also Chap. 37)

When the volume of blood pumped by the left ventricle into the systemic vascular bed is reduced, a complex sequence of adjustments occurs that ultimately results in the abnormal accumulation of fluid. On the one hand, many of the troubling clinical manifestations ofHF are secondary to this excessive retention of fluid; on the other, this abnormal fluid accumulation and the expansion of blood volume that accompanies it

also constitute an important compensatory mechanism that tends to maintain cardiac output and therefore perfusion of the vital organs. Except in the terminal stages of HF, the ventricle operates on an ascending, albeit depressed and flattened, function curve (Fig. 231-6, p. 1313), and the augmented ventricular end-diastolic volume and pressure characteristic of HF must be regarded as helping to maintain the reduced cardiac output, despite causing pulmonary and/or systemic venous congestion.

CongestiveHF is also characterized by a complex series of neurohumoral adjustments. The activation of the adrenergic nervous system is discussed on p. 1315; there is also activation of theRAAsystem and increased release of antidiuretic hormone and endothelin. These influences elevate systemic vascular resistance and enhance sodium and water retention and potassium excretion. These actions are, to a minor extent, opposed by the release of atrial and brain natriuretic peptide, which also occurs in congestive HF. Patients with severe HF may exhibit a reduced capacity to excrete a water load, which may result in dilutional hyponatremia. In the presence of HF, effective filling of the systemic arterial bed is reduced, a condition that initiates the renal and hormonal changes mentioned above (Fig. 37-2).

The elevation of systemic venous pressure and the alterations of renal and adrenal function characteristic ofHF vary in their relative importance in the production of edema in different patients. The RAAaxis is activated most intensely by acute HF, and its activity tends to decline as HF becomes chronic. In patients with tricuspid valve disease or constrictive pericarditis, the elevated venous pressure and the transudation of fluid from systemic capillaries appear to play the dominant role in edema formation. On the other hand, severe edema may be present in patients with ischemic or hypertensive heart disease, in whom systemic venous pressure is within normal limits or is only minimally elevated. In such patients, the retention of salt and water is probably due primarily to a redistribution of cardiac output and a concomitant reduction in renal perfusion, as well as activation of the RAA axis. Regardless of the mechanisms involved in fluid retention, untreated patients with chronic congestive HF have elevations of total blood volume, interstitial fluid volume, and body sodium. These abnormalities diminish after clinical compensation has been achieved by effective treatment, especially with diuretics.

CLINICAL MANIFESTATIONS OF HEART FAILURE

DYSPNEA

Respiratory distress that occurs as the result of increased effort in breathing is the most common symptom ofHF(Chap. 32). In early HF, dyspnea is observed only during activity, when it may simply represent an aggravation of the breathlessness that occurs normally under these circumstances. As HF advances, however, dyspnea appears with progressively less strenuous activity and ultimately is present even when the patient is at rest. The principal difference between exertional dyspnea in normal persons and in patients with HF is the degree of activity necessary to induce this symptom. Cardiac dyspnea is observed most frequently in patients with elevations of pulmonary venous and capillary pressures. Such patients usually have engorged pulmonary vessels and interstitial pulmonary edema, which may be evident on radiologic examination. This interstitial pulmonary edema reduces the compliance of the lungs and thereby increases

the work of the respiratory muscles required to inflate the lungs. The activation of receptors in the lungs results in the rapid, shallow breathing characteristic of cardiac dyspnea. The oxygen cost of breathing is increased by the excessive work of the respiratory muscles. This is coupled with the diminished delivery of oxygen to these muscles, which occurs as a consequence of the reduced cardiac output and which may contribute to fatigue of the respiratory muscles and the sensation of shortness of breath.

Orthopnea Dyspnea in the recumbent position is usually a later manifestation ofHF than exertional dyspnea. Orthopnea occurs because of the redistribution of fluid from the abdomen and lower extremities into the chest during recumbency causing an increase in the pulmonary capillary hydrostatic pressure, as well as elevation of the diaphragm accompanying supine posture. Patients with orthopnea must elevate their heads on several pillows at night and frequently awaken short of breath or coughing (the so-called nocturnal cough) if their heads slip off the pillows. The sensation of breathlessness is usually relieved by sitting upright, since this position reduces venous return and pulmonary capillary pressure, and many patients report that they find relief from sitting in front of an open window. In advanced HF, orthopnea may become so severe that patients cannot lie down at all and must spend the entire night in a sitting position. On the other hand, in other patients with long-standing, severe left ventricular failure, symptoms of pulmonary congestion may actually diminish with time as the function of the right ventricle becomes impaired.

Paroxysmal (Nocturnal) Dyspnea This term refers to attacks of severe shortness of breath and coughing that generally occur at night, usually awaken the patient from sleep, and may be quite frightening. Though simple orthopnea may be relieved by sitting upright at the side of the bed with legs dependent, in the patient with paroxysmal nocturnal dyspnea, coughing and wheezing often persist even in this position. Paradoxical nocturnal dyspnea may be caused in part by the depression of the respiratory center during sleep, which may reduce ventilation sufficiently to lower arterial oxygen tension, particularly in patients with interstitial lung edema and reduced pulmonary compliance. Also, ventricular function may be further impaired at night because of reduced adrenergic stimulation of myocardial function. *Cardiac asthma* is closely related to paroxysmal nocturnal dyspnea and nocturnal cough and is characterized by wheezing secondary to bronchospasm -- most prominent at night. *Acute pulmonary edema* (Chap. 32) is a severe form of cardiac asthma due to marked elevation of pulmonary capillary pressure leading to alveolar edema, associated with extreme shortness of breath, rales over the lung fields, and the transudation and expectoration of blood-tinged fluid. If not treated promptly, acute pulmonary edema may be fatal.

CHEYNE-STOKES RESPIRATION

Also known as *periodic respiration* or *cyclic respiration*, Cheyne-Stokes respiration is characterized by diminished sensitivity of the respiratory center to arterial P_{CO_2}. There is an apneic phase, during which the arterial P_{O_2}falls and the arterial P_{CO_2}rises. These changes in the arterial blood stimulate the depressed respiratory center, resulting in hyperventilation and hypocapnia, followed in turn by recurrence of apnea. Cheyne-Stokes respiration occurs most often in patients with cerebral atherosclerosis and other cerebral lesions, but the prolongation of the circulation time from the lung to

the brain that occurs inHF, particularly in patients with hypertension and coronary artery disease and associated cerebral vascular disease, also appears to precipitate this form of breathing.

FATIGUE AND WEAKNESS

These nonspecific but common symptoms ofHF are related to the reduction of perfusion of skeletal muscle. Exercise capacity is reduced by the limited ability of the failing heart to increase its output and deliver oxygen to the exercising muscle.

ABDOMINAL SYMPTOMS

Anorexia and nausea associated with abdominal pain and fullness are frequent complaints and may be related to the congested liver and portal venous system.

CEREBRAL SYMPTOMS

In severeHF, particularly in elderly patients with accompanying cerebral arteriosclerosis, reduced cerebral perfusion, and arterial hypoxemia, there may be alterations in the mental state characterized by confusion, difficulty in concentration, impairment of memory, headache, insomnia, and anxiety. *Nocturia* is common in HF and may contribute to insomnia.

PHYSICAL FINDINGS (SeeChap. 225)

In moderateHF, the patient is in no distress at rest except that he or she may be uncomfortable when lying flat for more than a few minutes. In more severe HF, the pulse pressure may be diminished, reflecting a reduction in stroke volume, and the diastolic arterial pressure may be elevated as a consequence of generalized vasoconstriction. In acute HF, severe hypotension may be present. There may be cyanosis of the lips and nail beds (Chap. 36) and sinus tachycardia, and the patient may insist on sitting upright. *Systemic venous pressure* is often abnormally elevated in HF, and this may be reflected in distention of the jugular veins. In the early stages of HF, the venous pressure may be normal at rest but may become abnormally elevated during and immediately after exertion as well as with sustained pressure on the abdomen (positive abdominojugular reflux).

Third and fourth heart sounds are often audible but are not specific forHF, and *pulsus alternans*, i.e., a regular rhythm in which there is alternation of strong and weak cardiac contractions and therefore alternation in the strength of the peripheral pulses, may be present. Pulsus alternans, a sign of severe HF, may be detected by sphygmomanometry and in more severe instances by palpation; it frequently follows an extrasystole and is observed most commonly in patients with cardiomyopathy or hypertensive or ischemic heart disease.

Pulmonary Rales Moist, inspiratory, crepitant rales and dullness to percussion over the lung bases are common in patients withHF and elevated pulmonary venous and capillary pressures. In patients with pulmonary edema, rales may be heard widely over both lung fields; they are frequently coarse and sibilant and may be accompanied by

expiratory wheezing. Rales may, however, be caused by many conditions other than left ventricular failure. Some patients with long-standing HF have no rales because of increased lymphatic drainage of alveolar fluid.

Cardiac Edema (See Chap. 37) This is usually symmetric and dependent, occurring in the legs, particularly in the pretibial region and ankles in ambulatory patients, in whom it is most prominent in the evening. Cardiac edema occurs in the sacral region of patients who are bed-ridden. Pitting edema of the arms and face occurs rarely and then only late in the course of HF.

Hydrothorax and Ascites Pleural effusion in congestiveHFresults from the elevation of pleural capillary pressure and transudation of fluid into the pleural cavities. Since the pleural veins drain into *both* the systemic and pulmonary veins, hydrothorax occurs most commonly with marked elevation of pressure in both venous systems but also may be seen with marked elevation of pressure in either venous bed. It is more frequent in the right pleural cavity than in the left. *Ascites* also occurs as a consequence of transudation and results from increased pressure in the hepatic veins and the veins draining the peritoneum (Chap. 46). Marked ascites occurs most frequently in patients with tricuspid valve disease and constrictive pericarditis.

Congestive Hepatomegaly An enlarged, tender, pulsating liver also accompanies systemic venous hypertension and is observed not only in the same conditions in which ascites occurs but also in milder forms ofHF from any cause. With prolonged, severe hepatomegaly, as in patients with tricuspid valve disease or chronic constrictive pericarditis, enlargement of the spleen, i.e., congestive splenomegaly, may also occur.

Jaundice This is a late finding in HFand is associated with elevations of both the direct- and indirect-reacting bilirubin; it results from impairment of hepatic function secondary to hepatic congestion and the hepatocellular hypoxia associated with central lobular atrophy. Hepatic enzymes are frequently elevated. If hepatic congestion occurs acutely, the jaundice may be severe and the enzymes strikingly elevated.

Cardiac Cachexia With severe chronicHF there may be serious weight loss and cachexia because of (1) elevation of circulating concentrations of tumor necrosis factor; (2) elevation of the metabolic rate, which results in part from the extra work performed by the respiratory muscles, the increased oxygen needs of the hypertrophied heart, and/or the discomfort associated with severe HF; (3) anorexia, nausea, and vomiting due to central causes, to digitalis intoxication, or to congestive hepatomegaly and abdominal fullness; (4) impairment of intestinal absorption due to congestion of the intestinal veins; and (5) rarely, due to protein-losing enteropathy in patients with particularly severe failure of the right side of the heart.

Other Manifestations With reduction of blood flow, the extremities may be cold, pale, and diaphoretic. Urine flow is depressed, and the urine contains albumin and has a high specific gravity and a low concentration of sodium. In addition, prerenal azotemia may be present. In patients with long-standing severeHF, impotence and depression are common.

ROENTGENOGRAPHIC AND ECHOCARDIOGRAPHIC FINDINGS

In addition to the enlargement of the particular chambers characteristic of the lesion responsible forHF, distention of pulmonary veins and redistribution to the apices is common in patients with HF and elevated pulmonary vascular pressures. Also, pleural effusions may be evident and associated with interlobar effusions.

DIFFERENTIAL DIAGNOSIS (FIG. 232-CD1)

The diagnosis of congestiveHF may be established by observing some combination of the clinical manifestations of HF described above, together with the findings characteristic of one of the etiologic forms of heart disease.Table 232-1 shows the Framingham criteria, which are useful in the diagnosis of HF. Since chronic HF is often associated with cardiac enlargement, the diagnosis should be questioned, but is by no means excluded, when all chambers are normal in size. Two-dimensional echocardiography (Chap. 227) is particularly useful in assessing the dimensions of each cardiac chamber. HF is sometimes difficult to distinguish from pulmonary disease, and the differential diagnosis is discussed inChap. 32. Pulmonary embolism also presents many of the manifestations of HF, but hemoptysis, pleuritic chest pain, a right ventricular lift, and the characteristic mismatch between ventilation and perfusion on lung scan should point to this diagnosis (Chap. 261).

Ankle edema may be due to varicose veins, cyclic edema, or gravitational effects (Chap. 37), but in these patients there is no jugular venous hypertension at rest or with pressure over the abdomen. Edema secondary to renal disease can usually be recognized by appropriate renal function tests and urinalysis and is rarely associated with elevation of venous pressure. Enlargement of the liver and ascites occur in patients with hepatic cirrhosis and also may be distinguished fromHF by normal jugular venous pressure and absence of a positive abdominojugular reflux.

TREATMENT

(SeePractice Guidelines) The treatment ofHF may be divided into four components: (1) removal of the precipitating cause, (2) correction of the underlying cause, (3) prevention of deterioration of cardiac function, and (4) control of the congestive HF state. The first two components are discussed in other chapters together with each specific disease entity or complication. Examples of removal of precipitating causes are the treatment of pneumococcal pneumonia or the restoration of sinus rhythm in a patient with atrial fibrillation. In many instances, surgical treatment will correct or at least alleviate the underlying cause of HF. The third component of the treatment of HF, i.e., the prevention of deterioration of cardiac function, involves the administration of angiotensin-converting enzyme (ACE) inhibitors andb-adrenergic blockers as well as reduction of cardiac work load. Control of the congestive heart failure state requires reduction of the excessive retention of salt and water as well as enhancement of myocardial contractility. The vigor with which each of these measures is pursued in any individual patient should depend on the severity of HF and the tempo of the disease. Following effective treatment, recurrence of the clinical manifestations of HF can often be prevented by continuing those measures that were originally effective.

While a simple rule for the treatment of all patients withHFcannot be formulated

because of its varied etiologies, hemodynamic features, clinical manifestations, and severity of HF, insofar as the treatment of chronic congestive failure is concerned, the administration of anACEinhibitor retards the development of HF and should be begun early in patients with left ventricular systolic dysfunction (ejection fraction< 0.40), even if they are asymptomatic. Then, as symptoms develop, simple measures such as moderate restriction of activity and sodium intake and oral diuretics should be tried.b-adrenergic receptor blockers and digitalis glycosides are given for patients with systolic HF. If these measures are insufficient, the next step is more rigorous restriction of salt intake and higher doses and multiple diuretics. If HF persists, hospitalization with rigid salt restriction, bed rest, intravenous vasodilators, and positive inotropic agents are tried. Assisted circulation and cardiac transplantation (Chap. 233) are considered for patients with severe, intractable HF and a poor prognosis.

Prevention of Deterioration of Myocardial Infarction Chronic activation of theRAA axis and of the sympathetic nervous systems inHFresult in a maladaptive response and cause further deterioration of cardiac function and/or potentially fatal arrhythmias (Chap. 231). Drugs that block these two systems have been found to be useful in the management of HF (Tables 232-2 and232-3).

Angiotensin-Converting Enzyme Inhibitors In many patients withHF, the left ventricular afterload is increased as a consequence of the several neural and humoral influences that act to constrict the peripheral vascular bed. In addition to the vasoconstriction, the ventricular end-diastolic and -systolic volumes rise in systolic HF. As a consequence of the operation of Laplace's law, which relates myocardial wall tension to the product of intraventricular pressure and radius (both of which may become elevated in HF), the aortic impedance, i.e., the force that opposes left ventricular ejection, or the ventricular afterload, rises, which reduces stroke volume (Fig. 231-10, p. 1316). In many patients with systolic HF, a modest reduction of systemic vascular resistance and afterload elevates the stroke volume and reduces the elevated ventricular filling pressure of the failing ventricle.

The pharmacologic reduction of impedance to left ventricular ejection with anACEinhibitor represents an important component of the management ofHF. This approach may be particularly helpful in (but is by no means limited to) patients with systolic HF due to myocardial infarction (Chap. 243), and in patients with valvular regurgitation (Chap. 236). ACE inhibition should not be used in hypotensive patients. In patients with both acute and chronic systolic HF who are treated with ACE inhibitors, cardiac output rises, the pulmonary wedge pressure falls, the signs and symptoms of HF are relieved, and a new steady state is achieved in which cardiac output is higher and afterload lower with no or only mild reduction of arterial pressure. The administration of ACE inhibitors has been shown to prevent or retard the development of HF in patients with left ventricular dysfunction without HF, to reduce symptoms, enhance exercise performance, and to reduce long-term mortality when they are begun in such patients shortly after acute myocardial infarction. These beneficial effects are related only in part to the salutary hemodynamic effects, i.e., the reduction of preload and afterload. Their major effect appears to be on inhibition of local (tissue) renin-angiotensin systems.

Lisinopril in doses of 20 mg qd or enalapril 10 mg bid have been shown to be useful in

the management of heart failure.

Angiotensin Receptor Blockers In patients who cannot tolerateACEinhibitors (because of cough, angioneurotic edema, leukopenia), an angiotensin II receptor blocker (type AT1) antagonist (e.g., losartan 50 mg qid) may be used instead.

Aldosterone Antagonist The activation of theRAA axis in HFincreases not only circulating and tissue angiotensin II but also aldosterone. The latter, in addition to causing sodium retention and worsening edema (Chaps. 331 and37), causes sympathetic activation, myocardial, vascular, and perivascular fibrosis and reduces arterial compliance. In one large multicenter trial in patients with advanced heart failure and reduced ejection fraction (RALES), spironolactone, 25 mg/d reduced total mortality, as well as sudden death and death from pump failure (Table 232-3). Since spironolactone is also a useful diuretic (see below), its widespread use in systolic heart failure should be considered.

b-Adrenoceptor Blockers While the abrupt administration of large doses ofb-adrenergic receptor blockers can intensifyHF, the administration of gradually escalating doses of metoprolol, carvedilol, and bisoprolol have been reported to improve the symptoms of HF, and to reduce all-cause death, cardiovascular death, sudden death, and pump failure death (Table 232-3). In patients with moderately severe HF (classes II and III), the administration of 12.5 mg metoprolol CR/XL qd, increasing over 4 weeks to a target dose of 200 mg qid, has been shown to be beneficial. b-Adrenoceptor blockers are not indicated in HF patients who are unstable, in New York Heart Association Class IV, in HF patients shortly after acute myocardial infarction, or in those with HF and normal ejection fraction, i.e., with diastolic HF.

Reduction of Cardiac Work Load This consists of reducing physical activity, instituting emotional rest, and reducing afterload (see above). Modest restriction of physical activity in mild cases and rest in bed or in a chair in severe failure are useful. In acute, severe failure, meals should be small in quantity, but more frequent, and every effort should be made to diminish the patient's anxiety; sometimes drugs such as diazepam (2 to 5 mg tid) for several days are useful. Physical and emotional rest tends to lower arterial pressure and reduce the load on the myocardium by diminishing the requirements for cardiac output.

Reduced physical exertion should be continued for several days after the patient's condition has stabilized. The hazards of phlebothrombosis and pulmonary embolism which occur with bed rest may be reduced with anticoagulants, leg exercises, and elastic stockings. *Absolute* bed rest is rarely required or advisable, and the patient should ordinarily be encouraged to sit in a chair. Heavy sedation should be avoided. In ambulatory patients with chronic, moderately severeHF, additional periods of rest on weekends frequently allow continuation of gainful employment. Following recovery from HF, the patient's activities should be assessed, and often, professional, community, and/or family responsibilities should be curtailed. Intermittent rest during the day (e.g., a scheduled 1-h nap or rest following lunch) and the avoidance of strenuous exertion are often helpful. Regular, nonexhausting exercise such as walking or riding a stationary-bicycle ergometer as tolerated should be employed once the patient has become compensated. Weight reduction by restriction of caloric intake in obese patients

with HF also diminishes cardiac work load and is an essential component of the therapeutic program.

Control of Excessive Fluid Many of the clinical manifestations ofHFresult from expansion of the extracellular fluid volume. A negative sodium balance can be achieved by reducing the dietary intake and increasing the urinary excretion of this ion with the aid of diuretics. Rarely, in severe HF, mechanical removal of extracellular fluid by means of thoracentesis and paracentesis may be necessary.

Diet In patients with mild HF, symptomatic improvement may result simply from reducing the sodium intake, particularly if accompanied by periods of physical rest. The normal diet contains approximately 6 to 10 g sodium chloride; this intake can be reduced by half simply by excluding salt-rich foods and salt added at the table. Reduction of the ordinary dietary intake to approximately one-fourth of normal may be achieved if, in addition, all salt is omitted from cooking. In patients with severe HF who have fluid accumulation despite diuretic therapy (see below), the dietary intake of sodium chloride should be reduced to between 500 and 1000 mg, and in order to achieve this, milk, cheese, bread, cereals, canned vegetables and soups, some salted cuts of meat, and some fresh vegetables (including spinach, celery, and beets) must be eliminated. A variety of fresh fruit, green vegetables, specially processed breads and milk, and salt substitutes are permissible. Late in the course of HF, dilutional hyponatremia may develop in patients who are unable to excrete a water load, sometimes because of excessive secretion of antidiuretic hormone. In such cases, water intake as well as sodium intake must be restricted.

Calories should be restricted in obese patients withHF. In patients with severe HF and cardiac cachexia, on the other hand, an attempt must be made to maintain nutritional intake and to avoid caloric and vitamin deficiencies; nutritional supplements may be in order.

Diuretics Diuretics should be given to relieve fluid accumulation and thus reduce or prevent edema and jugular venous distention. A variety of diuretic agents are available (Table 246-6, p. 1422), and almost all are effective in patients with mildHF. However, in the more severe forms of HF, the selection of diuretics is more difficult, and abnormalities in serum electrolytes must be taken into account. Overtreatment must be avoided, since the resultant hypovolemia may reduce cardiac output, interfere with renal function, and produce profound weakness and lethargy.

THIAZIDE DIURETICS These agents are used widely and are useful by themselves in patients with mildHF and in combination with other diuretics in those with severe HF. In patients with chronic mild or moderate HF, the continued administration of a thiazide diuretic abolishes or diminishes the need for rigid dietary sodium restriction, although salty foods and table salt still should be avoided. Thiazide diuretics reduce the reabsorption of sodium and chloride in the first half of the distal convoluted tubule and a portion of the cortical ascending limb of the loop of Henle, and water follows the unreabsorbed salt. Thiazides fail to increase free water clearance and in some instances reduce it. This may result in the excretion of a hypertonic urine and may contribute to dilutional hyponatremia. As a consequence of increased delivery of sodium to the distal nephron, sodium-potassium ion exchange is enhanced, and kaliuresis

results. In contrast to the loop diuretics, which enhance calcium excretion, the thiazides have the opposite effect.

Thiazide diuretics are effective and useful in the treatment ofHF as long as the glomerular filtration rate exceeds approximately 50% of normal. Chlorothiazide is administered in doses of up to 500 mg every 6 h. Many derivatives of this compound are available but differ principally in dosage and duration of action. Chlorthalidone (25 to 50 mg/d) is especially useful since it may be administered once daily.

Potassium depletion and metabolic alkalosis (the latter due to increased H^+secretion as a substitute for the depleted intracellular stores of potassium) are the chief adverse metabolic effects following prolonged administration of the thiazides, of metolazone, and of the loop diuretics. Hypokalemia may seriously enhance the dangers of digitalis intoxication (see below), and induce fatigue and lethargy; these may be prevented by oral supplementation with potassium chloride or preferably by the addition of a potassium-retaining diuretic, such as a spironolactone or triamterene. Other side effects of thiazides include reduction of the excretion of uric acid, which may lead to hyperuricemia, and impaired glucose tolerance, which rarely may precipitate hyperosmolar coma in poorly regulated diabetic patients. Skin rashes, thrombocytopenia, and granulocytopenia have also been reported.

METOLAZONE This quinethazone derivative has a site of action and potency similar to those of the thiazides but has been reported to be effective in the presence of moderate renal failure. The usual dose is 5 to 10 mg/d. Metolazone may be added to thiazide and loop diuretics in severeHF.

FUROSEMIDE, BUMETANIDE, ETHACRYNIC ACID, PIRETANIDE, AND TORSEMIDE These "loop" diuretics are similar physiologically but differ chemically from one another. These drugs reversibly inhibit the reabsorption of sodium, potassium, and chloride in the thick ascending limb of Henle's loop, apparently by blocking a cotransport system in the luminal membrane. They may induce renal cortical vasodilatation and can produce rates of urine formation that may be as high as one-fourth of the glomerular filtration rate. Metabolic alkalosis may be caused by a large increase in the urinary excretion of chloride, hydrogen, and potassium ions. Hypokalemia, hyperuricemia, and hyperglycemia are observed occasionally, as with thiazide diuretics. The reabsorption of free water is decreased. All five of these drugs are readily absorbed orally, are excreted in the bile and urine, and are usually effective both intravenously and by mouth. Weakness, nausea, and dizziness may complicate the administration of all loop diuretics; ethacrynic acid has been associated with transient or even permanent deafness as well as with skin rash and granulocytopenia.

These powerful diuretics are useful in all forms ofHF, particularly in patients with otherwise refractory HF and pulmonary edema. They have been shown to be effective in patients with hypoalbuminemia, hyponatremia, hypochloremia, hypokalemia, and with reductions in the glomerular filtration rate and to produce a diuresis in patients in whom thiazide diuretics and aldosterone antagonists, alone and in combination, are ineffective. In patients with refractory HF, the action of loop diuretics may be potentiated by intravenous administration and by the addition of other diuretics, i.e., thiazides, metozalone, osmotic diuretics, and the potassium-sparing diuretics -- spironolactone,

triamterene, and amiloride.

ALDOSTERONE ANTAGONISTS These agents act on the cortical collecting ducts, are relatively weak, and therefore are rarely indicated as sole agents. However, their potassium-sparing properties make them particularly useful in conjunction with the more potent kaliuretic agents, i.e., the loop diuretics, thiazides, and metozalone. The potassium-sparing agents fall into two classes.

The spironolactones resemble aldosterone structurally and act by competitive inhibition of aldosterone, thereby blocking the exchange between sodium and both potassium and hydrogen in the distal tubules and collecting ducts. These agents produce a sodium diuresis, and in contrast to the thiazides, ethacrynic acid, and furosemide, they result in potassium retention. Although secondary hyperaldosteronism exists in some patients with congestiveHF, the spironolactones are effective even in patients in whom the serum aldosterone concentration is within normal limits.

Spironolactone may be administered in doses of 25 mg daily to 50 mg three to four times daily by mouth. The maximal effect of this regimen is not observed for approximately 4 days. Spironolactones are most effective when administered in combination with loop and/or thiazide diuretics. The opposing action of these drugs on urine and serum potassium makes possible a sodium diuresis without either hyper- or hypokalemia when spironolactone and one of these other agents are administered in combination. Also, since spironolactone, triamterene, and amiloride act on the distal tubule, they are particularly effective when used in combination with one of these other diuretics that act more proximally. Spironolactone, triamterene, and amiloride should not be administered alone to patients with hyperkalemia, renal failure, or hyponatremia. Reported complications of Aldactone A include nausea, epigastric distress, mental confusion, drowsiness, gynecomastia, and erythematous eruptions.

As mentioned above, a lower dose of spironolactone (25 mg/d), which exerts little if any diuretic effect, has been shown to prolong life in patients with advancedHF(Table 232-3).

Triamterene and *amiloride* exert renal effects similar to those of the spironolactones; i.e., they block sodium reabsorption and secondarily inhibit potassium secretion in the distal tubules. However, their action does not depend on the presence of aldosterone. The effective dose of triamterene is 100 mg once or twice daily, and that of amiloride is 5 mg daily. Side effects include nausea, vomiting, diarrhea, headache, granulocytopenia, eosinophilia, and skin rash. Both triamterene and the chemically unrelated diuretic amiloride resemble Aldactone A in that their diuretic potency is not great, but they are effective in preventing the hypokalemia characteristic of loop diuretics and thiazides. A number of diuretic preparations contain a combination of a thiazide and either triamterene or amiloride in a single capsule. They may be useful in patients who develop hypokalemia with a thiazide but should not be used in patients with impaired renal function and/or hyperkalemia.

When *choosing a diuretic*, orally administered loop diuretics or thiazides are the agents of choice in the treatment of chronic cardiac edema of mild to moderate degree in patients without hyperglycemia, hyperuricemia, or hypokalemia. Spironolactones,

triamterene, and amiloride are not potent diuretics when used alone, but they potentiate the thiazide and loop diuretics. Loop diuretics, given alone or with spironolactone or triamterene, are the agents of choice in patients with severe HF refractory to other diuretics. In very severe HF, the combination of a loop diuretic, a thiazide, and a potassium-sparing diuretic is required.

Vasodilators Direct vasodilators may be useful in patients with severe, acuteHF who demonstrate systemic vasoconstriction despiteACEinhibitor therapy. The ideal vasodilator for the treatment of *acute* HF should have a rapid onset and brief duration of action when administered by intravenous infusion; sodium nitroprusside (0.1 to 3.0 ug/kg per minute) qualifies as such a drug, but its use requires careful monitoring of the arterial pressure and, if possible, of the pulmonary artery wedge pressure. The combination of hydralazine (up to 300 mg qd orally) and isosorbide diuretics (up to 160 mg qd orally) may be useful for chronic oral administration.

Enhancement of Myocardial Contractility

Digitalis The improvement of myocardial contractility by means of cardiac glycosides is useful in the control ofHF. *Digoxin*, which has a half-life of 1.6 days, is filtered in the glomeruli and secreted by the renal tubules. Significant reductions of the glomerular filtration rate reduce the elimination of digoxin and, therefore, may prolong digoxin's effect, allowing it to accumulate to toxic levels. In patients with normal renal function, a plateau concentration in the blood and tissue is reached after 5 days of daily maintenance treatment without a loading dose (seeFig. 70-2).

MECHANISM OF ACTION The most important effect of digitalis on cardiac muscle is to shift its force-velocity relation upward (Fig. 231-5, p. 1313). Cardiac glycosides inhibit the monovalent cation transport enzyme-coupled Na^+,K^+-ATPase and increase intracellular sodium content; this, in turn, increases intracellular Ca^{2+}through a Na^+-Ca^{2+}exchange carrier mechanism. The increased myocardial uptake of Ca^{2+}augments Ca^{2+}released to the myofilaments during excitation and, therefore, invokes a positive inotropic response.

Cardiac glycosides also produce alterations in the electrical properties of both the contractile cells and the specialized automatic cells, leading to increased automaticity and ectopic impulse activity. They also prolong the effective *refractory period* of the atrioventricular node and thereby slow ventricular rate in atrial flutter and fibrillation.

USE IN HEART FAILURE Digitalis is particularly effective in patients with systolicHFcomplicated by atrial flutter and fibrillation and a rapid ventricular rate, who benefit from both slowing of the ventricular rate and the positive inotropic effect. Although digitalis does not improve survival in patients with systolic HF and sinus rhythm, it reduces the need for hospitalization. By stimulating myocardial contractility moderately, digitalis improves ventricular emptying; i.e., it increases cardiac output, augments the ejection fraction, promotes diuresis, and reduces the elevated diastolic pressure and volume and the end-systolic volume of the failing ventricle. This action reduces symptoms resulting from pulmonary vascular congestion and elevated systemic venous pressure. Digitalis is of little or no value in patients with HF, sinus rhythm, and the following conditions: hypertrophic cardiomyopathy, myocarditis, mitral stenosis,

chronic constrictive pericarditis, and any form of diastolic HF.

The maintenance dose of digoxin is 0.25 mg qd for most adults; in the elderly and others with mild impairment of renal function, it is 0.125 mg qd. Loading doses, four times the maintenance dose, may be administered in acute systolic failure.

DIGITALIS INTOXICATION This is a serious and potentially fatal complication. Advanced age, acute myocardial infarction or ischemia, hypoxemia, magnesium depletion, renal insufficiency, hypercalcemia, electrical cardioversion, and hypothyroidism all may reduce tolerance to digitalis. The most common precipitating cause of digitalis intoxication, however, is depletion of potassium stores, which often occurs in patients withHF as a result of diuretic therapy and secondary hyperaldosteronism.

Anorexia, nausea, and vomiting are among the earliest signs of digitalis intoxication. The most frequent disturbances of cardiac rhythm are ventricular premature beats, bigeminy, ventricular tachycardia, and, rarely, ventricular fibrillation. Atrioventricular block of varying degrees of severity may occur. Nonparoxysmal atrial tachycardia with variable atrioventricular block is characteristic of digitalis intoxication. Chronic digitalis intoxication may be insidious in onset and characterized by exacerbations ofHF, weight loss, cachexia, neuralgias, gynecomastia, yellow vision, and delirium.

The administration of quinidine, verapamil, amiodarone, and propafenone to patients receiving digoxin raises the serum concentration of the latter by reducing both the renal and nonrenal elimination of digoxin and by reducing its volume of distribution. These drugs increase the propensity to digitalis intoxication, and the dose of digitalis should be reduced by half in patients receiving these drugs.

TREATMENT OF DIGITALIS INTOXICATION When tachyarrhythmias result from digitalis intoxication, withdrawal of the drug and treatment withb-adrenoceptor blocker or lidocaine are indicated. If hypokalemia is present, potassium should be administered cautiously and by the oral route. Fab fragments of purified, intact digitalis antibodies are a potentially lifesaving approach to the treatment of severe intoxication.

Sympathomimetic Amines (See also Chap. 72) Two sympathomimetic amines that act largely on b-adrenergic receptors -- dopamine and dobutamine -- improve myocardial contractility (Table 72-1) and are effective in the management ofHF; they must be administered by constant intravenous infusion for up to 1 week and are useful in patients with intractable, severe HF, particularly those with a reversible component, such as exists in patients who have undergone cardiac surgery, in patients with acute myocardial infarction and shock or pulmonary edema, and in patients with refractory HF as a "bridge" to transplantation. While these sympathomimetic amines improve the hemodynamics and symptoms in these conditions, it is not clear that they improve survival. Their administration should be accompanied by careful and continuous monitoring of the electrocardiogram, arterial pressure, and, if possible, pulmonary artery wedge pressure.

Dopamine is a naturally occurring immediate precursor of norepinephrine and has a combination of actions that makes it particularly useful in the treatment of a variety of

hypotensive states ofHF. At very low doses, i.e., 1 to 2 (ug/kg)/min, it dilates renal and mesenteric blood vessels through stimulation of specific dopaminergic receptors, thereby augmenting renal and mesenteric blood flow and sodium excretion. In the range of 2 to 10 (ug/kg)/min, dopamine stimulates myocardial$b_1$receptors but induces relatively little tachycardia, while at higher doses it also stimulates a-adrenergic receptors and elevates arterial pressure.

Dobutamine is a synthetic catecholamine that acts onb_1,b_2, anda receptors. It exerts a potent inotropic action, has only a modest cardioaccelerating effect, and lowers peripheral vascular resistance, but since it simultaneously raises cardiac output, it may not lower systemic arterial pressure in patients with severeHF. Dobutamine, given in continuous infusions of 2.5 to 10 (ug/kg)/min, is useful in the treatment of acute HF without hypotension.

A major problem with sympathomimetics is the loss of responsiveness, apparently due to "downregulation" of adrenergic receptors, which becomes evident within 8 h of continuous administration. This problem may be managed by intermittent therapy.

Phosphodiesterase Inhibitors These bipyridines, amrinone and milrinone, are noncatecholamine, nonglycoside agents that exert both positive inotropic and vasodilator actions by inhibiting a specific phosphodiesterase. They are suitable for intravenous use only; by simultaneously stimulating cardiac contractility and dilating the systemic vascular bed they reverse the major hemodynamic abnormalities associated with intractableHF. Amrinone and milrinone may be administered for the same conditions in which sympathomimetics are useful and may be employed together with dopamine or dobutamine.

Other Measures

Anticoagulants Patients with severeHF are at increased risk of pulmonary emboli secondary to venous thrombosis and of systemic emboli secondary to intracardiac thrombi and should be treated with warfarin. Patients with HF and atrial fibrillation, previous venous thrombosis, and pulmonary or systemic emboli are at especially high risk and should receive heparin followed by warfarin.

Diastolic Heart Failure The major goal in the treatment of this condition is to eliminate or reduce the causes of diastolic dysfunction, such as ventricular hypertrophy, fibrosis, or ischemia. The second is to reduce pulmonary and/or systemic venous congestion, a major consequence of diastolic dysfunction.

Management of Arrhythmias (See also Chap. 230) Premature ventricular contractions and episodes of asymptomatic ventricular tachycardia are common in advancedHF. Sudden death, presumably due to ventricular fibrillation, is responsible for about one-half of all deaths in this condition. (The remainder are due to failure of the cardiac pump.) The management of arrhythmias should commence with correction of electrolyte and acid-base disturbances (Chaps. 49 and50), especially diuretic-induced hypokalemia, as well as digitalis intoxication (see above). Treatment with class I antiarrhythmics such as quinidine, procainamide, or flecainide (Chap. 230) is fraught with danger because these drugs are proarrhythmic in patients with HF. Amiodarone, a

class III antiarrhythmic, on the other hand, is well tolerated and is the drug of choice for patients with heart failure and atrial fibrillation. Patients who have been resuscitated from sudden death, those with syncope or presyncope due to ventricular arrhythmias, and those with asymptomatic ventricular tachyarrhythmias in whom ventricular tachycardia can be induced during electrophysiologic testing should be considered for the implantable automatic defibrillator. This may prevent recurrence of the arrhythmia and sudden death; back-up pacing may prevent sudden death due to bradyarrhythmias.

Refractory Heart Failure When the response to ordinary treatment is inadequate,HF is considered to be refractory. Before assuming that this condition simply reflects advanced, terminal, myocardial depression, careful consideration must be given to several possibilities: (1) an underlying and overlooked cause of the heart disease that may be amenable to specific surgical or medical therapy, such as infective endocarditis, hypertension, thyrotoxicosis, or silent aortic or mitral stenosis; (2) one or a combination of the precipitating causes of HF, such as pulmonary or urinary tract infection, recurrent pulmonary emboli, arterial hypoxemia, anemia, or arrhythmia; and (3) complications of overly vigorous therapy, such as digitalis intoxication, hypovolemia, or electrolyte imbalance. Recognition and proper treatment of the aforementioned complications are likely to restore responsiveness to therapy.

Hyponatremia is a manifestation of advanced refractoryHF. It may be a complication of overaggressive diuresis leading to reduced glomerular filtration rate and decreased delivery of NaCl to the diluting sites in the distal tubule. Hyponatremia may also result from nonosmotic stimuli for the continued secretion of antidiuretic hormone. Therapy involves improvement of the cardiovascular status, if possible (sometimes requiring the administration of a sympathomimetic amine), as well as temporary cessation of diuretic therapy and restriction of oral water intake. Hypertonic saline is very rarely indicated because total-body sodium is usually elevated, not depressed, in HF.

The combination of the intravenously administered vasodilator sodium nitroprusside, a phosphodiesterase inhibitor (amrinone or milrinone), together with a sympathomimetic amine (dopamine or dobutamine) often results in additive effects, raising cardiac output and lowering filling pressure.

In hospitalized patients with refractoryHF, therapy guided by hemodynamic measurements provided by a balloon flotation (Swan-Ganz) catheter may be helpful. The goal of manipulating diuretics, vasodilators, and inotropic agents is to achieve a pulmonary capillary wedge pressure of 15 to 18 mmHg, a right atrial pressure of 5 to 8 mmHg, a cardiac index > 2.2 (L/min)/m^2, and a systemic vascular resistance of 800 to 1200 dyne×s/cm^5. Once these values are achieved, an attempt should be made to convert the patient from intravenous to oral vasodilator therapy.

Assisted Circulation/Cardiac Transplantation When patients withHFbecome unresponsive to a combination of all the aforementioned therapeutic measures, are in New York Heart Association class IV, and are deemed unlikely to survive 1 year, they should be considered for temporary assisted circulation and/or cardiac transplantation (seeChap. 233).

Treatment of Acute Pulmonary Edema Pulmonary edema secondary to left ventricular

failure or mitral stenosis is described in Chap. 32. It is life-threatening and must be considered a medical emergency. As is the case for the more chronic forms of HF, in the treatment of pulmonary edema, attention must be directed to identifying and removing any precipitating causes of decompensation, such as an arrhythmia or infection. However, because of the acute nature of the problem, a number of additional nonspecific measures are necessary. If it does not delay treatment unduly, recording pulmonary vascular pressures through a Swan-Ganz catheter and intraarterial pressure directly is advisable. The first six measures listed below are ordinarily applied simultaneously or nearly so.

1. Morphine is administered intravenously repetitively, as needed, in doses from 2 to 5 mg. This drug reduces anxiety, reduces adrenergic vasoconstrictor stimuli to the arteriolar and venous beds, and thereby helps to break a vicious cycle. Naloxone should be available in case respiratory depression occurs.

2. Because the alveolar edema interferes with O_2 diffusion resulting in arterial hypoxemia, 100% O_2 should be administered, preferably under positive pressure. The latter increases intraalveolar pressure, reduces transudation of fluid from the alveolar capillaries, and impedes venous return to the thorax, reducing pulmonary capillary pressure.

3. The patient should be maintained in the sitting position, with the legs dangling along the side of the bed, if possible, which tends to reduce venous return.

4. Intravenous loop diuretics, such as furosemide or ethacrynic acid (40 to 100 mg) or bumetanide (1 mg), will, by rapidly establishing a diuresis, reduce circulating blood volume and thereby hasten the relief of pulmonary edema. In addition, when given intravenously, furosemide also exerts a venodilator action, reduces venous return, and thereby improves pulmonary edema even before the diuresis commences.

5. Afterload reduction is achieved with intravenous sodium nitroprusside at 20 to 30 ug/min in patients whose systolic arterial pressures exceed 100 mmHg.

6. Inotropic support should be provided by dopamine or dobutamine as described on p. 1327. Patients with systolic HF who are not receiving digitalis should receive 0.75 to 1.0 mg digoxin intravenously over 15 min.

7. Sometimes, aminophylline (theophylline ethylenediamine), 240 to 480 mg intravenously, is effective in diminishing bronchoconstriction, increasing renal blood flow and sodium excretion, and augmenting myocardial contractility.

8. If the above-mentioned measures are not sufficient, rotating tourniquets should be applied to the extremities.

After these emergency measures have been instituted and the precipitating factors treated, the diagnosis of the underlying cardiac disorder responsible for the pulmonary edema must be established, if it is not already known. After stabilization of the patient's condition, a long-range strategy for prevention of future episodes of pulmonary edema must be established, and this may require surgical treatment.

PROGNOSIS

The prognosis in patients withHFdepends primarily on the nature of the underlying heart disease and on the presence or absence of a precipitating factor that can be treated. When one of the latter can be identified and removed, the outlook for immediate survival is far better than if HF occurs without any obvious precipitating cause. In the latter situation, survival usually ranges between 6 months and 4 years depending on the severity (Fig. 232-2). The long-term prognosis is more favorable when the underlying forms of heart disease, e.g., valvular heart disease, can be treated effectively. The prognosis can be estimated by observing the response to treatment. When clinical improvement occurs with only modest dietary sodium restriction and small doses of diuretics, the outlook is far better than if, in addition to these measures, intensive diuretic therapy and vasodilators are necessary. Other factors that have been shown to be associated with a poor prognosis include a severely depressed ejection fraction (<25%), a reduced maximal O_2uptake [<10 (mL/kg)/min], the inability to walk on the level and at a normal pace for more than 3 min, reduced (<133 mEq/L) serum sodium concentration, reduced (<3 mEq/L) serum potassium concentration, elevated circulating atrial and brain natriuretic peptide and norepinephrine concentrations, as well as frequent ventricular extrasystoles. A large fraction of patients with HF die suddenly, presumably of ventricular fibrillation. Unfortunately, there is no evidence that this complication can be prevented by the administration of antiarrhythmic agents. SeeGuideline.

233. CARDIAC TRANSPLANTATION - *John S. Schroeder*

Orthotopic allograft cadaver cardiac transplantation as a treatment for end-stage cardiac disease achieved its thirty-third anniversary on December 7, 2000. On that day in 1967 Dr. Christiaan Barnard accomplished the first successful cardiac transplant in a human, quickly followed by Dr. Norman Shumway and Dr. Richard Lower at Stanford University. After an initial early wave of enthusiasm, the problems of immunosuppression slowed application of the procedure until the introduction of cyclosporine in 1980. A subsequent worldwide expansion of cardiac transplantation has resulted in approximately 2500 cardiac transplants per year, with further increases limited only by the donor supply. Current 1- and 5-year survival rates of 85 and 70% (Fig. 233-CD1) indicate that cardiac transplantation is the therapy of choice in patients with end-stage heart disease who are unlikely to survive the next 6 to 12 months.

INDICATIONS AND SELECTION OF CANDIDATES

The limited donor supply and relatively high cost of cardiac transplantation have restricted it to patients most likely to survive and resume a functional life after transplantation. It is estimated that only 2000 potential donors in the United States, for a pool of at least 20,000 candidates based on current guidelines, become available yearly. Attempts to increase donor awareness in both physicians and the public are being made. Optimal candidates for this procedure are those who would be expected to return to a functional life if their hearts were replaced (Table 233-1). This requires a mentally vigorous, medically compliant person who has not suffered extensive other end-stage organ damage from cardiac failure, does not have other systemic disease such as severe diabetes mellitus or collagen vascular disease, or is not positive for HIV. Long-standing pulmonary hypertension or recurrent pulmonary emboli and infarction may result in irreversible pulmonary hypertension leading to intraoperative death. Several heart transplant centers have initiated cardiac transplantation for newborns with left ventricular hypoplasia, but long-term survival experience is still very limited.

Timing of the recommendation to undergo cardiac transplantation can be difficult and requires assessment of the patient's current disability, stability of course, and likelihood of surviving the next 6 to 12 months. Generally, left ventricular ejection fractions under 15 to 20% and presence of serious ventricular arrhythmias indicate a 1-year survival rate of 50% or less. Estimating prognosis remains very challenging. A maximal oxygen uptake during exercise (maximal$_{O2}$) of<10 mL O_2 per kilogram per minute usually indicates poor likelihood of survival for 1 year and has been a criterion for transplant candidacy in some programs. Maximal$_{O2}$values between 10 and 14 mL O_2 per kilogram per minute are in a borderline range, with values>14 usually predicting good 1- to 2-year survival. The increasing acceptance of cardiac transplantation as a treatment modality for heart failure without a corresponding increase in donor availability has led to prolonged waiting times of as much as 2 years or more. This longer waiting time has led to more rigorous medical care of the patient awaiting transplant with meticulous monitoring of electrolytes, fluid status, and overall well-being. Aggressive therapy for congestive heart failure with high-dose angiotensin-converting enzyme inhibitors and beta blockers and meticulous monitoring of serum electrolytes and renal function have led to stabilization and many times some improvement in the functional status of patients awaiting a donor. This has led to as many as 30 to 40% of listed patients being

placed "on hold" based on their improved status. Whether these patients can maintain their improved state or will subsequently deteriorate remains to be seen. Recurrent hospitalizations may be required. Patients may become dopamine/dobutamine-dependent to maintain adequate cardiac output. This dependency on an inotropic agent plus the need for a balloon flotation catheter for hemodynamic monitoring moves the patient to the highest priority (1a) for a donor heart.

In addition to these pharmacologic bridges to transplantation, mechanical bridges are occasionally used where pharmacologic therapy is no longer effective. Three approaches are currently used. The first is intraaortic balloon pumping, which can increase cardiac output by 15 to 20%. The second is a left ventricular assist device (LVAD) (Fig. 233-CD2), which empties blood via a tube placed in the apex of the left ventricle and pumps it with an electrically driven "bellows-type" mechanism into the abdominal aorta. This approach is highly effective and has been used for several months with successful subsequent transplantation. Limitations include right ventricular failure and/or high pulmonary vascular resistance, since the LVAD does not "unload" the right ventricle. Blood clotting in the device remains a problem, in addition to the obvious problems of infection. Finally, total mechanical heart replacement is also applied in some transplant centers. This complete replacement circumvents the problem of right ventricular failure but is limited by the greater complexity of the device, which can lead to clotting and systemic emboli. Patients who underwent mechanical assistance *and* received a donor heart have 1-year survival statistics similar to those who went directly to transplantation.

Tissue cross-matching between donor and recipient has generally not been done because of difficulty in obtaining good matches and lack of correlation between match and outcome. Size, ABO matching, negative lymphocyte cross-match, and avoidance of a transplantation from a cytomegalovirus (CMV)-positive donor to a CMV-negative recipient are more important.

OPERATIVE PROCEDURE

The surgeon removes the diseased heart but leaves the posterior wall of the right atrium in place and the superior and inferior venae cavae intact. The posterior wall of the left atrium is also left in situ with pulmonary veins intact. The donor heart is then removed in toto with the posterior wall of the right and left atria incised, which allows suturing of left atrial donor rim to recipient rim and right atrial donor rim to recipient rim, with anastomosis of the aorta and pulmonary artery.

IMMUNOSUPPRESSION AND REJECTION

Controlling rejection while avoiding the adverse side effects of immunosuppressive agents is pivotal to successful transplantation. Rejection is characterized by perivascular infiltration of killer T lymphocytes, which migrate into the myocardium and cause cellular necrosis if not checked. Since early rejection can be silent, it is important to detect it before necrosis occurs. Immunologic monitoring of activated T lymphocytes in peripheral blood offers clues to the timing of a rejection process but has not been sufficiently reliable to dictate antirejection therapy. Therefore, repeated percutaneous transvenous right ventricular endomyocardial biopsies via the right internal jugular vein

are required for histologic determination of the state of immunosuppression and rejection.

One widely used scheme for grading the stages of rejection is as follows: cannot rule out rejection, mild early rejection, moderate rejection, and severe rejection. Serial biopsies are taken every 1 to 2 weeks early after transplantation, with gradually widening intervals depending on the patient's course and rejection history. Prolongation of isovolumic relaxation time measured by echocardiography may also provide early clues to rejection.

Immunosuppressive therapy regimens vary but usually include triple therapy with cyclosporine, azathioprine, and prednisone. The immunosuppressive agent tacrolimus, as either "rescue therapy" for graft rejection unresponsive to cyclosporine or as initial immunosuppressive therapy, is increasingly popular. Another immunosuppressive agent, mycophenolate mofetil, has been introduced initially as a substitute for azathioprine, and in one trial appeared to be superior in reducing transplant coronary atherosclerosis and mortality. Prophylactic courses of monoclonal antibody OKT3 or antithymocyte globulin may also be given early after transplantation. Careful monitoring of the adverse side effects of these agents is extremely important because they include nephrotoxicity, bone marrow suppression, and opportunistic infections. For discussion of immunosuppressive drugs, see Chap. 272.

EARLY COURSE AND COMPLICATIONS

It is rare for a cardiac transplant patient to have a completely uncomplicated postoperative course. In the immediate postoperative period, right-sided heart failure due to pulmonary vascular disease is most life-threatening. During the 2 to 3 weeks after transplantation, the patient is hospitalized with meticulous monitoring for evidence of rejection and infections, repeated percutaneous transvenous endomyocardial biopsies, and adjustment of immunosuppressive drugs. During the ensuing 4 to 6 weeks, infectious complications, including bacterial, viral, and protozoan infections, are common. A successful transplant program requires a highly aggressive and sophisticated approach to diagnosis and therapy of infections in the immunocompromised host.CMVinfection involving multiple organs is common and accelerates graft rejection as well. Prophylaxis with ganciclovir can dramatically reduce severe CMV infections and graft rejection, leading to less morbidity and improved survival. Depending on the degree of cardiac cachexia preoperatively, the patient is usually functional at 1 week and discharged from the hospital at 2 to 3 weeks if no major complication occurs.

The average first-year cost ranges from $100,000 to $150,000, depending on the need for repeated hospitalization and cardiac biopsies, and is occasionally much higher. Yearly costs for immunosuppressive agents range from $10,000 to $30,000, in addition to the expense of medical surveillance for rejection or complications.

PHYSIOLOGY AND FUNCTION

Since the allografted heart remains denervated, cardiac function differs from that of the innervated heart during both rest and exercise. The electrocardiogram of a recipient

shows two P waves; the P wave of the recipient's heart reflects the residual sinus node and posterior walls of the remaining native atria but is dissociated from the QRS, since the depolarization impulse does not cross the suture line. Although it does not control donor heart rate, the recipient's sinus node remains innervated and under the influence of the autonomic nervous system. The donor sinus node controls the rate of the transplanted heart. The donor heart's P wave has a regular PR interval, reflecting conduction to the ventricles. Since the controlling sinus node is denervated, it maintains a heart rate of 100 to 110 beats per minute, and rate increase depends on alterations in chronotropic agents perfusing the sinus node. Partial reinnervation may occur in some patients late after transplantation. This is manifested primarily by the occurrence of angina-like symptoms in patients who have developed accelerated graft atherosclerosis (see below).

Ventricular function in response to isometric and isotonic exercise has been studied extensively. The early response to exercise is more dependent on the Frank-Starling mechanism and change in ventricular volume and filling pressure. As exercise proceeds and catecholamines are released with their positive inotropic and chronotropic effects, cardiac output begins to rise. The cardiac transplant recipient can achieve approximately 70% of the maximal cardiac output expected for his or her age, easily sufficient for the stresses of everyday life.

LATE COURSE AND COMPLICATIONS

Although the rejection process partially subsides, lifelong administration of immunosuppressive drugs, albeit at lower doses, is still required and remains a hazard. Infectious complications and unsuspected rejection continue to occur, requiring ongoing surveillance and monitoring. Routine cardiac biopsies are performed at 3-month intervals to monitor for unsuspected early rejection. Acute rejection or infection predominates in the first year after transplantation. Chronic rejection (i.e., accelerated coronary vascular disease) becomes the most important cause of death after the first year. The process is a fibrointimal hyperplasia that can go undetected by coronary arteriography at first and then cause diffuse atherosclerotic changes. Risk factors for its development may include repeated rejection episodes and elevated lipid levels.CMVinfections have also been associated with higher frequency of this disease. Immunocytochemistry on endomyocardial biopsies in cardiac transplant recipients has shown a high incidence of arterial endothelial cell activation, as reflected by the presence of intercellular adhesion molecule 1 and histocompatibility antigen HLA-DR during the first 3 months after transplantation. The presence of these markers has been associated with a high risk of the subsequent development of graft coronary artery atherosclerosis, with death or the need for a second transplant. Thus, activation of the arterial/arteriolar endothelium predicts development of coronary artery disease in and the subsequent failure of the transplanted heart.

Angina is rare, and patients may present with sudden death or silent myocardial infarction. This diffuse accelerated vascular process affects both proximal and distal coronary vessels so that standard approaches, such as angioplasty or coronary artery bypass grafting, are not generally useful but occasionally are successful.

Uncontrolled trials with anticoagulation, aspirin, and improved immunosuppression with

cyclosporine have done little to lower this frequency; 40 to 50% of patients show arteriographic evidence of coronary vascular disease 5 years after transplantation. Retransplantation has been employed for some patients with severe graft atherosclerosis, but it is limited by the scarcity of donors and poorer survival expectations after the second transplant. Diltiazem has been reported to reduce the severity and occurrence of this accelerated vascular process when started at the time of transplantation. Calcium channel blockers are the agents of choice for cyclosporine-induced hypertension, a common complication in the posttransplant patient. Pravastatin and simvastatin have been reported not only to lower lipid levels but also to reduce graft vessel coronary artery disease and improve survival. Administration of one of these drugs is advisable for all heart transplant recipients. A comparative trial of azathioprine versus mycophenolate mofetil reported less graft disease and cardiovascular mortality in the latter group.

In addition to the well-known hazards of long-term glucocorticoid usage, the immunosuppressed patient is at increased risk for neoplasia. An unusual form of lymphoma can occur frequently in extranodal locations, which is linked to prior Epstein-Barr viral infection. This lymphoma can be polyclonal or monoclonal, is associated with excessive immunosuppression, and may respond to simply lowering doses of cyclosporine and administration of acyclovir rather than requiring more aggressive chemo- or radiotherapy. Many cases regress fully and do not recur.

HEART-LUNG TRANSPLANTATION

Patients with congenital heart disease with Eisenmenger's complex (Chap. 234) or primary pulmonary hypertension (Chap. 260) are now considered for heart-lung transplantation. The surgical technique is similar to that for heart transplantation, except that the pulmonary venous attachments to the left atrium are left intact, and a tracheal anastomosis is required. The postoperative period is more complex, since the lungs may be rejected separately from the heart, requiring repeated endobronchoscopic biopsies when rejection is suspected. The immunosuppressive regimen is similar to that for heart transplants, except that glucocorticoids are avoided in the first 1 to 2 weeks to allow healing of the tracheal anastamosis. Long-term survival has in the past been limited by obliterative bronchiolitis due to chronic unrecognized rejection; survival rates have been approximately 60% at 1 year and 50% at 2 years but appear to be improving. Heart-lung transplants have also been applied to primary pulmonary hypertension, but more recent experience with single-lung transplants for these patients has been satisfactory, thus utilizing scarce donors more effectively. Single-lung transplants are also being applied increasingly for patients with advanced emphysema. Double-lung transplants for patients with cystic fibrosis have also become the operation of choice for this group.**For further discussion, see Chap. 267.*

234. CONGENITAL HEART DISEASE IN THE ADULT - *William F. Friedman, John S. Child*

Congenital heart disease complicates approximately 1% of all live births. It occurs in about 4% of offspring of women with congenital heart disease. Substantial numbers of affected infants reach adulthood because of successful medical and/or surgical management, or because the alteration caused in cardiovascular physiology is well tolerated.

ETIOLOGY AND PREVENTION

Congenital cardiovascular malformations are generally the result of aberrant embryonic development of a normal structure, or failure of such a structure to progress beyond an early stage of embryonic or fetal development. Malformations are due to complex multifactorial genetic and environmental causes. Recognized chromosomal aberrations and mutations of single genes account for<10% of all cardiac malformations (Table 234-1).

The presence of a cardiac malformation as one component of the multiple system involvement in Down's, Turner's, and the trisomy 13-15(D1) and 17-18 (E) syndromes may be anticipated in occasional pregnancies by detection of abnormal chromosomes in fetal cells obtained from amniotic fluid or chorionic villus biopsy. Identification in such cells of the enzyme disorders characteristic of Hurler's syndrome, homocystinuria, or type II glycogen storage disease may also allow one to predict cardiac disease.

PATHOPHYSIOLOGY

The anatomic and physiologic changes in the heart and circulation due to any specific congenital cardiocirculatory lesion are not static but rather progress from prenatal life to adulthood. Thus, malformations that are benign or escape detection in childhood may become clinically significant in the adult. For example, the functionally normal, congenitally bicuspid aortic valve may thicken and calcify with time, resulting in significant aortic stenosis; or the well-tolerated left-to-right shunt of an atrial septal defect may not result in cardiac decompensation, with or without pulmonary hypertension, until the fourth or fifth decade.

Pulmonary Hypertension This is a common companion of many congenital cardiac lesions, and the status of the pulmonary vascular bed is often the principal determinant of the clinical manifestations, the course, and the feasibility of surgical repair. Increases in pulmonary arterial pressure result from elevation of pulmonary blood flow and/or resistance, the latter due sometimes to an increase in vascular tone but usually the result of obstructive, obliterative structural changes within the pulmonary vascular bed. Because pulmonary vascular obstructive disease can be the determining factor in assessing the advisability of operation, it is important to quantitate and compare pulmonary to systemic flows and resistances in patients with severe pulmonary hypertension. The causes of pulmonary vascular obstructive disease are unknown, although increased pulmonary blood flow, increased pulmonary arterial blood pressure, elevated pulmonary venous pressure, erythrocytosis, systemic hypoxemia, acidosis, and the bronchial circulation have been implicated. The designation *Eisenmenger*

syndrome is applied to patients with a large communication between the two circulations at the aortopulmonary, ventricular, or atrial levels and bidirectional or predominantly right-to-left shunts because of high-resistance and obstructive pulmonary hypertension. No specific treatment has proved beneficial for obstructive pulmonary vascular disease, although both single lung transplantation with intracardiac defect repair, and total heart-lung transplantation show promise (Chaps. 233 and267).

Erythrocytosis The chronic hypoxemia in cyanotic congenital heart disease results in *erythrocytosis* due to increased erythropoietin production (Chap. 36). The commonly used term *polycythemia* is a misnomer because white cell counts are normal and platelet counts are normal to decreased. Cyanotic patients with erythrocytosis may have compensated or decompensated hematocrits. Compensated erythrocytosis with iron-replete equilibrium hematocrits rarely results in symptoms of hyperviscosity at hematocrits <65% and occasionally not even with hematocrits ³70%. Therapeutic phlebotomy is rarely required in compensated erythrocytosis. In contrast, patients with decompensated erythrocytosis fail to establish equilibrium with unstable, rising hematocrits and recurrent hyperviscosity symptoms. Therapeutic phlebotomy, a two-edged sword, allows temporary relief of symptoms but begets instability of the hematocrit and compounds the problem by iron depletion. Iron-deficiency symptoms are usually indistinguishable from those of hyperviscosity; progressive symptoms after recurrent phlebotomy are usually due to iron depletion with hypochromic microcytosis. Iron depletion results in a larger number of smaller (microcytic) hypochromic red cells that are less capable of carrying oxygen and less deformable in the microcirculation. Because these microcytes are less deformable in the microcirculation and there are more of them relative to the plasma volume, the viscosity is greater than for an equivalent hematocrit with fewer, larger, iron-replete, deformable cells. As such, iron-depleted erythrocytosis results in increasing symptoms due to decreased oxygen delivery to the tissues.

Hemostasis is abnormal in cyanotic congenital heart disease, due in part to the increased blood volume and engorged capillaries, abnormalities in platelet function and sensitivity to aspirin or nonsteroidal anti-inflammatory agents, and abnormalities of the extrinsic and intrinsic coagulation system. Oral contraceptives are contraindicated for cyanotic women because of the enhanced risk of vascular thrombosis.

The risk of stroke is greatest in children younger than 4 years with cyanotic heart disease and iron deficiency, often with dehydration as an aggravating cause. In contrast, adults with cyanotic congenital heart disease do not appear to be at increased risk for stroke, unless there are excessive injudicious phlebotomies, inappropriate use of aspirin or anticoagulants, or the presence of atrial arrhythmias or infective endocarditis.

Symptoms of hyperviscosity can be produced in any cyanotic patient with erythrocytosis if dehydration causes a reduction of plasma volume. Phlebotomy, when required for symptoms of hyperviscosity not due to dehydration or iron deficiency, is a simple outpatient removal of 500 mL of blood over 45 min with isovolumetric replacement with isotonic saline (5% dextrose if congestive heart failure exists). Acute phlebotomy without volume replacement is contraindicated. Iron repletion in decompensated iron-depleted erythrocytosis ameliorates iron-deficiency symptoms but must be done gradually to avoid a sudden excessive rise in hematocrit and resultant hyperviscosity.

Pregnancy The physiologic alterations during normal gestation (Chap. 7) can create symptoms and physical findings that may be attributed erroneously to heart disease. Dyspnea due to the hormonal influence of progesterone and elevation of the diaphragm in association with peripheral edema and fatigability may be attributed inappropriately to heart failure. The jugular venous pulsations normally become more apparent after the twentieth week. Elevation of the diaphragm can cause basal rales (which disappear with deep breathing). Both ventricles are more easily palpated due to the normal increase in ventricular volumes and elevation of the diaphragm. Third heart sounds, already relatively frequent in normal nongravid young women, increase in frequency and intensity with pregnancy because of increased heart rate and volume of flow across the mitral and tricuspid valves. Midsystolic murmurs across the pulmonary outflow tract and supraclavicular systolic murmurs are caused by increased cardiac output. Venous hums and mammary souffles are usual during pregnancy.

These normal circulatory changes may impinge upon the woman's cardiac reserve. The mother is most at risk if she has a cardiovascular lesion associated with pulmonary vascular disease and pulmonary hypertension (e.g., Eisenmenger's physiology or mitral stenosis) or left ventricular (LV) outflow tract obstruction (e.g., aortic stenosis) but also risks death with any malformation that may cause heart failure or a hemodynamically important arrhythmia (Table 234-2). The fetus is most at risk in the presence of maternal cyanosis, heart failure, or pulmonary hypertension. Women with aortic coarctation or Marfan's syndrome are at risk for aortic dissection. Patients with cyanotic heart disease, pulmonary hypertension, or Marfan's syndrome should not become pregnant; those with correctable lesions should be counseled about the risks of pregnancy with an uncorrected malformation versus repair and later pregnancy. The effect of pregnancy in postoperative patients depends on the outcome of the repair including the presence and severity of residua, sequelae, or complications. Contraception is an important topic with such patients. Tubal ligation should be considered in those in whom pregnancy is strictly contraindicated.

INFECTIVE ENDOCARDITIS (See also Chap. 126)

Routine antimicrobial prophylaxis is recommended for most patients with congenital heart disease whether operated on or not. Antibiotic prophylaxis is not uniformly effective. Nonetheless, it is recommended for all dental procedures, gastrointestinal and genitourinary surgery, and diagnostic procedures such as proctosigmoidoscopy and cystoscopy. The clinical and bacteriologic profile of infective endocarditis in patients with congenital heart disease has changed with the advent of intracardiac surgery and of prosthetic devices. Two major predisposing causes of infective endocarditis are a susceptible cardiovascular substrate and a source of bacteremia. Prophylaxis includes both chemotherapeutic (antimicrobial) and nonchemotherapeutic (hygienic) measures. Meticulous dental and skin care is required.

EXERCISE

Advice on athletics and exercise is governed by the nature of the exercise and by the type and severity of the congenital cardiovascular lesion. Patients with lesions characterized byLVoutflow tract obstruction, if more than mild to moderate, or

pulmonary vascular disease, risk syncope or even sudden death. In Fallot's tetralogy, isotonic exercise-induced decrease in systemic vascular resistance relative to the right ventricular (RV) outflow obstruction augments the right-to-left shunt, increases hypoxemia, and causes an increase in subjective breathlessness due to the response of the respiratory center to the changes in blood gases and pH.

INSURABILITY AND EMPLOYABILITY

Most patients with congenital heart disease must pay significantly more than standard life insurance rates, assuming their anomaly places them in a category that companies have determined is eligible for insurance. A paucity of actuarial survival data beyond adolescence for persons with most congenital cardiac lesions that have undergone operative repair has made it difficult to convince insurance companies to offer reasonable cost insurance even to individual patients whose long-term prognosis is quite good.

Employment is affected by the patient's physical capacity relative to the type of job sought. Job discrimination exists, often because the employer is reluctant to accept health insurance responsibilities. Eligibility for some occupations is governed by public safety regulations, e.g., airline pilots, bus drivers.

SPECIFIC CARDIAC DEFECTS

Table 234-3 provides a classification of cardiac anomalies that recognizes the general categories of clinical presentation, functional consequences, and site of origin of congenital defects.

Categorizing the defect(s) in an individual patient requires an answer to a number of basic questions. Is the patient acyanotic or cyanotic? Is pulmonary arterial blood flow increased or not? Does the malformation originate in the left or right side of the heart? Which is the dominant ventricle? Is pulmonary hypertension present or not? With the above information as a foundation, the use of more refined diagnostic techniques such as transthoracic (precordial) and transesophageal echocardiography and Doppler imaging, magnetic resonance imaging, and/or hemodynamic study and angiocardiography leads to a precise anatomic and functional assessment.

ACYANOTIC CONGENITAL HEART DISEASE WITH A LEFT-TO-RIGHT SHUNT

ATRIAL SEPTAL DEFECT

This common cardiac anomaly in adults occurs more frequently in females. The *sinus venosus* type occurs high in the atrial septum near the entry of the superior vena cava and is associated frequently with anomalous connection of pulmonary veins from the right lung to the junction of the superior vena cava and right atrium (RA). *Ostium primum* anomalies are a form of atrioventricular septal defect that lie immediately adjacent to the atrioventricular valves, either of which may be deformed and incompetent. Ostium primum defects occur commonly in patients with Down's syndrome, although the more complex atrioventricular septal defects with a common atrioventricular valve and a posterior defect of the basal portion of the interventricular septum are more

characteristic of this chromosomal defect. The most common atrial septal defect involves the fossa ovalis, is midseptal in location, and is of the *ostium secundum* type. This type of defect should not be confused with a *patent foramen ovale*. Anatomic obliteration of the foramen ovale ordinarily follows its functional closure soon after birth, but residual "probe patency" is a normal variant; atrial septal defect denotes a true deficiency of the atrial septum and implies functional and anatomic patency.

The magnitude of the left-to-right shunt through an atrial septal defect depends on the defect size, the diastolic properties of both ventricles, and the relative impedance in the pulmonary and systemic circulations. The left-to-right shunt causes diastolic overloading of the RVand increased pulmonary blood flow.

Patients with atrial septal defect are usually asymptomatic in early life, although there may be some physical underdevelopment and an increased tendency for respiratory infections; cardiorespiratory symptoms occur in many older patients. Beyond the fourth decade, a significant number of patients develop atrial arrhythmias, pulmonary arterial hypertension, bidirectional and then right-to-left shunting of blood, and cardiac failure. Patients exposed to the chronic environmental hypoxia of high altitude tend to develop pulmonary hypertension at younger ages. In some older patients, left-to-right shunting across the defect increases as progressive systemic hypertension and/or coronary artery disease result in reduced compliance of theLV.

Physical Examination Examination usually reveals a prominentRVcardiac impulse and palpable pulmonary artery pulsation. The first heart sound is normal or split, with accentuation of the tricuspid valve closure sound. Increased flow across the pulmonic valve is responsible for a midsystolic pulmonary ejection murmur. The second heart sound is widely split and is relatively fixed in relation to respiration. A middiastolic rumbling murmur, loudest at the fourth intercostal space and along the left sternal border, reflects increased flow across the tricuspid valve. In patients with ostium primum defects, an apical thrill and holosystolic murmur indicate associated mitral or tricuspid incompetence or a ventricular septal defect.

The physical findings are altered when an increase in the pulmonary vascular resistance results in diminution of the left-to-right shunt. Both the pulmonary and tricuspid murmurs decrease in intensity, the pulmonic component of the second heart sound and a systolic ejection sound are accentuated, the two components of the second heart sound may fuse, and a diastolic murmur of pulmonic regurgitation appears. Cyanosis and clubbing accompany the development of a right-to-left shunt.

In adults with an atrial septal defect and atrial fibrillation, the physical findings may be confused with the findings of mitral stenosis with pulmonary hypertension because the tricuspid flow murmur and widely split second heart sound may be mistakenly thought to represent the diastolic murmur of mitral stenosis and the mitral "opening snap," respectively.

Electrocardiogram In patients with an ostium secundum defect, the electrocardiogram (ECG) usually shows right axis deviation and an rSr¢ pattern in the right precordial leads representing delayed posterobasal activation of the ventricular septum and enlargement of theRVoutflow tract. An ectopic atrial pacemaker or first-degree heart

block occurs occasionally in patients with defects of the sinus venosus type. In patients with an ostium primum defect, the RV conduction defect is characteristically accompanied by left axis deviation and by superior orientation and counterclockwise rotation of the QRS loop in the frontal plane. Varying degrees of RV andRAhypertrophy may occur with each type of defect, depending on the height of the pulmonary artery pressure. *Chest roentgenograms* reveal enlargement of the RA and RV, dilatation of the pulmonary artery and its branches, and increased pulmonary vascular marking.

Echocardiogram This test shows pulmonary arterial andRVdilatation, and anterior systolic (paradoxical) or flat interventricular septal motion if a significant RV volume overload is present. The defect may be visualized directly from subcostal, right parasternal, or apical echocardiographic windows. In most institutions, two-dimensional echocardiography, supplemented by conventional or color Doppler flow examination, has supplanted cardiac catheterization as the confirmatory test for atrial septal defect. Transesophageal echocardiography is indicated if the transthoracic echocardiogram is ambiguous, which is often the case with sinus venosus defects. Cardiac catheterization is then performed if inconsistencies exist in the clinical data, if significant pulmonary hypertension or associated malformations are suspected, or if coronary artery disease is a possibility.

TREATMENT

Operative repair, ideally in children age 3 to 6 years, should be advised for all patients with uncomplicated atrial septal defects in whom there is significant left-to-right shunting, i.e., with pulmonary-to-systemic flow ratios exceeding ~2.0:1.0. Excellent results may be anticipated, at low risk, even in patients older than 40 years in the absence of pulmonary hypertension. The defect is closed, usually with a patch of pericardium or of prosthetic material, with the patient on cardiopulmonary bypass. In patients with ostium primum defects, cleft, deformed, and incompetent valves often require repair. Intraoperative transesophageal echocardiography is used to monitor the surgical results of mitral valve repair. Operation should not be carried out in patients with small defects and trivial left-to-right shunts, or in those with severe pulmonary vascular disease without a significant left-to-right shunt.

Patients with atrial septal defect of the sinus venosus or ostium secundum types rarely die before the fifth decade. During the fifth and sixth decades the incidence of progressive symptoms, often leading to severe disability, increases substantially. Medical management should include prompt treatment of respiratory tract infections, antiarrhythmic medications for atrial fibrillation or supraventricular tachycardia, and the usual measures for hypertension, coronary disease, or heart failure (Chap. 232), if these complications occur. The risk of infective endocarditis is quite low unless the defect is complicated by valvular regurgitation or has recently been repaired with a patch (Chap. 126).

VENTRICULAR SEPTAL DEFECT

Defects of the ventricular septum are common as isolated defects and as one component of a combination of anomalies. The opening is usually single and situated in the membranous portion of the septum. The functional disturbance is dependent

primarily on its size and on the status of the pulmonary vascular bed, rather than on the location of the defect. Only small or moderate-size defects are usually seen initially in adulthood as most patients with isolated large defects come to medical and, often, surgical attention very early in life.

A wide spectrum exists in the natural history of ventricular septal defect, ranging from spontaneous closure to congestive cardiac failure and death in early infancy. Within this spectrum is the possible development of pulmonary vascular obstruction,RVoutflow tract obstruction, aortic regurgitation, and infective endocarditis. Spontaneous closure is more common in patients born with a small ventricular septal defect and occurs in early childhood in most patients.

Patients with large ventricular septal defects and pulmonary hypertension are those at greatest risk for developing pulmonary vascular obstruction. Thus, large defects should be corrected surgically early in life when pulmonary vascular disease is still reversible or not yet developed. In patients with severe pulmonary vascular obstruction (Eisenmenger syndrome), symptoms in adult life consist of exertional dyspnea, chest pain, syncope, and hemoptysis. The right-to-left shunt leads to cyanosis, clubbing, and erythrocytosis. In all patients, the degree to which pulmonary vascular resistance is elevated before operation is a critical factor determining prognosis. If the pulmonary vascular resistance is one-third or less of the systemic value, progression of pulmonary vascular disease after operation is unusual. However, if a moderate to severe increase in pulmonary vascular resistance exists preoperatively, either no change or a progression of pulmonary vascular disease is common postoperatively.

RVoutflow tract obstruction develops in ~5 to 10% of patients who present in infancy with a moderate to large left-to-right shunt. With time, as subvalvular RV outflow tract obstruction progresses, the findings in these patients begin to resemble more closely those of the cyanotic tetralogy of Fallot.

In ~5% of patients, incompetence of the aortic valve results from insufficient cusp tissue or prolapse of the cusp through the interventricular defect; the aortic regurgitation then complicates and usually dominates the clinical course.

Two-dimensional *echocardiography* with conventional or color Doppler examination can usually define the number and location of defects in the ventricular septum and detect associated anomalies. Hemodynamic and angiographic study may be employed to assess the status of the pulmonary vascular bed and clarify details of the altered anatomy.

TREATMENT

Surgery is not recommended for patients with normal pulmonary arterial pressures with small shunts (pulmonary-to-systemic flow ratios of less than 1.5 to 2.0:1.0). Operative correction is indicated when there is a moderate to large left-to-right shunt with a pulmonary-to-systemic flow ratio>1.5:1.0 or 2.0:1.0, in the absence of prohibitively high levels of pulmonary vascular resistance.

PATENT DUCTUS ARTERIOSUS

The ductus arteriosus is a vessel leading from the bifurcation of the pulmonary artery to the aorta just distal to the left subclavian artery. Normally, the vascular channel is open in the fetus but closes immediately after birth. The flow across the ductus is determined by the pressure and resistance relationships between the systemic and pulmonary circulations and by the cross-sectional area and length of the ductus. In most adults with this anomaly, pulmonary pressures are normal and a gradient and shunt from aorta to pulmonary artery persist throughout the cardiac cycle, resulting in a characteristic thrill and a continuous "machinery" murmur with a late systolic accentuation at the upper left sternal edge. In adults who were born with a large left-to-right shunt through the ductus arteriosus, pulmonary vascular obstruction (Eisenmenger syndrome) with pulmonary hypertension, right-to-left shunting, and cyanosis have usually developed. Severe pulmonary vascular disease results in reversal of flow through the ductus, unoxygenated blood is shunted to the descending aorta, and the toes, but not the fingers, become cyanotic and clubbed, a finding termed *differential cyanosis*. The leading causes of death in adults with patent ductus are cardiac failure and infective endocarditis; occasionally severe pulmonary vascular obstruction may cause aneurysmal dilatation, calcification, and rupture of the ductus.

TREATMENT

In the absence of severe pulmonary vascular disease and predominant left-to-right shunting of blood, the patent ductus should be surgically ligated or divided. Transcatheter closure is experimental, using coils, buttons, plugs, and umbrellas. Thoracoscopic surgical approaches are considered experimental. Operation should be deferred for several months in patients treated successfully for infective endocarditis, because the ductus may remain somewhat edematous and friable.

AORTIC ROOT TO RIGHT HEART SHUNTS

The three most common causes of aortic root to right heart shunts are congenital aneurysm of an aortic sinus of Valsalva with fistula, coronary arteriovenous fistula, and anomalous origin of the left coronary artery from the pulmonary trunk. *Aneurysm of an aortic sinus of Valsalva* consists of a separation or lack of fusion between the media of the aorta and the annulus fibrosis of the aortic valve. Rupture usually occurs in the third or fourth decade of life; most often the aorticocardiac fistula is between the right coronary cusp and theRV, but occasionally, when the noncoronary cusp is involved, the fistula drains into theRA. Abrupt rupture causes chest pain, bounding pulses, a continuous murmur accentuated in diastole, and volume overload of the heart. Diagnosis is confirmed by two-dimensional and Doppler echocardiographic studies; cardiac catheterization quantitates the left-to-right shunt, and thoracic aortography visualizes the fistula. Medical management is directed at cardiac failure, arrhythmias, or endocarditis. At operation, the aneurysm is closed and amputated, and the aortic wall is reunited with the heart, either by direct suture or with a prosthesis.

Coronary arteriovenous fistula, an unusual anomaly, consists of a communication between a coronary artery and another cardiac chamber, usually the coronary sinus,RA, orRV. The shunt is usually of small magnitude, and myocardial blood flow is not usually compromised. Potential complications include infective endocarditis, thrombus formation

with occlusion or distal embolization, rupture of an aneurysmal fistula, and rarely, pulmonary hypertension and congestive failure. A loud, superficial, continuous murmur at the lower or midsternal border usually prompts a further evaluation of asymptomatic patients. Doppler echocardiography demonstrates the site of drainage; if the site of origin is proximal, it may be detectable by two-dimensional echocardiography. Retrograde thoracic aortography or coronary arteriography permits identification of the size and anatomic features of the fistulous tract, which may be closed by suture or transcatheter obliteration.

The third anomaly causing a shunt from the aortic root to the right heart is *anomalous origin of the left coronary artery from the pulmonary artery*. Myocardial infarction and fibrosis commonly lead to death within the first year, though up to 20% of patients survive to adolescence and beyond without surgical correction. The diagnosis is supported by theECGfindings of an anterolateral myocardial infarction. Operative management of adults consists of coronary artery bypass with an internal mammary artery graft or saphenous vein-coronary artery graft.

ACYANOTIC CONGENITAL HEART DISEASE WITHOUT A SHUNT

CONGENITAL AORTIC STENOSIS

Malformations that cause obstruction toLVoutflow include congenital valvular aortic stenosis, discrete subaortic stenosis, supravalvular aortic stenosis, and hypertrophic obstructive cardiomyopathy (Chap. 238).

Valvular Aortic Stenosis This malformation occurs three to four times more often in males than in females. The congenital bicuspid aortic valve, which is not necessarily stenotic, is one of the most common congenital malformations of the heart, although it may go undetected in early life. Because bicuspid valves may become stenotic with time or be the site of infective endocarditis, the lesion may be difficult to distinguish in adults from acquired rheumatic or degenerative calcific aortic stenosis.

The dynamics of blood flow associated with a congenitally deformed, rigid aortic valve commonly lead to thickening of the cusps and, in later life, to calcification. Hemodynamically significant obstruction causes concentric hypertrophy of theLV wall and dilatation of the ascending aorta.**The clinical manifestations and hemodynamic abnormalities are discussed in Chap. 236.*

TREATMENT

The medical management of congenital valvular aortic stenosis includes prophylaxis against infective endocarditis and, in patients with diminished cardiac reserve, the administration of digitalis and diuretics and sodium restriction while awaiting operation. If severe aortic stenosis is present, strenuous physical activity should be avoided even when the patient is asymptomatic, and participation in competitive sports should probably be restricted in patients with milder degrees of obstruction. Aortic valve replacement is indicated in adults with critical obstruction, i.e., with an aortic valve area<0.5 cm^2/m^2, with symptoms secondary toLVdysfunction or myocardial ischemia, or with hemodynamic evidence of LV dysfunction. In asymptomatic children or adolescents

or young adults with critical aortic stenosis without valvular calcification or these features, aortic balloon valvuloplasty is often useful (Chap. 245). If surgery is contraindicated in older patients because of a complicating medical problem such as malignancy or renal or hepatic failure, balloon valvuloplasty may provide short-term improvement. It may serve as a bridge to aortic valve replacement in patients with severe heart failure.

Subaortic Stenosis The most common form of subaortic stenosis is the *idiopathic hypertrophic* variety, also termed *hypertrophic cardiomyopathy*, which is present at birth in about one-third of the patients and is discussed inChap. 238. In contrast, both clinically and physiologically, the *discrete* form of subaortic stenosis resembles valvular aortic stenosis. The lesion usually consists of a membranous diaphragm or fibrous ring encircling the LV outflow tract just beneath the base of the aortic valve. Echocardiography demonstrates the subaortic obstruction; Doppler studies show turbulence proximal to the aortic valve and also detect and quantitate the pressure gradient and severity of aortic regurgitation. Treatment consists of excision of the membrane or fibrous ridge.

Supravalvular Aortic Stenosis This anomaly consists of a localized or diffuse narrowing of the ascending aorta originating just above the level of the coronary arteries at the superior margin of the sinuses of Valsalva. In contrast to other forms of aortic stenosis, the coronary arteries are subjected to elevated systolic pressures from theLV, are often dilated and tortuous, and are susceptible to premature atherosclerosis. New information indicates that a genetic defect for the anomaly is located in the same chromosomal subunit as elastin on chromosome 7.

COARCTATION OF THE AORTA

Narrowing or constriction of the lumen of the aorta may occur anywhere along its length but is most common distal to the origin of the left subclavian artery near the insertion of the ligamentum arteriosum. Coarctation occurs in ~7% of patients with congenital heart disease, is twice as common in males as in females, and is most frequent in patients with gonadal dysgenesis. Clinical manifestations depend on the site and extent of obstruction and the presence of associated cardiac anomalies, most commonly a bicuspid aortic valve. Aneurysmal arterial dilatation of the circle of Willis produces a high risk of sudden rupture and death.

Most children and young adults with isolated, discrete coarctation are asymptomatic. Headache, epistaxis, cold extremities, and claudication with exercise may occur, and attention is usually directed to the cardiovascular system when a heart murmur or hypertension in the upper extremities and absence, marked diminution, or delayed pulsations in the femoral arteries are detected on physical examination. Enlarged and pulsatile collateral vessels may be palpated in the intercostal spaces anteriorly, in the axillae, or posteriorly in the interscapular area. The upper extremities and thorax may be more developed than the lower extremities. A midsystolic murmur over the anterior part of the chest, back, and spinous processes may become continuous if the lumen is narrowed sufficiently to result in a high-velocity jet across the lesion throughout the cardiac cycle. Additional systolic and continuous murmurs over the lateral thoracic wall may reflect increased flow through dilated and tortuous collateral vessels.

TheECGusually revealsLVhypertrophy. Roentgenograms may show a dilated left subclavian artery high on the left mediastinal border and a dilated ascending aorta. Indentation of the aorta at the site of coarctation and pre- and poststenotic dilatation (the "3" sign) along the left paramediastinal shadow are almost pathognomonic. Notching of the ribs, an important radiographic sign, is due to erosion by dilated collateral vessels. Two-dimensional echocardiography from para- or suprasternal windows identifies the site and length of coarctation, while Doppler studies record and quantitate the pressure gradient. Transesophageal echocardiography and magnetic resonance imaging or digital angiography allow visualization of the length and severity of the obstruction and the associated collateral arteries. In adults, cardiac catheterization is indicated primarily to evaluate the coronary arteries.

The chief hazards result from severe hypertension and include the development of cerebral aneurysms and hemorrhage, rupture of the aorta, premature coronary arteriosclerosis,LVfailure, and infective endocarditis.

TREATMENT

Treatment is usually surgical; resection and end-to-end anastomosis or subclavian flap angioplasty are used commonly, although it may be necessary to use a tubular graft, patch, or bypass conduit if the narrowed segment is long. Systemic hypertension postoperatively, in the absence of residual coarctation, appears to be related to the duration of preoperative hypertension. Percutaneous balloon dilatation is controversial in native unoperated aortic coarctation but commonly successful for postsurgical recoarctation, often with deployment of a stent.

PULMONARY STENOSIS WITH INTACT VENTRICULAR SEPTUM

Obstruction toRVoutflow may be localized to the supravalvular, valvular, or subvalvular levels or occur at a combination of these sites. Multiple sites of narrowing of the peripheral pulmonary arteries are a feature of *rubella embryopathy* and may occur with both the familial and sporadic forms of supravalvular aortic stenosis. Valvular pulmonic stenosis is the most common form of isolated RV obstruction.

The severity of the obstructing lesion, rather than the site of narrowing, is the most important determinant of the clinical course. In the presence of a normal cardiac output, a peak systolic transvalvular pressure gradient between 50 and 80 mmHg is considered to be moderate stenosis; levels below and above that range are classified as mild and severe, respectively. Patients with mild pulmonic stenosis are generally asymptomatic and demonstrate little or no progression in the severity of obstruction with age. In patients with more significant stenosis, the severity may increase with time. Symptoms vary with the degree of obstruction. Fatigue, dyspnea,RVfailure, and syncope may limit the activity of older patients, in whom moderate or severe obstruction may prevent an augmentation of cardiac output with exercise. In patients with severe obstruction, the systolic pressure in the RV may exceed that in theLV, since the ventricular septum is intact. RV ejection is prolonged with moderate or severe stenosis, and the sound of pulmonary valve closure is delayed and soft. RV hypertrophy reduces the compliance of that chamber, and a forcefulRAcontraction is necessary to augment RV filling. A fourth heart sound, prominent *a* waves in the jugular venous pulse, and, occasionally,

presystolic pulsations of the liver reflect vigorous atrial contraction. The clinical diagnosis is supported by a right parasternal lift and harsh systolic ejection murmur and thrill at the upper left sternal border, typically preceded by a systolic ejection sound, if the obstruction is valvular. The holosystolic decrescendo murmur of tricuspid regurgitation may accompany severe pulmonic stenosis, especially in the presence of congestive heart failure. Cyanosis usually reflects right-to-left shunting through a patent foramen ovale or atrial septal defect. In patients with supravalvular or peripheral pulmonary arterial stenosis, the murmur is systolic or continuous and is best heard over the area of narrowing, with radiation to the peripheral lung fields.

TheECG may be helpful in assessing the degree ofRVobstruction. In mild cases, the ECG is often normal, whereas moderate and severe stenoses are associated with right axis deviation and RV hypertrophy. A ventricular strain pattern, as well as high-amplitude P waves in leads II and V_1, indicatingRAenlargement, is associated with severe stenosis. The chest roentgenogram with mild or moderate pulmonic stenosis often shows a heart of normal size and normal vascularity of the lungs. In the presence of valvular stenosis, poststenotic dilatation of the main and left pulmonary arteries may be evident. With severe obstruction and resultant RV failure, RA and RV enlargement are generally evident. The pulmonary vascularity may be reduced with severe stenosis, RV failure, and/or a right-to-left shunt at the atrial level. Two-dimensional echocardiography visualizes pulmonary valve morphology; the outflow tract pressure gradient can be estimated by Doppler ultrasonography.

TREATMENT

The cardiac catheter technique of balloon valvuloplasty (Chap. 228) is usually effective. Direct surgical relief of moderate and severe obstruction may be accomplished at a low risk. Multiple stenoses of the peripheral pulmonary arteries are usually inoperable, but narrowing of a single branch or at the bifurcation of the main pulmonary trunk may be corrected.

CYANOTIC CONGENITAL HEART DISEASE WITH INCREASED PULMONARY BLOOD FLOW

COMPLETE TRANSPOSITION OF THE GREAT ARTERIES

In this condition the aorta arises from theRV to the right of and anterior to the pulmonary artery, which emerges from theLV(Fig. 234-1, *left panel*). This results in two separate and parallel circulations, and some communication between them must exist after birth to sustain life. Most patients have an interatrial communication, two-thirds have a patent ductus arteriosus, and about one-third have an associated ventricular septal defect. Transposition is more common in males and accounts for ~10% of cyanotic heart disease.

The course is determined by the degree of tissue hypoxia, the ability of each ventricle to sustain an increased work load in the presence of reduced coronary arterial oxygenation, the nature of the associated cardiovascular anomalies, and the status of the pulmonary vascular bed. Pulmonary vascular obstruction develops by 1 to 2 years of age in patients with an associated large ventricular septal defect or large patent ductus

arteriosus in the absence of obstruction toLVoutflow.

TREATMENT

The balloon or blade catheter or surgical creation or enlargement of an interatrial communication in the neonate is the simplest procedure for providing increased intracardiac mixing of systemic and pulmonary venous blood. Systemic-pulmonary artery anastomosis may be indicated in the patient with severe obstruction toLVoutflow and diminished pulmonary blood flow. Intracardiac repair may be accomplished by rearranging the venous returns (intra-atrial switch, i.e., Mustard or Senning operation) so that the systemic venous blood is directed to the mitral valve and thence to the LV and pulmonary artery, while the pulmonary venous blood is diverted through the tricuspid valve andRV to the aorta. The late survival after these repairs is good, but late sudden death is the most worrisome feature. Preferably, this malformation is corrected in infancy by transposing both coronary arteries to the posterior artery and transecting, contraposing, and anastomosing the aorta and pulmonary arteries (arterial switch operation). For those patients with a ventricular septal defect in whom it is necessary to bypass a severely obstructed LV outflow tract, corrective operation employs an intracardiac ventricular baffle and extracardiac prosthetic conduit to replace the pulmonary artery (Rastelli procedure).

SINGLE VENTRICLE

This is a family of complex lesions with both atrioventricular valves or a common atrioventricular valve opening to a single ventricular chamber. Associated anomalies include abnormal great artery positional relationships, pulmonic valvular or subvalvular stenosis, and subaortic stenosis.

Survival to adulthood depends on a relatively normal pulmonary blood flow and good ventricular function. Modifications of the Fontan approach are generally applied to these patients with creation of a pathway(s) from the systemic veins to the pulmonary arteries.

CYANOTIC CONGENITAL HEART DISEASE WITH DECREASED PULMONARY BLOOD FLOW

TRICUSPID ATRESIA

This malformation is characterized by atresia of the tricuspid valve, an interatrial communication, and, frequently, hypoplasia of theRV and pulmonary artery. The clinical picture is usually dominated by severe cyanosis due to obligatory admixture of systemic and pulmonary venous blood in theLV. TheECGcharacteristically showsRAenlargement, left axis deviation, and LV hypertrophy.

Atrial septostomy and palliative operations to increase pulmonary blood flow, often by anastomosis of a systemic artery or vein to a pulmonary artery, may allow survival to the second or third decade. A Fontan atriopulmonary connection may then allow functional correction in those patients with normal or low pulmonary arterial resistance pressure and good LVfunction.

EBSTEIN'S ANOMALY

Characterized by a downward displacement of the tricuspid valve into theRV, due to anomalous attachment of the tricuspid leaflets, the Ebstein tricuspid valve tissue is dysplastic and results in tricuspid regurgitation. The abnormally situated tricuspid orifice produces an "atrialized" portion of the RV lying between the atrioventricular ring and the origin of the valve, which is continuous with theRAchamber. Often the RV is hypoplastic. Although the clinical manifestations are variable, some patients come to initial attention because of progressive cyanosis from right-to-left atrial shunting, or symptoms due to tricuspid regurgitation and RV dysfunction, or paroxysmal atrial tachyarrhythmias. Diagnostic findings by two-dimensional echocardiography include the abnormal positional relation between the tricuspid and mitral valves with apical displacement of the septal tricuspid leaflet. Tricuspid regurgitation is quantitated by Doppler examination. Surgical approaches include prosthetic replacement of the tricuspid valve when the leaflets are tethered or repair of the native valve.

TETRALOGY OF FALLOT

The four components of the tetralogy of Fallot are ventricular septal defect, obstruction toRVoutflow, aortic override (straddle) of the ventricular septal defect, and RV hypertrophy (Fig. 234-1, right panel).

The severity ofRVoutflow obstruction determines the clinical presentation. The severity of hypoplasia of the RV outflow tract varies from mild to complete (pulmonary atresia). Pulmonary valve stenosis and supravalvular and peripheral pulmonary arterial obstruction may coexist; rarely there is unilateral absence of a pulmonary artery (usually the left). A right-sided aortic arch and descending aorta occur in ~25% of patients with tetralogy.

The relationship between the resistance to blood flow from the ventricles into the aorta and into the pulmonary vessels plays a major role in determining the hemodynamic and clinical picture. Thus, the severity of obstruction toRVoutflow is of fundamental significance. When the obstruction is severe, the pulmonary blood flow is reduced markedly, and a large volume of desaturated systemic venous blood is shunted from right to left across the ventricular septal defect. Severe cyanosis and erythrocytosis occur, and symptoms and sequelae of systemic hypoxemia are prominent. In many infants and children the obstruction is mild but progressive.

TheECGordinarily showsRV and, less often,RAhypertrophy. Radiologic examination characteristically reveals a normal-sized, boot-shaped heart (*coeur en sabot*) with prominence of the RV and a concavity in the region of the pulmonary conus. The pulmonary vascular markings are typically diminished, and the aortic arch and knob may be on the right side. Two-dimensional echocardiography from the parasternal or subcostal windows demonstrates the malalignment of the ventricular septal defect and the subpulmonary stenosis. Selective angiocardiography with RV injection provides architectural details of the RV outflow tract, pulmonary valve and annulus, and caliber of the main branches of the pulmonary artery; coronary arteriography identifies the anatomy and course of the coronary arteries.

TREATMENT

Factors that may complicate the treatment of patients with tetralogy of Fallot include infective endocarditis, paradoxic embolism, excessive erythrocytosis, coagulation defects, and cerebral infarction or abscess. Corrective operation is advisable at some point for almost all patients with this anomaly. Successful correction avoids progressive infundibular obstruction, delayed growth, and complications due to hypoxemia and excessive erythrocytosis. The size of the pulmonary arteries rather than the age or size of the infant or child is the most important determinant in establishing candidacy for primary repair. Pronounced hypoplasia of the pulmonary arteries is a relative contraindication for an early corrective surgical procedure. When this problem is present, a palliative operation, such as creation of a systemic arterial-pulmonary arterial shunt, is carried out and is usually followed by complete correction, which can be carried out at a lower risk later in childhood.

OTHER FORMS OF CONGENITAL HEART DISEASES

CONGENITALLY CORRECTED TRANSPOSITION

The two fundamental anatomic abnormalities in this malformation are transposition of the ascending aorta and pulmonary trunk and inversion of the ventricles. This arrangement results in desaturated systemic venous blood passing from theRAthrough the mitral valve to theLV and into the pulmonary trunk, whereas arterialized pulmonary venous blood flows from the left atrium (LA) through the tricuspid valve to theRV and into the aorta. Thus, the circulation is corrected functionally. The clinical presentation, course, and prognosis of patients with congenitally corrected transposition vary depending on the nature and severity of any complicating intracardiac anomalies. Ebstein-type anomalies of the left-side tricuspid atrioventricular valve, ventricular septal defect, obstruction to outflow from the venous ventricle, and congenital heart block are often associated with corrected transposition. The diagnosis of the malformation and associated lesions can often be established by two-dimensional echocardiography and Doppler examination.

MALPOSITIONS OF THE HEART

Positional anomalies refer to conditions in which the cardiac apex is in the right side of the chest (dextrocardia), or at the midline (mesocardia), or in which there is a normal location of the heart in the left side of the chest but abnormal position of the viscera (isolated levocardia). Knowledge of the position of the abdominal organs and of the branching pattern of the main stem bronchi is important in categorizing these malpositions. When dextrocardia occurs without situs inversus, when the visceral situs is indeterminate, or if isolated levocardia is present, associated, often complex, multiple cardiac anomalies are usually present. In contrast, mirror-image dextrocardia is usually observed with complete situs inversus, which occurs most frequently in individuals whose hearts are otherwise normal.

SURGICALLY MODIFIED CONGENITAL HEART DISEASE

Because of the enormous strides in cardiovascular surgical techniques that have

occurred in the past 20 years, a large number of long-term survivors of corrective operations in infancy and childhood have reached adulthood. These patients are often challenging because of the diversity of anatomic, hemodynamic, and electrophysiologic residua and sequelae of cardiac operations.

The proper care of the survivor of operation for congenital heart disease requires that the clinician understand the details of the malformation before operation; pay meticulous attention to the details of the operative procedure; and recognize the postoperative residua (conditions left totally or partially uncorrected), the sequelae (conditions caused by surgery), and the complications that may have resulted from the operation. With the exception of ligation and division of an uncomplicated patent ductus arteriosus, almost every other surgical repair of an anomaly leaves behind or causes some abnormality of the heart and circulation that may range from trivial to serious. Intraoperative transesophageal echocardiography assists in detecting unsuspected lesions, in monitoring the repair, and in verifying a satisfactory result or directing further repair. Thus, even with results that are considered clinically to be good to excellent, continued long-term postoperative follow-up is advisable.

Table 234-4 lists the categories of common late postoperative problems. Cardiac operations importantly involving the atria, such as closure of atrial septal defect, repair of total or partial anomalous pulmonary venous return, or venous switch corrections of complete transposition of the great arteries (the Mustard or Senning operations), may be followed years later by sinus node or atrioventricular node dysfunction or by atrial arrhythmias. Intraventricular surgery may also result in electrophysiologic consequences, including complete heart block necessitating pacemaker insertion to avoid sudden death. In addition, valvular problems may arise late after initial cardiac operation. An example is the progressive stenosis of an initially nonobstructive bicuspid aortic valve in the patient who underwent aortic coarctation repair. Such aortic valves may also be the site of infective endocarditis. After repair of the ostium primum atrial septal defect, the cleft mitral valve may become progressively incompetent. Tricuspid regurgitation may also be progressive in the postoperative patient with tetralogy of Fallot ifRVoutflow tract obstruction was not relieved adequately at initial surgery. In many patients with surgically modified congenital heart disease, inadequate relief of an obstructive lesion, or a residual regurgitant lesion, or a residual shunt will cause or hasten the onset of clinical signs and symptoms of myocardial dysfunction. Despite a good hemodynamic repair, many patients with a subaortic RV develop RV decompensation and signs of "left heart failure." In many patients, particularly those who were cyanotic for many years before operation, a preexisting compromise in ventricular performance is due to the original underlying malformation.

A final category of postoperative problems involves the use of prosthetic valves, patches, or conduits in the operative repair. The special risks include infective endocarditis, thrombus formation, and premature degeneration and calcification of the prosthetic materials. There are many patients in whom extracardiac conduits are required to correct the circulation functionally and often to carry blood to the lungs from theRA orRV. These conduits may develop intraluminal obstruction, and, if they include a prosthetic valve, it may show progressive calcification and thickening.

235. RHEUMATIC FEVER - *Edward L. Kaplan*

In many parts of the world, especially in industrialized countries, acute rheumatic fever is less common than it was during the early and mid-years of the twentieth century. In the late 1940s, patients with rheumatic fever and rheumatic heart disease accounted for more than half of schoolchildren recognized to have cardiovascular problems in the United States. During the Second World War, there were more than 20,000 cases of acute rheumatic fever in U.S. Navy personnel alone. The incidence of rheumatic fever has declined remarkably in the industrialized countries of the world, where the disease has become rare. However, in many developing countries, which account for almost two-thirds of the world's population, streptococcal infections, rheumatic fever, and rheumatic heart disease remain a very significant public health problem. The magnitude of the problem in these countries today is similar to that in North America 50 years ago.

The decreased incidence of acute rheumatic fever and the low prevalence of rheumatic heart disease in industrialized countries have led many physicians and public health authorities to the incorrect conclusion that these conditions are no longer a problem. However, starting in the 1980s, unexpected scattered outbreaks of acute rheumatic fever among both adults and children in North America have confirmed the capacity for this potentially serious illness to reappear and pose significant public health problems. Neither antimicrobial agents nor other public health measures have been totally effective in the control of rheumatic fever in the industrialized or industrializing world.

EPIDEMIOLOGY

The epidemiology of acute rheumatic fever is identical to that of group A streptococcal upper respiratory tract infections (Chap. 140). As is the case for streptococcal sore throat, acute rheumatic fever most often occurs in children; the peak age-related incidence is between 5 and 15 years. Most initial attacks in adults take place at the end of the second and beginning of the third decades of life. Rarely, initial attacks occur as late as the fourth decade and recurrent attacks have been documented as late as the fifth decade.

Epidemiologic risk factors classically associated with individual attacks and especially with outbreaks of acute rheumatic fever include lower standards of living, especially crowding; the disease has been more common among socially and economically disadvantaged populations. However, the outbreaks in the United States in the late 1980s and early 1990s cannot be explained entirely by these factors. The large Utah outbreak of more than 500 cases during 13 years has affected primarily middle class patients with ready access to medical care. Therefore, one can conclude that the organism itself as well as the degree of host/herd immunity to the prevalent serotypes in an affected community are equally important risk factors.

Studies have shown that approximately 3% of individuals with untreated group A streptococcal pharyngitis will develop rheumatic fever. The epidemiology of rheumatic fever is also influenced by the serotypes of group A streptococci present in a population. The concept of "rheumatogenecity" of specific strains is largely based upon epidemiologic evidence associating certain serotypes with rheumatic fever (e.g., serotypes 1, 3, 5, 6, 18, etc.). Mucoid isolates are frequently associated with virulence

and with rheumatic fever.

PATHOGENESIS

More than half a century ago the pioneering studies of Lancefield differentiated beta-hemolytic streptococci into serologic groups. This ultimately led to the association of infection by the group A organism of the pharynx and tonsils (not of the skin) and the subsequent development of acute rheumatic fever. However, the mechanism(s) responsible for the development of rheumatic fever after an infection remains incompletely defined. Historically, approaches to understanding the pathogenesis of rheumatic fever have been grouped into three major categories: (1) direct infection by the group A streptococcus; (2) a toxic effect of streptococcal extracellular products on the host tissues; and (3) an abnormal or dysfunctional immune response to one or more as yet unidentified somatic or extracellular antigens produced by all (or perhaps only by some) group A streptococci.

There is insufficient evidence to support direct infection of the heart as the inciting event. Additionally, while toxins such as streptolysin O and others have been postulated to have a pathogenetic role, there is relatively little convincing evidence of this at the present time. Major efforts have focused on an abnormal immune response by the human host to one or more group A streptococcal antigens.

The hypothesis of "antigenic mimicry" between human and group A streptococcal antigens has been studied extensively and has concentrated on two interactions. The first is the similarity between the group-specific carbohydrate of the group A streptococcus and the glycoprotein of heart valves; the second involves the molecular similarity among the streptococcal cell membrane, streptococcal M protein sarcolemma, and other moieties of the human myocardial cell.

The possibility of a predisposing genetic influence in some individuals is one of the most tantalizing of the incompletely understood factors that might contribute to susceptibility to rheumatic fever. The precise genetic factors influencing the attack rate have never been adequately defined. Observations have been described that support the concept that this nonsuppurative sequel to a group A streptococcal upper respiratory tract infection results from an abnormal immune response by the human host. Thus, differences in immune responses to streptococcal antigens have been reported. Further, new data suggest that a unique surface marker on non-T lymphocytes in patients with rheumatic fever and rheumatic heart disease may prove helpful in defining which individuals are susceptible to developing rheumatic fever after a streptococcal infection because of abnormal immune responses.

DIAGNOSIS

There is no specific laboratory test that can establish a diagnosis of rheumatic fever. The diagnosis, therefore, is a clinical one but requires supporting evidence from the clinical microbiology and clinical immunology laboratories. Because of the variety of signs and symptoms associated with the rheumatic fever syndrome, in 1944 Jones first proposed criteria to assist the clinician in standardizing the diagnosis of rheumatic fever. The most recent modification of the *Jones criteria* (Updated Jones Criteria) was

published in 1992 by a Special Writing Group of the American Heart Association (Table 235-1).

There are five criteria termed *major* because they are most commonly found in patients with rheumatic fever: carditis, migratory polyarthritis, Sydenham's chorea, subcutaneous nodules, and erythema marginatum.

The *carditis* of acute rheumatic fever is a pancarditis involving the pericardium, myocardium, and endocardium. In most published series, between 40 and 60% of patients with acute rheumatic fever have evidence of carditis, which is characterized by one or more of the following: sinus tachycardia, the murmur of mitral regurgitation, an S_3gallop, a pericardial friction rub, and cardiomegaly. The introduction of echocardiography has assisted in the identification of subtle abnormalities of the mitral valve, and these may be present in an additional 20% of patients who do not have an audible heart murmur. A prolonged PR interval and evidence of heart failure may be present as well, but these are nonspecific and may be found in a number of other diseases.

Healing of the rheumatic valvulitis may cause fibrous thickening and adhesion, resulting in the most serious complication of rheumatic fever, i.e., valvular stenosis and/or regurgitation (Chap. 236). The mitral valve is involved most frequently, followed by the aortic valve. However, isolated aortic valve disease as a consequence of acute rheumatic fever is quite rare. In patients with aortic valve disease due to rheumatic fever, the mitral valve is almost always simultaneously affected. Even minor degrees of rheumatic valvular involvement can lead to susceptibilities to infective endocarditis (Chap. 126). Although rheumatic pericarditis can cause a serous effusion, fibrin deposits, and even pericardial calcification, it does not lead to constrictive pericarditis.

A *migratory polyarthritis* is present in as many as 75% of cases, most often affecting the ankles, wrists, knees, and elbows over a period of days. It usually does not affect the small joints of the hands or feet and seldom involves the hip joints. Since salicylates and other anti-inflammatory drugs usually cause prompt resolution of joint symptoms, it is important that the clinician *not* prescribe these medications until it is determined whether the arthritis is migratory. The arthritis of acute rheumatic fever is extremely painful. Pain can be controlled with codeine or similar analgesics until the diagnosis is established. The difference between arthralgia (subjective joint pain) and arthritis (joint pain and swelling) must be understood. Too often, arthralgia is used (incorrectly) as a major criterion.

Sydenham's chorea occurs in fewer than 10% of patients with rheumatic fever. The latent period between the onset of the initiating streptococcal infection and the onset of Sydenham's chorea may be as long as several months. While differing from the other manifestations, this central nervous system disorder is a part of the rheumatic fever complex and should be managed as such. Many patients who appear to have only chorea may present several decades later with evidence of typical rheumatic valvular disease. There is no definitive laboratory test for establishing a diagnosis of Sydenham's chorea, and the diagnosis is one of exclusion. Patients with Sydenham's chorea should be given secondary prophylaxis for prevention of recurrent attacks, even if they do not appear to have rheumatic heart disease.

Subcutaneous nodules and *erythema marginatum* are rare major manifestations, usually present in fewer than 10% of cases. Subcutaneous nodules are found over extensor surfaces of joints, are seen most often in patients with long-standing rheumatic heart disease, and are extremely rare in patients experiencing an initial attack. Erythema marginatum is an uncommon manifestation. It is an evanescent macular eruption with rounded borders -- usually concentrated on the trunk.

The *minor criteria* (Table 235-1) are nonspecific and may be present in many clinical conditions.

To fulfill the Jones criteria, either two major criteria, or one major criterion and two minor criteria, *plus* evidence of an antecedent streptococcal infection are required. The latter may be provided by recovery of the organism on culture or by evidence of an immune response to one of the commonly measured group A streptococcal antibodies (e.g., anti-streptolysin O, anti-deoxyribonuclease B, anti-hyaluronidase). Since the accurate diagnosis of rheumatic fever has future medical and financial implications, the clinician is obligated to evaluate any patient completely until the suspected diagnosis is either established or excluded.

Both the clinical microbiology and the clinical immunology laboratories have important roles in confirming the diagnosis of rheumatic fever. An attempt should be made to recover the organism from a throat culture, although group A streptococci can be recovered from the upper respiratory tract of only 25 to 40% of patients at the time the diagnosis is made. If a rapid antigen detection test is used but is negative, a confirmatory throat culture must be performed. It is helpful to obtain two or three cultures from the throat at the time the diagnosis is suspected but before initiating antibiotic therapy in order to confirm the presence of the organism.

At least 80% of patients with acute rheumatic fever have an elevated anti-streptolysin O titer at presentation. If one employs two additional streptococcal antibody tests such as the anti-DNAse B or anti-hyaluronidase test, the percentage of patients who show evidence of a preceding group A streptococcal infection will rise to more than 95%. While an initially elevated titer is convincing, being able to demonstrate a rise in titer from the acute to the convalescent phase is a more reliable means of documenting the recent infection. If three antibody tests are done and there is no evidence of a preceding infection, the diagnosis must be seriously reconsidered.

TREATMENT

There are two necessary therapeutic approaches to patients with acute rheumatic fever: anti-streptococcal antibiotic therapy and therapy for the clinical manifestations of the disease. At the time of diagnosis, *all* patients with acute rheumatic fever should be treated as if they have a group A streptococcal infection, whether or not the organism is recovered by culture. In addition to the relatively large percentage of such patients who may have a negative throat culture at the time of diagnosis, others may have only a few organisms present in the throat. Conventional antibiotic treatment should be started immediately: a complete 10-day course in adults of either oral penicillin V (500 mg twice daily), or erythromycin (250 mg four times daily) for those with penicillin allergy. Many

choose intramuscular benzathine penicillin G (a single intramuscular injection of 1.2 million units) for the treatment of the presumed streptococcal infection; this will also serve as the first dose of secondary prophylaxis for the prevention of recolonization of the upper respiratory tract in the future. Intramuscular benzathine penicillin G has been reported to result in a transient elevation of the erythrocyte sedimentation rate, which can prove confusing in the acute phase of the disease.

Following the initial anti-streptococcal therapy, secondary prophylaxis should be initiated to prevent subsequent colonization of the upper respiratory tract with group A streptococci. Recommendations of the American Heart Association and of the World Health Organization are for intramuscular injection of 1.2 million units of benzathine penicillin G every 4 weeks or for oral penicillin V (250 mg twice daily) or oral sulfadiazine (1.0 g daily). Recent studies have shown that in those individuals who are at high risk for recurrence of rheumatic fever, intramuscular benzathine penicillin G given every 3 weeks is more effective in reducing the risk of recurrence. Since it is known that the risk of recurrence of rheumatic fever is highest during the first 5 years after the attack, secondary prophylaxis is always given for at least this period. After that the decision to continue or discontinue secondary prophylaxis is dependent upon whether the patient has documented rheumatic heart disease and whether the patient is at high risk of exposure to streptococci (e.g., students, school teachers, medical and military personnel, etc.). Many believe that those with documented recurrences and/or documented rheumatic valvular heart disease should receive secondary prophylaxis for life. The duration of prophylaxis is often individualized for specific patients.

Medical therapy for the manifestations of rheumatic fever depends on the clinical status of the patient. For adult patients with the arthritis of rheumatic fever, salicylates in doses escalating to 2 g four times daily are very effective and will result in marked clinical improvement, often within 12 h. When this prompt relief does not occur, one should reexamine the original diagnosis. Salicylates may be given for 4 to 6 weeks and gradually tapered so as to prevent a rebound. The erythrocyte sedimentation rate is one method for determining the rate of taper for salicylates. Usually this requires at least 2 weeks. There are no conclusive data to support using nonsteroidal anti-inflammatory drugs for acute rheumatic fever. There is no indication for the use of steroids (usually prednisone) solely for the treatment of the arthritis of rheumatic fever.

Most experienced physicians believe that there is a role for steroids in patients with severe carditis accompanied by congestive heart failure. However, neither salicylates nor glucocorticoids influence the future development of valvular heart disease. In adults, prednisone can be started in doses as high as 30 mg four times daily in especially severe cases, and, as the patient improves, salicylates can be added during the tapering of the steroid dose; this may require 4 to 6 weeks.

In the presence of congestive heart failure, conventional medical measures (Chap. 232) are indicated. In the past, patients with acute rheumatic fever were kept at complete bed rest for months. This is inappropriate unless there is a specific reason such as persistent active carditis or severe heart failure. Patients with arthritis will begin to feel better very soon after anti-inflammatory therapy with salicylates is begun. They may be released from bed rest but should not resume full activity until signs of inflammatory process have abated and the acute-phase reactants have returned to normal.

236. VALVULAR HEART DISEASE - *Eugene Braunwald*

The role of physical examination in the evaluation of patients with valvular disease is also considered in Chap. 225; of electrocardiography inChap. 226; of echocardiography inChap. 227; and of cardiac catheterization and angiography in Chap. 228.

MITRAL STENOSIS

ETIOLOGY AND PATHOLOGY

Two-thirds of all patients with mitral stenosis (MS) are female. MS is generally rheumatic in origin; very rarely, it is congenital. Pure or predominant MS occurs in approximately 40% of all patients with rheumatic heart disease. In others, lesser degrees of MS may accompany mitral regurgitation (MR) and aortic valve lesions. With reductions in the incidence of acute rheumatic fever, particularly in temperate climates and developed nations, the incidence of MS is declining. In rheumatic stenosis the valve leaflets are diffusely thickened by fibrous tissue and/or calcific deposits. The mitral commissures fuse, the chordae tendineae fuse and shorten, the valvular cusps become rigid, and these changes, in turn, lead to narrowing at the apex of the funnel-shaped (fish-mouth) valve. Although the initial insult to the mitral valve is rheumatic, the later changes may be a nonspecific process resulting from trauma to the valve caused by altered flow patterns due to the initial deformity. Calcification of the stenotic mitral valve immobilizes the leaflets and narrows the orifice further. Thrombus formation and arterial embolization may arise from the calcific valve itself, but more frequently arise from the dilated left atrium (LA) in patients with atrial fibrillation (AF).

PATHOPHYSIOLOGY

In normal adults the mitral valve orifice is 4 to 6 cm^2. In the presence of significant obstruction, i.e., when the orifice is less than approximately 2 cm^2, blood can flow from theLA to the left ventricle (LV) only if propelled by an abnormally elevated left atrioventricular pressure gradient (seeFig. 228-2), the hemodynamic hallmark ofMS. When the mitral valve opening is reduced to 1 cm^2, a LA pressure of approximately 25 mmHg is required to maintain a normal cardiac output (CO). The elevated pulmonary venous and pulmonary arterial (PA) wedge pressures reduce pulmonary compliance, contributing to exertional dyspnea. The first bouts of dyspnea are usually precipitated by clinical events that increase the rate of blood flow across the mitral orifice, resulting in further elevation of the LA pressure (see below). To assess the severity of obstruction, both the transvalvular pressure gradient and the flow rate must be measured (Chap. 228). The latter depends not only on the CO but on the heart rate as well. An increase in heart rate shortens diastole proportionately more than systole and diminishes the time available for flow across the mitral valve. Therefore, at any given level of CO, tachycardia augments the transvalvular gradient and elevates further the LA pressure. (Similar considerations apply to the tricuspid valve.)

TheLVdiastolic pressure is normal in isolatedMS; coexisting aortic valve disease, systemic hypertension,MR, ischemic heart disease, and perhaps the residua of damage produced by rheumatic myocarditis are sometimes responsible for elevations that reflect impaired LV function and/or reduced LV compliance. LV dysfunction, as reflected in

reduced LV ejection fraction (EF), occurs in about one-fourth of patients with severe, chronic MS and may be a consequence of prolonged reduction of preload and/or extension of scarring from the valve into the adjacent myocardium. In pure MS and sinus rhythm, the elevatedLA andPA wedge pressures exhibit a prominent atrial contraction (*a* wave) and a gradual pressure decline after mitral valve opening (*y* descent) (seeFig. 228-4). In severe MS and whenever the pulmonary vascular resistance is significantly increased, the pulmonary arterial pressure (PAP) is elevated even when the patient is at rest, and in extreme cases it may approach the systemic arterial pressure. Further elevations of LA, PA wedge, and PAP occur during exercise. When the PA systolic pressure exceeds approximately 50 mmHg in patients with MS, or for that matter with any lesion affecting the left side of the heart, the increased right ventricle (RV) afterload impedes the emptying of this chamber, and the RV end-diastolic pressure and volume usually rise.

Cardiac Output The hemodynamic response to mitral obstruction ranges from a normalCO and a high left atrioventricular pressure gradient to a markedly reduced CO and low transvalvular pressure gradient. In most patients with moderateMS, the CO is normal or almost so at rest but rises subnormally during exertion. In patients with severe MS, particularly those in whom the pulmonary vascular resistance is strikingly elevated, the CO is subnormal at rest and may fail to rise or may even decline during activity.

Pulmonary Hypertension The clinical and hemodynamic features ofMS are influenced importantly by the level of thePAP. Pulmonary hypertension results from (1) passive backward transmission of the elevatedLApressure; (2) pulmonary arteriolar constriction, which presumably is triggered by LA and pulmonary venous hypertension (reactive pulmonary hypertension); (3) interstitial edema in the walls of the small pulmonary vessels; and (4) organic obliterative changes in the pulmonary vascular bed. Severe pulmonary hypertension results in tricuspid regurgitation (TR) and pulmonary incompetence as well as right-sided heart failure. The changes in the pulmonary vascular bed also may be considered to exert a protective effect; the elevated precapillary resistance reduces the likelihood of symptoms of pulmonary congestion by reducing the surge of blood into the pulmonary capillary bed during activity. However, this protection occurs at the expense of a reduced, fixedCO.

SYMPTOMS

In temperate climates the latent period between the initial attack of rheumatic carditis (in the increasingly rare circumstances in which a history of one can be elicited) and the development of symptoms due toMS is generally about two decades; most patients begin to experience disability in the fourth decade. Studies carried out before the development of mitral valvotomy revealed that once a patient with MS became seriously symptomatic, the disease progressed continuously to death within 2 to 5 years. In economically deprived areas, in tropical and subtropical climates, particularly on the Indian subcontinent, in Central America, and in the Middle East, MS tends to progress more rapidly and frequently causes serious symptoms in patients less than the age of 20 years. In contrast, slowly progressive MS in the elderly is being recognized with increasing frequency in the United States and western Europe.

When valvular obstruction is mild, the physical signs ofMS may be present without

symptoms. However, even in patients whose mitral orifices are large enough to accommodate a normal blood flow with only mild elevations ofLApressure, marked elevations of this pressure leading to dyspnea and cough may be precipitated by severe exertion, excitement, fever, severe anemia, paroxysmal tachycardia, sexual intercourse, pregnancy, and thyrotoxicosis. As MS progresses, lesser stresses precipitate dyspnea, and the patient becomes limited in daily activities. The redistribution of blood from the dependent portions of the body to the lungs, which occurs when the recumbent position is assumed, leads to orthopnea and paroxysmal nocturnal dyspnea. *Pulmonary edema* develops when there is a sudden surge in flow across a markedly narrowed mitral orifice. When moderately severe MS has existed for several years, *atrial arrhythmias* -- premature contractions, paroxysmal tachycardia, flutter, andAF -- occur with increasing frequency. The rapid ventricular rate associated with untreated or inadequately treated AF is frequently responsible for acute exacerbations of dyspnea. The development of permanent AF often marks a turning point in the patient's course and is generally associated with acceleration of the rate at which symptoms progress.

Hemoptysis (Chap. 33) results from rupture of pulmonary-bronchial venous connections secondary to pulmonary venous hypertension. It occurs most frequently in patients who have elevatedLApressures without markedly elevated pulmonary vascular resistances and is almost never fatal.

As the severity ofMSprogresses and the pulmonary vascular resistance rises or when tricuspid stenosis (TS) orTRdevelop, symptoms secondary to pulmonary congestion sometimes diminish, and the episodes of acute pulmonary edema and hemoptysis may become reduced in frequency and severity. The elevation of pulmonary vascular resistance further increasesRVsystolic pressure, leading to RV failure, fatigue, abdominal discomfort due to hepatic congestion, and edema.

Recurrent pulmonary emboli (Chap. 261), sometimes with infarction, are an important cause of morbidity and mortality late in the course ofMS. *Pulmonary infections*, i.e., bronchitis, bronchopneumonia, and lobar pneumonia, commonly complicate untreated MS. *Infective endocarditis* (Chap. 126) is rare in pure MS but is not uncommon in patients with combined MS andMR. *Chest pain* occurs in about 10% of patients with severe MS; it may be due to pulmonary hypertension or myocardial ischemia secondary to accompanying coronary atherosclerosis.

Pulmonary Changes In addition to the aforementioned changes in the pulmonary vascular bed, fibrous thickening of the walls of the alveoli and pulmonary capillaries occurs commonly inMS. The vital capacity, total lung capacity, maximal breathing capacity, and oxygen uptake per unit of ventilation are reduced (Chap. 250), and the latter fails to rise normally during exertion. Pulmonary compliance falls further as pulmonary capillary pressure rises during exercise. In some patients, airway resistance is abnormally increased. These alterations in pulmonary mechanics contribute to an increase in the work of breathing and dyspnea. The diffusing capacity may be reduced, particularly during exertion, as a result of structural changes in the diffusing surface and reduction of the pulmonary capillary blood volume. These changes in the lungs are due, in part, to increased transudation of fluid from the pulmonary capillaries into the interstitial and alveolar spaces. However, the increased capacity of the pulmonary lymphatic system to drain excess fluid retards the development of alveolar edema.

Thrombi and Emboli *Thrombi* may form in the left atria, particularly in the enlarged atrial appendages of patients withMS. If they *embolize*, they do so most commonly to the brain, kidneys, spleen, and extremities. Embolization occurs much more frequently in patients withAF or other unstable atrial arrhythmias, in older patients, and in those with a reduced cardiac output. However, systemic embolization may be the presenting complaint in otherwise asymptomatic patients with mild MS. At operation, thrombi are not found more frequently in theLA of patients with a past history of embolization than in those without this complication, indicating that usually the freshly formed clots are the ones that dislodge. Patients who have had one or more systemic emboli have an increased predilection for further embolic episodes. Rarely, a large pedunculated thrombus or a free-floating clot may suddenly obstruct the stenotic mitral orifice. Such "ball valve" thrombi produce syncope, angina, and changing auscultatory signs with alterations in position, findings that resemble those produced by an LA myxoma (Chap. 240).

PHYSICAL FINDINGS (See also Chap. 225)

Inspection and Palpation In patients with severeMS, there may be a malar flush with pinched and blue facies. In patients with sinus rhythm and severe pulmonary hypertension or associatedTS, the jugular venous pulse reveals prominent *a* waves due to vigorous right atrial systole. In patients withAF, the jugular pulse reveals only a single expansion during systole (*c-v* wave). The systemic arterial pressure is usually normal or slightly low. ARV tap along the left sternal border signifies an enlarged RV. A diastolic thrill is frequently present at the cardiac apex, particularly with the patient in the left lateral recumbent position.

Auscultation The first heart sound (S_1) is generally accentuated and snapping, and since the mitral valve does not close until theLVpressure reaches the level of the elevatedLApressure, this sound is often slightly delayed, causing a prolonged Q-S_1interval on the phonocardiogram. The pulmonary component of the second heart sound (P_2) is often accentuated, and the two components of the second heart sound (S_2) are closely split. A pulmonary systolic ejection click may be heard in patients with severe pulmonary hypertension. The opening snap (OS) of the mitral valve is most readily audible in expiration at, or just medial to, the cardiac apex but also may be easily heard along the left sternal edge or at the base of the heart. This sound generally follows the sound of aortic valve closure (A_2) by 0.05 to 0.12 s; that is, it follows P_2. Since the OS occurs when the LV pressure falls below the LA pressure, the time interval between A_2 and OS varies inversely with the severity of theMS. The intensities of the OS and S_1correlate with the mobility of the anterior mitral leaflet.

TheOS is followed by a low-pitched, rumbling, diastolic murmur, heard best at the apex with the patient in the left lateral recumbent position (seeFig. 225-4). It is accentuated by mild exercise (e.g., a few rapid sit-ups) carried out just before auscultation. In general, the duration of this murmur correlates with the severity of the stenosis. In patients with sinus rhythm, the murmur often reappears or becomes reaccentuated during atrial systole, as atrial contraction reelevates the rate of blood flow across the narrowed orifice. Soft (grade I or II/VI) systolic murmurs are commonly heard at the apex or along the left sternal border in patients with pure MSand do not necessarily signify the

presence ofMR. Hepatomegaly, ankle edema, ascites, and pleural effusion, particularly in the right pleural cavity, may occur in patients with MS andRVfailure.

Associated Lesions With severe pulmonary hypertension, a pansystolic murmur produced by functionalTR may be audible along the left sternal border. Characteristically, this murmur is accentuated by inspiration and diminishes during forced expiration (Carvallo's sign) or during performance of the Valsalva maneuver; it should not be confused with the apical pansystolic murmur ofMR.

The recognition of associatedMR is of considerable clinical importance in patients withMS. A presystolic murmur and an accentuated S_1 speak against the presence of serious associated MR, but when the $S_1$and/or theOS are soft or absent in a patient with mitral valve disease who also has an apical systolic murmur, it is likely that significant MR and/or serious calcification of the deformed mitral valve leaflets are present. A third heart sound (S_3) at the apex often signifies that the MR is serious; this sound is generally duller, is lower pitched, and follows the OS. Occasionally, in patients with pure MS, physical signs may falsely suggest MR. ARVS_3 and an enlarged RV that forms the cardiac apex may give the erroneous impression ofLVenlargement. The rumbling diastolic murmur of MS become less prominent or may even disappear and be replaced by the systolic murmur of functionalTR, which is mistaken for MR. WhenCO is markedly reduced in a patient with MS, the typical auscultatory findings, including the diastolic rumbling murmur, may not be detectable (silent MS), but they may reappear as compensation is restored. AssociatedTS also tends to obscure many of the physical signs of MS.

The Graham Steell murmur of pulmonary regurgitation (PR), a high-pitched, diastolic, decrescendo blowing murmur along the left sternal border, results from dilatation of the pulmonary valve ring and occurs in patients with mitral valve disease and severe pulmonary hypertension. This murmur may be indistinguishable from the more common murmur produced by aortic regurgitation (AR), except that it is rarely audible at the second right intercostal space and may disappear after successful surgical treatment of theMS.

LABORATORY EXAMINATION

Electrocardiogram InMS and sinus rhythm, the P wave usually suggestsLAenlargement (see Fig. 226-10). It may become tall and peaked in lead II and upright in lead V_1 when severe pulmonary hypertension orTScomplicates MS and right atrial (RA) enlargement occurs. The QRS complex is usually normal. However, with severe pulmonary hypertension, right axis deviation andRVhypertrophy are often present.

Roentgenogram The earliest changes are straightening of the left border of the cardiac silhouette, prominence of the main pulmonary arteries, dilatation of the upper lobe pulmonary veins, and backward displacement of the esophagus by an enlargedLA. In severeMS, however, all chambers and vessels upstream to the narrowed valve are prominent, including both atria, pulmonary arteries and veins,RV, and superior vena cava. Kerley B lines are fine, dense, opaque, horizontal lines that are most prominent in the lower and midlung fields and that result from distention of interlobular septa and

lymphatics with edema when the resting mean LA pressure exceeds approximately 20 mmHg.

Echocardiogram (See also Chap. 227) This is the most sensitive and specific noninvasive method for diagnosing MS. Transthoracic two-dimensional color flow Doppler echocardiographic imaging and Doppler ultrasound provide critical information, including an estimate of the transvalvular gradient and of mitral orifice size, the presence and severity of accompanying MR, the extent of restriction of valve leaflets, their thickness, and the degree of distortion of the subvalvular apparatus, and the anatomic suitability for balloon mitral valvotomy. In addition, echocardiography provides an assessment of the size of the cardiac chambers, an estimation of the PAP, and an indication of the presence and severity of associated TR and PR. Transesophageal echocardiography provides superior images and should be employed when transthoracic imaging is inadequate for guiding therapy.

DIFFERENTIAL DIAGNOSIS

Significant MR may also be associated with a prominent diastolic murmur at the apex, but this murmur commences slightly later in patients with MR than in patients with MS, and there is often clear-cut evidence of LV enlargement. An apical pansystolic murmur of at least grade III/VI intensity as well as an S_3 should arouse the suspicion of significant associated MR. Similarly, the apical middiastolic murmur associated with AR (Austin Flint murmur) may be mistaken for MS. TS, which occurs rarely in the absence of MS, may mask many of the clinical features of MS. Echocardiography is particularly useful in detecting MS in patients who have or are suspected of having other valve lesions and in defining the severity of the various lesions.

Primary pulmonary hypertension (Chap. 260) results in a number of the clinical and laboratory features of MS. It occurs most frequently in young women. However, the OS and diastolic rumbling murmur are absent, and the pulmonary artery wedge and LA pressures are normal, as is the size of the LA on echocardiography. *Atrial septal defect* (Chap. 234) also may be mistaken for MS; in both conditions there is often clinical, electrocardiographic, and roentgenographic evidence of RV enlargement and accentuation of the pulmonary vascularity. The widely split S_2 of atrial septal defect may be confused with the mitral OS, and the diastolic flow murmur across the tricuspid valve may be mistaken for the mitral diastolic murmur. However, the absence of LA enlargement and of Kerley B lines and the demonstration of fixed splitting of S_2 favor atrial septal defect over MS.

Left atrial myxoma (Chap. 240) may obstruct LA emptying, causing dyspnea, a diastolic murmur, and hemodynamic changes resembling those of MS. However, patients with an LA myxoma often have features suggestive of a systemic disease, such as weight loss, fever, anemia, systemic emboli, and elevated erythrocyte sedimentation rate and serum IgG concentration. Usually an OS is not audible, and the auscultatory findings may change markedly with body position. The diagnosis can be established by the demonstration of a characteristic echo-producing mass in the LA with two-dimensional echocardiography.

CARDIAC CATHETERIZATION AND ANGIOCARDIOGRAPHY

Left heart catheterization is useful for clarifying the picture when there is a discrepancy between clinical and echocardiographic findings (seeFig. 228-2). It is helpful in assessing associated lesions such as aortic stenosis (AS) andAR. Catheterization and coronary arteriography are not usually necessary to aid in the decision about surgery in younger patients with typical findings of severe obstruction on clinical examination and echocardiography. In males over 45 years of age, females over 55 years of age, and younger patients with coronary risk factors, especially those with positive noninvasive stress tests for myocardial ischemia, coronary angiography is usually advisable preoperatively to detect patients with critical coronary obstructions that should be bypassed at the time of operation. Catheterization andLVangiography are also indicated in most patients who have undergone balloon mitral valvotomy or previous mitral valve operations and who have redeveloped serious symptoms.

TREATMENT

In the asymptomatic adolescent with mitral valve disease, penicillin prophylaxis ofb-hemolytic streptococcal infections (Chap. 235) and prophylaxis for infective endocarditis (Chap. 126) are important. In symptomatic patients, some improvement usually occurs with restriction of sodium intake and maintenance doses of oral diuretics. Digitalis glycosides do not alter the hemodynamics and usually do not benefit patients with pureMS and sinus rhythm but are necessary for slowing the ventricular rate of patients withAF. Small doses of beta blockers (e.g., atenolol 25 to 50 mg/d) may be added when cardiac glycosides fail to control ventricular rate in such patients. Anticoagulants should be administered for at least 1 year to patients with MS who have suffered systemic and/or pulmonary embolization and permanently to those with AF.

IfAF is of relatively recent origin in a patient whoseMS is not severe enough to warrant balloon mitral valvotomy or surgical valvotomy, reversion to sinus rhythm pharmacologically or by means of electrical countershock is indicated. Usually this reversion should be undertaken after the patient has had 3 weeks of anticoagulant treatment. Conversion to sinus rhythm is rarely helpful in patients with severe MS, particularly those in whom theLA is especially enlarged or in whom AF has been present for more than 1 year, since sinus rhythm is rarely sustained.

Mitral Valvotomy Unless there is a specific contraindication, mitral valvotomy is indicated in the symptomatic patient with isolatedMS whose effective orifice is less than approximately 1.0 cm^2/m^2body surface area, or <1.6 cm^2 in normal-sized adults. Mitral valvotomy can be carried out by two techniques: percutaneous balloon mitral valvotomy and surgical valvotomy. In balloon mitral valvotomy (Figs. 236-1 and236-2), a catheter is directed into theLA after transseptal puncture and a balloon (Inoue balloon) is directed across the valve and inflated in the valvular orifice. This has become the procedure of choice for patients with uncomplicated MS.

An "open" valvotomy with cardiopulmonary bypass is usually preferable to closed valvotomy. In addition to opening the valve commissures, it is important to loosen any subvalvular fusion of papillary muscles and chordae tendineae and to remove large deposits of calcium, thereby improving valvular function, as well as to remove atrial thrombi.

Valvotomy, whichever technique is used, usually results in striking symptomatic and hemodynamic improvement and prolongs survival. In uncomplicated cases, the mortality rate is<2%. However, there is no evidence that the procedure improves the prognosis of patients with slight or no functional impairment unless they develop severe pulmonary hypertension on exertion. Therefore, unless recurrent systemic embolization has occurred, valvotomy is *not* recommended for patients who are entirely asymptomatic, regardless of hemodynamic findings. When there is little symptomatic improvement after valvotomy, it is likely that the procedure was ineffective, that it inducedMR, or that associated valvular or myocardial disease was present. The recurrence of symptoms several years after what appeared to be a satisfactory initial result is usually due to an inadequate valvotomy, but progression of other valvular lesions, mitral restenosis, or some combination of these conditions also may be responsible. About half of all patients undergoing mitral valvotomy require reoperation by 10 years. In the pregnant patient withMS, valvotomy should be carried out if pulmonary congestion occurs despite intensive medical treatment.

In patients withMS and significant associatedMR, those in whom the valve has been severely distorted by previous transcatheter or operative manipulation, or those in whom the surgeon does not find it possible to improve valve function significantly, mitral valve replacement (MVR) may have to be carried out. Since the operative mortality rate of isolated MVR is still approximately 6% (Table 236-1), and since there are long-term complications of valve replacement, patients in whom preoperative evaluation suggests the possibility that MVR may be required should be operated on only if they have critical MS, i.e., an orifice <0.6 cm^2/m^2body surface area and are in New York Heart Association class III, i.e., symptomatic with ordinary activity, despite optimal medical therapy. The overall 10-year survival of surgical survivors is approximately 70%. Long-term prognosis is worse in older patients and those with marked disability and striking depression of the cardiac index preoperatively.

MITRAL REGURGITATION

ETIOLOGY

Chronic rheumatic heart disease is the cause of severeMR in about one-third of cases. In contrast toMS, rheumatic MR occurs more frequently in males. The rheumatic process produces rigidity, deformity, and retraction of the valve cusps and commissural fusion, as well as shortening, contraction, and fusion of the chordae tendineae. Mitral valve prolapse (MVP), an important cause of MR, is considered in the next section. MR also may occur as a congenital anomaly (Chap. 234), most commonly as a defect of the endocardial cushions (atrioventricular cushion defects). MR may occur with fibrosis of a papillary muscle in patients with healed myocardial infarction as well as in patients with infarction involving the base of a papillary muscle. Transient MR also may occur during periods of ischemia involving a papillary muscle or the adjacent myocardium and may accompany bouts of angina pectoris. MR may occur with markedLVenlargement of any cause in which dilatation of the mitral annulus and lateral displacement of the papillary muscles interfere with coaptation of the valve leaflets. In hypertrophic cardiomyopathy, the anterior leaflet of the mitral valve is displaced anteriorly during systole, leading to regurgitation (Chap. 238). Calcification of the mitral annulus of unknown cause,

presumably degenerative, which occurs most commonly in elderly women, also can be responsible for significant MR. Acute MR may occur secondary to infective endocarditis involving the valve or chordae tendineae, in acute myocardial infarction with rupture of a papillary muscle or one of its heads, as a consequence of trauma, or after chordal rupture.

Regardless of cause, severeMR is often progressive, since enlargement of theLAplaces tension on the posterior mitral leaflet, pulling it away from the mitral orifice and thereby aggravating the valvular dysfunction. Similarly, the dilatation of theLVincreases the regurgitation, which in turn enlarges the LA and LV further, causing chordal rupture and resulting in a vicious circle; hence the aphorism, "mitral regurgitation begets mitral regurgitation."

PATHOPHYSIOLOGY

The resistance toLVemptying is reduced in patients withMR. As a consequence, the LV is decompressed into theLAduring ejection, and with the reduction in LV size there is a rapid decline in LV tension. The initial compensation to acute MR is more complete LV emptying. However, LV volume increases progressively as the severity of the regurgitation increases and as LV function deteriorates. This increase in LV volume is often accompanied by a depressed forwardCO. The regurgitant volume varies directly with the LV systolic pressure and the size of the regurgitant orifice; the latter, in turn, is influenced profoundly by the extent of LV dilatation.

The *v* wave in the LApressure pulse is usually prominent (seeFig. 228-3). During early diastole, as the distended LA empties, there is a particularly rapid *y* descent (as long as there is no associatedMS). In chronicMR, there is often an increase inLVcompliance, so that LV volume rises with little elevation in LV diastolic pressure. The effective (forward)CO is usually reduced in seriously symptomatic patients. A brief, early diastolic atrioventricular pressure gradient may occur in patients with pure MR as a result of the very rapid flow of blood across a normal-sized mitral orifice.

The prompt appearance of contrast material in theLA after its injection into theLVsignifies the presence ofMR. The regurgitant volume can be measured by determining the difference between the total LV stroke volume, estimated angiocardiographically, and the effective forward stroke volume determined by the Fick method (Chap. 228). In severe cases, as much as 50% of the total LV stroke volume regurgitates with each beat. Qualitative, but clinically useful, estimates of the severity of regurgitation may be made by observation on cineangiograms of the degree of LA opacification after the injection of contrast material into the LV. Color flow Doppler imaging is most commonly used for this purpose (see below).

The compliance, i.e., the pressure-volume relationship, of theLA and pulmonary venous bed affects the clinical picture. Patients with acuteMRusually have *normal or reduced compliance*, little enlargement of the LA, but marked elevation of the LA pressure, particularly of the *v* wave. Pulmonary edema is common. Patients with a *marked increase in LA compliance* are at the opposite end of the spectrum, having long-standing, severe MR, marked enlargement of the LA, and normal or only slightly elevated LA and PApressures. These patients usually complain of severe fatigue and

exhaustion secondary to a lowCO, while symptoms resulting from pulmonary congestion are less prominent;AF is almost invariably present. Most common are patients whose clinical and hemodynamic features are between those in the two aforementioned groups, with variable degrees of enlargement of the LA and with significant elevation of the LA pressure. Symptoms are secondary to a combination of reduced forward CO and pulmonary congestion.

SYMPTOMS

Fatigue, exertional dyspnea, and orthopnea are the most prominent complaints in patients with chronic, severeMR. Systemic embolism occurs less frequently than inMS. Right-sided heart failure, with painful hepatic congestion, ankle edema, distended neck veins, ascites, andTR, occurs in patients with MR who have associated pulmonary vascular disease and marked pulmonary hypertension. In patients with acute, severe MR,LVfailure with acute pulmonary edema is common.

PHYSICAL FINDINGS

The arterial pressure is usually normal, and in patients with severeMR the arterial pulse may show a sharp upstroke. The jugular venous pulse shows abnormally prominent *a* waves in patients with sinus rhythm and marked pulmonary hypertension and prominent *v* waves in those with accompanying severeTR. A systolic thrill is often palpable at the cardiac apex, theLV is hyperdynamic with a brisk systolic impulse and a palpable rapid-filling wave, and the apex beat is often displaced laterally. AnRV tap and the shock of pulmonary valve closure may be palpable in patients with marked pulmonary hypertension.

Auscultation The $S_1$is generally absent, soft, or buried in the systolic murmur; indeed, an accentuated mitral closure sound is useful in excluding severeMR. In patients with severe MR, the aortic valve may close prematurely, resulting in wide splitting of the S_2. AnOSindicates associatedMS but does not exclude predominant regurgitation. A low-pitched S_3occurring 0.12 to 0.17 s after the aortic valve closure sound, i.e., at the completion of the rapid-filling phase of theLV, is believed to be caused by the sudden tensing of the papillary muscles, chordae tendineae, and valve leaflets and is an important auscultatory feature of severe MR. The absence of an S_3indicates that if MR exists, it may not be severe. The S_3 may be followed by a short, rumbling, diastolic murmur, even in the absence of MS. A fourth heart sound (S_4) is often audible in patients with acute, severe MR of recent onset who are in sinus rhythm. A presystolic murmur is not ordinarily heard with isolated MR but is present in patients with sinus rhythm and associated MS.

A systolic murmur of at least grade III/VI intensity, is the most characteristic auscultatory finding in severeMR. It is usually holosystolic (see Fig. 225-4), but it may be decrescendo and cease in late systole in patients with acute, severe MR when the tall *v* wave in the LApressure pulse reduces the late systolicLV-LA (reverse) pressure gradient. In MR due to papillary muscle dysfunction orMVP, the systolic murmur commences in midsystole (see below). The systolic murmur is usually most prominent at the apex and radiates into the axilla. However, in patients with ruptured chordae tendineae or primary involvement of the posterior mitral leaflet, the regurgitant jet strikes

the LA wall adjacent to the aortic root. In this situation, the systolic murmur is transmitted to the base of the heart and therefore may be confused with the murmur ofAS. In patients with ruptured chordae tendineae the systolic murmur may have a cooing or "sea gull" quality, while a flail leaflet may cause a murmur with a musical quality. The systolic murmur of MR is intensified by isometric strain but is reduced during the Valsalva maneuver.

LABORATORY EXAMINATION

Electrocardiogram In patients with sinus rhythm there is evidence ofLAenlargement, butRAenlargement also may be present when pulmonary hypertension is severe. Chronic, severeMR is generally associated withAF. In many patients there is no clear-cut electrocardiographic evidence of enlargement of either ventricle. In others the signs ofLVhypertrophy are present.

Roentgenogram The LAand LVare the dominant chambers; in chronic cases, the former may be massively enlarged and forms the right border of the cardiac silhouette. Pulmonary venous congestion, interstitial edema, and Kerley B lines are sometimes noted. Marked calcification of the mitral leaflets occurs commonly in patients with long-standing combinedMR andMS. Calcification of the mitral annulus may be visualized.

Echocardiogram Color flow Doppler imaging is the most accurate noninvasive technique for the detection and estimation ofMR. Two-dimensional echocardiography is useful for assessingLVfunction from end systolic and end-diastolic volumes andEF. TheLA is usually enlarged and/or exhibits increased pulsations; the LV may be hyperdynamic. Findings that help to determine the etiology of MR can often be identified by two-dimensional echocardiography. Transesophageal imaging provides greater detail than transthoracic imaging. With ruptured chordae tendineae or a flail leaflet, coarse, errative motion of the involved leaflets may be noted. Vegetations associated with infective endocarditis, incomplete coaptation of the anterior and posterior mitral leaflets, and annular calcification, as well as MR secondary to LV dilatation, aneurysm, or dyskinesis may be recognized. The echocardiogram in patients withMVP is described in the next section.

TREATMENT

Medical The nonsurgical management of patients with severeMRbegins with restricting those physical activities that regularly produce dyspnea and excessive fatigue, reducing sodium intake, and enhancing sodium excretion with the appropriate use of diuretics (Chap. 232). Vasodilators and digitalis glycosides increase the forward output of the failingLV. Intravenous nitroprusside or nitroglycerin to reduce afterload and thereby the volume of regurgitant flow are useful in stabilizing patients with acute and/or severe MR. Angiotensin-converting enzyme inhibitors are useful in the treatment of chronic MR. The same considerations as in patients withMS apply to the reversion ofAF to sinus rhythm. In the late stages of heart failure anticoagulants and leg binders are used to diminish the likelihood of venous thrombi and pulmonary emboli.

Surgical In the selection of patients with severeMR for surgical treatment, the chronic,

often slowly progressive nature of the condition must be balanced against the immediate and long-term risks associated with valve reconstruction or replacement. Patients with MR who are asymptomatic or who are limited only during strenuous exertion are not considered to be candidates for surgical treatment, since their condition may remain stable for many years. By contrast, unless there are contraindications, surgical treatment should be offered to patients with severe MR whose limitations do not allow full time employment or the performance of normal household activities despite optimal medical management. Surgical treatment of severe MR is indicated even for asymptomatic patients or those with mild symptoms whenLVdysfunction is progressive, with LV ejection fraction declining below 60% and/or end-systolic cavity dimension on echocardiography rising above 50 mm. In patients with impaired LV function, the risk of surgery rises sharply, the recovery of LV performance is incomplete, and the long-term survival is reduced (Fig. 236-3). However, conservative management has little to offer these patients, so operative treatment may be indicated even at an advanced stage of the disease; and occasionally, the clinical and hemodynamic improvement that follows surgical treatment of patients with advanced disease is dramatic. Though most patients who survive surgery appear to be greatly improved, some degree of myocardial dysfunction may persist.

When surgical treatment is contemplated, left-sided heart catheterization and angiocardiography may be helpful in confirming the presence of severeMR in patients in whom there is a discrepancy between the clinical picture and the echocardiographic findings; these procedures may also aid in detecting and assessing the severity of associated valve lesions. Importantly, coronary arteriography identifies patients who require concomitant coronary revascularization.

Surgical treatment ofMR, especially that caused by valves that are markedly deformed, with shrunken, calcified leaflets secondary to rheumatic fever, requiresMVR with a prosthesis. However, in an increasing fraction of patients, particularly those with severe annular dilatation, flail leaflets,MVP, ruptured chordae, or infective endocarditis, reconstruction of the mitral valve apparatus (mitral valvuloplasty) and/or mitral annuloplasty with an annuloplasty ring may be successful. Valve reconstruction should be carried out whenever feasible since the operative risk is about half (~3%) of that associated with MVR (Table 236-1). Also, reconstruction spares the patient the long-term adverse consequences of valve replacement (i.e., thromboembolic and hemorrhagic complications in the case of mechanical prostheses and late valve failure necessitating repeat valve replacement in the case of bioprostheses). In addition, by preserving the integrity of the papillary muscles and subvalvular apparatus, mitral valvuloplasty maintainsLVfunction.

MITRAL VALVE PROLAPSE

MVP, also variously termed the *systolic click-murmur syndrome*, *Barlow's syndrome*, *floppy-valve syndrome*, and *billowing mitral leaflet syndrome*, is a relatively common, but highly variable, clinical syndrome resulting from diverse pathogenic mechanisms of the mitral valve apparatus. Among these are excessive or redundant mitral leaflet tissue, which is commonly involved with myxomatous degeneration and greatly increased concentration of acid mucopolysaccharide. It is a frequent finding in patients with heritable disorders of connective tissue, including the Marfan syndrome (Chap.

351), osteogenesis imperfecta, and the Ehler-Danlos syndrome. In most patients with MVP, however, myxomatous degeneration is confined to the mitral (or less commonly the tricuspid or aortic) valves without other clinical or pathologic manifestations of disease; the posterior leaflet is usually more affected than the anterior, and the mitral valve annulus is often greatly dilated. In many patients, elongated redundant chordae tendineae cause or contribute to the regurgitation.

In most patients withMVP, the cause is unknown, but in some it appears to be a genetically determined collagen tissue disorder. A reduction in the production of type III collagen has been incriminated, and electron microscopy has revealed fragmentation of collagen fibrils. MVP may be associated with thoracic skeletal deformities similar to but not as severe as those in the Marfan syndrome, including a high arched palate and alterations of the chest and thoracic spine, including the so-called straight back syndrome. MVP also may occur as a sequel of acute rheumatic fever, in ischemic heart disease, and in cardiomyopathies, as well as in 20% of patients with ostium secundum atrial septal defect.

MVPmay lead to excessive stress on the papillary muscles, which in turn leads to dysfunction and ischemia of the papillary muscles and subjacent ventricular myocardium; rupture of chordae tendineae and progressive annular dilatation and calcification also contribute to valvular regurgitation, which then places more stress on the diseased mitral valve apparatus, thereby creating a vicious cycle. The electrocardiographic changes (see below) and ventricular arrhythmias appear to result from regional ventricular dysfunction related to increased stress placed on the papillary muscles.

CLINICAL FEATURES

MVPis more common in females. It affects individuals in a wide age range but most commonly between the ages of 14 and 30 years. The clinical course is often benign. MVP may also be observed in older (>50 years) patients, often males, and in themMR is more often severe and requires surgical treatment. There is an increased familial incidence for some patients, suggesting an autosomal dominant form of inheritance. MVP encompasses a broad spectrum of severities in patients, ranging from only a systolic click and murmur and mild prolapse of the posterior leaflet of the mitral valve to severe MR due to chordal rupture and massive prolapse of both leaflets. In many patients, this condition progresses over years or decades.

Most patients are asymptomatic and remain so for their entire lives. However,MVP is now the most common cause of isolated severeMRrequiring surgical treatment in North America. Arrhythmias, most commonly ventricular premature contractions and paroxysmal supraventricular and ventricular tachycardia, have been reported and may cause palpitations, light-headedness, and syncope. Sudden death has been noted but is a very rare complication. Many patients have chest pain that is difficult to evaluate. It is often substernal, prolonged, poorly related to exertion, and rarely resembles typical angina pectoris. Transient cerebral ischemic attacks secondary to emboli from the mitral valve due to endothelial disruption have been reported. Infective endocarditis may occur in patients with MR associated with MVP.

Auscultation The most important finding is the mid- or late (nonejection) systolic click, which occurs 0.14 s or more after the S_1 and is thought to be generated by the sudden tensing of slack, elongated chordae tendineae or by the prolapsing mitral leaflet when it reaches its maximum excursion. Systolic clicks may be multiple and may be followed by a high-pitched, late systolic crescendo-decrescendo murmur, which occasionally is "whooping" or "honking," and is heard best at the apex. The click and murmur occur earlier with standing, during the strain of the Valsalva maneuver, and any intervention that decreasesLVvolume, exaggerating the propensity of mitral leaflet prolapse. Conversely, squatting and isometric exercise, which increase LV volume, diminish mitral prolapse, and the click-murmur complex is delayed and may even disappear. Some patients have a midsystolic click without the murmur; others have the murmur without a click. Still others have both sounds at different times.

LABORATORY EXAMINATION

The *electrocardiogram* most commonly is normal but may show biphasic or inverted T waves in leads II, III, and aVF, and occasionally supraventricular or ventricular premature contractions. *Two-dimensional echocardiography* is particularly effective in identifying the abnormal position and prolapse of the mitral valve leaflets; a useful echocardiographic definition ofMVP is systolic displacement (in the parasternal view) of the mitral valve leaflets by at least 2 mm into theLAsuperior to the plane of the mitral annulus. Thickening of the mitral valve leaflets identifies a subgroup of patients at higher risk of infective endocarditis and the development of severeMR. Prolapse of the tricuspid and/or aortic valve may be found. *Color-imaging* and *Doppler studies* are helpful in revealing and evaluating accompanying MR. *Angiocardiography* generally shows prolapse of the posterior and sometimes of both mitral valve leaflets.

TREATMENT

The management of patients withMVPconsists of reassurance of the asymptomatic patient without severeMR or arrhythmias and the prevention of infective endocarditis with antibiotic prophylaxis in patients with a systolic murmur and/or thickening of mitral valve leaflets on endocardiography. Beta blockers have been found to relieve chest pain. If symptomatic tachyarrhythmias have occurred, antiarrhythmic agents as dictated by electrophysiologic studies should be administered. If the patient is symptomatic from severe MR, mitral valve repair (or rarely, replacement) is indicated. Antiplatelet aggregation agents such as aspirin should be given to patients with transient ischemic attacks, and if these are not effective, anticoagulants should be used.

AORTIC STENOSIS

ASoccurs in about one-fourth of all patients with chronic valvular heart disease; approximately 80% of adult patients with symptomatic valvular AS are male.

ETIOLOGY

ASin adults may be congenital in origin, it may be secondary to rheumatic inflammation of the aortic valve, or it may be due to degenerative calcification of the aortic cusps of unknown cause. The *congenitally affected valve* may already be stenotic at birth (Chap.

234) and may become progressively more fibrotic, calcified, and stenotic. In other cases the valve may be congenitally deformed, usually bicuspid, without serious narrowing of the aortic orifice during childhood; its abnormal architecture makes its leaflets susceptible to otherwise ordinary hemodynamic stresses, which ultimately lead to valvular thickening, calcification, increased rigidity, and narrowing of the aortic orifice.

Rheumatic endocarditis of the aortic leaflets produces commissural fusion, sometimes resulting in a bicuspid valve. This condition in turn, makes the leaflets more susceptible to trauma and ultimately leads to fibrosis, calcification, and further narrowing. By the time the obstruction toLVoutflow causes serious clinical disability, the valve is usually a rigid calcified mass, and careful examination may make it difficult or even impossible to determine the etiology of the underlying process. RheumaticAS is almost always associated with rheumatic involvement of the mitral valve. A rheumatic etiology is favored by a history of active rheumatic fever and by associated severeAR.

*Age-related degenerative calcific**AS*(also known as senile or sclerocalcific AS) is now the most common cause of AS in adults in North America and Western Europe. About 30% of persons>65 years exhibit aortic valve sclerosis, many of whom have a systolic murmur of AS but without obstruction, while an additional 2% exhibit frank stenosis.

OTHER FORMS OF OBSTRUCTION TO LEFT VENTRICULAR OUTFLOW

Besides valvularAS, three other lesions may be responsible for obstruction toLVoutflow.

1. *Hypertrophic cardiomyopathy* (Chap. 238). This condition is characterized by marked hypertrophy of theLV and involves in particular the interventricular septum; it may cause subaortic obstruction.

2. *Discrete congenital subvalvular**AS*(Chap. 234). This congenital anomaly is produced by either a membranous diaphragm or a fibrous ridge just below the aortic valve.

3. *Supravalvular**AS*(Chap. 234). This uncommon congenital anomaly is produced by narrowing of the ascending aorta or by a fibrous diaphragm with a small opening just above the aortic valve.

PATHOPHYSIOLOGY

The obstruction toLVoutflow produces a systolic pressure gradient between the LV and aorta. When severe obstruction is suddenly produced experimentally, the LV responds by dilatation and reduction of stroke volume. However, in patients the obstruction may be present at birth and/or increases gradually over the course of many years, and LV output is maintained by the presence of concentric LV hypertrophy. This serves as a useful compensatory mechanism because it reduces toward normal the systolic stress developed by the myocardium. A large transaortic valvular pressure gradient may exist for many years without a reduction ofCO or LV dilatation; ultimately, however, these changes occur.

A peak systolic pressure gradient>50 mmHg in the face of a normal cardiac output or an effective aortic orifice less than approximately 0.5 cm^2/m^2body surface area, i.e., less

than approximately one-third of the normal orifice, is generally considered to represent critical obstruction toLVoutflow. The elevated LV end-diastolic pressure observed in many patients with severeASsignifies the presence of LV dilatation and/or diminished compliance of the hypertrophied LV wall. A large *a* wave in theLApressure pulse is usually present. Loss of an appropriately timed, vigorous atrial contraction, as occurs inAF or atrioventricular dissociation, may result in a rapid aggravation of symptoms. Although theCO at rest is within normal limits in most patients with severe AS, it usually fails to rise normally during exercise. Late in the course the CO and LV-aortic pressure gradient decline, and the mean LA,PA, andRVpressures rise.

The hypertrophiedLVmuscle mass elevates myocardial oxygen requirements. In addition, even in the absence of obstructive coronary artery disease, there may be interference with coronary blood flow, because the pressure compressing the coronary arteries exceeds the coronary perfusion pressure, often causing ischemia, especially in the subendocardium and during tachycardia both in the presence and in the absence of coronary arterial narrowing.

A significant fraction of patients with rheumaticAS has associated mitral valve disease. AS intensifies the severity of accompanyingMR by increasing the pressure driving blood from theLV to theLA.

SYMPTOMS

ASis rarely of hemodynamic or clinical importance until the valve orifice has narrowed to approximately 0.5 cm^2/m^2body surface area in adults. Even critical AS may exist for many years without producing any symptoms because of the ability of the hypertrophiedLV to generate the elevated intraventricular pressures required for a normal stroke volume.

Most patients with pure or predominantAS have gradually increasing obstruction for years but do not become symptomatic until the sixth to eighth decades. Exertional dyspnea, angina pectoris, and syncope are the three cardinal symptoms. Often there is a history of insidious progression of fatigue and dyspnea associated with gradual curtailment of activities. *Dyspnea* results primarily from elevation of the pulmonary capillary pressure caused by elevations ofLA andLVdiastolic pressures secondary to reduced compliance and/or LV dilatation. *Angina pectoris* usually develops somewhat later and reflects an imbalance between the augmented myocardial oxygen requirements and reduced oxygen availability; the former results from the increased myocardial mass and intraventricular pressure, while the latter may result from accompanying coronary artery disease, which is not uncommon in patients with AS, as well as from compression of the coronary vessels by the hypertrophied myocardium. Therefore, angina may occur in severe AS even without obstructive epicardial coronary artery disease. *Exertional syncope* may result from a decline in arterial pressure caused by vasodilatation in the exercising muscles and inadequate vasoconstriction in nonexercising muscles in the face of a fixedCO or from a sudden fall in CO produced by an arrhythmia.

Since theCO at rest is usually well maintained until late in the course, marked fatigability, weakness, peripheral cyanosis, and other clinical manifestations of a low CO

are usually not prominent until this stage is reached. Orthopnea, paroxysmal nocturnal dyspnea, and pulmonary edema, i.e., symptoms of LV failure, also occur only in the advanced stages of the disease. Severe pulmonary hypertension leading to RV failure and systemic venous hypertension, hepatomegaly, AF, and TR are usually late findings in patients with isolated, severe AS.

When AS and MS coexist, the reduction of cardiac output induced by MS lowers the pressure gradient across the aortic valve and thereby masks many of the clinical findings produced by AS. Left heart catheterization is helpful in defining the relative importance of each valvular abnormality.

PHYSICAL FINDINGS

The rhythm is generally regular until very late in the course; at other times, AF should suggest the possibility of associated mitral valve disease. The systemic arterial pressure is usually within normal limits. In the late stages, however, when stroke volume declines, the systolic pressure may fall and the pulse pressure narrow. Systemic hypertension is unusual in patients with marked AS, and a basal systolic arterial pressure >200 mmHg essentially excludes severe narrowing of this valve. The peripheral arterial pulse, as palpated in the carotid or brachial arteries, rises slowly to a delayed sustained peak (pulsus parvus et tardus) (see Fig. 225-2*B*). In the elderly, the stiffening of the arterial wall may mask this important physical sign. A palpable double systolic arterial pulse, the so-called bisferiens pulse, excludes pure or predominant AS and signifies dominant AR. In the late stages of AS, when the pulse pressure is reduced, the pulse amplitude may be so small that the anacrotic nature of the pulse and the delay in its upstroke may become difficult to appreciate. In many patients the *a* wave in the jugular venous pulse is accentuated. This results from the diminished distensibility of the RV cavity caused by the bulging, hypertrophied interventricular septum.

The LV impulse is usually active and displaced laterally, reflecting the presence of LV hypertrophy. A double apical impulse may be recognized, particularly with the patient in the left lateral recumbent position. A systolic thrill is generally present at the base of the heart, in the jugular notch, and along the carotid arteries. In patients who do not have marked pulmonary emphysema, a thick chest wall, thoracic deformity, or heart failure, the absence of a systolic thrill suggests that the AS is relatively mild.

Auscultation An early systolic ejection sound, actually the OS of the aortic valve, is frequently audible in children and adolescents with congenital noncalcific valvular AS. This sound usually disappears when the valve becomes calcified and rigid. As AS increases in severity, LV systole may become prolonged so that the aortic valve closure sound no longer precedes the pulmonic valve closure sound, and the two components may become synchronous, or aortic valve closure may even follow pulmonic valve closure, causing paradoxic splitting of the S_2 (Chap. 225). The sound of aortic valve closure can be heard most frequently in patients with AS who have pliable valves, and calcification diminishes the intensity of this sound. Frequently, an S_4 is audible at the apex and reflects the presence of LV hypertrophy and an elevated LV end-diastolic pressure; an S_3 generally occurs when the LV dilates.

The murmur of AS is characteristically an ejection (mid) systolic murmur that

commences shortly after the S_1, increases in intensity to reach a peak toward the middle of ejection, and ends just before aortic valve closure (seeFig. 225-4). It is characteristically low-pitched, rough, and rasping in character, loudest at the base of the heart, most commonly in the second right intercostal space. It is transmitted upward along the carotid arteries. Occasionally, it is transmitted downward and to the apex where it may be confused with the systolic murmur ofMR; the latter, however, is usually holosystolic. In almost all patients with severe obstruction, the murmur is at least grade III/VI. In patients with mild degrees of obstruction or in those with severe stenosis with heart failure in whom the stroke volume and therefore the transvalvular flow rate are reduced, the murmur may be relatively soft and brief.

LABORATORY EXAMINATION

Electrocardiogram The main finding in most patients with severeAS isLVhypertrophy (see Fig. 226-10). In advanced cases, ST-segment depression and T-wave inversion (LV "strain") in standard leads I and aVL and in the left precordial leads are evident. However, there is no close correlation between the electrocardiogram and the hemodynamic severity of obstruction, and the absence of electrocardiographic signs of LV hypertrophy does not exclude severe obstruction. The presence ofLAenlargement should suggest the possibility of associated mitral valve disease.

Roentgenogram The chest roentgenogram may show no or little overall cardiac enlargement for many years, since the development of concentricLVhypertrophy is the initial response to obstruction to LV outflow. Hypertrophy without dilatation may produce some rounding of the cardiac apex in the frontal projection and slight backward displacement in the lateral view; criticalAS is often associated with poststenotic dilatation of the ascending aorta. Aortic calcification is usually readily apparent on fluoroscopic examination or by echocardiography; *the absence of valvular calcification in an adult suggests that severe valvular AS is not present*. In later stages of the disease as the LV dilates, there is increasing roentgenographic evidence of LV enlargement; pulmonary congestion; and enlargement of theLA,PA, and right side of the heart.

Echocardiogram The key findings areLVhypertrophy and, in patients with valvular calcification (i.e., most adult patients with symptomaticAS), multiple, bright, thick, echoes from within the aortic root. Eccentricity of the aortic valve cusps is characteristic of congenitally bicuspid valves (Plate I-3). Transesophageal imaging displays the obstructed orifice extremely well. LV dilatation and reduced systolic shortening reflect impairment of LV function. The transaortic valvular gradient can be estimated by Doppler echocardiography. Echocardiography is particularly useful for identifying valvular abnormalities such asMS andAR, which sometimes accompany AS, and for differentiating valvular AS from obstructive hypertrophic cardiomyopathy.

Catheterization Catheterization of the left side of the heart and coronary arteriography should generally be carried out in patients suspected of having severeAS who are being considered for operative treatment. These investigations are especially indicated in the following:

1. Patients with clinical signs ofAS and symptoms of myocardial ischemia, in whom associated coronary artery disease is suspected. An effort should be made to determine

whether AS or coronary atherosclerosis is primarily responsible for the symptoms, and coronary arteriography should be carried out in an effort to identify patients who require coronary bypass grafting at the time of aortic valve surgery.

2. Patients with multivalvular disease, in whom the role played by each valvular deformity should be defined to aid in the planning of definitive operative treatment.

3. Young, asymptomatic patients with noncalcific congenital AS, to define the severity of obstruction toLVoutflow, since operation [which does not usually require aortic valve replacement (AVR)] or balloon valvotomy may be indicated for them if severeAS is present, even in the absence of symptoms. Balloon valvotomy may follow left heart catheterization immediately.

4. Patients in whom it is suspected that the obstruction toLVoutflow may not be at the aortic valve but rather in the sub- or supravalvular regions.

NATURAL HISTORY

Death in patients with severeASoccurs most commonly in the seventh and eighth decades. Based on data obtained at postmortem examination in patients not treated surgically, the average time to death after the onset of various symptoms was as follows: angina pectoris, 3 years; syncope, 3 years; dyspnea, 2 years; and congestive heart failure, 1.5 to 2 years. Moreover, in >80% of patients who died with AS, symptoms had existed for <4 years. Congestive heart failure was considered to be the cause of death in one-half to two-thirds of patients. Among adults dying with valvular AS, sudden death, which presumably results from an arrhythmia, occurred in 10 to 20% and at an average age of 60 years. However, most sudden deaths occur in patients who had previously been symptomatic.

TREATMENT

All patients with moderate or severeASrequire careful periodic follow-up. In patients with severe AS, strenuous physical activity should be avoided even in the asymptomatic stage. Digitalis glycosides, sodium restriction, and the cautious administration of diuretics are indicated in the treatment of congestive heart failure, but care must be taken to avoid volume depletion since this may cause a marked reduction ofCO. While nitroglycerin is helpful in relieving angina pectoris, vasodilator therapy for heart failure is usually of little value and may, in fact, be harmful.

Surgical Treatment The most critical decision in the management ofASconcerns the advisability of surgical treatment which, in most adults with calcific AS and critical obstruction (aortic orifice<0.5 cm^2/m^2body surface area), consists ofAVR. In most instances, it is prudent to postpone operation in patients with severe calcific AS who are asymptomatic (unless they exhibitLVdysfunction), since their future course is difficult to predict and they may continue to do well for many years. However, they should be followed carefully by clinical examination for the development of symptoms and by serial echocardiograms for evidence of deteriorating LV function. Operation is generally indicated in patients with severe AS who are asymptomatic, irrespective of their LV function, as well as those who exhibit LV dysfunction, even if they are asymptomatic. In

patients without heart failure, the operative risk of AVR is approximately 4% (Table 236-1).

When angina pectoris, syncope, orLVdecompensation develops in adults with severe valvularAS, the outlook, despite medical treatment, is very poor and can be improved significantly byAVR. The operative risk is considerably lower than the risk of nonoperative treatment; moreover, the symptomatic improvement in some survivors of operation has been remarkable. Regression of LV hypertrophy may occur after relief of obstruction.

Operation should, if possible, be carried out before frankLVfailure develops; at this late stage, the operative risk is high (15 to 20%), and evidence of myocardial disease may persist even when the operation is technically successful. Furthermore, long-term postoperative survival also correlates inversely with preoperative LV dysfunction. Nonetheless, in view of the very poor prognosis of such patients when they are treated medically, there is usually little choice but to advise surgical treatment. In patients in whom severeAS and coronary artery disease coexist, relief of the AS and revascularization of the myocardium by means of aortocoronary bypass grafting may result in striking clinical and hemodynamic improvement.

Because many patients with calcificAS are elderly, particular attention must be directed to the adequacy of hepatic, renal, and pulmonary function beforeAVR is recommended. The mortality rate depends to a substantial extent on the patient's preoperative clinical and hemodynamic state. The 10-year survival rate of patients with AVR is approximately 60%. Approximately 30% of bioprosthetic valves evidence primary valve failure in 10 years, requiring re-replacement, and an approximately equal percentage of patients with mechanical prostheses develop significant hemorrhagic complications as a consequence of treatment with anticoagulants.

Percutaneous Balloon Aortic Valvuloplasty This procedure is preferable to operation in children and young adults with congenital, noncalcificAS. It is not commonly used in elderly patients with severe calcific AS because of a high restenosis rate. Nonetheless, this procedure has been used successfully in patients who are too ill or frail to undergo operation, in patients with life-threatening AS and advanced extracardiac disease, and as a "bridge to operation" in patients with severeLVdysfunction.

AORTIC REGURGITATION

ETIOLOGY

ARmay be caused by primary valve disease or by primary aortic root disease.

Primary Valve Disease Approximately three-fourths of patients with pure or predominant valvularAR are males; females predominate among patients with AR who have associated mitral valve disease. In approximately two-thirds of patients with AR the disease is rheumatic in origin, resulting in thickening, deformity, and shortening of the individual aortic valve cusps, changes that prevent their proper opening during systole and closure during diastole. A rheumatic origin is less common in patients with isolated AR. Acute AR may result from infective endocarditis, which can develop on a

valve previously affected by rheumatic disease, a congenitally deformed valve, or, rarely, a normal aortic valve, and perforate or erode one or more of the leaflets. Patients with congenital membranous subaortic stenosis often develop thickening of the aortic valve leaflets, which makes the valves particularly susceptible to endocarditis. AR also may occur in patients with congenital bicuspid aortic valves. Prolapse of an aortic cusp, resulting in progressive chronic AR, occurs in approximately 15% of patients with ventricular septal defect (Chap. 234). Congenital fenestrations of the aortic valve occasionally produce mild AR. Although traumatic rupture of the aortic valve is an uncommon cause of acute AR, it does represent the most frequent serious lesion in patients surviving nonpenetrating cardiac injuries. The coexistence of hemodynamically significantAS with AR usually excludes all the rarer forms of AR because it occurs almost exclusively in patients whose AR is rheumatic or congenital in origin. In patients with AR due to primary valvular disease, dilatation of the aortic annulus may occur secondarily and intensify the regurgitation.

Primary Aortic Root Disease AR, both acute and chronic, also may be due entirely to marked aortic dilatation, i.e., aortic root disease, without primary involvement of the valve leaflets; widening of the aortic annulus and separation of the aortic leaflets are responsible for the AR (Chap. 247). Cystic medial necrosis of the ascending aorta, which may or may not be associated with other manifestations of the Marfan syndrome, idiopathic dilatation of the aorta, osteogenesis imperfecta, and severe hypertension all may widen the aortic annulus and lead to progressive AR. Occasionally, AR is caused by retrograde dissection of the aorta involving the aortic annulus. Syphilis and ankylosing rheumatoid spondylitis may be associated with cellular infiltration and scarring of the media of the thoracic aorta, leading to aortic dilatation, aneurysm formation, and severe regurgitation. In syphilis of the aorta, the involvement of the intima may narrow the coronary ostia, which in turn may be responsible for myocardial ischemia.

PATHOPHYSIOLOGY

The total stroke volume ejected by theLV(i.e., the sum of the effective forward stroke volume and the volume of blood that regurgitates back into the LV) is increased in patients withAR. In patients with wide-open (free) AR, the volume of regurgitant flow may equal the effective forward stroke volume. In contrast toMR, in which a fraction of the LV stroke volume is delivered into the low-pressureLA, in AR the entire LV stroke volume is ejected into a high-pressure zone, the aorta. An increase in the LV end-diastolic volume (increased preload) constitutes the major hemodynamic compensation for AR. The dilatation of the LV allows this chamber to eject a larger stroke volume without requiring any increase in the relative shortening of each myofibril. Therefore, severe AR may occur with a normal effective forward stroke volume and a normal left ventricular/ejection fraction (EF) [total (forward plus regurgitant) stroke volume/end-diastolic volume], together with an elevated LV end-diastolic pressure and volume. However, through the operation of Laplace's law (which holds that myocardial wall tension is the product of intracavitary pressure and LV radius), LV dilatation increases the LV systolic tension required to develop any given level of systolic pressure. As LV function deteriorates, the end-diastolic volume rises and the forward stroke volume and EF decline. Deterioration of LV function often precedes the development of symptoms. Considerable thickening of the LV wall also occurs with

chronic AR, and at autopsy the hearts of these patients may be among the largest encountered, sometimes weighing >1000 g.

The reverse pressure gradient from aorta toLV, which is responsible for theAR flow, falls progressively during diastole (seeFig. 228-4), accounting for the decrescendo nature of the diastolic murmur. Equilibration between aortic and LV pressures may occur toward the end of diastole in patients with severe AR, particularly when the heart rate is slow, and the LV end-diastolic pressure may be elevated, occasionally to extremely high levels (>40 mmHg). Rarely, in acute, severe AR, the LV pressure exceeds theLApressure toward the end of diastole, and this reversed pressure gradient closes the mitral valve prematurely or causes diastolic MR.

In patients with severeAR, the effective forwardCOusually is normal or only slightly reduced at rest, but often it fails to rise normally during exertion. Early signs of LV dysfunction include reduction in theEF, determined by echocardiography or radionuclide angiography. In advanced stages there may be considerable elevation of theLA,PAwedge, PA, andRVpressures and lowering of the forward CO at rest.

Myocardial ischemia may occur in patients withARbecause myocardial oxygen requirements are elevated by bothLVdilatation and elevated LV systolic tension. However, the major portion of coronary blood flow occurs during diastole, when arterial pressure is subnormal, thereby reducing coronary perfusion pressure. This combination of increased oxygen demand and reduced supply may cause myocardial ischemia, particularly of the subendocardium.

HISTORY

A family history may frequently be elicited from patients withARassociated with the Marfan syndrome. A history compatible with infective endocarditis may sometimes be elicited from patients with rheumatic or congenital involvement of the aortic valve, and the infection often precipitates or seriously aggravates preexisting symptoms. Ankylosing spondylitis is usually self-evident.

Chronic, severeAR may have a long latent period, and patients may remain relatively asymptomatic for as long as 10 to 15 years. However, uncomfortable awareness of the heartbeat, especially on lying down, may be an early complaint. Sinus tachycardia during exertion or with emotion or premature ventricular contractions may produce particularly uncomfortable palpitations, as well as head pounding. These complaints may persist for many years before the development of exertional dyspnea, usually the first symptom of diminished cardiac reserve. The dyspnea is followed by orthopnea, paroxysmal nocturnal dyspnea, and excessive diaphoresis. Chest pain occurs frequently, even in younger patients, and it is not necessary to invoke the presence of coronary artery disease to explain this symptom in patients with severe AR. Anginal pain may develop at rest as well as during exertion. Nocturnal angina may be a particularly troublesome symptom, and it may be accompanied by marked diaphoresis. The anginal episodes can be prolonged and often do not respond satisfactorily to sublingual nitroglycerin. Systemic fluid accumulation, including congestive hepatomegaly and ankle edema may develop late in the course of the disease.

In patients with acute, severeAR, as may occur in infective endocarditis or trauma, theLVcannot dilate sufficiently to maintain stroke volume, and LV diastolic pressure rises rapidly with associated elevations ofLA andPA wedge pressures. Pulmonary edema and/or cardiogenic shock may develop rapidly.

PHYSICAL FINDINGS

In severeAR, the jarring of the entire body and the bobbing motion of the head with each systole can be appreciated, and the abrupt distention and collapse of the larger arteries are easily visible. The examination should be directed toward the detection of conditions predisposing to AR, such as the Marfan syndrome, rheumatoid spondylitis, and ventricular septal defect.

Arterial Pulse A rapidly rising "water-hammer" pulse, which collapses suddenly as arterial pressure falls rapidly during late systole and diastole (Corrigan's pulse), and capillary pulsations, an alternate flushing and paling of the skin at the root of the nail while pressure is applied to the tip of the nail (Quincke's pulse), are characteristic of freeAR. A booming, "pistol-shot" sound can be heard over the femoral arteries (Traube's sign), and a to-and-fro murmur (Duroziez's sign) is audible if the femoral artery is lightly compressed with a stethoscope.

The arterial pulse pressure is widened, with an elevation of the systolic pressure, sometimes to as high as 300 mmHg, and a depression of the diastolic pressure. The measurement of arterial diastolic pressure with a sphygmomanometer may be complicated by the fact that systolic sounds are frequently heard with the cuff completely deflated. However, the level of cuff pressure at the time of muffling of the Korotkoff sounds generally corresponds fairly closely to the true intraarterial diastolic pressure. The severity ofAR does not always correlate directly with the arterial pulse pressure, and severe regurgitation may exist in patients with arterial pressures in the range of 140/60 mmHg. As the disease progresses and theLVend-diastolic pressure rises markedly, the arterial diastolic pressure may actually rise also, since the aortic diastolic pressure cannot fall below the LV end-diastolic pressure.

Palpation TheLVimpulse is heaving and displaced laterally and inferiorly. The systolic expansion and diastolic retraction of the apex are prominent and contrast with the sustained systolic thrust characteristic of severeAS. A diastolic thrill is often palpable along the left sternal border, and a prominent systolic thrill may be palpable in the jugular notch and transmitted upward along the carotid arteries. This thrill and the accompanying systolic murmur are due to the markedly increased blood flow across the aortic orifice and do not necessarily signify the coexistence of AS. In many patients with pureAR or with combined AS and AR, the carotid arterial pulse is bisferiens, i.e., with two systolic waves separated by a trough.

Auscultation In patients with severeAR, the aortic valve closure sound is usually absent. An S_3 and systolic ejection sound are frequently audible, and occasionally, an S_4 also may be heard. The murmur of AR is typically a high-pitched, blowing, decrescendo diastolic murmur, heard best in the third intercostal space along the left sternal border (see Fig. 225-4). In patients with mild AR, this murmur is brief, but as the severity increases, generally becomes louder and longer, indeed holodiastolic. When

the murmur is soft, it can be heard best with the diaphragm of the stethoscope and with the patient sitting up, leaning forward, and with the breath held in forced expiration. In patients in whom the AR is caused by primary valvular disease, the diastolic murmur is usually louder along the left than the right sternal border. However, when the murmur is heard best along the right sternal border, it suggests that the AR is caused by aneurysmal dilatation of the aortic root. "Cooing" or musical diastolic murmurs suggest eversion of an aortic cusp vibrating in the regurgitant stream. Unless it is trivial in magnitude, the AR is usually accompanied by peripheral signs such as a widened pulse pressure or a collapsing pulse. By contrast, with the Graham Steell murmur of pulmonary regurgitation, which may be confused with the diastolic murmur of AR, there usually is clinical evidence of severe pulmonary hypertension, including a loud and palpable pulmonary component of the S_2.

A midsystolic ejection murmur is frequently audible in AR. It is generally heard best at the base of the heart and is transmitted along the carotid vessels. This murmur may be quite loud without signifying aortic obstruction; it is often higher pitched, shorter, and less rasping in quality than the ejection systolic murmur heard in patients with predominant AS. A third murmur frequently heard in patients with severe AR is the Austin Flint murmur, a soft, low-pitched, rumbling middiastolic bruit. It is probably produced by the displacement of the anterior leaflet of the mitral valve by the AR stream but does not appear to be associated with hemodynamically significant mitral obstruction. Both the Austin Flint murmur and the rumbling diastolic murmur of MS are loudest at the apex, but the murmur of MS is usually accompanied by a loud S_1 and immediately follows the OS of the mitral valve, whereas the Austin Flint murmur is often shorter in duration than the murmur of MS; in patients with sinus rhythm the latter exhibits presystolic accentuation. The auscultatory features of AR are intensified by isometric exercise such as strenuous handgrip, which augments systemic resistance, and reduced by inhalation of amyl nitrite. A blowing holosystolic murmur at the apex, which is transmitted to the axilla, also may be heard in patients with AR who have marked LV dilatation and functional MR.

In acute, severe AR, the elevation of LV end-diastolic pressure may lead to early closure of the mitral valve, an associated middiastolic sound, a soft or absent S_1, a pulse pressure that is not particularly wide, and a soft, short diastolic murmur.

LABORATORY EXAMINATION

Electrocardiogram In patients with mild AR, there may be no electrocardiographic abnormalities, but with severe, chronic AR, the electrocardiographic signs of LV hypertrophy become manifest (Chap. 226). In addition, these patients frequently exhibit ST-segment depression and T-wave inversion in leads I, aVL, V_5, and V_6 ("LV strain"). Left axis deviation and/or QRS prolongation denote diffuse myocardial disease, generally associated with patchy fibrosis, and usually signify a poor prognosis.

Roentgenogram In severe chronic AR, the apex is displaced downward and to the left in the frontal projection, and frequently the cardiac shadow extends below the left diaphragm. LV enlargement also may be apparent in the left anterior oblique and lateral projections, in which the LV is displaced posteriorly and encroaches on the spine. In patients in whom primary valvular disease is responsible for the AR, the ascending

aorta and aortic knob may be moderately dilated. When AR is caused by primary disease of the aortic wall, aneurysmal dilatation of the aorta may be noted, and the aorta may fill the retrosternal space in the lateral view.

Echocardiogram Increased systolic excursion of the posterior left ventricular wall is evident; the extent and velocity of wall motion are normal or even supernormal, until myocardial contractility declines. A rapid, high-frequency fluttering of the anterior mitral leaflet produced by the impact of the regurgitant jet is a characteristic finding. The echocardiogram is also useful in determining the cause ofAR, by detecting dilatation of the aortic annulus (Plate I-3). Thickening and failure of coaptation of the leaflets also may be noted. Color flow Doppler echocardiographic imaging is very sensitive in the detection of AR, and Doppler echocardiography is helpful in assessing its severity. Serial two-dimensional echocardiography is valuable in evaluatingLVperformance and in detecting progressive myocardial dysfunction.

Cardiac Catheterization and Angiography In addition to providing an accurate confirmation of the magnitude of regurgitation and the status ofLVfunction, the condition of the coronary arterial bed may be evaluated preoperatively.

TREATMENT

Although operation constitutes the principal treatment ofAR and should be carried out before the development of heart failure, the latter usually responds briefly to treatment with digitalis glycosides, salt restriction, diuretics, and vasodilators, especially ACE inhibitors. Digitalis also may be indicated in patients with severe regurgitation and dilated left ventricles without frankLVfailure. Cardiac arrhythmias and infections are poorly tolerated in patients with free AR and must be treated promptly and vigorously. Although nitroglycerin and long-acting nitrates are not as helpful in relieving anginal pain as in patients with ischemic heart disease, they are worth a trial. Long-acting nifedipine has been found to delay the need for operation. Patients with syphilitic aortitis should receive a full course of penicillin therapy (Chap. 172).

Surgical Treatment In deciding on the advisability and proper timing of surgical treatment, two points should be kept in mind: (1) patients with chronicARusually do not become symptomatic until after the development of myocardial dysfunction, and (2) surgical treatment often does not restore normalLVfunction. Therefore, in patients with severe AR, careful clinical follow-up and noninvasive testing with echocardiography at approximately 6-month intervals are necessary if operation is to be undertaken at the optimal time, i.e., *after* the onset of LV dysfunction but *prior* to the development of severe symptoms. Operation can be deferred as long as the patient both remains asymptomatic and retains normal LV function. In general, operation should be carried out even in asymptomatic patients with progressive LV dysfunction and an LVEF<55% or a LV end-systolic volume>55 mL/m^2. (The latter has been referred to as the "55/55 rule.")

AVRwith a suitable mechanical or tissue prosthesis is generally necessary in patients with rheumaticAR and in many patients with other forms of regurgitation. Rarely, when a leaflet has been perforated during an episode of infective endocarditis or torn from its attachments to the aortic annulus, surgical repair may be possible. When AR is due to

aneurysmal dilatation of the annulus and ascending aorta rather than to primary valvular involvement, it may be possible to reduce the regurgitation by narrowing the annulus or by excising a portion of the aortic root without replacing the valve. More frequently, however, regurgitation can be eliminated only by replacing the aortic valve, excising the dilated or aneurysmal ascending aorta responsible for the regurgitation, and replacing the latter with a graft. This formidable procedure entails a higher risk than isolated AVR.

As in patients with other valvular abnormalities, both the operative risk and the late mortality are largely dependent on the stage of the disease and on myocardial function at the time of operation. The overall operative mortality for isolatedAVR is 4.3% (Table 236-1). However, patients with marked cardiac enlargement and prolongedLVdysfunction experience an operative mortality rate of approximately 10% and a late mortality rate of approximately 5% per year due to LV failure despite a technically satisfactory operation. Nonetheless, because of the very poor prognosis with medical management, even patients with LV failure should be considered for operation.

ACUTE AORTIC REGURGITATION

Infective endocarditis, aortic dissection, and trauma are the most common causes of severe, acuteAR. Since theLV has not had time to dilate in this condition, stroke volume declines and ventricular diastolic pressure rises markedly; the arterial pulse pressure is often not markedly widened, and the physical signs characteristic of severe chronic AR may be absent. Premature closure of the mitral valve is common and can be recognized by echocardiography. The S_1 is soft or absent; the aortic diastolic murmur is characteristically brief. Patients present with pulmonary congestion and edema, as well as hypotension secondary to a low cardiac output. Acute, severe AR requires prompt surgical treatment, which may be lifesaving.

TRICUSPID STENOSIS

TS, a relatively uncommon valvular lesion in North America and western Europe, is more common in tropical and subtropical climates, especially on the Indian subcontinent, and in Latin America. It is generally rheumatic in origin and is more common in women than in men. It does not occur as an isolated lesion but is usually associated withMS. Hemodynamically significant TS occurs in 5 to 10% of patients with severe MS; rheumatic TS is commonly associated with some degree ofTR.

PATHOPHYSIOLOGY

A diastolic pressure gradient between theRA andRV can be recorded with a double-lumen cardiac catheter. It is augmented when the transvalvular blood flow increases during inspiration and declines during expiration. A mean diastolic pressure gradient >4 mmHg is usually sufficient to elevate the mean RA pressure to levels that result in systemic venous congestion and, unless sodium intake has been restricted and diuretics administered, it is associated with ascites and edema, sometimes severe. In patients with sinus rhythm, the RA *a* wave may be extremely tall and may even approach the level of the RV systolic pressure. The restingCO is usually depressed and fails to rise during exercise. The low CO is responsible for the normal or only slightly elevatedLA,PA, and RV systolic pressures despite the presence ofMS.

SYMPTOMS

Since the development ofMSgenerally precedes that ofTS, many patients initially have symptoms of pulmonary congestion. Amelioration of these symptoms should raise the possibility that TS may be developing. Characteristically, patients complain of relatively little dyspnea for the degree of hepatomegaly, ascites, and edema that they have. Fatigue secondary to a low cardiac output and discomfort due to refractory edema, ascites, and marked hepatomegaly are common in patients with TS and/orTR. In some patients, TS may be suspected for the first time when symptoms ofRVfailure persist after an adequate mitral valvulotomy.

PHYSICAL FINDINGS

SinceTSusually occurs in the presence of other obvious valvular disease, the diagnosis may be missed unless it is specifically considered and searched for. Severe TS is associated with marked hepatic congestion, often resulting in cirrhosis, jaundice, serious malnutrition, anasarca, and ascites. Congestive hepatomegaly and, in cases of severe tricuspid valve disease, splenomegaly are present. The jugular veins are distended, and in patients with sinus rhythm there may be giant *a* waves. The *v* waves are less conspicuous, and since tricuspid obstruction impedesRAemptying during diastole, there is a slow *y* descent. In patients with sinus rhythm there may be prominent presystolic pulsations of the enlarged liver as well.

On auscultation, the pulmonic valve closure sound is not accentuated, and occasionally, anOS of the tricuspid valve may be heard approximately 0.06 s after pulmonic valve closure. The diastolic murmur ofTS has many of the qualities of the diastolic murmur ofMS, and since TS almost always occurs in the presence of MS, the less common valvular lesion may be missed. However, the tricuspid murmur is generally heard best along the left lower sternal margin and over the xiphoid process and is most prominent during presystole in patients with sinus rhythm. The diastolic murmur is reduced in amplitude as the stethoscope is inched laterally, only to intensify or reappear as the mitral murmur at the apex. The murmur of TS is augmented during inspiration, and it is reduced during expiration and particularly during the strain of Valsalva maneuver, when tricuspid blood flow is reduced. This finding is often most easily elicited when the patient is in the erect position.

LABORATORY EXAMINATION

The electrocardiographic features ofRAenlargement (Chap. 226) include tall, peaked P waves in lead II, as well as prominent, upright P waves in lead V_1. The *absence* of electrocardiographic evidence of renovascular hypertension (RVH) in a patient with right-sided heart failure who is believed to haveMSshould suggest associated tricuspid valve disease. The chest roentgenogram in patients with combinedTS and MS show particular prominence of the RA and superior vena cava without much enlargement of thePA and with less evidence of pulmonary vascular congestion than occurs in patients with isolated MS. On echocardiographic examination, the tricuspid valve is usually thickened; the transvalvular gradient can be estimated by Doppler echocardiography.

TREATMENT

Patients with TSgenerally exhibit marked systemic venous congestion; intensive salt restriction and diuretic therapy are required during the preoperative period. Such a preparatory period may diminish hepatic congestion and thereby improve hepatic function sufficiently so that the risks of operation are diminished. Surgical relief of the TS should be carried out, preferably at the time of mitral valvotomy, in patients with moderate or severe TS who have mean diastolic pressure gradients exceeding approximately 4 mmHg and tricuspid orifices less than 1.5 to 2.0 cm^2. TS is almost always accompanied by significantTR. Open-heart repair may permit substantial improvement of tricuspid valve function. If this cannot be accomplished, the tricuspid valve may have to be replaced with a prosthesis, preferably a large bioprosthetic valve.

TRICUSPID REGURGITATION

Most commonly,TR is functional and secondary to marked dilatation of theRV and the tricuspid annulus. Functional TR may complicate RV enlargement of any cause, including inferior wall infarcts that involve the RV, and it is commonly seen in the late stages of heart failure due to rheumatic or congenital heart disease with severe pulmonary hypertension, as well as in ischemic heart disease, cardiomyopathy, and cor pulmonale. It is in part reversible if pulmonary hypertension is relieved. Rheumatic fever may produce organic TR, often associated withTS. Infarction of RV papillary muscles, tricuspid valve prolapse, carcinoid heart disease, endomyocardial fibrosis, infective endocarditis, and trauma all may produce TR. Less commonly, TR results from congenitally deformed tricuspid valves, and it occurs with defects of the atrioventricular canal as well as with Ebstein's malformation of the tricuspid valve (Chap. 234).

As is the case forTS, the clinical features ofTRresult primarily from systemic venous congestion and reduction ofCO. With the onset of TR in patients with pulmonary hypertension, symptoms of pulmonary congestion diminish, but the clinical manifestations of right-sided heart failure become intensified. The neck veins are distended with prominent *v* waves; and marked hepatomegaly, ascites, pleural effusions, edema, systolic pulsations of the liver, and positive hepatojugular reflux are common. A prominentRVpulsation along the left parasternal region and a blowing holosystolic murmur along the lower left sternal margin, which may be intensified during inspiration and reduced during expiration or the strain of the Valsalva maneuver, are characteristic findings;AF is usually present.

The electrocardiogram usually shows changes characteristic of the lesion responsible for the enlargement of the RVthat leads toTR. Roentgenographic examination usually reveals enlargement of both theRA and RV. Echocardiography may be helpful by demonstrating RV dilatation and prolapsing or flail tricuspid leaflets; the diagnosis of TR can be made by color flow Doppler echocardiography, and the severity estimated by Doppler examination. The latter is also useful in estimatingPApressure.

In patients with severeTR, theCO is usually markedly reduced, and theRApressure pulse may exhibit no *x* descent during early systole but a prominent *c-v* wave with a rapid *y* descent. The mean RA and the RV end-diastolic pressures are often elevated.

TREATMENT

IsolatedTR, in the absence of pulmonary hypertension, such as that occurring as a consequence of infective endocarditis or trauma, is usually well tolerated and does not require operation. Indeed, even total excision of an infected tricuspid valve is often well tolerated if thePApressure is normal. Treatment of the underlying cause of heart failure usually reduces the severity of functional TR. In patients with mitral valve disease and TR secondary to pulmonary hypertension and massiveRVenlargement, effective surgical correction of the mitral valvular abnormality results in lowering of the PA pressures and gradual reduction or disappearance of the TR without direct treatment of the tricuspid valve. However, recovery may be much more rapid in patients with severe secondary TR if, at the time of mitral valve surgery, tricuspid annuloplasty (generally with the insertion of a plastic ring), open tricuspid valve repair, or, in the rare instance of severe organic tricuspid valve disease, tricuspid valve replacement is performed. Surgical treatment of the TR also should be carried out in patients with severe regurgitation secondary to deformity of the tricuspid valve due to rheumatic fever, particularly those *without* severe pulmonary hypertension.

PULMONIC VALVE DISEASE

The pulmonic valve is affected by rheumatic fever far less frequently than are the other valves, and it is uncommonly the seat of infective endocarditis. The most common *acquired* abnormality affecting the pulmonic valve is regurgitation secondary to dilatation of the pulmonic valve ring as a consequence of severe pulmonary hypertension. This produces the Graham Steell murmur, a high-pitched, decrescendo, diastolic blowing murmur along the left sternal border, which is difficult to differentiate from the far more common murmur produced byAR. It is usually of little hemodynamic significance; indeed, surgical removal or destruction of the pulmonic valve by infective endocarditis does not produce heart failure unless serious pulmonary hypertension is also present. The *carcinoid syndrome* may cause pulmonic stenosis and/or regurgitation.**Congenital pulmonic stenosis* is discussed in Chap. 234.

VALVE REPLACEMENT

The results of replacement of any valve are dependent primarily on (1) the patient's myocardial function and general medical condition at the time of operation, (2) the technical abilities of the operative team and the quality of the postoperative care, and (3) the durability, hemodynamic characteristics, and thrombogenicity of the prosthesis. Increased operative mortality is associated with the higher levels of preoperative functional disability and pulmonary hypertension. Late complications of replacement of any valve, which are declining in incidence, include paravalvular leakage, thromboemboli, bleeding due to anticoagulants, mechanical dysfunction of the prosthesis, and infective endocarditis.

The considerations involved in the choice between a bioprosthetic (tissue) and artificial mechanical valve are similar in the mitral and aortic positions and in the treatment of stenotic, regurgitant, or mixed lesions. All patients who have undergone replacement of any valve with a mechanical prosthesis must be maintained permanently on anticoagulants, but this treatment imposes a hazard of hemorrhage. The primary

advantage of bioprostheses over mechanical prostheses is the reduction of thromboembolic complications; and except for patients with chronicAF, few such instances have been associated with their use. The major disadvantage of bioprosthetic valves is their mechanical deterioration, the incidence of which is inversely proportional with age. This results in the need to replace the prosthesis in 30% of patients by 10 years and in 50% by 15 years. Bioprostheses are ordinarily not used in younger patients (<35 years) because of accelerated deterioration but are particularly useful in the elderly (>70 years), in whom there is more concern about chronic anticoagulation than about long-term (>15 years) valve durability. These valves are also indicated in women who expect to become pregnant, as well as others in whom anticoagulation may be contraindicated. Alternative bioprostheses are homograft (allograft) aortic valves obtained from cadavers and cryopreserved, pericardial autografts as well as pulmonary autograft transplanted into the aortic position. In patients without contraindications to anticoagulants, particularly those under 65 years, a mechanical prosthesis may be preferable. Many surgeons now select the St. Jude prosthesis, a double-disk tilting prosthesis, for replacement of both aortic and mitral valves because of somewhat more favorable hemodynamic characteristics and a suggestion of lower thrombogenicity.

237. COR PULMONALE - *Eugene Braunwald*

DEFINITIONS

Cor pulmonale is defined as enlargement of the right ventricle (RV) secondary to abnormalities of the lungs, thorax, pulmonary ventilation, or circulation. It sometimes leads to RV failure, with an elevation of transmural RV end-diastolic pressure. Cor pulmonale and RV failure may be acute, as in pulmonary thromboembolism; or chronic, as in stable, severe chronic obstructive lung disease (COLD); or "acute on chronic," as in COLD with a superimposed infection and intensification of hypoxia. Approximately 20% of hospital admissions for heart failure are caused by RV failure associated with cor pulmonale. More than half of the patients with COLD have cor pulmonale, and this condition constitutes between 5 and 10% of all adult heart diseases in the United States. Cor pulmonale constitutes a higher percentage of all forms of heart disease in countries where the incidence of COLD is higher, such as the United Kingdom, and in areas such as Mexico City where air pollution is severe.

NORMAL FUNCTION OF THE PULMONARY CIRCULATION

The pulmonary circulation is interposed between the right and left ventricles for the purpose of gas exchange, the filtering out of particles, and the chemical modification of the blood, such as the conversion of angiotensin I to angiotensin II. Normally, flow through the pulmonary vascular bed depends not only on the pumping action of theRV but also on respiratory movements and on the filling and contraction of the left ventricle. Respiratory motion facilitates pulmonary blood flow by enhancing venous return into the thorax on inhalation; the positive pressure of exhalation then aids in propelling blood into the systemic vascular bed.

The stroke volume of theRV, as of the left, is regulated by its preload, contractility, and afterload (Chap. 231). Since the RV is a relatively thin, compliant reservoir, acute changes in venous return (e.g., an increase with inhalation and decline with exhalation) can occur with little change in transmural RV pressure. However, the ability of the RV to increase its systolic pressure is limited. Normally, the RV afterload, which is closely related to the pulmonary artery pressure, is low. The pulmonary artery pressure normally rises slightly when blood is displaced into the chest at the start of exercise; on assuming recumbency; or with cold, anxiety, or pain. A driving pressure of only about 5 cmH_2O between the pulmonary artery (15 cmH_2O) and the left atrium (10 cmH_2O) normally propels the entire cardiac output of approximately 5 L/min at rest through the lungs, and only a modest increase in pressure is necessary to drive a flow of up to 25 L/min through the pulmonary capillary bed during maximal exercise.

The resistance of the pulmonary circulation (*R*), i.e., the pulmonary vascular resistance (Chap. 228), is calculated as the intravascular driving pressure (*DP*), i.e., pulmonary artery pressure minus pulmonary venous or left atrial pressure, divided by the pulmonary blood flow rate (). The caliber of a distensible vessel depends on its transmural pressure. Calculated *R* increases when vessels collapse, narrow, or lengthen, or when the viscosity of the blood increases.

where *K*= constant; *l* =length; *r* = radius; andm = viscosity. Calculated *R* decreases with increasing pulmonary blood flow because pulmonary vessels are distended and collapsed vessels are recruited.

PATHOPHYSIOLOGY

The severity ofRVenlargement in cor pulmonale is a function of the increase in afterload. When the pulmonary vascular resistance is elevated and relatively fixed, as in pulmonary vascular or severe parenchymal lung disease, an elevation in cardiac output as occurs with physical exertion can elevate pulmonary artery pressure markedly. RV afterload may be augmented when the lungs are hyperinflated, as inCOLD, due to the compression of the alveolar capillaries and the lengthening of the pulmonary vessels. RV afterload can also increase when lung volume is reduced following extensive pulmonary resection, as well as in restrictive lung diseases in which pulmonary vessels are compressed and distorted. RV afterload rises with hypoxic pulmonary vasoconstriction caused by hypoxia or acidosis, which are important causes of pulmonary hypertension. Hypoxic vasoconstriction in regions of the lung affected by disease distributes blood flow to normally ventilated regions. Hypoxic vasoconstriction results from alveolar, rather than intravascular, hypoxia and is exaggerated by hypercapnia, probably because of the associated acidosis. When the hematocrit becomes markedly elevated with chronic hypoxemia (secondary polycythemia), the increase in blood viscosity can also aggravate the pulmonary hypertension. Chronic hypoxic pulmonary vasoconstriction may cause pulmonary vascular disease with endothelial swelling and medial hypertrophy (see below).

The elevation ofRVafterload responsible for cor pulmonale is caused principally by pulmonary vascular or parenchymal disease. The principal syndromes and their pathophysiologic mechanisms are summarized inTable 237-1.

PULMONARY VASCULAR DISEASES

In these conditions theRVafterload is elevated as a consequence of restriction to pulmonary blood flow. In cor pulmonale secondary to pulmonary vascular disease, pulmonary hypertension is usually more severe than in pulmonary parenchymal disease. Chronic cor pulmonale secondary to pulmonary vascular disease may result from repeated pulmonary emboli, pulmonary vasculitis, pulmonary vasoconstriction secondary to high altitude, congenital heart disease with left-to-right shunting (e.g., atrial or ventricular septal defect, patent ductus arteriosus;Chap. 234), as well as pulmonary venoocclusive disease. When the cause of elevated pulmonary vascular resistance responsible for cor pulmonale cannot be defined, the condition is referred to as *primary pulmonary hypertension* (Chap. 260).

COR PULMONALE DUE TO PULMONARY EMBOLI

This condition is associated with two distinct syndromes.

Acute Cor Pulmonale It has been estimated that in the United States about 50,000 people die each year from pulmonary thromboembolism (Chap. 261). Probably half die

within the first hour from acute right heart failure due to massive or multiple emboli. A sudden, large embolic burden causes a low-output state resulting from theRV's inability to generate the pressure necessary to drive blood through the acutely compromised pulmonary vascular bed. Depression of cardiac output can also occur with a moderate-sized embolism if the pulmonary circulation has been critically compromised by previous pulmonary vascular or parenchymal disease. The RV begins to fail when systolic pressure is forced to double acutely, i.e., to exceed approximately 50 mmHg. Acute RV failure secondary to pulmonary embolism is suggested by the history of the sudden onset of severe dyspnea and cardiovascular collapse in a patient with, or predisposed to, venous thrombosis.

Clinical Manifestations Acute RVfailure causes pallor, sweating, hypotension, and a rapid pulse of small amplitude. The neck veins are distended and often exhibit prominent *v* waves secondary to tricuspid regurgitation. The liver may be pulsatile, distended, and tender. A systolic murmur of tricuspid regurgitation along the left sternal border may be accompanied by a presystolic (S_4) gallop sound. Arterial blood gas frequently shows reduced Pa_{O_2} due to ventilation/perfusion mismatching and a low Pa_{CO_2}due to hyperventilation.

TREATMENT

If the cardiac output remains adequate to sustain the patient during the critical first 2 or 3 h, endogenous thrombolysis usually results in fragmentation of the clot and the pulmonary artery pressure returns to normal rapidly. Although it has been shown that treatment with thrombolytic agents lyses clots more rapidly than does heparin (Chap. 261), this therapy is probably indicated only when cardiac output is critically reduced and theRVfails. In acute cor pulmonale [and in RV failure due to acute RV infarction (Chap. 243)], an increase in RV preload can be achieved by a cautious expansion of blood volume, which helps to maintain cardiac output. When hypoxic pulmonary vasoconstriction contributes to pulmonary hypertension, inhalation of 100% O_2reduces RV afterload.

Chronic Cor Pulmonale Secondary to Pulmonary Vascular Disease In contrast to acute, massive thromboembolism, when the elevation in pulmonary vascular resistance and theRVhypertrophy develop gradually, higher pulmonary vascular pressures, sometimes even approaching systemic arterial levels, may be generated. Chronic cor pulmonale can be caused by recurrent, medium-sized emboli that fail to lyse, but organize, resulting in chronic thromboembolic pulmonary hypertension. Particles from intravenous drug abuse, parasites, or tumor tissue that embolizes into the pulmonary vascular bed may also cause persistent pulmonary hypertension. Chronic cor pulmonale can also be caused by *primary pulmonary hypertension* (Chap. 260) or any chronic widespread vasculitis, such as occurs in association with collagen vascular disorders and that may affect the pulmonary vascular bed, particularly the CREST syndrome (Chap. 313).

Clinical Manifestations Dyspnea and tachypnea are characteristic features of pulmonary hypertension secondary to pulmonary vascular disease. They may be distressing during mild exertion or even at rest and are *not* relieved by sitting upright. An unproductive cough is another frequent complaint. Anterior chest pain, due to acute

dilation of the root of the pulmonary artery orRVischemia, can occur. The elevation in systemic venous pressure can cause hepatomegaly and ankle edema.

Occasionally there is cyanosis due to arterial hypoxemia and low cardiac output. ARV heave may be palpable along the left sternal border or in the epigastrium, and a high-pitched pulmonary ejection click may be audible to the left of the upper sternum. The second (pulmonary) component of the second heart sound is intensified and may be palpable; fixed narrow splitting of the second heart sound and a right ventricular protodiastolic gallop (S_3) that may increase during inspiration can be present. A systolic murmur of tricuspid regurgitation, which is augmented by inspiration, is often audible; occasionally, a diastolic murmur of pulmonary regurgitation is also heard. Prominent *a* (and sometimes also *v*) waves in the jugular venous pulse are evident. The onset of RV failure is reflected by an increase of venous pressure, the development of larger *v* waves associated with increasing tricuspid regurgitation, a positive hepatojugular reflux, and a gallop rhythm with both third and fourth heart sounds. These physical findings of RV failure can disappear rapidly when pulmonary artery pressure is reduced by relief of hypoxemia.

Hypocapnia due to alveolar hyperventilation is an important feature of chronic pulmonary hypertension secondary to pulmonary vascular disease. Usually there are no abnormalities on spirometry, but the ratio of dead space to tidal volume may be high, particularly when large-vessel obstruction is present. The diffusing capacity of the lung is reduced when the pulmonary vascular disease is associated with a capillary vasculitis and/or loss of capillary blood volume. Typically, exertion causes a marked fall in Pa_{O_2}. The assessment of exercise capacity may be a useful way of following changes in the severity of pulmonary vascular disease in patients with chronic cor pulmonale, because exercise ability is limited by cardiac output and the latter, in turn, by the severity of the pulmonary vascular obstruction.

Laboratory Examination On *radiologic examination* the pulmonary trunk and hilar vessels are enlarged, as is the descending right pulmonary artery. Ventilation and perfusion lung scans and systemic venography showing deep vein thrombosis in the lower extremities are helpful in confirming the diagnosis of embolic pulmonary vascular disease. In the presence of severe pulmonary hypertension, the *electrocardiogram* (ECG) shows P pulmonale, right axis deviation, andRVhypertrophy (Chap. 226).

Echocardiography allows measurement of the thickness of theRV wall and may show enlargement of the RV cavity in relation to the left. The interventricular septum may be displaced leftward and may move paradoxically during the cardiac cycle. Pulmonary artery and RV systolic pressure can be estimated from measurement of the peak tricuspid regurgitant flow and pulmonic regurgitant flow with Doppler echocardiography.

*Magnetic resonance imaging*is useful for measuringRV mass, wall thickness, cavity volume, and ejection fraction.

Failure of theRVejection fraction (measured by radionuclide ventriculography) to increase on exercise is a good indicator of pulmonary hypertension and/or intrinsic RV dysfunction. *Myocardial perfusion scintigraphy* with thallium 201 or sestamibi is also useful in diagnosing cor pulmonale, since the hypertrophied RV is visualized by these

radionuclides. (Normally the RV is not imaged by these radionuclides because of the much greater uptake by the left ventricle.)

Cardiac catheterization provides precise measurement of pulmonary vascular pressures, calculation of pulmonary vascular resistance, and their responses to oxygen and vasodilators. Catheterization is sometimes helpful in patients with cor pulmonale to exclude congenital and left heart diseases, and it allows pulmonary angiography to be carried out to confirm the nature of the pulmonary vascular obstruction. Measurements of pulmonary vascular pressure and flow during exercise may reveal abnormal pressure increments of pulmonary artery systolic and diastolic andRVdiastolic pressures and an inadequate responses of cardiac output.

Lung biopsy can be useful in demonstrating vasculitis in some types of pulmonary vascular disease such as the collagen vascular diseases, rheumatoid arthritis, and Wegener's granulomatosis.

PARENCHYMAL PULMONARY DISEASES

The pathogenesis of cor pulmonale in patients with chronic parenchymal pulmonary disease is shown inFig. 237-1. Cor pulmonale may be caused by both obstructive and restrictive lung diseases, more frequently the former. In these conditions there are usually only modest elevations of pulmonary artery pressure. The development of cor pulmonale confers a poor prognosis on patients with respiratory disease, not becauseRVfailure cannot be treated, but because it reflects the seriousness of the underlying pulmonary disease.

CHRONIC OBSTRUCTIVE LUNG DISEASE (See alsoChap. 258)

This is the most common cause of chronic cor pulmonale. The enlargement of theRV is attributed to the mild-to-moderate pulmonary hypertension that is common in severe obstructive bronchitis and emphysema. Pulmonary artery systolic pressure is typically in the range of 50 to 60 mmHg, far below the systemic levels that may occur in patients with congenital heart disease and in those with primary pulmonary hypertension. Patients with cor pulmonale due toCOLDusually have an advanced form of the disease with FEV_1< 1.0 L and Pa_{O2}< 60 mmHg (Chap. 250). RV failure secondary to COLD often occurs when there is "acute-on-chronic" respiratory failure with intensification of hypoxemia.

Pulmonary hypertension inCOLD is caused by one or more of the following:

1. Pulmonary vasoconstriction secondary to alveolar hypoxia, acidemia, and hypercapnia. When these vasoconstrictor stimuli persist, medial thickening of the smaller muscular arteries develops by the mechanical effects of the high lung volume on the pulmonary vessels.

2. The loss of small vessels in the vascular bed in regions of emphysema and lung destruction.

3. The increased cardiac output and blood viscosity caused by polycythemia secondary

to hypoxia.

Of these causes, hypoxia is the most important. Pulmonary artery pressure rises further on exercise and often falls acutely on inspiration of 100% O_2. Cardiac output tends to be high in the absence of heart failure if hypoxia and hypercapnia are present. Because of the importance of hypoxic pulmonary vasoconstriction in causing pulmonary hypertension, the hypoventilating "blue bloater" with alveolar hypoxia and hypercapnia more frequently suffers from pulmonary hypertension and consequent cor pulmonale than does the emphysematous "pink puffer" without alveolar hypoxia. Ischemic left ventricular dysfunction is a frequent accompaniment since patients with cor pulmonale secondary to COLD usually have a history of heavy cigarette smoking, a major risk factor for ischemic heart disease. The elevation of pulmonary artery pressure may be secondary, in part, to the increase in left atrial pressure resulting from left heart dysfunction. Almost half of all patients who die with cor pulmonale due to COLD also have left ventricular hypertrophy on postmortem examination.

Right ventricular failure often complicates cor pulmonale when patients withCOLDdevelop ventilatory failure and/or a superimposed acute respiratory infection with hypoxia and hypercapnia, and worsening of pulmonary hypertension. Both supraventricular and ventricular arrhythmias may occur. The liver is engorged, tender, and displaced downward by the low diaphragm; a hepatojugular reflux may be present.

An exacerbation of airway obstruction elevates intrathoracic pressure, which impedes venous return, raises jugular venous pressure, and may cause peripheral edema. The venous hypertension due to airflow obstruction declines, sometimes very rapidly, with relief of the obstruction.

Pathology TheRVhypertrophies progressively inCOLD. The main pulmonary arteries are enlarged, and the muscular pulmonary arteries show prominent longitudinal muscle, fibrosis, and elastic changes that continue into the arterioles, where the media becomes muscularized. The small vessels and capillaries are distorted or disappear in regions of lung hyperinflation.

Clinical Manifestations A history of a productive cough and dyspnea, perhaps with wheezing, is frequently elicited. Breathlessness limits the patient's ability in the minor stresses of daily living. Frequently there is a history of emergency hospital admissions because of respiratory infection, sometimes necessitating mechanical ventilation. In breathing oxygen, there may be increasing somnolence or other symptoms of hypercapnia such as recurring headaches, confusion, and even vomiting which, when combined with blurred optic discs (also due to cerebral vasodilation), constitutes the "pseudo tumor cerebri" syndrome. Hypoxia due to hypoventilation is usually worse at night.

Physical Findings Often there is nicotine staining of the fingers, a tell-tale sign reflecting many years of heavy cigarette smoking. The skin may be warm and the arterial pulse bounding in the high cardiac output state induced by hypoxia and hypercapnia. The distention of the chest due to the airflow obstruction and the presence of rhonchi and wheezes secondary to chronic bronchitis usually make cardiac auscultation difficult. A right-sided protodiastolic gallop sound (S_3) and a systolic murmur of tricuspid regurgitant

may be audible. Signs of right heart failure are, as discussed above, difficult to separate from those due to severe airflow obstruction. Peripheral edema may worsen with elevation of systemic venous pressure when atrial fibrillation occurs or when pulmonary infection supervenes. A positive hepatojugular reflux suports the diagnosis ofRVfailure.

Laboratory Examination *Pulmonary function studies* show marked airflow obstruction with hypoxemia and hypercapnia. Exercise is limited by ventilatory rather than cardiac dysfunction untilRVfailure develops. The *chest roentgenogram* reveals hyperinflation, which makes the degree of right heart enlargement difficult to assess. The central pulmonary arteries are large, but at the periphery the vessels are narrowed and disappear, particularly in regions of the lungs that are markedly emphysematous. The ECGis relatively insensitive in demonstrating right heart enlargement because the enlarged lungs are poor electrical conductors and the inspiratory position of the chest is associated with a vertically positioned heart. Arrhythmias, particularly atrial fibrillation and multifocal atrial tachycardia, are common.

Echocardiographic imaging is often difficult because of the air in the distended lungs but usually reveals an increased cross-section of the right ventricular cavity, abnormal thickening of the RVwall, and pulmonary hypertension. Myocardial perfusion scintigraphy shows an abnormally high ratio of right-to-left ventricular uptake.

Right heart catheterization can be carried out at the bedside with a balloon-tipped, flow-directed, multilumen catheter fitted with thermocouples for measuring cardiac output by thermodilution (Chap. 228). The pulmonary artery wedge pressure is usually normal at rest in patients with uncomplicated cor pulmonale. Cardiac catheterization may be useful in assessing the severity of the pulmonary hypertension and its response to respiring oxygen.

TREATMENT

First, medical management of the acute and/or chronic lung disease must be optimal (Chaps. 258 and265). Acute respiratory infection, often the precipitant ofRVfailure, must be treated promptly and vigorously. Alveolar hypoxia at rest and during exertion and sleep should be corrected by improving alveolar ventilation through relieving the airflow obstruction and by judiciously increasing the inspired O_2concentration. Long-term O_2therapy is helpful in patients with severeCOLD and reduces pulmonary artery pressure and pulmonary vascular resistance. When the lung disease improves and pulmonary vasoconstriction secondary to the alveolar hypoxia and hypercapnia are corrected, tachypnea and the signs attributed to right heart failure are relieved. Bronchodilators and antibiotics lessen airflow obstruction, and diuretics relieve the edema. Loop diuretics must be used with care since they may cause a metabolic alkalosis and thereby blunt the respiratory drive. Digitalis should be used cautiously in the presence of overt RV failure, and small phlebotomies should be considered when the hematocrit exceeds 55 to 60%. Inhalation of nitric oxide and infusion of prostacyclin are undergoing evaluation as agents to reduce pulmonary hypertension.The prognosis in cor pulmonale depends on that of the underlying pulmonary disease.

RESTRICTIVE LUNG DISEASES (See alsoChap. 259)

Cor pulmonale in a variety of restrictive disorders of the lung is often associated with obliteration of the pulmonary vascular bed by lung destruction and fibrosis. Treatment of the underlying disorder and management ofRVfailure, as described above, are indicated.

DISORDERS OF VENTILATION

A variety of disorders of the neuromuscular apparatus, diaphragm, and chest wall cause pulmonary hypertension and cor pulmonale secondary to chronic hypoxia and/or compression of pulmonary vessels. Disorders of ventilatory control, including the sleep apnea syndrome, and upper airways obstruction may be responsible for chronic hypoxia, secondary pulmonary hypertension, cor pulmonale, and eventualRVfailure. Management consists of treating the underlying disorder, as discussed in Chaps. 263 and264; the inhalation of oxygen; and the management of RV failure with diuretics and digoxin.

CHRONIC MOUNTAIN SICKNESS (MONGE'S DISEASE)

Residents at high altitudes with chronic hypoxia and secondary polycythemia may develop pulmonary hypertension and cor pulmonale. Psychiatric symptoms -- confusion and loss of mental acuity -- are common features. Descent to a lower altitude and/or cautious phlebotomy result in lowering of pulmonary artery pressure and relief of symptoms.

238. THE CARDIOMYOPATHIES AND MYOCARDITIDES - *Joshua Wynne*, *Eugene Braunwald*

The cardiomyopathies are diseases that involve the myocardium directly and are not the result of hypertension or congenital, valvular, coronary, arterial, or pericardial abnormalities.

*Diffuse myocardial fibrosis secondary to multiple myocardial scars produced by extensive coronary arterial narrowing and occlusion can impair left ventricular function and is frequently referred to as *ischemic cardiomyopathy*. This is a colloquial use of the term, however, and should be avoided; the term *cardiomyopathy* should be restricted to a condition *primarily* involving heart muscle. In so-called ischemic cardiomyopathy the *primary* involvement is of the coronary vessels.

When the cardiomyopathies are classified on an etiologic basis, two fundamental forms are recognized: (1) a primary type, consisting of heart muscle disease of unknown cause; and (2) a secondary type, consisting of myocardial disease of known cause or associated with a disease involving other organ systems (Table 238-1). (In the World Health Organization classification, *specific cardiomyopathy* is used to describe heart muscle diseases associated with certain systemic or cardiac disorders; examples include hypertensive and metabolic cardiomyopathy.) In many cases, however, it is not possible to arrive at a specific etiologic diagnosis, and thus it is often more desirable to classify the cardiomyopathies on the basis of differences in their pathophysiology and clinical presentation (Tables 238-2 and238-3).

DILATED CARDIOMYOPATHY

Left and/or right ventricular systolic pump function is impaired, leading to progressive cardiac enlargement, a process called *remodeling*, and often, but not invariably, producing symptoms of congestive heart failure. There is, however, no close correlation between the degree of contractile dysfunction and the severity of symptoms. Mural thrombi may be present, particularly in the left ventricular apex. Histologic examination reveals extensive areas of interstitial and perivascular fibrosis. Myocyte necrosis and cellular infiltration may be present but are not prominent.

Although no cause is apparent in many cases, dilated cardiomyopathy is probably the end result of myocardial damage produced by a variety of toxic, metabolic, or infectious agents. Dilated cardiomyopathy may be the late sequel of acute viral myocarditis, possibly mediated through an immunologic mechanism. Most commonly a disease of middle-aged men and more common in African Americans than in whites, it may occur in any patient population. The prevalence of this condition appears to be increasing. A reversible form of dilated cardiomyopathy may be found with alcohol abuse, pregnancy, selenium deficiency, hypophosphatemia, hypocalcemia, thyroid disease, cocaine use, and chronic uncontrolled tachycardia. Approximately 20% of patients have familial forms of the disease, with mutations of genes encoding myocardial structure proteins as well as transcription factors that control the expression of other myocyte genes. The disease is genetically heterogeneous; autosomal dominant, autosomal recessive, and X-linked transmission have been documented.

Right ventricular dysplasia is a unique cardiomyopathy marked by progressive replacement of the right ventricular wall with adipose tissue. Often associated with ventricular arrhythmias, the clinical course is variable, but sudden death is a constant threat. Catheter ablation of putative arrhythmia sites and insertion of an implantable cardioverter-defibrillator are often employed.

CLINICAL MANIFESTATIONS

Symptoms of left- and right-sided congestive failure (Chap. 232), manifested by exertional dyspnea, fatigue, orthopnea, paroxysmal nocturnal dyspnea, peripheral edema, and palpitations, develop gradually in most patients. Some patients have left ventricular dilatation for months or even years before becoming symptomatic. Others develop symptoms after recovery from a viral infection. Although vague chest pain may be present, typical angina pectoris is unusual and suggests the presence of concomitant ischemic heart disease. Systemic embolism, stroke, and syncope may occur.

PHYSICAL EXAMINATION

Variable degrees of cardiac enlargement and findings of congestive heart failure are noted. In patients with advanced disease, the pulse pressure is narrow and the jugular venous pressure is elevated. Third and fourth heart sounds are common, and mitral or tricuspid regurgitation may occur.

LABORATORY EXAMINATIONS

The chest roentgenogram demonstrates enlargement of the cardiac silhouette due to left ventricular enlargement, although generalized cardiomegaly is often seen. The lung fields may demonstrate evidence of pulmonary venous hypertension and interstitial or alveolar edema. The electrocardiogram often shows sinus tachycardia or atrial fibrillation, ventricular arrhythmias, left atrial abnormality, diffuse nonspecific ST-T wave abnormalities, and sometimes intraventricular conduction defects and low voltage. Echocardiography and radionuclide ventriculography show left ventricular dilatation, with normal or minimally thickened or thinned walls, and systolic dysfunction (reduced ejection fraction) (Fig. 238-CD1).

Cardiac catheterization and coronary angiography are usually performed to exclude ischemic heart disease, although hemodynamic monitoring may occasionally be helpful in the management of the acutely decompensated patient. The left ventricular end-diastolic, left atrial, and pulmonary capillary wedge pressures are usually elevated; when failure of the right side of the heart supervenes, the right ventricular end-diastolic, right atrial, and central venous pressures also rise. Angiography reveals a dilated, diffusely hypokinetic left ventricle, often with some degree of mitral regurgitation; the coronary arteries are normal, thereby excluding so-called ischemic cardiomyopathy. Transvenous endomyocardial biopsy is usually not necessary in idiopathic or familial dilated cardiomyopathy, in which it reveals nonspecific findings of myocyte hypertrophy and fibrosis. However, it may be helpful in the recognition of secondary cardiomyopathies such as myocardial infiltration with amyloid and of acute myocarditis.

TREATMENT

Most patients pursue an inexorably downhill course, and the majority, particularly those over 55 years of age, die within 3 years of the onset of symptoms (Fig. 238-CD2). African Americans are more likely to suffer progressive heart failure and death than Caucasians. Spontaneous improvement or stabilization occurs in about a quarter of patients. Death is due to either congestive heart failure or ventricular tachy- or bradyarrhythmia; sudden death is a constant threat. Systemic embolization is a concern, and patients with heart failure secondary to cardiomyopathy should be considered for chronic anticoagulation. Standard therapy of heart failure with salt restriction, angiotensin-converting enzyme (ACE) inhibitors, diuretics, and digitalis produces symptomatic improvement (Chap. 232). An angiotensin II receptor blocker may be substituted in ACE-intolerant patients. Most ambulatory patients profit as well from the addition of a b-adrenergic blocker. Some patients with dilated cardiomyopathy who have biopsy evidence of myocardial inflammation have been treated with immunosuppressive therapy, but long-term evidence of efficacy is lacking. Alcohol should be avoided because of its cardiac toxic effects. Antiarrhythmic agents are best avoided for fear of proarrhythmic and other side effects, unless they are needed to treat symptomatic or serious arrhythmias. Insertion of an implantable cardioverter-defibrillator is useful in patients with malignant arrhythmias. In patients with advanced disease who are refractory to medical therapy, cardiac transplantation should be considered (Chap. 233).

ALCOHOLIC CARDIOMYOPATHY

Individuals who consume large quantities of alcohol over many years may develop a clinical picture identical to idiopathic dilated cardiomyopathy; indeed, alcoholic cardiomyopathy is the major form of secondary dilated cardiomyopathy in the western world. Ceasing alcohol consumption before severe heart failure has developed may halt the progression or even reverse the course of this disease, unlike the idiopathic variety, which is marked by progressive deterioration. Alcoholic patients with advanced heart failure have a poor prognosis, particularly if they continue to drink; fewer than one-quarter survive 3 years. The key to the treatment of alcoholic cardiomyopathy is total and permanent abstinence.

A second presentation of alcoholic cardiotoxicity may be found in individuals without overt heart failure and consists of recurrent supraventricular or ventricular tachyarrhythmias. Termed the *holiday heart syndrome*, it typically appears after a drinking binge; atrial fibrillation is seen most frequently, followed by atrial flutter and ventricular premature depolarizations. Other patients develop left ventricular hypertrophy, perhaps related to concomitant systemic hypertension; they may present with symptoms of pulmonary congestion due to abnormal diastolic stiffness (diminished compliance) of the left ventricle (Chap. 231).

PERIPARTUM CARDIOMYOPATHY (See Chap. 7)

Cardiac dilatation and congestive heart failure of unexplained cause may develop during the last trimester of pregnancy or within 6 months after delivery; most women develop symptoms in the month before or immediately after delivery. The cause of this disorder is unknown, but in some patients endomyocardial biopsy has shown evidence of a myocarditis. Necropsy shows cardiac enlargement, often with mural thrombi, along with

histologic evidence of myocardial degeneration and fibrosis. The patient who develops peripartum cardiomyopathy typically is multiparous, African American, and over the age of 30, although the disease may be found in a wide spectrum of patients. The symptoms, signs, and treatment are similar to those in patients with idiopathic dilated cardiomyopathy. The mortality rate is quite variable but may be as high as 25 to 50%. The prognosis in these patients appears to be closely related to whether the heart size returns to normal after the first episode of congestive heart failure. If it does, subsequent pregnancies may sometimes be well tolerated; if the heart remains enlarged, however, further pregnancies frequently produce increasing myocardial damage, ultimately leading to refractory congestive heart failure and death. Those who recover should be encouraged to avoid further pregnancies, particularly if cardiomegaly persists.

NEUROMUSCULAR DISEASE (See also Chap. 381)

Cardiac involvement is common in many of the muscular dystrophies. In *Duchenne's progressive muscular dystrophy*, mutations in a gene that encodes a cardiac structural protein called *dystrophin* lead to myocyte death. Myocardial involvement is most frequently indicated by a distinctive and unique electrocardiographic pattern consisting of tall R waves in right precordial leads with an R/S ratio greater than 1.0, often associated with deep Q waves in the limb and lateral precordial leads. These electrocardiographic abnormalities appear to result from selective transmural necrosis of the posterobasal left ventricle and associated papillary muscle. A variety of supraventricular and ventricular arrhythmias are frequently found. Rapidly progressive congestive heart failure may develop despite extended periods of apparent circulatory stability during which the only detectable abnormalities are in the electrocardiogram. *Myotonic dystrophy* is characterized by a variety of electrocardiographic abnormalities, especially disorders of impulse formation and conduction, but other overt clinical evidence of heart disease is uncommon. Because of these abnormalities, syncope and sudden death are major hazards; in appropriate patients, insertion of a permanent pacemaker may be effective. In *limb-girdle dystrophy* and *fascioscapulohumeral dystrophy*, cardiac involvement is uncommon and seldom severe, although arrhythmias and conduction disturbances may be seen on occasion. Involvement of the heart is very common in *Friedreich's ataxia* (manifested by abnormal electrocardiographic or echocardiographic findings), with as many as half the patients developing cardiac symptoms. The electrocardiogram most commonly demonstrates ST-segment and T-wave abnormalities. The echocardiogram may demonstrate left ventricular hypertrophy, with either symmetric or asymmetric hypertrophy of the left ventricular septum compared with the free wall. Although morphologically similar to some cases of hypertrophic cardiomyopathy, cellular disarray is lacking.

DRUGS

A variety of pharmacologic agents may damage the myocardium acutely, producing a pattern of inflammation (myocarditis), or they may lead to chronic damage of the type seen with idiopathic dilated cardiomyopathy (Chap. 71). Certain drugs produce only electrocardiographic abnormalities, while others may precipitate fulminant congestive heart failure and death.

The anthracycline derivatives, particularly *doxorubicin* (Adriamycin), are powerful

antineoplastic agents that, when given in high doses (more than 550 mg/m^2 for doxorubicin), may produce fatal heart failure. The incidence of heart failure is related not only to the dose of the drug but also to the presence or absence of several risk factors (cardiac irradiation, age>70 years, underlying heart disease, hypertension, treatment with cyclophosphamide); at any dose, patients with these risk factors have an eight- to tenfold greater frequency of developing heart failure than do patients lacking them. Radionuclide ventriculography and echocardiography, usually combined with exercise stress, may document preclinical deterioration of left ventricular function and allow appropriate dose adjustments; by so monitoring left ventricular function, it is often possible to continue doxorubicin even in patients at high risk for developing heart failure. Efforts to modify the dose schedule by giving the drug more slowly, along with the selective use of potentially cardioprotective agents such as the iron-chelator dexrazoxone, have further reduced the risk of cardiotoxicity. Some patients with congestive heart failure, even those with severe depression of left ventricular function, have demonstrated recovery of cardiac function with aggressive management withACEinhibitors and diuretics. In others, late asymptomatic contractile dysfunction is common, even in those without initial cardiotoxicity. Children may demonstrate reduced myocardial hypertrophy and mass over time, presumably due to doxorubicin's inhibition of myocardial cell growth.

High-dose *cyclophosphamide* may produce congestive heart failure acutely or within 2 weeks of administration; a characteristic histopathologic feature is myocardial edema and hemorrhagic necrosis. Rarely, patients treated with *5-fluorouracil* will develop chest pain and electrocardiographic changes of myocardial ischemia or infarction. Electrocardiographic changes and arrhythmias may result from treatment with tricyclic antidepressants, the phenothiazines, emetine, lithium, and various aerosol propellants. *Cocaine abuse* is associated with a variety of life-threatening cardiac complications, including sudden death, myocarditis, dilated cardiomyopathy, and acute myocardial infarction (resulting from coronary spasm and/or thrombosis with or without underlying coronary artery stenosis). Nitrates and calcium channel blockers have been used to treat cocaine-induced cardiotoxicities; b-adrenergic blockers should be avoided.

HYPERTROPHIC CARDIOMYOPATHY

Hypertrophic cardiomyopathy (HCM) is characterized by left ventricular hypertrophy, typically of a nondilated chamber, without obvious cause such as hypertension or aortic stenosis (Fig. 238-CD3). It is found in about 1 in 500 of the general population. Two features of HCM have attracted the greatest attention: (1) heterogeneous left ventricular hypertrophy, often with preferential hypertrophy of the interventricular septum resulting in asymmetric septal hypertrophy; and (2) a dynamic left ventricular outflow tract pressure gradient, related to a narrowing of the subaortic area as a consequence of the midsystolic apposition of the anterior mitral valve leaflet against the hypertrophied septum, i.e., systolic anterior motion (SAM) of the mitral valve (Fig. 238-CD4). Initial studies of this disease emphasized the dynamic "obstructive" features, and it has been termed *idiopathic hypertrophic subaortic stenosis* and *hypertrophic obstructive cardiomyopathy*. It has become clear, however, that only about one-quarter of patients with HCM demonstrate an outflow tract pressure gradient. The ubiquitous pathophysiologic abnormality is not systolic but rather *diastolic* dysfunction (Chap. 231), characterized by increased stiffness of the hypertrophied muscle. This results in

elevated diastolic filling pressures and is present despite a hyperdynamic left ventricle.

The pattern of hypertrophy is distinctive in HCM and differs from that seen in secondary hypertrophy (as in hypertension). Most patients have striking regional variations in the extent of hypertrophy in different portions of the left ventricle, and the majority demonstrate a ventricular septum whose thickness is disproportionately increased when compared with the free wall. Other patients may demonstrate disproportionate involvement of the apex or left ventricular free wall; 10% or more of patients have concentric involvement of the ventricle. A bizarre and disorganized arrangement of cardiac muscle cells in the septum occurs, with disorganization of the myofibrillar architecture, along with a variable degree of myocardial fibrosis and thickening of the small intramural coronary arteries. In some children, systolic compression of an intramyocardial segment of a coronary artery may lead to ischemia and death.

GENETIC CONSIDERATIONS

About half of all patients with HCMhave a positive family history compatible with autosomal-dominant transmission, and more than 100 different mutations have been identified. About 40% of these are associated with mutations of the cardiac b-myosin heavy chain gene on chromosome 14, with certain mutations associated with more malignant prognoses. About 15% have a mutation of the cardiac troponin T gene on chromosome 1, 20% a mutation of myosin-binding protein C (chromosome 11), and about 5% a mutation of the a-tropomyosin gene. The remainder of familial cases are due to mutations of other genes such as the gene for troponin I. Echocardiographic studies have confirmed that about one-third of the first-degree relatives of patients with familial HCM have evidence of the disease, although in many of these patients the extent of hypertrophy is mild, no outflow tract pressure gradient is present, and symptoms are not prominent. Since the hypertrophic characteristics may not be apparent in childhood and often appear first in adolescence, a single normal echocardiogram in a child does not exclude the presence of the disease. Many sporadic cases of HCM probably represent spontaneous mutations.

HEMODYNAMICS

In contrast to the obstruction produced by a fixed narrowed orifice, such as valvular aortic stenosis, the pressure gradient inHCM, when present, is dynamic and may change between examinations and even from beat to beat. Obstruction appears to result from further narrowing of an already small left ventricular outflow tract bySAM of the mitral valve against the hypertrophied septum. While SAM is occasionally found in a variety of conditions besides HCM, it is *always* found when obstruction is present in HCM. Three basic mechanisms are involved in the production and intensification of the dynamic pressure gradient: (1) increased left ventricular contractility, (2) decreased ventricular volume (preload), and (3) decreased aortic impedance and pressure (afterload). Interventions that increase myocardial contractility, such as exercise, sympathomimetic amines, and digitalis glycosides, and those that reduce ventricular volume, such as the Valsalva maneuver, sudden standing, nitroglycerin, amyl nitrite, or tachycardia, may all cause an increase in the gradient and the murmur. Conversely, elevation of arterial pressure by phenylephrine, squatting, sustained handgrip, augmentation of venous return by passive leg raising, and expansion of the blood

volume all increase ventricular volume and ameliorate the gradient and murmur.

CLINICAL FEATURES

The clinical course ofHCM is highly variable. Many patients are asymptomatic or mildly symptomatic and may be relatives of patients with known disease. Unfortunately, the first clinical manifestation of the disease may be sudden death, frequently occurring in children and young adults, often during or after physical exertion. In symptomatic patients, the most common complaint is dyspnea, largely due to increased stiffness of the left ventricular walls, which impairs ventricular filling and leads to elevated left ventricular diastolic and left atrial pressures. Other symptoms include angina pectoris, fatigue, syncope, and near-syncope ("graying-out spells"). Symptoms are not closely related to the presence or severity of an outflow pressure gradient. Most patients with gradients demonstrate a double or triple apical precordial impulse, a rapidly rising carotid arterial pulse, and a fourth heart sound. The hallmark of obstructive HCM is a systolic murmur, which is typically harsh, diamond-shaped, and usually begins well after the first heart sound, since ejection is unimpeded early in systole (Fig. 238-CD5). The murmur is best heard at the lower left sternal border as well as at the apex, where it is often more holosystolic and blowing in quality, no doubt due to the mitral regurgitation that usually accompanies obstructive HCM.

LABORATORY EVALUATION

The *electrocardiogram* commonly shows left ventricular hypertrophy and widespread, deep, broad Q waves that suggest an old myocardial infarction. Many patients demonstrate arrhythmias, both atrial (supraventricular tachycardia or atrial fibrillation) and ventricular (ventricular tachycardia), during ambulatory (Holter) monitoring. *Chest roentgenography* may be normal, although a mild to moderate increase in the cardiac silhouette is common. The mainstay of the diagnosis ofHCM is the *echocardiogram* (Fig. 238-CD6), which demonstrates left ventricular hypertrophy, often with the septum 1.3 or more times the thickness of the high posterior left ventricular free wall. The septum may demonstrate an unusual "ground-glass" appearance, probably related to its abnormal cellular architecture and myocardial fibrosis.SAM of the mitral valve is found in patients with pressure gradients. The left ventricular cavity typically is small in HCM, with vigorous posterior wall motion but reduced septal excursion. A rare form of HCM, characterized by apical hypertrophy, is often associated with giant negative T waves on the electrocardiogram and a "spade-shaped" left ventricular cavity on angiography; it usually has a benign clinical course. *Radionuclide scintigraphy* with thallium 201 frequently reveals evidence of myocardial perfusion defects even in asymptomatic patients.

Although cardiac catheterization is not required to diagnose HCM, the two typical *hemodynamic* features are an elevated left ventricular diastolic pressure due to diminished left ventricular compliance and, when obstruction is present, a systolic pressure gradient between the body of the left ventricle and the subaortic region. When a gradient is not present, it can be induced in some patients by provocative maneuvers such as infusion of isoproterenol, inhalation of amyl nitrite, or the Valsalva maneuver.

TREATMENT

Since sudden death often occurs during or just after physical exertion, competitive sports and probably strenuous activity should be proscribed. Dehydration should be avoided, and diuretics should be used with caution.b-Adrenergic blockers are often used and ameliorate angina pectoris and syncope in one-third to one-half of patients. Resting intraventricular pressure gradients are usually unchanged, although these drugs may limit the increase in the gradient that occurs during exercise. It is not known whether b-adrenergic blockers offer any protection against sudden death. Amiodarone appears to be effective in reducing the frequency of supraventricular as well as life-threatening ventricular arrhythmias, and anecdotal data suggest that it may reduce the risk of sudden death. Verapamil and diltiazem may reduce the stiffness of the ventricle, reduce the elevated diastolic pressures, increase exercise tolerance, and, in some instances, reduce the severity of outflow tract pressure gradients, although adverse side effects occur in about one-quarter of patients. Nifedipine should be avoided. The combination of beta blockers and calcium antagonists should be used with caution. Disopyramide has been used in some patients to reduce left ventricular contractility and the outflow pressure gradient.

If atrial fibrillation occurs, a strenuous effort should be made to restore and then maintain sinus rhythm. Dual-chamber permanent pacing with a short PR interval has been reported to improve symptoms and reduce the outflow gradient in some patients with severe symptoms, presumably by altering the pattern of ventricular depolarization and contraction. Infarction of the interventricular septum induced by ethanol injections into the septal artery has also been reported to reduce obstruction. The insertion of an implantable cardioverter defibrillator should be considered in patients surviving cardiac arrest and those with high-risk ventricular tachyarrhythmias (Chap. 230). A surgical myotomy/myectomy of the hypertrophied septum may result in lasting symptomatic improvement in about three-quarters of severely symptomatic patients with large pressure gradients who are unresponsive to medical management. The effect of any of these therapies on the natural history is not clear. Digitalis, diuretics, nitrates, vasodilators, and b-adrenergic agonists are best avoided if possible, particularly in patients with known left ventricular outflow tract pressure gradients. Even social alcohol ingestion may produce sufficient vasodilatation to exacerbate an outflow pressure gradient.

First-degree relatives of patients with HCMshould be screened by echocardiography.

PROGNOSIS

The natural history ofHCM is variable, although many patients never exhibit any clinical manifestations. Others demonstrate an improvement of symptoms with time. Atrial fibrillation is common late in the course of the disease; its onset may lead to an increase in symptoms, due to loss of the atrial contribution to filling of the thickened ventricle. Infective endocarditis occurs in fewer than 10% of patients, and endocarditis prophylaxis is indicated, particularly in patients with resting obstruction and mitral regurgitation. Progression of HCM to left ventricular dilatation and dysfunction without an outflow pressure gradient has been reported but is unusual; in about 5 to 10% of patients, however, some degree of left ventricular systolic impairment, wall thinning, and chamber enlargement occurs over time. The major cause of mortality in HCM is sudden death,

which may occur in asymptomatic patients or interrupt an otherwise stable course in symptomatic ones. Predictors of sudden death include age less than 30 years, ventricular tachycardia on ambulatory monitoring, marked ventricular hypertrophy, syncope (especially in children), genetic mutations associated with an increased risk, and a family history of sudden death. There is no correlation between the risk of sudden death and the severity of symptoms or the presence or severity of an outflow tract pressure gradient.

RESTRICTIVE CARDIOMYOPATHY

The hallmark of the restrictive cardiomyopathies is abnormal diastolic function (Chap. 231); the ventricular walls are excessively rigid and impede ventricular filling. Myocardial fibrosis, hypertrophy, or infiltration due to a variety of causes (Fig. 238-CD7) is usually responsible. The infiltrative diseases, which represent important causes for secondary restrictive cardiomyopathy, may also show some impairment of systolic function. Myocardial involvement with *amyloid* is a common cause of secondary restrictive cardiomyopathy, although restriction is also seen in hemochromatosis, glycogen deposition, endomyocardial fibrosis, sarcoidosis, Fabry's disease, the eosinophilias, and scleroderma; in the transplanted heart and following mediastinal radiation; and in neoplastic infiltration and myocardial fibrosis of diverse causes. In many of these conditions, particularly those with substantial concomitant endocardial involvement, partial obliteration of the ventricular cavity by fibrous tissue and thrombus contributes to the abnormally increased resistance to ventricular filling. Thromboembolic complications ensue in about a third of patients.

The inability of the ventricle to fill limits cardiac output and raises filling pressure. Therefore, exercise intolerance and dyspnea are usually the most prominent symptoms. As a result of persistently elevated venous pressure, these patients commonly have dependent edema, ascites, and an enlarged, tender, and often pulsatile liver. The jugular venous pressure is elevated and does not fall normally, or it may rise with inspiration (Kussmaul's sign). The heart sounds may be distant, and third and fourth heart sounds are common. In contrast to constrictive pericarditis, which the restrictive cardiomyopathies resemble in many respects, the apex impulse is usually easily palpable, and mitral regurgitation is more common. The electrocardiogram often shows low-voltage, nonspecific ST-T-wave changes and various arrhythmias. Pericardial calcification on x-ray, which would suggest constrictive pericarditis, is absent. Echocardiography typically reveals symmetrically thickened left ventricular walls and normal or slightly reduced ventricular volumes and systolic function. Doppler recordings demonstrate accentuated early diastolic filling. Cardiac catheterization shows a decreased cardiac output, elevation of the right and left ventricular end-diastolic pressures, and a dip-and-plateau configuration of the diastolic portion of the ventricular pressure pulse resembling that seen in constrictive pericarditis.

Differentiation from constrictive pericarditis may be challenging (Chap. 239). This distinction is of importance because the latter condition is potentially curable by operation. Helpful in the differentiation of these two diseases are right ventricular transvenous endomyocardial biopsy (by revealing myocardial infiltration or fibrosis in restrictive cardiomyopathy) and computed tomography or magnetic resonance imaging (by demonstrating a thickened pericardium in constrictive pericarditis). Treatment is

usually disappointing, except for hemochromatosis (where desferoxamine has been helpful in reducing myocardial iron content). Chronic anticoagulation is often recommended to reduce the risk of embolization from the heart.

ENDOMYOCARDIAL FIBROSIS

This is a progressive disease of unknown cause that occurs most commonly in children and young adults residing in tropical and subtropical Africa, particularly Uganda and Nigeria. Endomyocardial fibrosis is a frequent cause of heart failure in Africa, accounting for up to one-quarter of deaths due to heart disease. The condition is characterized by fibrous endocardial lesions of the inflow portion of the right or left ventricle (or both) and often involves the atrioventricular valves, producing valvular regurgitation. The apex of the ventricles may be obliterated by a mass of thrombus and fibrous tissue. In some ways this disease resembles eosinophilic endomyocardial disease (see below), although they occur in quite different geographic areas and age groups and generally are felt to be different diseases.

The clinical picture depends on which ventricle and atrioventricular valve show predominant involvement; left-sided involvement results in symptoms of pulmonary congestion, while predominant right-sided disease presents features of a restrictive cardiomyopathy. Medical treatment is often disappointing, and surgical excision of the fibrotic endocardium and replacement of the involved atrioventricular valve have led to substantial symptomatic improvement in some patients.

EOSINOPHILIC ENDOMYOCARDIAL DISEASE

Also called *Loeffler's endocarditis* and *fibroplastic endocarditis*, this disease appears to be a subcategory of the hypereosinophilic syndrome in which the heart is predominantly involved, with cardiac damage the apparent result of the toxic effects of eosinophilic proteins. Typically, the endocardium of either or both ventricles thickens markedly, with involvement of the underlying myocardium. Large mural thrombi may develop in either ventricle, thereby compromising the size of the ventricular cavity and serving as a source of pulmonary and systemic emboli. Hepatosplenomegaly and localized eosinophilic infiltration of other organs are usually present. Management usually includes diuretics, afterload-reducing agents, and anticoagulation. The use of glucocorticoids and cytotoxic drugs (hydroxyurea in particular) appears to have improved survival substantially. Surgical treatment, as for endomyocardial fibrosis, may be helpful in selected patients.

DIFFERENTIAL DIAGNOSIS

Involvement of the heart is the most frequent cause of death in *primary amyloidosis* (Chap. 319), while clinically significant cardiac involvement is uncommon in the secondary form. Focal deposits of amyloid in elderly patients (*senile cardiac amyloidosis*) are common and usually clinically insignificant. Aspiration of abdominal fat or biopsy of the rectal mucosa, gingiva, liver, kidney, or myocardium permits the diagnosis to be made before death in over three-quarters of cases. The heart is firm, rubbery, and noncompliant, and four clinical presentations (alone or in combination) are seen: (1) diastolic dysfunction (restrictive cardiomyopathy), (2) systolic dysfunction, (3)

arrhythmias and conduction disturbances, and (4) orthostatic hypotension. The two-dimensional echocardiogram may be helpful in making the diagnosis of amyloidosis and may show a thickened myocardial wall with a distinctive "speckled" appearance. Chemotherapy, often with alkylating agents, appears to have improved survival in specific cases, but the overall prognosis is poor.

Hemochromatosis (Chap. 345) is often the result of multiple transfusions or a hemoglobinopathy; the familial (autosomal recessive) form should be suspected if cardiomyopathy occurs in the setting of diabetes mellitus, hepatic cirrhosis, and increased skin pigmentation. The diagnosis may be confirmed by endomyocardial biopsy. Phlebotomy may be of some benefit if employed early in the course of the disease. Continuous subcutaneous administration of deferoxamine may reduce body iron stores and result in clinical improvement.

Myocardial *sarcoidosis* (Chap. 318) is generally associated with other manifestations of systemic disease and may cause restrictive as well as congestive features, since cardiac infiltration by sarcoid granulomas results not only in increased stiffness of the myocardium but also in diminished systolic contractile function. A variety of arrhythmias, including high-grade atrioventricular block, have been noted. A common cardiac manifestation of systemic sarcoidosis is right heart overload due to pulmonary artery hypertension as a result of parenchymal pulmonary involvement. The *carcinoid syndrome* results in endocardial fibrosis and stenosis and/or regurgitation of the tricuspid and/or pulmonary valve (Chap. 236); morphologically similar lesions have been seen with the use of the anorexic agents fenfluramine and phentermine.

MYOCARDITIDES

Myocarditis, i.e., cardiac inflammation, is most commonly the result of an infectious process. Myocarditis may also result from a hypersensitivity to drugs or may be caused by radiation, chemicals, or physical agents. In an unknown number of cases, acute myocarditis progresses to chronic dilated cardiomyopathy. While almost every infectious agent is capable of producing myocarditis (Table 238-1), clinically significant acute myocarditis in the United States is caused most commonly by viruses, especially coxsackievirus B. The clinical manifestations range from an asymptomatic state, with the presence of myocarditis inferred only by the finding of transient electrocardiographic ST-T-wave abnormalities, to a fulminant condition with arrhythmias, heart failure, and death. In some patients, myocarditis simulates acute myocardial infarction, with chest pain, electrocardiographic changes, and elevated serum levels of myocardial enzymes.

The physical examination is often normal, although more severe cases may show a muffled first heart sound, along with a third heart sound and a murmur of mitral regurgitation. A pericardial friction rub may be audible in patients with associated pericarditis.

Though viral myocarditis is most often self-limited and without sequelae, severe involvement may recur, and it is likely that acute viral myocarditis occasionally progresses to a chronic form and to dilated cardiomyopathy. Patients with viral myocarditis often give a history of a preceding upper respiratory febrile illness or a flulike syndrome, and viral nasopharyngitis or tonsillitis may be evident clinically. The

isolation of virus from the stool, pharyngeal washings, or other body fluids and changes in specific antibody titers are helpful clinically. Endomyocardial biopsy, carried out early in the illness, may show round-cell infiltration and necrosis of adjacent myocytes.

Experimental studies suggest that exercise may be deleterious in patients with viral myocarditis, and strenuous activity should be proscribed until the electrocardiogram has returned to normal. Patients who develop congestive heart failure respond to the usual measures (ACEinhibitors, diuretics, and salt restriction), but they appear to be unusually sensitive to digitalis. Arrhythmias are common and are occasionally difficult to manage. Deaths attributed to heart failure, tachyarrhythmias, and heart block have been reported, and it seems prudent to monitor the electrocardiogram of patients with arrhythmias, especially during the acute illness.

HIV MYOCARDITIS (See alsoChap. 309)

Many HIV-infected patients have subclinical cardiac involvement, including pericardial effusion, right-sided chamber enlargement, and neoplastic involvement. Overt clinical involvement is seen in 10% of HIV patients, and the most common finding is left ventricular dysfunction that in some cases appears to be due to infiltration of the myocardium by the virus itself. In other patients, the heart is affected by any of the various opportunistic infections common in AIDS, such as toxoplasmosis, as well as by cardiac metastases in Kaposi's sarcoma. The clinical manifestations of cardiac involvement may be incorrectly attributed to concurrent noncardiac problems such as pneumonia. This is unfortunate, since the dilated cardiomyopathy of HIV infection may respond at least transiently to standard therapy with digitalis, diuretics, and ACE inhibitors.

BACTERIAL MYOCARDITIS

Bacterial involvement of the heart is uncommon, but when it does occur, it is usually as a complication of bacterial endocarditis (typically due to *Staphylococcus aureus* and enterococci). Myocardial abscess formation may involve the valve rings and interventricular septum. *Diphtheritic myocarditis* develops in over one-quarter of the patients with diphtheria, is one of the most serious complications, and is the most common cause of death (Chap. 141). Cardiac damage is due to the liberation of a toxin that inhibits protein synthesis and leads to a dilated, flabby, hypocontractile heart; the conducting system is frequently involved as well. Cardiomegaly and severe congestive heart failure typically appear after the first week of illness. Prompt therapy with antitoxin is crucial; antibiotic therapy is also indicated but is of less urgency.

CHAGAS' DISEASE

Chagas' disease, caused by the protozoan *Trypanosoma cruzi* and transmitted by an insect vector (Chap. 216), produces an extensive myocarditis that typically becomes evident years after the initial infection. It is one of the most common causes of heart disease encountered in Central and South America; in rural endemic areas 20 to 75% of the population may be affected. An increasing number of cases are found in the United States as patients migrate from endemic areas. Although only about 1% of infected individuals have an acute illness, which may include acute myocarditis, upwards of

one-third develop chronic myocardial damage many years later. The chronic form is characterized by dilatation of several cardiac chambers, fibrosis and thinning of the ventricular wall, aneurysm formation (especially at the left ventricular apex), and mural thrombi. Chronic progressive heart failure is the rule and is associated with poor survival. The electrocardiogram is abnormal in most patients with cardiac involvement and typically shows right bundle branch block and left anterior hemiblock, which may progress to complete atrioventricular block. The *echocardiogram* may reveal a unique pattern of hypokinesis of the posterior left ventricular wall and relatively preserved septal motion. Ventricular arrhythmias are common and are seen especially during and after exertion; oral amiodarone appears to be particularly effective in treating ventricular tachyarrhythmias. The cause of death is either intractable congestive heart failure or an arrhythmia, with a minority of patients dying from embolic phenomena.

TREATMENT

Therapy is directed toward amelioration of the congestive heart failure and arrhythmias; progressive conduction system disease and heart block may require implantation of a pacemaker. Anticoagulation (if feasible) may reduce the risk of thromboembolism. Medical therapy is often unsatisfactory or unavailable (especially in poor rural areas), however, and a more promising tactic in endemic areas has been the institution of public health measures, particularly the use of insecticides to eliminate the vector.

GIANT CELL MYOCARDITIS

This rare myocarditis of unknown cause is characterized by the presence of multinucleated giant cells in the myocardium. It usually causes rapidly fatal congestive heart failure and arrhythmia in young to middle-aged adults. At necropsy, the distinctive features include cardiac enlargement, ventricular thrombi, grossly visible serpiginous areas of myocardial necrosis in both ventricles, and microscopic evidence of giant cells within an extensive inflammatory infiltrate. The cause of giant cell myocarditis remains obscure, although it occurs in association with thymoma, systemic lupus erythematosus, and thyrotoxicosis. While treatment with immunosuppressive therapy may help in some patients, cardiac transplantation is the treatment of choice.

LYME CARDITIS(See also Chap. 176)

Lyme disease is caused by a tick-borne spirochete and is most common in the Northeast, upper Midwest, and Pacific Coastal regions of the United States during the summer months. About 10% of patients develop symptomatic cardiac involvement during the acute phase of the disease. Atrioventricular nodal conduction abnormalities are the most common manifestations of involvement, and may lead to syncope. Concomitant myopericarditis is not uncommon, and mild asymptomatic left ventricular dysfunction may occur. Intravenous ceftriaxone or penicillin is used in all but the mildest forms of Lyme carditis, in which case oral amoxicillin or doxycycline is employed. Hospitalization with electrocardiographic monitoring is indicated in patients with second- or third-degree atrioventricular block. A temporary pacemaker may be needed for symptomatic heart block; the utility of glucocorticoids in reversing heart block is uncertain, but they are usually employed. Long-term cardiac manifestations of Lyme disease are uncommon.

239. PERICARDIAL DISEASE - *Eugene Braunwald*

NORMAL FUNCTIONS OF THE PERICARDIUM

The visceral pericardium is a serous membrane that is separated by a small quantity (15 to 50 mL) of fluid, an ultrafiltrate of plasma, from a fibrous sac, the parietal pericardium. The pericardium normally prevents sudden dilatation of the cardiac chambers during exercise and with hypervolemia. As the result of the development of a negative intrapericardial pressure during ejection, the pericardial sac facilitates atrial filling during ventricular systole. The pericardium also restricts the anatomic position of the heart, minimizes friction between the heart and surrounding structures, prevents displacement of the heart and kinking of the great vessels, and probably retards the spread of infections from the lungs and pleural cavities to the heart. Notwithstanding the foregoing, total absence of the pericardium does not produce obvious clinical disease. In partial left pericardial defects the main pulmonary artery and left atrium may bulge through the defect; very rarely, herniation and subsequent strangulation of the left atrium may cause sudden death.

ACUTE PERICARDITIS

Acute pericarditis, by far the most common pathologic process involving the pericardium, may be classified both clinically and etiologically (Table 239-1). Pain, a pericardial friction rub, electrocardiographic changes, and pericardial effusion with cardiac tamponade and paradoxic pulse are cardinal manifestations of many forms of acute pericarditis and will be considered prior to a discussion of the most common forms of the disorder.

Chest pain is an important but not invariable symptom in various forms of acute pericarditis (Chap. 13); it is usually present in the acute infectious types and in many of the forms presumed to be related to hypersensitivity or autoimmunity. Pain is often absent in a slowly developing tuberculous, postirradiation, neoplastic, or uremic pericarditis. The pain of pericarditis is often severe. It is characteristically retrosternal and left precordial, referred to the back and the left trapezius ridge. Often the pain is pleuritic consequent to accompanying pleural inflammation, i.e., sharp and aggravated by inspiration, coughing, and changes in body position, but sometimes it is a steady, constricting pain that radiates into either arm or both arms and resembles that of myocardial ischemia; therefore, confusion with myocardial infarction is common. Characteristically, however, pericardial pain may be relieved by sitting up and leaning forward and is intensified by lying supine. The differentiation of acute myocardial infarction from acute pericarditis becomes perplexing when, with acute pericarditis, the serum creatine kinase level rises, presumably because of concomitant involvement of the epicardium. However, these enzyme elevations, if they occur, are quite modest, given the extensive electrocardiographic ST-segment elevation in pericarditis.

The *pericardial friction rub* is the most important physical sign of acute pericarditis; it may have up to three components per cardiac cycle and is high-pitched, scratching, and grating, as described in Chap. 225; it can sometimes be elicited only when firm pressure with the diaphragm of the stethoscope is applied to the chest wall at the left lower sternal border. It is heard most frequently during expiration with the patient in the sitting

position. The rub is often inconstant and the loud to-and-fro leathery sound may disappear within a few hours, possibly to reappear the following day.

The *electrocardiogram* (ECG) in acute pericarditis without massive effusion usually displays changes secondary to acute subepicardial inflammation (seeFig. 226-18, p. 1270). There is widespread elevation of the ST segments, often with upward concavity, involving two or three standard limb leads and V_2 to V_6, with reciprocal depressions only in aVR and sometimes V_1. Usually there are no significant changes in QRS complexes, except for some reduction in voltage in patients with large pericardial effusions. After several days, the ST segments return to normal, and only then do the T waves become inverted. In contrast, in acute myocardial infarction, reciprocal depression of ST segments is usually more prominent; QRS changes occur, particularly the development of Q waves, as well as notching and loss of R-wave amplitude; and T-wave inversions usually occur within hours *before* the ST segments have become isoelectric. Sequential ECGs are useful in distinguishing acute pericarditis from acute myocardial infarction. In the latter, elevated ST segments return to normal within hours. Early repolarization is a normal variant and may also cause widespread ST-segment elevation, most prominent in left precordial leads. However, in this condition the T waves are usually tall and the ST/T ratio is under 0.25, but this ratio is higher in acute pericarditis. Depression of the PR segment (below the TP segment) is also common and reflects atrial involvement. With large pericardial effusions, the QRS voltage is reduced; atrial premature beats and atrial fibrillation are sometimes noted.

PERICARDIAL EFFUSION

In acute pericarditis, pericardial effusion is usually associated with pain and/or the above-mentionedECGchanges characteristic of pericarditis and an enlargement of the cardiac silhouette. Pericardial effusion is especially important clinically when it develops within a relatively short time, since it may lead to cardiac tamponade (see below). Differentiation from cardiac enlargement may be difficult on physical examination, but heart sounds tend to become faint with pericardial effusion; the friction rub may disappear, and the apex impulse may vanish, but sometimes it remains palpable, albeit medial to the left border of cardiac dullness. The base of the left lung may be compressed by pericardial fluid, producing Ewart's sign, a patch of dullness beneath the angle of the left scapula. The chest roentgenogram may show a "water bottle" configuration of the cardiac silhouette but may also be normal or almost so. Lucent pericardial fat lines may be seen deep within the cardiopericardial silhouette. Fluoroscopic examination may show the ventricular pulsations to be diminished. Pericardial effusion is common after cardiac surgery and myocardial infarction.

Diagnosis *Echocardiography* is the most effective diagnostic laboratory technique available, since it is sensitive, specific, simple, noninvasive, may be performed at the bedside, and can identify accompanying cardiac tamponade (see below). The presence of pericardial fluid is recorded by two-dimensional transthoracic echocardiography as a relatively echo-free space between the posterior pericardium and left ventricular epicardium in patients with small effusions and as a space between the anterior right ventricle and the parietal pericardium just beneath the anterior chest wall in those with larger effusions. In the latter the heart may swing freely within the pericardial sac; when severe, the extent of this motion alternates and may be associated with electrical

alternans. Echocardiography allows localization and estimation of the quantity of pericardial fluid. The diagnosis of pericardial fluid or thickening may be confirmed by computed tomography (CT) or magnetic resonance imaging (MRI); these techniques may be superior to echocardiography in detecting loculated pericardial effusions and pericardial thickening.

Pericardiocentesis When pericardial fluid is removed for diagnostic and/or therapeutic purposes, a needle attached to a properly groundedECG lead is inserted into the pericardial space, usually through a subxiphoid approach, and, if possible, using echocardiographic control. Intrapericardial pressure should be measured before fluid is withdrawn. Pericardial effusion nearly always has the physical characteristics of an exudate. Bloody fluid is commonly due to tuberculosis or tumor but may also be found in the effusion of rheumatic fever, post-cardiac injury, and post-myocardial infarction (especially following the administration of anticoagulant), and in uremic pericarditis. Transudative pericardial effusions may occur in heart failure.

CARDIAC TAMPONADE

The accumulation of fluid in the pericardium in an amount sufficient to cause serious obstruction to the inflow of blood to the ventricles results in cardiac tamponade. This complication may be fatal if it is not recognized and treated promptly. The three most common causes of tamponade are neoplastic disease, idiopathic pericarditis, and uremia. Tamponade may also result from bleeding into the pericardial space either following cardiac operations and trauma (including cardiac perforation during diagnostic procedures) or from tuberculosis and hemopericardium. The latter may occur when a patient with any form of acute pericarditis is treated with anticoagulants.

The three principal features of tamponade are elevation of intracardiac pressures, limitation of ventricular filling, and reduction of cardiac output. The quantity of fluid necessary to produce this critical state may be as small as 200 mL when the fluid develops rapidly or more than 2000 mL in slowly developing effusions when the pericardium has had the opportunity to stretch and adapt to an increasing volume. The volume of fluid required to produce tamponade also varies directly with the thickness of the ventricular myocardium and inversely with the thickness of the parietal pericardium.

Table 239-2 lists the features that distinguish cardiac tamponade from constrictive pericarditis. The classic findings of falling arterial pressure, rising venous pressure, and faint heart sounds usually occur only with severe, acute tamponade, as occurs with cardiac trauma or rupture. Tamponade may also develop more slowly, and under these circumstances the clinical manifestations may resemble those of heart failure, including dyspnea, orthopnea, hepatic engorgement, and jugular venous hypertension. A high index of suspicion for cardiac tamponade is required, since, in many instances, no obvious cause for pericardial disease is apparent. Tamponade should be considered in any patient with hypotension and elevation of jugular venous pressure with a prominent *x* descent; in contrast to constrictive pericarditis, in which the *y* descent is prominent (Chap. 225), in cardiac tamponade it is diminutive or absent. A positive Kussmaul sign (see below) is rare in cardiac tamponade, as is a pericardial knock. Their presence suggests that an organizing process and epicardial constriction are present in addition to effusion. A widening of the area of flatness to percussion across the anterior aspect

of the chest wall, a paradoxical pulse (see below), hypotension, relatively clear lung fields, diminished pulsations of the cardiac silhouette on fluoroscopy, enlargement of the cardiac silhouette (especially in subacute or chronic tamponade), reduction in amplitude of the QRS complexes, and *electrical alternans* of the P, QRS, and T waves should raise the suspicion of cardiac tamponade.

Paradoxical Pulse This important clue to the presence of cardiac tamponade consists of *a greater than normal (10 mmHg) inspiratory decline in systolic arterial pressure.* When severe, it may be detected by palpating weakness or disappearance of the arterial pulse during inspiration, but usually sphygmomanometric measurement of systolic pressure during slow respiration is required (Fig. 239-CD1).

Since both ventricles share a tight incompressible covering, i.e., the pericardial sac, the inspiratory enlargement of the right ventricle in cardiac tamponade compresses and reduces left ventricular volume; leftward bulging of the interventricular septum further reduces the left ventricular cavity as the right ventricle enlarges during inspiration (Fig. 239-CD2). Thus in cardiac tamponade the normal inspiratory augmentation of right ventricular volume causes an exaggerated reciprocal reduction in left ventricular volume. Also, respiratory distress increases the fluctuations in intrathoracic pressure, which exaggerates the mechanism just described. Right ventricular infarction (Chap. 243) may resemble cardiac tamponade with hypotension, elevated jugular venous pressure, an absent *y* descent in the jugular venous pulse, and occasionally pulsus paradoxus. The differences between these two conditions are shown inTable 239-2.

Paradoxical pulse occurs not only in cardiac tamponade but also in approximately one-third of patients with constrictive pericarditis. Paradoxical pulse is not pathognomonic of pericardial disease because it may be observed in some cases of hypovolemic shock, acute and chronic obstructive airways disease, and pulmonary embolus.

Low-pressure tamponade refers to mild tamponade in which the intrapericardial pressure is increased from its slightly subatmospheric levels to +5 to +10 mmHg; in some instances hypovolemia coexists. As a consequence, the central venous pressure is normal or only slightly elevated, while arterial pressure is unaffected and there is no paradoxical pulse. The patients are asymptomatic or complain of mild weakness and dyspnea. The diagnosis is aided by echocardiography, and both hemodynamic and clinical manifestations improve following pericardiocentesis.

Diagnosis Since immediate treatment of cardiac tamponade may be lifesaving, prompt measures to establish the diagnosis by echocardiography should be undertaken (Fig 239-1). When pericardial effusion causes tamponade, during inspiration right ventricular diameter increases while left ventricular diameter and mitral valve opening decrease. Often the right ventricular cavity is reduced in diameter, and there is late diastolic inward motion (collapse) of the right ventricular free wall and of the right atrium. Doppler ultrasound shows exaggerated pulmonic (and tricuspid) flow during inspiration, with reciprocal changes in aortic (and mitral) flow (Fig 239-2).

If measured, the pericardial pressure is elevated and equal to the right atrial pressure. There is "equalization" of pressures, i.e., the pulmonary artery wedge is equal, or close,

to right atrial, right ventricular, and pulmonary artery diastolic pressures. The "square root" sign in the ventricular pressure pulses and the prominent *y* descent in atrial and jugular venous pressure are characteristic of constrictive pericarditis (see below) and are rarely present in tamponade.

TREATMENT

Patients with acute pericarditis should be observed frequently for the development of an effusion; if a large effusion is present, the patient should be hospitalized and watched closely for signs of tamponade. In the presence of an effusion, arterial and venous pressures and heart rate should be monitored or followed carefully and serial echocardiograms obtained. If manifestations of tamponade appear, pericardiocentesis must be carried out at once, since relief of the intrapericardial pressure may be lifesaving. It is helpful, though not essential, to carry this out in the catheterization laboratory with hemodynamic and fluoroscopic monitoring. A small catheter advanced over the needle inserted into the pericardial cavity may be left in place to allow draining of the pericardial space if fluid reaccumulates. When a *diagnostic* pericardiocentesis of a large effusion is carried out, an attempt should be made to remove as much fluid as possible. Surgical drainage through a limited thoracotomy may be required in recurrent tamponade and/or when it is necessary to obtain tissue for diagnosis.

VIRAL OR IDIOPATHIC FORM OF ACUTE PERICARDITIS

In some cases of this common disorder, an A or B coxsackievirus or the virus of influenza, echovirus, mumps, herpes simplex, chickenpox, adenovirus, or Epstein-Barr has been isolated from pericardial fluid and/or appropriate elevations in viral antibody titers have been noted. In many instances, acute pericarditis occurs in association with illnesses of known viral origin and, presumably, are caused by the same agent. Commonly, there is an antecedent infection of the respiratory tract, but in many patients such an association is not evident and viral isolation and serologic studies are negative. Most frequently, a viral causation cannot be established; the term *acute idiopathic pericarditis* is then appropriate. Acute pericarditis is a common complication in patients infected with AIDS (Chap. 309). It may be caused by HIV itself; by opportunistic infections, such as cytomegalovirus and tuberculosis; or by associated neoplasms, such as lymphoma or Kaposi's sarcoma.

Acute pericarditis occurs at all ages but is more frequent in young adults. Regardless of the specific cause, the clinical manifestations are similar. Acute pericarditis is often associated with pleural effusions and pneumonitis. The almost simultaneous development of fever and precordial pain, often 10 to 12 days after a presumed viral illness, constitutes an important feature in the differentiation of acute pericarditis from myocardial infarction, in which pain precedes fever. The constitutional symptoms are usually mild to moderate, but occasionally the initial symptoms are stormy, the temperature rising to 40°C. A pericardial friction rub is often audible. The disease ordinarily runs its course in a few days to 4 weeks, but one or more recurrences occur in about one-fourth of patients. Although accumulation of some pericardial fluid is common, tamponade is unusual, and constrictive pericarditis is a possible complication. The ST-segment alterations in theECGusually disappear after 1 or more weeks, but the abnormal T waves may persist for several years and be a source of confusion in

persons without a clear history of pericarditis. Pleuritis and pneumonitis frequently accompany pericarditis. Granulocytosis followed by lymphocytosis is common.

TREATMENT

There is no specific therapy, but bed rest and anti-inflammatory treatment with aspirin, if necessary up to 900 mg qid, may be given. If this is ineffective, one of the nonsteroidal anti-inflammatory agents, such as indomethacin (25 to 75 mg qid) or a glucocorticoid (e.g., prednisone, 40 to 80 mg daily) usually suppresses the clinical manifestations of the acute illness and may be useful in patients in whom the purulent and tuberculous forms of pericarditis have been excluded. Anticoagulants should be avoided. After the patient has been asymptomatic and afebrile for about a week, the dose of the anti-inflammatory agent is gradually tapered. When recurrences are multiple, frequent, disabling, and continue beyond 2 years, pericardiectomy may be effective in terminating the illness.

POST-CARDIAC INJURY SYNDROME

Acute pericarditis may appear under a variety of circumstances that have one common feature: previous injury to the myocardium, with blood in the pericardial cavity. The syndrome may develop after a cardiac operation (postpericardiotomy syndrome); after cardiac trauma (Chap. 240), e.g., a stab wound, contusions after a nonpenetrating blow to the chest; or after perforation of the heart with a catheter. Rarely, it follows myocardial infarction.

The clinical picture of the post-cardiac injury syndrome mimics acute viral or acute idiopathic pericarditis. The principal symptom is the pain of acute pericarditis, which usually develops 1 to 4 weeks following the cardiac injury but sometimes appears only after an interval of months. Recurrences of pericarditis are common and may occur up to 2 years or more after the injury. Fever with temperature up to 40°C, pericarditis, pleuritis, and pneumonitis are the outstanding features, and the bout of illness usually subsides in 1 or 2 weeks. The pericarditis may be of the fibrinous variety, or it may be a pericardial effusion, which is often serosanguineous, and may be accompanied by arthralgias, but rarely causes tamponade. Leukocytosis, an increased sedimentation rate, and electrocardiographic changes typical of acute pericarditis also may occur.

The mechanisms responsible for this syndrome have not been identified, but they are probably the result of a hypersensitivity reaction in which the antigen originates from injured myocardial tissue and/or pericardium; the suggested designation of *post-cardiac injury syndrome* for this group of disorders implies that they may have a common pathogenetic mechanism. Circulating autoantibodies to myocardium occur frequently, but their precise role has not been defined. Viral infection may also play an etiologic role, since antiviral antibodies are often elevated in patients who develop this syndrome following cardiac surgery.

Often no treatment is necessary aside from aspirin and analgesics. The management of pericardial effusion and tamponade has already been discussed. When the illness is followed by a series of disabling recurrences, therapy with a nonsteroidal anti-inflammatory agent or a glucocorticoid is usually effective.

Differential Diagnosis Since there is no specific test for *acute idiopathic pericarditis*, the diagnosis is one of exclusion. Consequently, all other disorders that may be associated with acute fibrinous pericarditis must be considered. A common diagnostic error is mistaking acute viral or idiopathic pericarditis for acute myocardial infarction and vice versa. When it is associated with *acute myocardial infarction*, acute fibrinous pericarditis may be confused with acute viral or idiopathic pericarditis; this complication of infarction, described in Chap. 243, is characterized by fever, pain, and a friction rub in the first 4 days following the development of the infarct (to be distinguished from the pericarditis in Dressler's syndrome, which is a form of post-cardiac injury pericarditis and which occurs a week or two following myocardial infarction).ECGabnormalities (such as the appearance of Q waves, brief ST-segment elevations with reciprocal changes, and earlier T-wave changes in myocardial infarction) and the extent of the elevations of myocardial enzymes are helpful in differentiating pericarditis from acute myocardial infarction.

Pericarditis secondary to post-cardiac injury is differentiated from acute idiopathic pericarditis chiefly by timing. If it occurs within a few weeks of a myocardial infarction or a chest blow, it may be justified to conclude that the two are probably related. If the infarct has been silent or the chest blow forgotten, the relationship to the pericarditis may not be recognized.

It is important to distinguish *pericarditis due to collagen vascular disease* from acute idiopathic pericarditis. Most important in the differential diagnosis is the pericarditis due to systemic lupus erythematosus (SLE;Chap. 311) or drug-induced (procainamide or hydralazine) lupus. In these conditions, pain is often present; sometimes in SLE the pericarditis appears as an asymptomatic effusion, and rarely, tamponade develops. When pericarditis occurs in the absence of any obvious underlying disorder, the diagnosis may be made on discovery of lupus erythematosus cells or a rise in the titer of antinuclear antibodies. Acute pericarditis may complicate the viral, pyogenic, mycobacterial, and fungal infections that occur in AIDS. Acute pericarditis is an occasional complication of *rheumatoid arthritis*, *scleroderma*, and *polyarteritis nodosa*, and other evidence of these diseases is usually obvious. Asymptomatic pericardial effusion is also frequent in these disorders. It is important to question every patient with acute pericarditis about the ingestion of procainamide, hydralazine, isoniazid, cromolyn, and minoxidil, since these drugs can cause this syndrome.

The pericarditis of *acute rheumatic fever* is generally associated with evidence of severe pancarditis and with cardiac murmurs (Chap. 235). *Pyogenic (purulent) pericarditis* is usually secondary to cardiothoracic operations, immunosuppressive therapy, rupture of the esophagus into the pericardial sac, or rupture of a ring abscess in a patient with infective endocarditis and with septicemia complicating aseptic pericarditis. It is accompanied by fever, chills, septicemia, and evidence of infection elsewhere. *Tuberculous pericarditis* (Chap. 169) may present as an acute pericarditis associated with fever, weight loss, and other clinical manifestations of active systemic tuberculosis; the diagnosis may be aided by a positive tuberculin test and evidence of pulmonary or mediastinal tuberculosis. Tubercle bacilli can be cultured from the pericardial space only infrequently, and a biopsy of the pericardium with bacteriologic and histologic examination may be required. Alternatively, tuberculous pericarditis may present as a

chronic asymptomatic effusion, as subacute effusive-constrictive pericarditis, or as frank chronic constrictive pericarditis (see below).

Uremic pericarditis (Chap. 270) occurs in up to one-third of patients with chronic uremia and is seen most frequently in patients undergoing chronic hemodialysis. It may be fibrinous and is generally associated with an effusion that may be sanguineous. A friction rub is common, but pain is usually absent. Treatment with an anti-inflammatory agent and intensification of hemodialysis is usually adequate. Occasionally, tamponade occurs and pericardiocentesis is required. When uremic pericarditis is recurrent, persistent, or very troubling, pericardiectomy may be necessary. Pericarditis due to *neoplastic diseases* results from extension or invasion of metastatic tumors (most commonly carcinoma of the lung and breast, malignant melanoma, lymphoma, and leukemia) to the pericardium; pain, atrial arrhythmias, and tamponade are complications that occur occasionally. *Mediastinal irradiation* for neoplasm may cause acute pericarditis and/or chronic constrictive pericarditis after eradication of the tumor. Unusual causes of acute pericarditis include syphilis, fungal infection (histoplasmosis, blastomycosis, aspergillosis, and candidiasis), and parasitic infestation (amebiasis, toxoplasmosis, echinococcosis, trichinosis).

CHRONIC PERICARDIAL EFFUSIONS

Chronic pericardial effusions are sometimes encountered in patients without an antecedent history of acute pericarditis. They may cause few symptoms per se, and their presence may be detected by finding an enlarged cardiac silhouette on chest roentgenogram.

Tuberculosis This is a common cause of chronic pericardial effusion, although less so in the United States than in other parts of the world (Chap. 169). The clinical picture is that of a chronic, systemic illness in a patient with pericardial effusion. It is important to consider this condition in a middle-aged or elderly person with fever and enlargement of the cardiac silhouette of undetermined origin, with or without elevation of venous pressure. Weight loss, fever, and fatigability are sometimes observed. Inasmuch as treatment is quite effective, overlooking a tuberculous pericardial effusion may have serious consequences. A chest roentgenogram for pulmonary tuberculosis should be obtained, and a search for tuberculosis in other organs carried out; tuberculin skin tests should be performed and repeated after several weeks. If the etiology of chronic pericardial effusion remains obscure, a pericardial biopsy, preferably by a limited thoracotomy, should be performed. If definitive evidence is then still lacking but the specimen shows caseation necrosis, antituberculous chemotherapy is indicated. If the biopsy specimen shows a thickened pericardium, pericardiectomy should be carried out in order to prevent the development of constriction.

Other Causes of Chronic Pericardial Effusion *Myxedema* may be responsible for a pericardial effusion that is sometimes massive but rarely, if ever, causes cardiac tamponade. The cardiac silhouette is markedly enlarged, and an echocardiogram is necessary to distinguish cardiomegaly from pericardial effusion. The diagnosis of myxedema is frequently overlooked. It is important, therefore, to carry out appropriate tests for thyroid function (Chap. 330) as well as echocardiography in patients with an enlarged cardiac outline of undetermined origin. *Cholesterol pericardial disease* is

sometimes associated with myxedema. It is characterized by large pericardial effusions with a high cholesterol content, which may induce an inflammatory response and constrictive pericarditis.

Neoplasms,SLE, rheumatoid arthritis, mycotic infections, radiation therapy, pyogenic infections, severe chronic anemia, and chylopericardium may also cause chronic pericardial effusion and should be considered and specifically looked for in such patients.

Aspiration and analysis of the pericardial fluid are often helpful in diagnosis. In infections the organism can often be identified by smear or culture. Grossly sanguineous pericardial fluid results most commonly from a neoplasm, tuberculosis, uremia, or slow leakage from an aortic aneurysm.

CHRONIC CONSTRICTIVE PERICARDITIS

This disorder results when the healing of an acute fibrinous or serofibrinous pericarditis or a chronic pericardial effusion is followed by obliteration of the pericardial cavity with the formation of granulation tissue. The latter gradually contracts and forms a firm scar, encasing the heart and interfering with filling of the ventricles. In some reports, a high percentage of cases has been of tuberculous origin. In North America, tuberculosis is now an infrequent cause. Chronic constrictive pericarditis may also follow purulent infection, trauma, cardiac operation of any type, mediastinal irradiation, histoplasmosis, neoplastic disease (especially breast cancer, lung cancer, and lymphoma), acute viral or idiopathic pericarditis, rheumatoid arthritis,SLE, and chronic renal failure with uremia treated by chronic dialysis. In many patients the cause of the pericardial disease is undetermined, and in them an asymptomatic or forgotten bout of viral pericarditis, acute or idiopathic, may have been the inciting event. The heart may also be constricted and compressed by malignant tumors or organized blood clot in the pericardial cavity.

The basic physiologic abnormality in symptomatic patients with chronic constrictive pericarditis, as in those with cardiac tamponade, is the inability of the ventricles to fill because of the limitations imposed by the rigid, thickened pericardium or the tense pericardial fluid. In constrictive pericarditis, ventricular filling is unimpeded during early diastole but is reduced abruptly when the elastic limit of the pericardium is reached, while in cardiac tamponade, ventricular filling is impeded throughout diastole. In chronic constrictive pericarditis, ventricular end-diastolic and stroke volumes are reduced and the end-diastolic pressures in both ventricles and the mean pressures in the atria, pulmonic veins, and systemic veins are all elevated to similar levels, i.e., within 5 mmHg. The fibrotic process may extend into the myocardium and cause myocardial scarring, and venous congestion may then be due to the combined effects of the myocardial and pericardial lesions. Despite these hemodynamic changes, myocardial function may be normal or only slightly impaired.

In constrictive pericarditis, the central venous and right and left atrial pressure pulses display an M-shaped contour, with prominent *x* and *y* descents; the *y* descent, which is absent or diminished in cardiac tamponade, is the most prominent deflection in constrictive pericarditis and is interrupted by a rapid rise in pressure during early diastole, when ventricular filling is impeded by the constricting pericardium. These

characteristic changes are transmitted to the jugular veins, where they may be recognized by inspection. In constrictive pericarditis, the ventricular pressure pulses in both ventricles exhibit characteristic "square root" signs during diastole (Fig. 239-3). These hemodynamic changes, although characteristic, are not pathognomonic of constrictive pericarditis but may also be observed in cardiomyopathies characterized by restriction of ventricular filling (Chap. 238).

CLINICAL AND LABORATORY FINDINGS (Table 239-2)

Weakness, fatigue, weight gain, increased abdominal girth, abdominal discomfort, and edema are common. The patient often appears to be chronically ill with decreased skeletal muscle mass and a protuberant abdomen. Exertional dyspnea is common, and orthopnea may occur, although it is usually not severe. Acute left ventricular failure (acute pulmonary edema) is very uncommon. The cervical veins are distended and may remain so even after intensive diuretic treatment, and venous pressure may fail to decline during inspiration (Kussmaul's sign). The latter is frequent in chronic pericarditis but may also occur in tricuspid stenosis, right ventricular infarction, and restrictive cardiomyopathy. The pulse pressure is normal or reduced. In about one-third of the cases a paradoxical pulse can be detected. Congestive hepatomegaly is pronounced and may impair hepatic function; ascites is common and is usually more prominent than dependent edema. In about half of patients the heart is normal in size; if it is enlarged, the enlargement is rarely extreme. The apical pulse is reduced in intensity, retracts in systole, and moves outward in diastole. The heart sounds may be distant; an early third heart sound, i.e., a pericardial knock, occurring 0.09 to 0.12 s after aortic valve closure that coincides with a sudden deceleration in ventricular filling, is often conspicuous, and murmurs are usually absent. Because of the high sustained venous pressure, congestive splenomegaly may make the spleen palpable. In the absence of infective endocarditis or tricuspid valve disease, splenomegaly in a patient with congestive heart failure should arouse suspicion of constrictive pericarditis. Protein-losing gastroenteropathy, due to impaired lymphatic drainage from the small intestine, and marked proteinuria or hypoalbuminemia may complicate chronic constrictive pericarditis.

The *ECG* frequently displays low voltage of the QRS complex and diffuse flattening or inversion of the T waves. P mitrale may be present in patients with sinus rhythm; atrial fibrillation is present in about one-third of patients. The *chest roentgenogram* shows a normal or slightly enlarged heart, sometimes with pericardial calcification.

Inasmuch as the usual physical signs of cardiac disease (murmurs, cardiac enlargement) may be inconspicuous or absent in chronic constrictive pericarditis, hepatic enlargement and dysfunction associated with intractable ascites may lead to a mistaken diagnosis of cirrhosis of the liver. This error can be avoided if the neck veins are inspected carefully in patients with ascites and hepatomegaly. *Given a clinical picture resembling hepatic cirrhosis, but with the added feature of distended neck veins, careful search for calcification of the pericardium by chest roentgenography and CT or MRI should be carried out and may disclose this curable or remediable form of heart disease.*

The echocardiogram typically shows pericardial thickening, atrial enlargement, dilatation of the inferior vena cava and hepatic veins, and a sharp halt in ventricular filling in early

diastole, with normal ventricular systolic function; there is a distinctive pattern of transvalvular flow velocity on Doppler echocardiography. There is an exaggerated reduction in blood flow velocity in the pulmonary veins and across the mitral valve during inspiration, with the opposite occurring during expiration. Diastolic flow velocity in the vena cavae into the right atrium and across the tricuspid valve increases in an exaggerated manner during inspiration and declines during expiration (Fig. 239-4). However, echocardiography cannot definitively exclude the diagnosis.MRI andCTscanning (Fig. 239-CD3), especially the latter (Fig. 239-5), are more accurate than echocardiography in establishing or excluding the presence of a thickened pericardium. Pericardial thickening and even pericardial calcification, however, are not synonymous with constrictive pericarditis since they may occur without seriously impairing ventricular filling.

DIFFERENTIAL DIAGNOSIS

Like cor pulmonale (Chap. 237), chronic constrictive pericarditis may be associated with severe systemic venous hypertension but little pulmonary congestion; the heart usually is not enlarged, and a paradoxical pulse may be present. However, in cor pulmonale advanced parenchymal pulmonary disease is usually obvious and venous pressure *falls* during inspiration, i.e., Kussmaul's sign is negative. *Tricuspid stenosis* (Chap. 236) may also simulate chronic constrictive pericarditis; congestive hepatomegaly, splenomegaly, ascites, and venous distention may be equally prominent, and the manifestations of left-sided heart failure may be inconspicuous. However, in tricuspid stenosis, a characteristic murmur as well as mitral stenosis are usually present. In tricuspid stenosis, a paradoxical pulse and a steep, deep *y* descent in the jugular venous pulse do not occur, serving to differentiate it from chronic constrictive pericarditis.

Because constrictive pericarditis can be corrected surgically, it is important, though often difficult, to distinguish chronic constrictive pericarditis from restrictive cardiomyopathy (Chap. 238), which has a similar physiologic abnormality, i.e., restriction of ventricular filling. In many of these patients the ventricular wall is thickened on echocardiographic examination (Table 239-2). The features favoring the diagnosis of restrictive cardiomyopathy over chronic constrictive pericarditis include a well-defined apex beat, cardiac enlargement, and pronounced orthopnea with attacks of acute left ventricular failure, left ventricular hypertrophy, gallop sounds (in place of a pericardial knock), bundle branch block, and in some cases abnormal Q waves on theECG. The echocardiogram in chronic constrictive pericarditis characteristically shows pericardial thickening, i.e., a distinct echo posterior to the left ventricular wall, and paradoxical septal motion. The left ventricular wall moves sharply outward in early diastole and then remains flat. Marked respiratory variations in atrioventricular flow velocities on Doppler echocardiography are characteristic of constrictive pericarditis but not restrictive cardiomyopathy (Fig. 239-4). The definitive diagnosis of restrictive cardiomyopathy, when it is due to an infiltrative disease such as amyloidosis, can often be established by endomyocardial biopsy.CTscanning andMRI are very useful in distinguishing between restrictive cardiomyopathy and chronic constrictive pericarditis. In the former, the ventricular walls are hypertrophied, while in the latter the pericardium is thickened and sometimes calcified.

When a patient has progressive, disabling, and unresponsive congestive failure and

displays any of the features of constrictive heart disease, the most careful and detailed clinical and laboratory studies must be carried out in order to detect or exclude constrictive pericarditis, since the latter is usually curable.

Occult Constrictive Disease Patients with this condition may have unexplained fatigue, dyspnea, and chest pain. No overt manifestations of pericardial disease are present, but following the rapid intravenous infusion of 1 L of saline solution, diastolic equilibration of intracardiac atrial and ventricular pressures found in overt constrictive pericarditis occur. Although symptomatic improvement may follow pericardiectomy, this procedure should not be carried out in asymptomatic persons.

TREATMENT

Pericardial resection is the only definitive treatment of constrictive pericarditis, but dietary sodium restriction and diuretics are useful during preoperative preparation. The benefits derived from cardiac decortication are often striking, and the improvement, though slight at first, usually is progressive over a period of months. The risk of this operation depends on the extent of penetration of the myocardium by the calcific process, by the severity of myocardial atrophy, by the extent of secondary impairment of hepatic and/or renal function, and by the patient's general condition. Operative mortality is in the range of 3 to 10%; the patients with the most severe and/or advanced disease are at highest risk. Therefore, surgical treatment should be carried out relatively early in the course.

Many cases of constrictive pericarditis are of tuberculous origin. Antituberculous therapy during the phase of effusion may prevent the development of constriction, and such therapy should be carried out before and after operation if a tuberculous origin can be diagnosed, is suspected, or cannot be excluded in a patient with chronic constrictive pericarditis (Chap. 169).

Subacute Effusive-Constrictive Pericarditis This form of pericardial disease is characterized by the combination of a tense effusion in the pericardial space and constriction of the heart by thickened pericardium. It shares a number of features both with chronic pericardial effusion (p. 1366) producing cardiac compression and with pericardial constriction. It may be caused by tuberculosis, multiple attacks of acute idiopathic pericarditis, radiation, traumatic pericarditis, uremia, and scleroderma. The heart is generally enlarged, and a paradoxical pulse and a prominent *x* descent (without a prominent *y* descent) are present in the atrial and jugular venous pressure pulses. Following pericardiocentesis, the physiologic findings may change from those of cardiac tamponade to those of pericardial constriction, with a "square root" sign in the ventricular pressure pulse and a prominent *y* descent in the atrial and jugular venous pressure pulses. Furthermore, the intrapericardial pressure and the central venous pressure may decline, but not to normal. In many patients the condition progresses to the chronic constrictive form of the disease. Wide excision of both the visceral and parietal pericardium is usually effective.

OTHER DISORDERS OF THE PERICARDIUM

Pericardial cysts appear as rounded or lobulated deformities of the cardiac silhouette,

most commonly at the right cardiophrenic angle. They do not cause symptoms, and their major clinical significance lies in the possibility of confusion with a tumor, ventricular aneurysm, or massive cardiomegaly. *Tumors* involving the pericardium are most commonly secondary to malignant neoplasms originating in or invading the mediastinum, including carcinoma of the bronchus and breast, lymphoma, and melanoma. The most common *primary* malignant tumor is the mesothelioma. The usual clinical picture of malignant pericardial tumor is an insidiously developing, often bloody, pericardial effusion. Surgical exploration is required to establish a definitive diagnosis and to carry out definitive or, more commonly, palliative treatment.

240. CARDIAC TUMORS, CARDIAC MANIFESTATIONS OF SYSTEMIC DISEASES, AND TRAUMATIC CARDIAC INJURY - *Wilson S. Colucci*, *Daniel T. Price*

TUMORS OF THE HEART

PRIMARY TUMORS

Primary tumors of the heart are rare. Approximately three-quarters are histologically benign, and the remainder, which in almost all cases are sarcomas, are malignant (Table 240-1). Because all cardiac tumors have the potential for causing life-threatening complications, and many are now curable by surgery, it is important that the diagnosis be made whenever possible.

Clinical Presentation Cardiac tumors may present with a wide array of cardiac and noncardiac manifestations. The location and the size of the tumor are the major determinants of the specific signs and symptoms, many of which are present in more common forms of heart disease, such as chest pain, syncope, heart failure, murmurs, arrhythmias, conduction disturbances, and pericardial effusion with or without tamponade.

Myxoma Myxomas are the most common type of primary cardiac tumor in all age groups, accounting for one-third to one-half of all cases at postmortem and for about three-quarters of the tumors treated surgically. They occur at all ages, most commonly in the third through sixth decades. There is a female predilection. Although most myxomas are sporadic, some are familial with autosomal dominant transmission or are part of a syndrome that involves a complex of abnormalities including lentigines or pigmented nevi, primary nodular adrenal cortical disease with or without Cushing's syndrome, myxomatous mammary fibroadenomas, testicular tumors, and/or pituitary adenomas with gigantism or acromegaly. Certain constellations of findings have been referred to as the *NAME* syndrome (nevi, atrial myxoma, myxoid neurofibroma, and ephelides) or the *LAMB* syndrome (lentigines, atrial myxoma, and blue nevi). Approximately 7% of cardiac myxomas are familial or part of the syndrome myxoma with the complex of abnormalities described above.

Pathologically, myxomas are gelatinous structures consisting of myxoma cells imbedded in a stroma rich in glycosaminoglycans. Most are pedunculated on a fibrovascular stalk and average 4 to 8 cm in diameter. The majority are solitary and located in the atria, particularly the left, where they arise from the interatrial septum in the vicinity of the fossa ovalis. In contrast to sporadic tumors, familial or syndrome myxoma tumors tend to occur in younger individuals, be multiple or ventricular in location, and have more postoperative recurrences, probably reflecting their multicentric nature.

Myxomas commonly present with obstructive, embolic, or constitutional signs and symptoms. The most common clinical presentation mimics that of mitral valve disease, either stenosis due to tumor prolapse into the mitral orifice or regurgitation due to tumor-induced valvular trauma. Ventricular myxomas may cause outflow obstruction similar to that caused by subaortic or subpulmonic stenosis. The symptoms and signs of myxoma may be of sudden onset or positional in nature, reflecting changes in tumor

position due to gravity. An ausculatory finding, termed a "tumor plop," is a characteristic low-pitched sound that may be audible during early or middiastole and is thought to result from the tumor abruptly stopping as it strikes the ventricular wall. Myxomas may also present with peripheral or pulmonary emboli, or constitutional signs and symptoms including fever, weight loss, cachexia, malaise, arthralgia, rash, clubbing, Raynaud's phenomenon, hypergammaglobulinemia, anemia, polycythemia, leukocytosis, elevated erythrocyte sedimentation rate, thrombocytopenia, or thrombocytosis. Not surprisingly, myxomas are frequently misdiagnosed as endocarditis, collagen vascular disease, or noncardiac tumor.

Two-dimensional transthoracic or transesophageal echocardiography is useful in the diagnosis of cardiac myxoma and allows determination of the site of tumor attachment and tumor size, which are important considerations in the planning of surgical excision (Fig. 240-1). Computed tomography and particularly magnetic resonance imaging may provide important information regarding size, shape, composition, and surface characteristics of the tumor. Because myxomas may be familial, echocardiographic screening of first-degree relatives is appropriate, particularly if the patient is young and has multiple tumors or evidence of syndrome myxoma. Although cardiac catheterization and angiography have previously been performed routinely before surgery, catheterization of the chamber from which the tumor arisees is attended by the risk of tumor emboli. Catheterization is no longer considered mandatory when adequate noninvasive information is available and other cardiac diseases (e.g., coronary artery disease) are not considered likely.

TREATMENT

Surgical excision utilizing cardiopulmonary bypass is indicated and is generally curative. Myxomas recur in approximately 12 to 22% of familial cases and in about 1 to 2% of sporadic cases. Tumor recurrence is most likely due to multifocal lesions in the former and inadequate resection in the latter.

Other Benign Tumors Cardiac *lipomas*, although relatively common, are usually incidental findings at postmortem examination. However, they may grow as large as 15 cm and may present with symptoms due to mechanical interference with cardiac function, arrhythmias, or conduction disturbances, or as an abnormality of the cardiac silhouette on chest x-ray. *Papillary fibroelastomas*, similarly, are relatively common findings on cardiac valves or the adjacent endothelium at postmortem, but seldom result in clinical symptoms. Occasionally, these growths may cause mechanical interference with valve function. *Rhabdomyomas* and *fibromas*, the most frequent tumors in infants and children, most commonly occur in the ventricles and therefore produce signs and symptoms by mechanical obstruction that may mimic valvular stenosis, congestive heart failure, restrictive or hypertrophic cardiomyopathy, and pericardial constriction. Rhabdomyomas are probably hamartomatous growths; are multiple in 90% of cases; and may be associated with tuberous sclerosis, adenoma sebaceum, and benign kidney tumors in approximately 30% of patients. Calcification of a cardiac tumor strongly suggests that it is a fibroma, although myxomas and sarcomas also may be calcified. *Hemangiomas* and *mesotheliomas* are generally small tumors, most often intramyocardial in location, and may cause atrioventricular conduction disturbances and even sudden death as a result of their propensity for location in the region of the AV

node. Other benign tumors arising from the heart include *teratoma*, *chemodectoma*, *neurilemoma*, *granular cell myoblastoma*, and *bronchogenic cysts*.

Sarcoma Almost all primary cardiac malignancies are sarcomas, which may be of several histologic types. In general, these tumors are characterized by a rapidly downhill course leading to the patient's death in weeks to months from the time of presentation as a result of hemodynamic compromise, local invasion, or distant metastases. Sarcomas commonly involve the right side of the heart, and because of their rapid growth, invasion of the pericardial space and obstruction of the cardiac chambers or venae cavae are common. Sarcomas can also occur on the left side of the heart and may be mistaken for myxomas.

TREATMENT

At the time of presentation these tumors have often spread too extensively for surgical excision. Although scattered reports exist of palliation with surgery, radiotherapy, and/or chemotherapy, the overall experience with cardiac sarcomas is poor. The one exception appears to be cardiac lymphosarcomas, which may respond to a combination of chemo- and radiotherapy.

TUMORS METASTATIC TO THE HEART

Tumors metastatic to the heart are many times more common than primary tumors; and as the life expectancy of patients with various forms of malignant neoplasms is extended by more effective therapy, the frequency of cardiac metastases will also increase. Although cardiac metastases occur in 1 to 20% of all tumor types, the relative incidence is especially high in malignant melanoma and, to a somewhat lesser extent, in leukemia and lymphoma. In absolute numbers, the most common primary originating sites of cardiac metastases are carcinoma of the breast and lung, reflecting the high incidence of these cancers. Cardiac metastases almost always occur in the setting of widespread primary disease, and most often either primary or metastatic disease exists elsewhere in the thoracic cavity. Nevertheless, a cardiac metastasis may occasionally be the initial presentation of a tumor elsewhere in the body.

Cardiac metastases reach the heart from the blood stream, the lymphatics, or by direct invasion. They generally are small, firm nodules. Diffuse infiltration may also occur, especially with sarcomas or hematologic neoplasms. The pericardium is most often involved, followed by myocardial involvement of any chamber, and, rarely, by involvement of the endocardium or cardiac valves.

Cardiac metastases result in clinical manifestations only about 10% of the time and rarely are the cause of death. In most instances the metastases are not the cause of the presenting clinical features but occur in the setting of a previously recognized malignant neoplasm. Although cardiac metastases may present with a large number of nonspecific signs and symptoms, the most common are dyspnea, signs of acute pericarditis, cardiac tamponade, a rapid increase in the cardiac silhouette on chest x-ray, new onset of ectopic tachyarrhythmia or AV block, and congestive heart failure. As with primary cardiac tumors, the clinical presentation is more closely related to the location and size of the tumor rather than histologic type. Many of these signs and symptoms also occur

with myocarditis, pericarditis, or cardiomyopathy resulting from radiotherapy or chemotherapy.

Electrocardiographic findings are nonspecific. On chest roentgenography the cardiac silhouette is most often normal but may reveal a pericardial effusion or bizarre contour. Echocardiography is useful for the diagnosis of pericardial effusion and the visualization of larger metastases. Computed tomography, magnetic resonance imaging, and radionuclide imaging with gallium or thallium may provide useful anatomic information. Angiography may delineate discrete lesions, and pericardiocentesis can allow a specific cytologic diagnosis.

TREATMENT

Because most patients with cardiac metastases have widespread disease, therapy generally consists of treatment of the primary tumor. Symptomatic malignant effusions are treated by removal of fluid by pericardiocentesis, with or without concomitant instillation of a sclerosing agent (e.g., tetracycline), or placement of a pericardial window for drainage to the pleural space to palliate symptoms and delay or prevent reaccumulation of the effusion.

CARDIAC EFFECTS OF CANCER THERAPY®*SEE CHAP. 238.*

CARDIOVASCULAR MANIFESTATIONS OF SYSTEMIC DISEASES

DIABETES MELLITUS (See alsoChap. 333)

There is an increased incidence of large vessel atherosclerosis and myocardial infarction in patients with both insulin- and non-insulin-dependent diabetes mellitus. Coronary artery disease is the most common cause of death in adults with diabetes mellitus. Diabetes mellitus is an independent risk factor for coronary artery disease (Chap. 241), and the incidence of coronary artery disease is related to the duration of diabetes. In patients with diabetes mellitus, myocardial infarctions are not only more frequent but also tend to be larger in size and more likely to result in complications such as heart failure, shock, and death. Patients with diabetes mellitus are more likely to have an abnormal or absent pain response to myocardial ischemia, probably as a result of generalized autonomic nervous system dysfunction. Ambulatory electrocardiographic monitoring has shown that up to 90% of episodes of ischemia are silent in diabetic patients with coronary artery disease; the presentation of ischemia may be exertional or episodic dyspnea, flash pulmonary edema, arrhythmias, heart block, or syncope. Since coronary artery disease is more common in in patients with diabetes mellitus and often is not associated with typical anginal symptoms, the threshold for the diagnosis should be low, particularly when the duration of disease is long and concomitant risk factors for coronary artery disease (e.g., hypertension, smoking, hyperlipidemia) are present.

Patients with diabetes mellitus may also have myocardial dysfunction characteristic of a restrictive cardiomyopathy in the absence of large-vessel (epicardial) coronary artery disease, with abnormal relaxation of the myocardium, and evidenced clinically by elevated left ventricular filling pressures. Histologically, these patients have interstitial fibrosis with increased amounts of collagen, glycoprotein, triglycerides, and cholesterol

in the myocardial interstitium; and in some cases intimal thickening, hyaline deposition, and inflammatory changes have been observed in small intramural arteries. Patients with diabetes mellitus have an increased risk of developing clinical heart failure, even after correction for the presence of coronary artery disease, hypertension, and obesity, and it is likely that diabetic cardiomyopathy contributes to excessive cardiovascular morbidity and mortality in these patients. There is some evidence that insulin therapy results in an amelioration of the myocardial dysfunction.

MALNUTRITION AND VITAMIN DEFICIENCY MALNUTRITION (See alsoChap. 74)

In patients whose intake of protein, calories, or both is severely deficient, the heart may become thin, pale, and flabby with myofibrillar atrophy and interstitial edema. The systolic pressure and cardiac output are low, and the pulse pressure is narrow. Generalized edema is common and is due to a combination of factors, including reduced serum oncotic pressure and myocardial dysfunction. Such profound states of malnutrition, termed *marasmus* in the case of caloric deficiency and *kwashiorkor* in the case of relative protein deficiency, are most common in underdeveloped countries. However, significant nutritional heart disease may also occur in developed nations, particularly in patients with chronic diseases such as AIDS, in patients with anorexia nervosa, and in patients with severe cardiac failure in whom gastrointestinal hypoperfusion and venous congestion may lead to anorexia and malabsorption. Open-heart surgery poses increased risk in malnourished patients, and they may benefit from preoperative hyperalimentation.

Thiamine Deficiency (Beriberi) (See also Chap. 75) In many cases, malnutrition is accompanied by thiamine deficiency, although this hypovitaminosis may also occur in the presence of an adequate protein and caloric intake, particularly in the Far East, where polished rice deficient in thiamine may be a major dietary component. In western nations, the widespread use of thiamine-enriched flour limits the presence of deficiency primarily to alcoholics and food faddists. The measurement of the thiamine-pyrophosphate effect (TPPE) can biochemically quantitate thiamine stores. An elevated TPPE, indicative of thiamine deficiency, has been found in 20 to 90% of patients with chronic heart failure. The deficiency appears to result from both reduced dietary intake and a diuretic-induced increase in the urinary excretion of thiamine. The acute administration of thiamine to these patients increases the left ventricular ejection fraction and the excretion of salt and water.

Clinically, there is usually evidence of generalized malnutrition, peripheral neuropathy, glossitis, and anemia. The characteristic cardiovascular syndrome is heart failure with increased cardiac output, tachycardia, and often elevated filling pressures in the left and right sides of the heart. The major cause of the high-output state is vasomotor depression, the precise mechanism of which is not understood but which leads to a reduced systemic vascular resistance. The cardiac examination reveals a wide pulse pressure, tachycardia, a third heart sound, and, frequently, an apical systolic murmur. The electrocardiogram may show decreased voltage, a prolonged QT interval, and T-wave abnormalities. The chest x-ray generally shows a large heart with signs of congestive heart failure. The response to thiamine is often dramatic, with an increase in systemic vascular resistance, decrease in cardiac output, clearing of pulmonary congestion, and a reduction in heart size often occurring in 12 to 48 h. Although the

response to digitalis and diuretics may be poor before thiamine therapy, these agents may be important *after* thiamine is given, since the left ventricle may not be capable of dealing with the increased workload presented by the return of vascular tone.

Vitamin B_6, B_{12}, and Folate Deficiency (See also Chap. 241) These vitamin cofactors in the metabolism of homocysteine probably contribute to the majority of cases of hyperhomocysteinemia in the general population. Hyperhomocysteinemia is associated with increased risk of atherosclerosis. Supplementation of these vitamins has reduced the incidence of hyperhomocysteinemia in the United States. The clinical benefit of normalizing elevated homocysteine levels, however, remains unproven.

OBESITY (See also Chap. 77)

Severe obesity, particularly when it occurs in an upper-body distribution, is associated with an increase in cardiovascular morbidity and mortality. Although obesity itself is not considered a disease, there is clearly an increased prevalence of hypertension, glucose intolerance, and atherosclerotic coronary artery disease in obese patients. In addition, these patients have a distinct abnormality of the cardiovascular system characterized by increases in total and central blood volumes, cardiac output, and left ventricular filling pressure. The elevated cardiac output appears to be required to support the metabolic needs of the excessive adipose tissue. Left ventricular filling pressure is often at the upper limits of normal and rises excessively with exercise. As a result of chronic volume overload, eccentric cardiac hypertrophy with cardiac dilatation and abnormal ventricular function may develop. Pathologically, there are left and, in some cases, right ventricular hypertrophy and generalized cardiac dilatation, which is not due simply to fatty infiltration of the myocardium. Although these patients may develop pulmonary congestion, peripheral edema, and exercise intolerance, the recognition of these findings may be difficult in massively obese patients.

Weight reduction is the most effective therapy and results in reduction in blood volume and in the return of cardiac output toward normal. However, rapid weight reduction may be dangerous, as cardiac arrhythmias and sudden death due to electrolyte imbalance have been described. Digitalis, sodium restriction, and diuretics may also be useful. This form of heart disease should be distinguished from the Pickwickian syndrome (Chap. 263), which may share several of the cardiovascular features of heart disease secondary to severe obesity but, in addition, frequently has components of central apnea, hypoxemia, pulmonary hypertension, and cor pulmonale.

THYROID DISEASE (See also Chap. 330)

Thyroid hormone exerts a major influence on the cardiovascular system by a number of direct and indirect mechanisms, and not surprisingly, cardiovascular effects are prominent in both hypo- and hyperthyroidism. Thyroid hormone causes increases in total-body metabolism and oxygen consumption that indirectly place an increased workload on the heart. In addition, although the exact mechanism has not been defined, thyroid hormone exerts direct inotropic, chronotropic, and dromotropic effects that are similar to those seen with adrenergic stimulation (e.g., tachycardia, increased cardiac output). Thyroid hormone increases the synthesis of myosin and of Na^+,K^+-ATPase, as well as the density of myocardial beta-adrenergic receptors.

Hyperthyroidism Cardiovascular presentations of hyperthyroidism include palpitations, systolic hypertension, fatigue, or, in patients with underlying heart disease, angina or heart failure. Sinus tachycardia is found in about 40% of patients and atrial fibrillation in about 15%. Other findings include a hyperdynamic precordium, a widened pulse pressure, an increase in the intensity of the first heart sound and the pulmonic component of the second heart sound, and a third heart sound. An increased incidence of mitral valve prolapse has been associated with hyperthyroidism, and in some cases there may be a midsystolic murmur heard best at the left sternal border with or without a systolic ejection click. A *Means-Lerman scratch* is a systolic scratchy sound, heard at the left second intercostal space during expiration; it is thought to result from the rubbing of the hyperdynamic pericardium against the pleura. Elderly patients with hyperthyroidism, so-called apathetic hyperthyroidism, may present with only the cardiovascular manifestations of thyrotoxicosis, such as atrial fibrillation, which may be resistant to therapy until the hyperthyroidism is controlled. Angina pectoris and congestive heart failure are unusual unless there is coexistent underlying heart disease, and in many cases symptoms resolve with treatment of the hyperthyroidism.

Hypothyroidism Cardiac manifestations of hypothyroidism include a reduction in cardiac output, stroke volume, heart rate, blood pressure, and pulse pressure. In about one-third of patients there is a pericardial effusion which only rarely results in tamponade. Increased capillary permeability results in pleural and pericardial effusions. Other clinical signs include cardiomegaly, bradycardia, weak arterial pulses, and distant heart sounds. Although the signs and symptoms of myxedema may suggest the diagnosis of congestive heart failure, in the absence of other cardiac disease, myocardial failure is uncommon. The electrocardiogram generally shows sinus bradycardia and low voltage and may show prolongation of the QT interval, decreased P-wave voltage, prolonged AV conduction time, intraventricular conduction disturbances, and nonspecific ST-T wave abnormalities. Chest x-ray may show cardiomegaly, often with a "water bottle" configuration, pleural effusions, and, in some cases, evidence of congestive heart failure. Pathologically, the heart is pale, dilated, and flabby, often with myofibrillar swelling, loss of striations, and interstitial fibrosis.

Patients with hypothyroidism frequently have elevations of cholesterol and triglycerides and severe atherosclerotic coronary artery disease. Before treatment with thyroid hormone, patients with hypothyroidism frequently do not have angina pectoris, presumably because of the low metabolic demands made by their condition. However, angina and myocardial infarction may be precipitated during initiation of thyroid hormone replacement, especially in elderly patients with underlying heart disease. Therefore, replacement should be done with care, starting with low doses that are increased gradually.

MALIGNANT CARCINOID (See alsoChap. 93)

These tumors elaborate a variety of vasoactive amines (e.g., serotonin), kinins, indoles, and other substances believed to be responsible for the diarrhea, flushing, and labile blood pressure in these patients. The cardiac lesions due to gastrointestinal carcinoids are almost exclusively in the right side of the heart and occur only when there are hepatic metastases, suggesting that the substance responsible for the cardiac lesions is

inactivated by passage through the liver and lungs. Similar lesions occur in the left side of the heart when there exists a right-to-left shunt or the tumor is located in the lungs. These lesions are fibrous plaques on the endothelium of the cardiac chambers, valves, and great vessels. These plaques, which result in distortion of the cardiac valves, consist of smooth-muscle cells embedded in a stroma of acid mucopolysaccharide and collagen and presumably result from healing of endothelial injury. The clinical syndrome is most often that of tricuspid regurgitation, pulmonic stenosis, or both. In some cases a high-output state may occur, presumably as a result of a decrease in systemic vascular resistance due to a vasoactive substance released by the tumor. Progression of the cardiac lesions does not appear to be affected by treatment with serotonin antagonists, and in some severely symptomatic patients valve replacement is indicated. Coronary artery spasm, presumably due to a circulating vasoactive substance, may occur in patients with carcinoid syndrome.

PHEOCHROMOCYTOMA (See alsoChap. 332)

In addition to causing labile or sustained hypertension, the high circulating levels of catecholamines may also cause direct myocardial injury. Focal myocardial necrosis and inflammatory cell infiltration are present in about 50% of patients who die with pheochromocytoma and may contribute to clinically significant left ventricular failure and pulmonary edema. Left ventricular function and congestive heart failure may resolve after removal of the tumor. In addition, hypertension results in left ventricular hypertrophy.

RHEUMATOID ARTHRITIS AND THE COLLAGEN VASCULAR DISEASES

Rheumatoid Arthritis (See also Chap. 312) There may be inflammation of any or all parts of the heart in patients with rheumatoid arthritis. Pericarditis is the most common cause of clinically apparent disease and may be found by echocardiography in 10 to 50% of all patients with rheumatoid arthritis, particularly those with subcutaneous nodules. However, only a small fraction of these patients have clinical evidence of pericarditis, which usually follows a benign course but occasionally may progress to cardiac tamponade or constrictive pericarditis. The pericardial fluid is generally an exudate, with decreased concentrations of complement and glucose and elevated cholesterol. Coronary arteritis with intimal inflammation and edema is present in about 20% of cases but only rarely results in angina pectoris or myocardial infarction. The cardiac valves, most often the mitral and aortic, may be involved by inflammation and granuloma formation that in some cases may cause clinically significant regurgitation due to valve deformity. Myocarditis rarely results in cardiac dysfunction.

Treatment is directed at the underlying rheumatoid arthritis and may include glucocorticoids. Pericardiectomy is usually required in cases of tamponade or persistent effusion.

Seronegative Arthropathies The seronegative arthropathies (Chaps. 315 and324), ankylosing spondylitis, Reiter's syndrome, psoriatic arthritis, and the arthritides associated with ulcerative colitis and regional enteritis may be accompanied by a pancarditis and proximal aortitis; the latter may result in aortic regurgitation and may extend into the anterior mitral valve ring and/or AV node. Conduction disturbances are

common, occurring in up to one-third of patients; they are more common in patients with aortic valve disease and appear to be associated with the presence of the HLA-B27 antigen. Both aortic regurgitation and AV block are more common in patients with peripheral joint involvement and long-standing disease; treatment with aortic valve replacement and permanent pacemaker placement may be required. Up to one-fifth of patients with peripheral joint involvement and disease for more than 30 years have significant aortic regurgitation. Occasionally, aortic regurgitation precedes the onset of arthritis, and, therefore, the diagnosis of a seronegative arthritis should be considered in young males with isolated aortic regurgitation.

Systemic Lupus Erythematosus (SLE) (See also Chap. 311) Pericarditis is common, occurring in about two-thirds of patients, and generally pursues a benign course, although rarely tamponade or constriction may result. The characteristic *endocardial lesions* of SLE, described by Libman and Sacks, consist of wartlike lesions most often located at the angles of the AV valves or on the ventricular surface of the mitral valve. Hemodynamically important valvular regurgitation is rare. Patients with the antiphospholipid syndrome have a higher incidence of cardiovascular abnormalities, including valvular disease (particularly regurgitant lesions), a variety of thrombotic disorders (venous and arterial thrombosis, thrombocytopenia, premature stroke), myocardial infarction, pulmonary hypertension, and cardiomyopathy. Myocarditis generally parallels the activity of the disease, and although common histologically, seldom results in clinical heart failure unless associated with hypertension. Although arteritis of large coronary arteries may rarely result in myocardial ischemia, there is also an increased frequency of coronary atherosclerosis that may be related to hypertension or glucocorticoid therapy.

TRAUMATIC HEART DISEASE

Cardiac damage may be due to either penetrating or nonpenetrating injuries. The most frequent cause of a *nonpenetrating injury* is the impact of the chest against the steering wheel of an automobile. The absence of external signs of thoracic trauma does not exclude serious injury of the heart. Although the commonest injury is myocardial contusion, any structure of the heart may be affected by the trauma.

Myocardial contusions are often not immediately recognized in trauma patients due to focus on more obvious injuries. Myocardial contusion may cause arrhythmias, bundle branch block, or electrocardiographic abnormalities resembling those of infarction or pericarditis, and so it is important to bear trauma in mind as a cause of otherwise unexplained electrocardiographic changes. Serum creatine kinase (CK) MB isoenzyme levels are increased in about 20% of patients, but false-positive elevations of MB may occur in the presence of massive injuries associated with large increases in total CK. Cardiac troponin levels may have a greater diagnostic value than CK-MB. Echocardiography can detect abnormal wall motion and the presence of pericardial effusion, in addition to aiding in diagnosis of other forms of cardiac trauma. Myocardial contusion may produce positive radionuclide scans and regional impairment of ventricular function, as occurs in myocardial infarction (Chap. 243). Pericardial effusion may occur weeks or even months after the accident. In these cases, the pericardial effusion is a manifestation of the postcardiac injury syndrome, which resembles the postpericardiotomy syndrome (Chap. 239).

Rupture of the heart valves or the supporting structures leads to acute valvular incompetence. The presence of a loud heart murmur followed by the development of rapidly progressive heart failure after trauma heralds this diagnosis, which can be made by either transthoracic or transesophageal echocardiography.

The most serious consequence of nonpenetrating injury is myocardial rupture, leading to tamponade or intracardiac shunting. Although it is generally immediately fatal, up to 40 percent of patients with cardiac rupture have been reported to survive long enough to reach a specialized trauma center. Hemopericardium may also follow tearing of a pericardial vessel or coronary artery.

Rupture of the aorta is a common consequence of nonpenetrating chest trauma. Indeed, rupture of the aorta at the isthmus or just above the aortic valve is the most common vascular deceleration injury. The clinical presentation is similar to that in aortic dissection (Chap. 247). The arterial pressure and pulse amplitude may be increased in the upper extremities and decreased in the lower extremities, and on chest roentgenogram there may be widening of the mediastinum. Occasionally, aortic rupture is limited by the aortic adventitia and results in a silent false aneurysm that may be discovered months or years after the injury.

Penetrating injuries of the heart, produced by bullets or stab wounds, usually result in immediate or very rapid death because of hemopericardium or massive hemorrhage. However, up to half of such patients may survive if they are resuscitated and/or survive long enough to reach a specialized trauma center. Perforation complicating the placement of an intravenous intracardiac catheter or pacemaker lead is another common cause of penetrating injuries to the heart and great vessels.

When great vessel rupture is due to a penetrating injury, there is usually a hemothorax and, less often, a hemopericardium. Hematoma formation may compress major vessels, and arteriovenous fistulae may form, sometimes resulting in high-output congestive heart failure.

Patients who suffer penetrating injuries of the heart should be carefully examined several weeks after the event to rule out a ventricular septal defect or mitral regurgitation that may have gone undetected at the time of emergency surgery. Sometimes the patient survives the acute incident and presents with a cardiac murmur and congestive heart failure. A left-to-right shunt due to traumatic ventricular septal defect, aortopulmonary artery fistula, or coronary arteriovenous fistula may be suspected and confirmed by cardiac catheterization and angiocardiography.

TREATMENT

The treatment of an uncomplicated myocardial contusion, with or without myocardial infarction, is similar to that for a myocardial infarction, except that anticoagulation is contraindicated, and should include monitoring for the development of complications such as arrhythmia and cardiac rupture (Chap. 243). Acute myocardial failure resulting from the rupture of a valve usually requires operative correction. Immediate thoractomy should be carried out for most cases of penetrating injury or if there is evidence of

cardiac tamponade and/or shock regardless of the type of trauma. Pericardiocentesis may be helpful in patients with tamponade, but usually only as holding maneuver on the way to the operating room. Pericardial hemorrhage often leads to constriction, which must be treated by decortication.

SECTION 4 -VASCULAR DISEASE

241. THE PATHOGENESIS OF ATHEROSCLEROSIS - *Peter Libby*

Atherosclerosis is the leading cause of death and disability in the developed world. Despite our familiarity with this disease, some of its fundamental characteristics remain poorly recognized and understood. Although many generalized or systemic risk factors predispose to its development, atherosclerosis affects various regions of the circulation preferentially and yields distinct clinical manifestations depending on the particular circulatory bed affected. Atherosclerosis of the coronary arteries commonly causes myocardial infarction (Chap. 243) and angina pectoris (Chap. 244). Atherosclerosis of the arteries supplying the central nervous system frequently provokes strokes and transient cerebral ischemia (Chap. 361). In the peripheral circulation, atherosclerosis causes intermittent claudication and gangrene and can jeopardize limb viability (Chap. 248). Involvement of the splanchnic circulation can cause mesenteric ischemia. Atherosclerosis can affect the kidneys either directly (e.g., renal artery stenosis) or as a frequent site of atheroembolic disease (Chap. 278).

Even within a given arterial bed, atherosclerosis tends to occur focally, typically in certain predisposed regions. In the coronary circulation, for example, the proximal left anterior descending coronary artery exhibits a particular predilection for developing atherosclerotic occlusive disease. Likewise, atherosclerosis preferentially affects the proximal portions of the renal arteries and, in the extracranial circulation to the brain, the carotid bifurcation. Indeed, atherosclerotic lesions often form at branching points of arteries, regions of disturbed blood flow. Not all manifestations of atherosclerosis result from stenotic, occlusive disease. Ectasia and development of aneurysmal disease, for example, frequently occur in the aorta (Chap. 247). The mechanisms that underlie this discontinuous anatomic distribution of atherosclerosis remain uncertain.

Atherosclerosis manifests itself focally not only in space, as just described, but in time as well. Atherogenesis in humans typically occurs over a period of many years, usually many decades. Growth of atherosclerotic plaques probably does not occur in a smooth linear fashion, but rather discontinuously, with periods of relative quiescence punctuated by periods of rapid evolution. After a generally prolonged "silent" period, atherosclerosis may become clinically manifest. The clinical expressions of atherosclerosis may be chronic, as in the development of stable, effort-induced angina pectoris or of predictable and reproducible intermittent claudication. Alternatively, a much more dramatic acute clinical event, such as myocardial infarction, a cerebrovascular accident, or sudden cardiac death, may first herald the presence of atherosclerosis. Other individuals may never experience clinical manifestations of arterial disease despite the presence of widespread atherosclerosis demonstrated post mortem.

INITIATION OF ATHEROSCLEROSIS

Lipoprotein Accumulation and Modification

Fatty Streak Formation An integrated view of experimental results in animals and study of human atherosclerosis suggests that the "fatty streak" represents the initial lesion of atherosclerosis (Fig. 241-1). The formation of these early lesions of atherosclerosis

most often seems to arise from focal increases in the content of lipoproteins within regions of the intima (Fig. 241-1*B*;Fig. 241-CD1). This accumulation of lipoprotein particles may not result simply from an increased permeability, or "leakiness," of the overlying endothelium. Rather, these lipoproteins may collect in the intima of arteries because they bind to constituents of the extracellular matrix, increasing the residence time of the lipid-rich particles within the arterial wall. Lipoproteins that accumulate in the extracellular space of the intima of arteries often associate with proteoglycan molecules of the arterial extracellular matrix. At sites of lesion formation, the balance of different matrix constituents may vary in important ways. Of the three major classes of proteoglycans, for example, a relative excess of heparan sulfate molecules in relation to keratan sulfate or chondritin sulfate may promote the retention of lipoprotein particles by binding them and slowing their egress from nascent lesions.

Lipoprotein particles in the extracellular space of the intima, particularly those bound to matrix macromolecules, may undergo chemical modifications. Accumulating evidence supports a pathogenic role for such modifications of lipoproteins in atherogenesis. Two types of such alterations in lipoproteins bear particular interest in the context of understanding how risk factors actually promote atherogenesis: oxidation and nonenzymatic glycation.

Lipoprotein Oxidation Lipoproteins sequestered from plasma antioxidants in the extracellular space of the intima may be particularly susceptible to oxidative modification. Oxidatively modified low-density lipoprotein (LDL), rather than being a defined homogenous entity, actually comprises a variable and incompletely defined mixture. Both the lipid and protein moieties of these particles can participate in oxidative modification. Modifications of the lipids may include formation of hydroperoxides, lysophospholipids, oxysterols, and aldehydic breakdown products of fatty acids. Recently recognized phospholipid oxidation products include palmitoyl-oxovaleroyl-glycero-phosphoryl choline (POVPC), palmitoyl-glutarolyl-glycero-phosphoryl choline (PGPC), and epoxyisoprostane E_2-glycero-phosphocholine (PEIPC). Modifications of the apoprotein moieties may include breaks in the peptide backbone as well as derivatization of certain amino acid residues. The side chain amino group of lysine may condense with components of the oxidized lipids (4-hydroxynonenol, or malondialdehyde). A more recently recognized modification may result from local hypochlorous acid production by inflammatory cells within the plaque, giving rise to chlorinated species such as chlorotyrosyl moieties. Ongoing work is characterizing specific chemical constituents of oxidized lipoproteins responsible for various biologic effects. Examples include oxovaleryl-phosphoryl choline. Considerable evidence supports the presence of such chemical entities in atherosclerotic lesions.

Nonenzymatic Glycation In diabetic patients with sustained hyperglycemia, nonenzymatic glycation of apolipoproteins and other arterial proteins likely occurs that may likewise alter their function and propensity to accelerate atherogenesis. A good deal of experimental work suggests that both oxidatively modified and glycated lipoproteins or their constituents can contribute to many of the subsequent cellular events of lesion development.

Leukocyte Recruitment After the accumulation of extracellular lipid, recruitment of

leukocytes occurs as a second step in formation of the fatty streak (Fig. 241-1*C*). The white blood cell types typically found in the evolving atheroma include primarily cells of the mononuclear lineage: monocytes and lymphocytes (Figs. 241-CD1 and241-CD2). A number of adhesion molecules or receptors for leukocytes expressed on the surface of the arterial endothelial cell likely participate in the recruitment of leukocytes to the nascent fatty streak. Adhesion molecules of particular interest include vascular cell adhesion molecule (VCAM) 1 and intercellular adhesion molecule (ICAM) 1 (members of the immunoglobulin gene superfamily) and P-selectin (a member of a distinct family of leukocyte receptors known as selectins). Lysophosphatidylcholine, a constituent of oxidatively modifiedLDL, can augment expression of VCAM-1. This example illustrates how the accumulation of lipoproteins in the arterial intima may link mechanistically with leukocyte recruitment and subsequent events in lesion formation.

Laminar shear forces, such as those encountered in most regions of normal arteries, can also suppress the expression of leukocyte adhesion molecules such asVCAM-1. Sites of predilection for forming atherosclerotic lesions (e.g., branch points) often have disturbed laminar flow. Ordered laminar shear of normal blood flow augments the production of nitric oxide by endothelial cells. This molecule, in addition to its vasodilator properties, can act at the low levels constitutively produced by arterial endothelium as a local anti-inflammatory autacoid, for example, limiting local VCAM-1 expression. These examples indicate how hemodynamic forces may influence the cellular events that underlie atherosclerotic lesion initiation and illustrate a potential explanation for the focal distribution of atherosclerotic lesions at certain sites predetermined by altered flow patterns.

Once adherent to the surface of the arterial endothelial cell via interaction with a receptor such asVCAM-1, the monocytes and lymphocytes penetrate the endothelial layer and take up residence in the intima (Fig. 241-1*D*). In addition to products of modified lipoproteins, cytokines (a class of protein mediators of inflammation) can regulate the expression of adhesion molecules involved in leukocyte recruitment. For example, the cytokines interleukin (IL) 1 or tumor necrosis factor (TNF) a induce or augment the expression of VCAM-1 andICAM-1 on endothelial cells. Because modified lipoproteins can induce cytokine release from vascular wall cells, this pathway may provide an additional link between accumulation and modification of lipoproteins and leukocyte recruitment. The directed migration of leukocytes into the arterial wall may also result from the actions of modified lipoprotein (Fig. 241-CD3). For example, oxidizedLDL may promote the chemotaxis of leukocytes. Also, oxidatively modified lipoproteins can elicit the production by vascular wall cells of chemoattractant cytokines such as monocyte chemoattractant protein 1.

Foam-cell Formation Once resident within the intima, the mononuclear phagocytes differentiate into macrophages and transform into lipid-laden foam cells. Transformation of mononuclear phagocytes into foam cells requires the uptake of lipoprotein particles by receptor-mediated endocytosis. One might suppose that the well-known recognized receptor forLDLmediates this lipid uptake. Patients or animals lacking effective LDL receptors due to genetic alterations (e.g., familial hypercholesterolemia), however, have abundant arterial lesions and extraarterial xanthomata rich in macrophage-derived foam-cells. Also, the exogenous cholesterol suppresses expression of the LDL receptor, such that under hypercholesterolemic conditions the level of this cell-surface receptor

for LDL decreases. Candidates for alternative receptors that can mediate lipid-loading of foam cells include a growing number of macrophage "scavenger" receptors, which preferentially endocytose modified lipoproteins, and other receptors for oxidized LDL orb-VLDL (very low density lipoprotein), a type of lipoprotein commonly encountered in certain hypercholesterolemic states (Chap. 344). By imbibing lipids from the extracellular space, the mononuclear phagocytes bearing such scavenger receptors may remove lipoproteins from the developing lesion. Some lipid-loaded macrophages may leave the artery wall, functioning to clear lipid from the artery. Lipid accumulation, and hence propensity to form atheroma, ensues if the amount of lipid entering the artery wall exceeds that exported by mononuclear phagocytes or other pathways. Macrophages may thus play a vital role in the dynamic economy of lipid accumulation in the arterial wall during atherogenesis. Some lipid-laden foam cells within the expanding intimal lesion perish. Some of the death of foam cells may result from a program of cell death known as *apoptosis*. This death of mononuclear phagocytes results in formation of the lipid-rich center of more complicated atherosclerotic plaques, often called the *necrotic core* of the lesion.

Macrophages taking up modified lipoproteins, much like intrinsic vascular wall cells, may elaborate cytokines and growth factors that can further signal some of the cellular events in lesion complication. A number of growth factors or cytokines elaborated by mononuclear phagocytes can stimulate smooth-muscle cell proliferation and production of extracellular matrix, which accumulates in atherosclerotic plaques.IL-1 andTNF-aare examples of cytokines that can induce local production of growth factors such as forms of platelet-derived growth factor, fibroblast growth factor, and others that may play a role in plaque evolution and complication. Other cytokines, notably interferon (IFN) g derived from activated T cells within lesions, can inhibit smooth-muscle proliferation and synthesis of interstitial forms of collagen. These examples illustrate how atherogenesis likely depends on a complex balance between mediators that can promote lesion formation and other pathways that can mitigate the atherogenic process.

Factors That Modulate Inhibition of Atheroma Elaboration of small molecules by activated mononuclear phagocytes and vascular wall cells in the evolving lesion may also modulate atherogenesis. Notably, reactive oxygen species can modulate growth of smooth-muscle cells, activate inflammatory gene expression via the nuclear factor kappa B (NFkB) transcriptional control system, and annihilate NO radicals, decreasing the effect of this endogenous vasodilator. However, the macrophage in the lesion may be activated to express the inducible form of the enzyme that can synthesize NO, known as inducible NO synthase. This high-capacity form of the enzyme can produce relatively large, potentially cytotoxic amounts of NO radicals. While at low concentrations of×NO produced by the constitutive NO synthase in endothelial cells, this radical may produce beneficial effects; when overproduced by activated phagocytes, it may prove deleterious.

Export by phagocytes may constitute one response to local lipid overload in the evolving lesion. Another mechanism, reverse cholesterol transport mediated by high-density lipoproteins (HDL), may provide an independent pathway for lipid removal from atheroma. Multiple observational studies have established a tight inverse relationship between the level of HDL cholesterol and the risk for coronary events. Increased HDL may explain why premenopausal women have less atherosclerosis than age-matched

men. In various in vitro models, HDL can mediate net cholesterol removal from lipid-laden macrophages. This process likely involves a family of scavenger receptors (the "B" family), highly expressed by steroidogenic tissues and by cells within atheroma as well. Such "reverse cholesterol transport" may also pertain during human atherogenesis and help to explain HDL's protective effect on lesion formation.

Although clear evidence supports lipoprotein disorders as predisposing factors for atheroma formation, other etiologies may contribute to or modulate atherogenesis (Table 242-1). For example, hypertension constitutes an independent risk factor for coronary events. Male gender and the postmenopausal state also augment the risk of developing coronary artery disease. Premenopausal women have increasedHDLlevels compared to age-matched men. However, a favorable lipoprotein pattern only partially accounts for the protection against atherosclerosis conferred by the premenopausal state. Thus, as yet poorly understood direct effects of estrogens on the arterial wall may account for some of this benefit. Studies in progress are investigating possible mechanisms of estrogen's possible "vasculoprotective" effect and the role of estrogen replacement therapy as an antiatherogenic strategy in postmenopausal women.

Diabetes mellitus accelerates atherogenesis. In addition to the well-known microvascular complications of diabetes (Chap. 333), macrovascular disease such as atherosclerosis causes a great deal of excess mortality in the diabetic populations. Diabetes-associated dyslipidemias strongly promote atherogenesis. In particular, the constellation of insulin resistance, high triglycerides, and low HDL, often in association with central adiposity and hypertension frequent in type 2 diabetic patients, seems to accelerate atherogenesis potently. As noted above, hyperglycemia may promote the nonenzymatic glycation ofLDL. LDL modified in this manner, like oxidatively modified LDL, may signal many of the initial events in atherogenesis. Other lipoproteins such as triglyceride-rich particles or lipoprotein (a) [Lp(a)] may also prove particularly atherogenic.

Lp(a)(often pronounced "lipoprotein little a" to distinguish it from apolipoprotein AI and others found in HDL) provides a potential link between hemostasis and blood lipids. The Lp(a) particle consists of an apoprotein (a) molecule bound by a sulfhydryl link to the apolipoprotein B moiety of aLDLparticle. Apoprotein (a) has homology with plasminogen and may inhibit fibrinolysis by competing with plasminogen. Other risk factors for atherosclerosis related to blood clotting include elevated levels of fibrinogen or of the inhibitor of fibrinolysis, plasminogen-activator inhibitor (PAI) 1. Another nonlipid risk factor for coronary events, elevated levels of *homocysteine*, may act by promoting thrombosis, although the pathophysiology of this association is uncertain at present.

The relationship between *tobacco use* and atherosclerosis also remains poorly understood (Chap. 390). The rapid reduction in risk for cardiac events after cessation of cigarette smoking implies that tobacco may promote thrombosis or some other determinant of plaque stability as well as evolution of the atherosclerotic lesion itself. For example, tobacco smokers have elevated fibrinogen levels, a variable associated with increased atherosclerosis and acute cardiovascular events.

In other situations, antecedent inflammatory states may predispose towards atherosclerosis. For example, *Kawasaki disease* in childhood may promote

development of vascular lesions in the arteries of adults (Chap. 317). Infectious agents continue to be proposed as instigators or potentiators of atherogenesis. Both viral and microbial pathogens have been invoked in this context (e.g., Herpesviridiae, including cytomegalovirus, or *Chlamydia*). In some patients, immune or autoimmune reactions may contribute to atherogenesis. In the particular example of the accelerated form of coronary arteriopathy that plagues heart transplant recipients, immunologic factors may contribute importantly to the pathogenesis. The roles of the immune response and of infectious diseases in usual atherosclerosis remain speculative.

Known genetic defects in lipoprotein metabolism account for only a fraction of the familial risk for coronary artery disease. Thus, other as yet undefined genetic factors must contribute to coronary risk. Mechanisms of disease susceptibility involving the arterial wall might account for some of the genetic predisposition to atherosclerosis unexplained by lipoprotein disorders. Application of molecular genetic techniques should help identify new polymorphisms linked to coronary risk and may eventually shed light on new pathophysiologic mechanisms. For example, some data suggest a link between certain alleles of the genes encoding angiotensin-converting enzyme or PAI-1 with increased risk of myocardial infarction. Large studies currently in progress should clarify these and other potential markers of genetic susceptibility to atherosclerosis.

ATHEROMA EVOLUTION AND COMPLICATION

Involvement of Arterial Smooth-Muscle Cells Although the fatty streak commonly precedes the development of a more advanced atherosclerotic plaque, not all fatty streaks progress to yield atheroma. Fatty streaks occur in populations not prone to develop late lesions (e.g., indigenous Africans). These findings raise several questions. Why do some fatty streaks progress to fibrous lesions but not others? By what mechanisms do fatty streaks evolve into more complex lesions? While accumulation of lipid-laden macrophages is the hallmark of the fatty streaks, accumulation of fibrous tissue typifies the more advanced atherosclerotic lesion. The smooth-muscle cell synthesizes the bulk of the extracellular matrix of the complex atherosclerotic lesion. Hence, arrival of smooth-muscle cells and their elaboration of extracellular matrix probably provides a critical transition, yielding a fibrofatty lesion in place of a simple accumulation of macrophage-derived foam cells.

Recent research has provided insight into the mechanisms that may trigger migration and proliferation of smooth-muscle cells into and within the evolving intimal lesion and signal the accumulation of extracellular matrix. Cytokines and growth factors elicited by modified lipoproteins or other agents from both vascular wall cells and infiltrating leukocytes can modulate functions of the smooth-muscle cell. For example, platelet-derived growth factors (PDGF) elaborated by activated endothelial cells can stimulate the migration of smooth-muscle cells (Fig. 241-CD2). In this manner, smooth-muscle cells resident in the tunica media may migrate into the intima. Various growth factors produced locally can stimulate the proliferation of both resident smooth-muscle cells in the intima and those that have migrated from the media. Transforming growth factor (TGF) b, among other mediators, potently stimulates interstitial collagen production by smooth-muscle cells. These mediators may arise not only from neighboring vascular cells or leukocytes (a "paracrine" pathway) but in some instances from the same cell that responds to the factor (an "autocrine" pathway).

Together, these alterations in smooth-muscle cells, signaled by these mediators acting at short distances, can hasten transformation of the fatty streak into a more fibrous smooth-muscle cell and extracellular matrix-rich lesion.

In addition to locally produced mediators, atherogenic risk factor signals related to blood coagulation and thrombosis likely contribute to atheroma evolution and complication. Current evidence suggests that fatty streak formation begins without frank denuding endothelial injury or desquamation. In advanced fatty streaks, however, microscopic breaches in endothelial integrity may occur. Microthrombi rich in platelets can form at such sites of limited endothelial denudation, due to exposure of the highly thrombogenic extracellular matrix of underlying basement membrane. Activated platelets release numerous factors that can promote the fibrotic response. In addition toPDGF andTGF-b, low-molecular-weight mediators such as serotonin can also alter smooth-muscle function. Most of these microthrombi probably resolve without clinical manifestation by a process of local fibrinolysis, resorption, and endothelial repair.

As atherosclerotic lesions advance, abundant plexi of microvessels develop in connection with the artery's vasa vasorum. These newly developing microvascular networks may contribute to lesion complication in several ways. These blood vessels provide an abundant surface area for leukocyte trafficking and may serve as the portal of entry and exit of white blood cells from the established atheroma. The plaques' microvessels may also furnish foci for intraplaque hemorrhage. Like the neovessels in the diabetic retina, microvessels of the plaque may be friable and prone to rupture and produce focal hemorrhage. Such a vascular leak leads to thrombosis in situ and thrombin generation from prothrombin. In addition to its role in blood coagulation, thrombin can modulate many aspects of vascular cell function including stimulation of proliferation and cytokine release from smooth-muscle cells and production of growth factors such asPDGFfrom endothelial cells. Atherosclerotic plaques often contain fibrin and hemosiderin, indicating episodes of intraplaque hemorrhage as an element in plaque complication.

As they advance, atherosclerotic plaques also accumulate calcium. Proteins specialized in binding of calcium usually associated with bone also occur in atherosclerotic lesions. For example, osteocalcin, osteopontin, and bone morphogenetic proteins localize in atherosclerotic plaques. In fact, complication of the atherosclerotic plaque recapitulates many aspects of bone formation.

Traditionally, atherosclerosis research has focused much attention on proliferation of smooth-muscle cells, yet these cells actually replicate rather slowly in complicated atherosclerotic lesions. Estimates of the rate of smooth-muscle cell division at a given time point in such lesions show replicative rate below 1%. Such observations do not exclude bursts of proliferative activity at certain junctures in the history of an atheroma, perhaps in association with local thrombin generation due to microvascular hemorrhage or formation of a microthrombus at a site of localized endothelial denudation, as discussed above. On the other hand, cell death has been recognized as a component of atherogenesis since the time of Virchow in the mid-nineteenth century. Indeed, complex atheroma often have a primarily fibrous character lacking the hypercellular appearance of less advanced lesions and actually exhibiting a paucity of smooth-muscle cells. This relative lack of smooth-muscle cells in advanced atheroma may result from the ultimate

predominance of cytostatic mediators such asTGF-borIFN-g, which can inhibit smooth-muscle cell proliferation. Also, smooth-muscle cells as well as macrophages in advanced atherosclerotic lesions can undergo programmed cell death, or apoptosis. Some of the same cytokines that activate atherogenic functions of vascular wall cells can also trigger the program of apoptosis in these cells.

Thus, during the evolution of the atherosclerotic plaque, a complex balance between entry and egress of lipoproteins and leukocytes, cell proliferation and cell death, extracellular matrix production and remodeling, as well as calcification and neovascularization contribute to lesion formation. Multiple and often competing signals trigger these various cellular events. Increasingly, we appreciate links between atherogenic risk factors and the altered behavior of intrinsic vascular wall cells and infiltrating leukocytes that underlie the complex pathogenesis of these lesions.

CLINICAL SYNDROMES OF ATHEROSCLEROSIS

Atherosclerotic lesions occur ubiquitously in western societies. Most atheroma produce no symptoms, and many never cause clinical manifestations. Numerous patients with diffuse atherosclerosis may succumb to unrelated illnesses without ever having experienced a clinically significant manifestation of atherosclerosis. What accounts for this variability in the clinical expression of atherosclerotic disease?

Arterial remodeling during atheroma formation (Fig. 241-2*A*) represents a frequently overlooked but clinically important feature of lesion evolution. During the initial phases of atheroma development, the plaque usually grows outward, in an abluminal direction. Vessels affected by atherogenesis tend to increase in diameter, a phenomenon known as *compensatory enlargement*, a type of vascular remodeling. The growing atheroma does not encroach upon the arterial lumen until the burden of atherosclerotic plaque exceeds approximately 40% of the area encompassed by the internal elastic lamina. Thus, during much of its life history, an atheroma will not cause stenosis that can limit blood flow.

Flow-limiting stenoses commonly form later in the history of the plaque. Many such plaques manifest themselves by stable syndromes such as demand-induced angina pectoris or intermittent claudication in the extremities. In the coronary and other circulations, even occlusion due to atheroma does not invariably lead to infarction. The hypoxic stimulus of repeated bouts of ischemia characteristically induces formation of collateral vessels in the myocardium, mitigating the consequences of an acute occlusion of an epicardial coronary artery. On the other hand, we now appreciate that many lesions that cause acute or unstable atherosclerotic syndromes, particularly in the coronary circulation, may arise from atherosclerotic plaques that do not produce a flow-limiting stenosis. Such lesions may produce only minimal luminal irregularities on traditional angiograms and often do not meet the traditional criteria for "significance" by arteriography. Instability of such nonocclusive stenoses may explain the frequency of myocardial infarction as an initial manifestation of coronary artery disease (in about a third of cases) in patients who report no prior history of angina pectoris, a syndrome usually caused by flow-limiting stenoses.

Pathologic studies afford considerable insight into the microanatomic substrate

underlying "instability" of plaques that are not critically stenotic. A superficial erosion of the endothelium or a frank plaque rupture or fissure usually produces the thrombus that causes episodes of unstable angina pectoris or the occlusive and relatively persistent thrombus that causes acute myocardial infarction (Fig. 241-2*C*). In the case of carotid atheroma, a deeper ulceration that provides a nidus for formation of platelet thrombi may underlie the unstable syndromes that cause transient ischemic attacks.

Rupture of the plaque's fibrous cap (Fig. 241-2*C*) permits contact of coagulation factors in the blood with highly thrombogenic tissue factor expressed by macrophage foam cells in the plaque's lipid-rich core. If the ensuing thrombus is nonocclusive or transient, the episode of plaque disruption may not cause symptoms or may result in ischemic symptoms such as rest angina. Occlusive thrombi that endure will often cause acute myocardial infarction, particularly in the absence of a well-developed collateral circulation supplying the affected territory. Repetitive episodes of plaque disruption and healing provide one likely mechanism of transition of the fatty streak to a more complex fibrous lesion (Fig. 241-2*D*). The healing process in arteries, as in skin wounds, involves the laying down of new extracellular matrix and fibrosis.

Not all atheroma exhibit the same propensity to rupture. Studies of the pathology of culprit lesions that have caused acute myocardial infarction reveal several characteristic features. Plaques that have proven vulnerable tend to have thin fibrous caps, relatively large lipid cores, and a high content of macrophages (Fig. 241-CD4). Morphometric studies of such culprit lesions show that macrophages and T lymphocytes predominate at the site of plaque rupture. On the other hand, sites of plaque rupture contain relatively few smooth-muscle cells. The cells that concentrate at sites of plaque rupture bear markers of inflammatory activation. The presence of the transplantation, or histocompatibility, antigen HLA-DR provides one convenient gauge of the degree of inflammation in cells in atheroma. Resting cells in normal arteries seldom express this transplantation antigen. However, macrophages and smooth-muscle cells at sites of human coronary artery plaque disruption do bear this inducible cell-surface marker. Therefore, the presence of HLA-DR-positive macrophages and T cells indicates an ongoing inflammatory response at sites of plaque rupture.

Inflammatory mediators may actually regulate processes that govern the integrity of the plaque's fibrous cap and hence its propensity to rupture. For example, the T cell-derived cytokineIFN-g, found in atherosclerotic plaques and required to induce the HLA-DR present at sites of rupture, can inhibit growth and collagen synthesis of smooth-muscle cells. Cytokines derived from activated macrophages such asTNF-aor IL-1 in addition to T cell-derived IFN-g can elicit the expression of genes that encode the proteinases that can degrade the extracellular matrix of the plaque's fibrous cap. Thus, inflammatory mediators can impair collagen synthesis required for maintenance and repair of the fibrous cap and trigger degradation of extracellular matrix macromolecules, processes that should weaken the plaque's fibrous cap and enhance its vulnerability to rupture. In contrast to vulnerable plaques, those with a dense extracellular matrix and relatively thick fibrous cap without substantial tissue factor-rich lipid cores seem generally resistant to rupture and unlikely to provoke thrombosis.

In conclusion, we now appreciate that features of the biology of the atheromatous plaque in addition to its degree of luminal encroachment influence the clinical

manifestations of this disease. This enhanced understanding of plaque biology provides insight into the diverse ways in which atherosclerosis can present clinically, and why the disease may remain silent or stable for prolonged periods and be punctuated by acute complications at certain times. Increased understanding of atherogenesis provides new insight into the ways in which current therapies may improve outcomes and also suggests new targets for future intervention.

242. PREVENTION AND TREATMENT OF ATHEROSCLEROSIS - *Peter Libby*

Atherosclerosis remains the major cause of death and premature disability in developed societies. Moreover, current predictions estimate that by the year 2020 cardiovascular diseases, notably atherosclerosis, will become the leading global cause of total disease burden, defined as the years subtracted from healthy life by disability or premature death. Substantial success has been achieved in recent years in reducing morbidity and mortality due to acute coronary events. However, the opportunity for treating the underlying disease process, atherosclerosis, and preventing its acute complications presents an enormous challenge and opportunity at the same time.

THE CONCEPT OF ATHEROSCLEROTIC RISK FACTORS

During the first half of the twentieth century, animal experiments and clinical observation linked certain variables, such as hypercholesterolemia, to the risk of atherosclerotic events. The systematic study of risk factors in humans, however, began approximately mid-century. The prospective, community-based Framingham Heart Study provided rigorous support for the concept that hypercholesterolemia, hypertension, and other factors correlated with cardiovascular risk. Similar observational studies performed in the United States and abroad provided independent support for the concept of "risk factors" for cardiovascular disease. Numerous studies, including the Seven Countries Study performed by Keys and colleagues, suggested a link between dietary habits and cardiovascular risk based upon population studies.

From a practical viewpoint, it is useful to group the cardiovascular risk factors that have emerged from such studies into two categories: (1) those modifiable by lifestyle and/or pharmacotherapy, and (2) those that are essentially unmodifiable (Table 242-1). The weight of evidence supporting various risk factor differs. For example, hypercholesterolemia and hypertension indubitably predict coronary risk, but other so-called nontraditional risk factors, such as levels of homocysteine, lipoprotein (a) [Lp(a)], or infection, remain controversial. It is worth distinguishing further between factors that actually participate in the pathogenesis of atherosclerosis and those that may merely serve as markers of risk without themselves playing a primary role in pathogenesis. The sections below will consider some of these risk factors and approaches to their modification.

LIPID DISORDERS (See also Chap. 344)

Abnormalities in plasma lipoproteins and derangements in lipid metabolism rank as the most firmly established and best understood risk factors for atherosclerosis. Descriptions of the lipoprotein classes, and a detailed explication of lipoprotein metabolism are given inChap. 344. The mechanisms by which lipoproteins may influence atherogenesis are considered inChap. 241. Therefore this section will focus on preventive aspects of treatment of lipid disorders.

Current national guidelines recommend cholesterol screening in all adults. The screen should include a fasting lipid profile [total cholesterol, triglycerides, low-density lipoprotein (LDL) cholesterol and high-density lipoprotein (HDL) cholesterol]. Dietary measures, including specific consultation by practitioners with training in nutrition,

should be offered to all patients with hyperlipidemia as defined by the National Cholesterol Education Project Adult Treatment Panel II (Table 242-2). A "normal" total cholesterol level should not falsely reassure individuals with additional risk factors for coronary heart disease or when the HDL level is below 1 mmol/L (40 mg/dL). Many patients with established atherosclerosis fall into this category. Such individuals should receive particular encouragement to adopt life-style measures such as diet and exercise aimed at increasing their HDL levels.

The addition of drug therapy to dietary and other nonpharmacologic measures to reduce the risk of atherosclerotic events in asymptomatic patients without manifest vascular disease remains unsettled. In asymptomatic patients with heterozygous familial hypercholesterolemia,LDLlowering by pharmacologic measures reduces atherosclerosis in both men and women. The West of Scotland Study established that lipid lowering with the HMG-CoA inhibitor pravastatin can effectively reduce cardiac events and total mortality in a cohort of patients with hypercholesterolemia but without prior myocardial infarction (Table 242-3). The recent AFCAPS/TexCAPS Study showed that treatment with lovastatin similarly reduced coronary events in patients without previous myocardial infarction but with "average" total and LDL cholesterol levels and somewhat decreasedHDLlevels.

Although the role of drug therapy in primary prevention of the manifestations of atherosclerosis remains incompletely defined, abundant evidence establishes the benefit of drug therapy in patients with hypercholesterolemia and established coronary artery disease (Table 242-3). A number of well-designed and -executed large-scale clinical trials have now shown that treatment with statins reduces recurrent myocardial infarction, reduces strokes, and lessens the need for revascularization or hospitalization for unstable angina pectoris. These studies have enrolled patients in numerous countries on at least three continents and encompass individuals with clearly elevated levels of cholesterol and those with "average" total andLDLcholesterol levels.

Lipid-lowering therapies do not appear to exert their beneficial effect on cardiovascular events by causing a marked "regression" of obstructive coronary lesions. Angiographically monitored studies of lipid lowering have shown at best a modest reduction in coronary artery stenoses over the duration of study. Yet these same studies consistently show substantial decreases in coronary events. These results suggest that the mechanism of benefit of lipid lowering does not require a substantial reduction in the fixed stenoses. Rather, the benefit may derive from "stabilization" of atherosclerotic lesions without decreased stenosis. Such stabilization of atherosclerotic lesions and the attendant decrease in coronary events may result from the egress of lipids or by favorably influencing aspects of the biology of atherogenesis discussed inChap. 241. In addition, as sizeable lesions may protrude abluminally rather than into the lumen, shrinkage of such plaques might not be apparent on angiograms.

The benefit ofLDLlowering by HMG-CoA reductase inhibitor (statin) therapy on cardiovascular events seems to require 6 to 24 months of treatment. Improvement of vasomotor responses to endothelial-dependent vasodilators occurs much more rapidly, requiring 6 months or less. Thus, HMG-CoA reductase inhibitors may act by two or more mechanisms on the arteries of hypercholesterolemic individuals. The relatively rapid improvement in endothelial-dependent vasomotion may reflect enhanced

production or reduced destruction of the endogenous vasodilator nitric oxide at the level of the arterial endothelium. Reduction in the thrombotic complications of atherosclerosis, such as myocardial infarction or unstable angina, probably requires more prolonged treatment to effect removal of lipid from deeper within the atheroma, yielding improvements in the biology underlying plaque destabilization described in Chap. 241.

Our current understanding of the mechanism by which elevated LDL levels promote atherogenesis relates to oxidative modification of these particles within the artery wall, promoting formation of macrophage-derived foam cells and providing a stimulus for inflammation (Chap. 241). These concepts have given rise to considerable interest in the possibility that antioxidants, either dietary or pharmacologic, might reduce atherogenesis. Considerable experimental evidence supports this notion. In addition, many observational studies show a correlation of antioxidant consumption and reduced cardiovascular risk. Rigorous, controlled clinical trial evidence, however, has not yet proven the effectiveness of antioxidant therapy, whether dietary or with supplements of vitamins or drugs, for prevention or treatment of atherosclerosis. Indeed, controlled trials withb-carotene have demonstrated no reduction in cardiovascular events. For these reasons, as its efficacy remains speculative, it is premature to consider antioxidant administration as a replacement for established therapies. Furthermore, general use of such treatments, particularly in lower risk individuals, should await the results of rigorous prospective studies designed to define the doses, appropriate patient groups, and evaluate the possibility of adverse or unwanted effects of antioxidants.

HYPERTENSION (See also Chap. 246)

The preponderance of epidemiologic data supports a relationship between hypertension and atherosclerotic risk. Clinical trial evidence available since the 1970s established that pharmacologic treatment of hypertension can reduce the risk of stroke and heart failure. However, clinical trial evidence demonstrating reduced risk of coronary events due to antihypertensive therapy has lagged. At present, the combined weight of the evidence supports a reduction in coronary risk by antihypertensive therapy. Some of the difficulty in demonstrating this benefit may derive from the potentially adverse effects of certain classes of antihypertensive drugs on the lipid profile, notably, thiazide diuretics and beta-blocking agents. Indeed, studies of patients with previous myocardial infarction or reduced left ventricular function have shown that treatment with angiotensin-converting enzyme (ACE) inhibitors can reduce the risk of coronary events, an unanticipated outcome. Therefore "lipid-neutral" antihypertensive agents such as ACE inhibitors or α_1-adrenergic blocking agents merit consideration in patients with other risk factors for coronary artery disease or with established atherosclerosis.

DIABETES MELLITUS AND INSULIN RESISTANCE (See also Chap. 333)

Most patients with diabetes mellitus die of atherosclerosis and its complications. Secular trends towards aging of the population and increased girth will make type 2 (noninsulin-dependent) diabetes mellitus an increasing public health problem in the coming years. The criteria for diagnosis of diabetes have recently undergone revision. Currently, a fasting plasma glucose level of 6.9 mmol/L (125 mg/dL) establishes the diagnosis of diabetes. In the intermediate range, plasma glucose levels between 6.1 and 6.9 mmol/L (110 and 125 mg/dL) indicate impaired fasting glucose. Thus, fasting

glucose>6.1 mmol/L (110 mg/dL) indicates abnormal glucose tolerance. These definitions based on fasting plasma glucose alone obviate the need for performing glucose tolerance tests.

A major feature of elevated cardiovascular risk in patients with type 2 diabetes probably relates to the abnormal lipoprotein profile associated with insulin resistance known as *diabetic dyslipidemia*. While diabetic patients may often haveLDLcholesterol levels near average, the LDL particles tend to be smaller and denser and thus more atherogenic (Chap. 344). Other features of diabetic dyslipidemia include lowHDL and elevated triglycerides. Establishing that strict glycemic control reduces the risk of macrovascular complications of diabetes has proven much more elusive than the established beneficial effects on microvascular complications such as retinopathy or renal disease. In the absence of clear-cut evidence that tight glycemic control reduces coronary risk in diabetic patients, attention to other aspects of risk in this patient population assumes even greater importance. In this regard, recent clinical trials have demonstrated unequivocal benefit of HMG-CoA reductase inhibitor therapy in diabetic patients, including those with "average" LDL cholesterol levels. Having diabetes places patients in the same risk category as those with established atherosclerotic disease. Therefore, recent guidelines promulgated by the American Diabetes Association recommend an aggressive approach to lipid lowering in the diabetic population, as supported by recent clinical trials. These guidelines establish a target LDL cholesterol level of 2.6 mmol/L (100 mg/dL) for the patient with diabetes.

MALE GENDER/POSTMENOPAUSAL STATE

Decades of observational studies have verified excess coronary risk in males compared with premenopausal females. After menopause, however, coronary risk accelerates in women. At least part of the apparent protection against coronary heart disease in premenopausal women derives from their relatively higherHDLlevels compared with those of men. After menopause, HDL values fall in concert with increased coronary risk. Estrogen therapy lowersLDLcholesterol and raises HDL cholesterol, changes that should decrease coronary risk. A multitude of observational studies has suggested that estrogen-replacement therapy (ERT) reduces coronary risk. Substantial experimental data support the biologic plausibility of a beneficial effect of estrogen in reducing atherosclerotic events, but a number of potential confounding factors render clinical trials necessary to establish the cardiovascular benefits of ERT. In men, high-dose estrogen treatment caused excess mortality, probably due to increased thromboembolic complications.

The recently reported Heart and Estrogen/Progestin Replacement Study (HERS) has highlighted the need for clinical trial evidence to substantiate the observational and experimental data regarding estrogen's beneficial effects on the vasculature and lipid profile. In this trial, postmenopausal female survivors of acute myocardial infarction were randomized to an estrogen/progestin combination or to placebo. This study showed no overall reduction in recurrent coronary events in the active treatment arm. Indeed, early in the 5-year course of this trial, there was a trend toward an actual increase in vascular events in the treated women. As in the previous Coronary Drug Project trial, the excess events may have resulted from an increase in thromboembolism. HERS does not definitively exclude a potential benefit of other combinations of estrogens with

progestins or a benefit of estrogens alone in patients lacking a uterus. A more prolonged follow-up might have disclosed an accrual of benefit in the treatment group, as the excess events appeared in the first years of the trial in the treated group. Moreover, drugs of the selective estrogen receptor modulator class might dissociate the increased risk of breast and/or uterine cancer from cardiovascular benefit. This possibility will likewise require randomized clinical trial evidence evaluating coronary events to validate widespread application. The current quandary surroundingERT as a means of reducing cardiovascular risk highlights the need for redoubled attention to known modifiable risk factors in women. In the recent clinical trials with HMG-CoA reductase inhibitors, women, when included, have derived benefits at least commensurate with those seen in men. Data from HERS itself showed that application of lipid-lowering therapy to female survivors of myocardial infarction lagged far behind guidelines. Choices regarding ERT in postmenopausal women remain complex. Physicians should work together with women to provide information and help weigh the risks and benefits of ERT, taking personal preferences into account.

DYSREGULATED COAGULATION OR FIBRINOLYSIS

Thrombosis ultimately causes the gravest complications of atherosclerosis. The propensity to form thrombi and/or to lyse clots once they form could clearly influence the manifestations of atherosclerosis. Thrombosis provoked by atheroma rupture and subsequent healing may promote plaque growth, as described inChap. 241. Certain individual characteristics can influence thrombosis or fibrinolysis and have received attention as potential coronary risk factors. For example, fibrinogen levels correlate with coronary risk and provide information regarding coronary risk independent of the lipoprotein profile. Elevated fibrinogen levels might promote a thrombotic diathesis. Alternatively, fibrinogen, an acute-phase reactant, may serve as a marker of inflammation rather than directly participating in the pathogenesis of coronary events.

The stability of an arterial thrombus depends on the balance between fibrinolytic factors, such as plasmin, and inhibitors of the fibrinolytic system, such as plasminogen activator inhibitor (PAI) 1. Certain genotypes of the PAI-1 gene appear to correlate with increased coronary risk. Yet, overall, the levels of tissue plasminogen activator and PAI-1 in plasma have not proven to add information beyond the lipid profile to assessment of cardiovascular risk. Likewise, the role ofLp(a)(Chap. 344) as a modulator of fibrinolysis remains controversial. Apo Lp(a) has high homology to plasminogen but lacks the enzymatic activity of this fibrinolytic molecule. Thus, Lp(a) might antagonize fibrinolysis, serving as a type of "dominant negative" competitor of plasminogen. However, in vivo evidence for this mechanism, and, indeed, the independent contribution of Lp(a), is clouded by difficulties in standardizing the assays and the highly polymorphic nature of this protein in humans.

HOMOCYSTEINE

A large body of literature suggests a relationship between hyperhomocysteinemia and coronary events. Several mutations in the enzymes involved in homocysteine accumulation correlate with thrombosis and, in some studies, coronary risk. Although thrombosis and atherosclerosis seem intimately linked, direct evidence of an atherogenic effect of hyperhomocysteinemia in humans remains weak. The role of

hyperhomocysteinemia in atherosclerotic complications, however, has important practical implications. The plasma level of homocysteine can vary with diet. Nutritional supplementation with folic acid can lower homocysteine levels in many individuals. A substantial portion of the elderly population in the United States has only a marginal sufficiency of folate intake. A fortification of the American diet with folic acid, aimed at reduction of neural tube defects, is lowering homocysteine levels in the population at large. Recommending a diet rich in folate or consumption of multivitamin supplements containing folic acid should be considered in individuals with atherosclerosis out of proportion to traditional or established risk factors and with elevated levels of homocysteine. The possibility that folate treatment might mask pernicious anemia should be considered when advising such supplementation. No clinical trial evidence currently establishes a reduction in coronary events in patients with hyperhomocysteinemia treated with folate.

INFECTION/INFLAMMATION

Recent years have witnessed a resurgence of interest in the possibility that infections may cause or contribute to atherosclerosis. A spate of recent publications has furnished evidence in support for a role of *Chlamydia pneumoniae*, cytomegalovirus, or other infectious agents in atherosclerosis and restenosis following coronary intervention. Some microorganisms exist in human atherosclerotic plaques. However, seroepidemiologic evidence for an association between infection with various agents and atherosclerosis remains inconclusive. Several ongoing large trials of antibiotic treatment in survivors of myocardial infarction may provide support for an etiologic or contributory role of microbial infection in recurrent coronary events. Even if positive, however, such clinical trials would neither inculpate any particular microorganisms nor even prove that a benefit derived from the antimicrobial action of the agent employed.

Although direct infection may not cause atherosclerosis, the infectious agents and the host defenses against these invaders might potentiate atherogenesis, acting as inflammatory stimuli. Just as inflammation may mediate some of the altered arterial biology in response to hyperlipoproteinemia, so might infectious agents incite an inflammatory response that could promote atherosclerosis and its complications. Thus, microbial pathogens might act in concert with traditional risk factors to accelerate atherogenesis or cause complication or aggravation of existing atheroma.

In this regard, evidence is accumulating that markers of inflammation correlate with coronary risk. For example, elevated plasma levels of C-reactive protein (CRP) can prospectively predict risk of myocardial infarction and correlate with outcome of patients with acute coronary syndromes. As in the case of fibrinogen, elevated levels of the acute-phase reactant CRP may merely reflect ongoing inflammation rather than a direct etiologic role for CRP in coronary artery disease. It remains uncertain whether elevations in acute-phase reactants such as fibrinogen or CRP serve as a marker for the overall atherosclerotic burden, and hence of coronary events. Alternatively, the elevation in acute-phase reactants could reflect extravascular inflammation that could potentiate atherosclerosis or its complications. In all likelihood, both factors contribute to elevation of inflammatory markers in patients at risk for coronary events. These observations raise the possibility that anti-inflammatory therapies might reduce atherosclerotic events. Indeed, lipid-lowering therapy may reduce coronary events in

part by reducing the inflammatory aspects of the pathogenesis of atherosclerosis.

LIFE-STYLE MODIFICATION

The prevention of atherosclerosis presents a long-term challenge to all health care professionals and for public health policy. Both individual practitioners and organizations providing health care should strive to help patients optimize their risk factor profile long before atherosclerotic disease might become manifest. The care plan for all patients seen by internists should include measures to assess and minimize cardiovascular risk. Physicians must counsel patients regarding the health risks of tobacco use and provide guidance regarding smoking cessation. Likewise, physicians should advise all patients about prudent dietary and exercise habits for maintaining ideal body weight. The recent National Institutes of Health Consensus Panel on Physical Activity and Cardiovascular Health established a goal of accumulating at least 30 min of moderate-intensity physical activity on a daily basis. Obesity, particularly the male pattern of centripetal or visceral fat accumulation, can promote an atherogenic dyslipidemia characterized by elevated triglycerides, a low HDL level, and glucose intolerance. Physicians should encourage their patients to take responsibility for behavior related to modifiable risk factors for development of premature atherosclerotic disease. Conscientious counseling and patient education may forestall the need for pharmacologic measures intended to reduce coronary risk.

ISSUES IN RISK ASSESSMENT

A growing panel of markers of coronary risk presents a perplexing array to the practitioner. Such markers include size fractionation of LDL particles, measurement of concentrations of homocysteine, Lp(a), fibrinogen, CRP, and PAI-1, among others. In general, such specialized tests add little to the information available from a careful history and physical examination and measurement of a plasma lipoprotein profile and fasting blood sugar. Evaluation of such specialized markers might be considered in individuals without evident risk factors other than premature vascular disease or a worrisome family history. A similar confusion surrounds the use of specialized radiographic estimations of coronary artery calcification. Information is accumulating that the amount of calcium determined by such techniques as electron beam computed tomography correlates with coronary risk. However, the utility of using such estimates of coronary artery calcium content as a guide to therapy remains unproven, particularly in asymptomatic individuals. Inappropriate use of such imaging modalities might promote excessive invasive diagnostic and therapeutic procedures. Widespread application of such modalities for screening should await proof that clinical benefit derives from their application.

THE CONCEPT OF GLOBAL RISK

Adoption of hygienic life-style changes to ameliorate coronary risk entails little expense or possibility of adverse effects. In contrast, pharmacotherapy can prove costly. Although lipid-lowering drugs such as the HMG-CoA reductase inhibitors have proven exceedingly well tolerated in clinical trials, the use of these or other lipid-lowering agents could produce adverse reactions in some individuals. The decision to initiate drug treatment for reduction of risk of atherosclerotic events requires careful consideration,

particularly in the setting of "primary prevention" or in patients without known atherosclerotic disease. In this regard, it is prudent to consider not only theLDLcholesterol but also the individual patient's global cardiovascular risk. For example, an individual with an average LDL but a lowHDL, hypertension, and a family history of premature coronary artery disease might warrant initiation of drug therapy more than an individual with the same LDL level in the absence of the other risk factors. Rather than considering plasma lipoprotein values in insolation, current European guidelines reserve drug treatment for individuals with a calculated absolute coronary heart disease risk of greater than 20% over 10 years. The calculation of coronary risk includes taking gender, smoking history, and systolic blood pressure into account, in addition to plasma cholesterol levels. This policy illustrates how estimations of global risk may be applied to optimize decisions regarding initiation of drug therapy to prevent atherosclerotic events (Fig. 242-1).

THE CHALLENGE OF IMPLEMENTATION: CHANGING PHYSICIAN AND PATIENT BEHAVIOR

Enormous strides have been made in the prevention and treatment of atherosclerosis. Despite declining age-adjusted rates of coronary death, cardiovascular mortality is on the rise due to the aging of the population overall. There is a powerful global trend toward increased atherosclerotic disease. Enormous challenges remain regarding translation of the current evidence base into practice. The obstacles to implementation of current evidence-based prevention and treatment of atherosclerosis include economics, education, physician awareness, and patient adherence to recommended regimens. Future goals in the field of treatment of atherosclerosis should include application of the current knowledge regarding risk factor management and, when appropriate, drug therapy.

243. ACUTE MYOCARDIAL INFARCTION - *Elliott M. Antman*, *Eugene Braunwald*

Acute myocardial infarction (AMI) is one of the most common diagnoses in hospitalized patients in industrialized countries. In the United States, approximately 1.1 million AMIs occur each year. The mortality rate with AMI is approximately 30%, with more than half of these deaths occurring before the stricken individual reaches the hospital. Although the mortality rate after admission for AMI has declined by about 30% over the last two decades, approximately 1 of every 25 patients who survives the initial hospitalization dies in the first year after AMI. Survival is markedly reduced in elderly patients (over age 75), whose mortality rate is 20% at 1 month and 30% at 1 year after AMI.

PATHOPHYSIOLOGY: ROLE OF ACUTE PLAQUE RUPTURE

AMIgenerally occurs when coronary blood flow decreases abruptly after a thrombotic occlusion of a coronary artery previously narrowed by atherosclerosis. Slowly developing, high-grade coronary artery stenoses usually do not precipitate AMI because of the development of a rich collateral network over time. Instead, AMI occurs when a coronary artery thrombus develops rapidly at a site of vascular injury. This injury is produced or facilitated by factors such as cigarette smoking, hypertension, and lipid accumulation. In most cases, infarction occurs when an atherosclerotic plaque fissures, ruptures, or ulcerates and when conditions (local or systemic) favor thrombogenesis, so that a mural thrombus forms at the site of rupture and leads to coronary artery occlusion (Fig. 243-CD1). Histologic studies indicate that the coronary plaques prone to rupture are those with a rich lipid core and a thin fibrous cap (Chap. 241). After an initial platelet monolayer forms at the site of the ruptured plaque, various agonists (collagen, ADP, epinephrine, serotonin) promote platelet activation. After agonist stimulation of platelets, there is production and release of thromboxane A_2 (a potent local vasoconstrictor), further platelet activation, and potential resistance to thrombolysis.

In addition to the generation of thromboxane A_2, activation of platelets by agonists promotes a conformational change in the glycoprotein IIb/IIIa receptor (Chap. 116). Once converted to its functional state, this receptor develops a high affinity for amino acid sequences on soluble adhesive proteins (i.e., integrins) such as von Willebrand factor (vWF) and fibrinogen. Since vWF and fibrinogen are multivalent molecules, they can bind to two different platelets simultaneously, resulting in platelet cross-linking and aggregation.

The coagulation cascade is activated on exposure of tissue factor in damaged endothelial cells at the site of the ruptured plaque. Factors VII and X are activated, ultimately leading to the conversion of prothrombin to thrombin, which then converts fibrinogen to fibrin (Chap. 117). Fluid-phase and clot-bound thrombin participate in an autoamplification reaction that leads to further activation of the coagulation cascade. The culprit coronary artery eventually becomes occluded by a thrombus containing platelet aggregates and fibrin strands.

In rare cases,AMI may be due to coronary artery occlusion caused by coronary emboli, congenital abnormalities, coronary spasm, and a wide variety of systemic -- particularly inflammatory -- diseases. The amount of myocardial damage caused by coronary occlusion depends on (1) the territory supplied by the affected vessel, (2) whether or not

the vessel becomes totally occluded, (3) the duration of coronary occlusion, (4) the quantity of blood supplied by collateral vessels to the affected tissue, (5) the demand for oxygen of the myocardium whose blood supply has been suddenly limited, (6) native factors that can produce early spontaneous lysis of the occlusive thrombus, and (7) the adequacy of myocardial perfusion in the infarct zone when flow is restored in the occluded epicardial coronary artery.

Patients at increased risk of developingAMIinclude those with multiple coronary risk factors (Chap. 241) and those with unstable angina or Prinzmetal's variant angina (Chap. 244). Less common underlying medical conditions predisposing patients to AMI include hypercoagulability, collagen vascular disease, cocaine abuse, and intracardiac thrombi or masses that can produce coronary emboli.

CLINICAL PRESENTATION

In up to one-half of cases, a precipitating factor appears to be present beforeAMI, such as vigorous physical exercise, emotional stress, or a medical or surgical illness (Fig. 243-CD2). Although AMI may commence at any time of the day or night, circadian variations have been reported such that clusters are seen in the morning within a few hours of awakening. The increased frequency early in the day may be due to a combination of an increase in sympathetic tone and an increased tendency to thrombosis between 6:00 A.M. and 12 noon.

Pain is the most common presenting complaint in patients withAMI. In some instances, it may be severe enough to be described asthe worst pain the patient has ever felt. The pain is deep and visceral; adjectives commonly used to describe it are *heavy*, *squeezing*, and *crushing*, although occasionally it is described as stabbing or burning (Chap. 13). It is similar in character to the discomfort of angina pectoris but usually is more severe and lasts longer. Typically the pain involves the central portion of the chest and/or the epigastrium, and on occasion it radiates to the arms. Less common sites of radiation include the abdomen, back, lower jaw, and neck. The frequent location of the pain beneath the xiphoid and patients' denial that they may be suffering a heart attack are chiefly responsible for the common mistaken impression of indigestion. The pain of AMI may radiate as high as the occipital area but not below the umbilicus. It is often accompanied by weakness, sweating, nausea, vomiting, anxiety, and a sense of impending doom. The pain may commence when the patient is at rest. When the pain begins during a period of exertion, it does not usually subside with cessation of activity, in contrast to angina pectoris.

Although pain is the most common presenting complaint, it is by no means always present. The proportion of painlessAMIs is greater in patients with diabetes mellitus, and it increases with age. In the elderly, AMI may present as sudden-onset breathlessness, which may progress to pulmonary edema. Other less common presentations, with or without pain, include sudden loss of consciousness, a confusional state, a sensation of profound weakness, the appearance of an arrhythmia, evidence of peripheral embolism, or merely an unexplained drop in arterial pressure. The pain of AMI can simulate pain from acute pericarditis (Chap. 239), pulmonary embolism (Chap. 261), acute aortic dissection (Chap. 247), costochondritis, and gastrointestinal disorders. These conditions should therefore be considered in the differential diagnosis.

PHYSICAL FINDINGS

Most patients are anxious and restless, attempting unsuccessfully to relieve the pain by moving about in bed, altering their position, and stretching. Pallor associated with perspiration and coolness of the extremities occurs commonly. The combination of substernal chest pain persisting for >30 min and diaphoresis strongly suggestsAMI. Although many patients have a normal pulse rate and blood pressure within the first hour of AMI, about one-fourth of patients with anterior infarction have manifestations of sympathetic nervous system hyperactivity (tachycardia and/or hypertension), and up to one-half with inferior infarction show evidence of parasympathetic hyperactivity (bradycardia and/or hypotension).

The precordium is usually quiet, and the apical impulse may be difficult to palpate. In patients with anterior wall infarction, an abnormal systolic pulsation caused by dyskinetic bulging of infarcted myocardium may develop in the periapical area within the first days of the illness and then may resolve. Other physical signs of ventricular dysfunction that may be present include, in order of decreasing incidence, fourth (S_4) and third (S_3) heart sounds, decreased intensity of heart sounds, and, in more severe cases, paradoxical splitting of the second heart sound (Chap. 225). A transient apical systolic murmur due to dysfunction of the mitral valve apparatus may be midsystolic or late systolic in timing. A pericardial friction rub is heard in many patients with transmuralAMI at some time in the course of the disease, if they are examined frequently. The carotid pulse is often decreased in volume, reflecting reduced stroke volume. Jugular venous distention with clear lung fields should raise suspicion of right ventricular infarction. Temperature elevations up to 38°C may be observed during the first week after AMI; however, a temperature exceeding 38°C should prompt a search for other causes. The arterial pressure is variable; in most patients with transmural infarction, systolic pressure declines by approximately 10 to 15 mmHg from the preinfarction state.

LABORATORY FINDINGS

Myocardial infarction (MI) progresses through the following temporal stages: (1) acute (first few hours to 7 days), (2) healing (7 to 28 days),and (3) healed (29 days and beyond). When evaluating the results of diagnostic tests forAMI, the temporal phase of the infarction process must be considered. The laboratory tests of value in confirming the diagnosis may be divided into 4 groups: (1) electrocardiogram (ECG), (2) serum cardiac markers, (3) cardiac imaging, and (4) nonspecific indexes of tissue necrosis and inflammation.

ELECTROCARDIOGRAM

The electrocardiographic manifestations ofAMI are described in Chap. 226. During the initial stage of the acute phase of MI, total occlusion of the infarct artery produces ST-segment elevation. Most patients initially presenting with ST-segment elevation evolve Q waves on theECG and are ultimately diagnosed as having sustained a Q-wave MI. A small proportion may sustain only a non-Q-wave MI. When the obstructing thrombus is not totally occlusive, obstruction is transient, or if a rich collateral network is present, no ST-segment elevation is seen. Such patients are initially considered to be

experiencing either unstable anigna or a non-ST-segment elevation MI (NSTEMI). Among patients presenting without ST-segment elevation, if a serum cardiac marker is detected and no Q wave develops, the diagnosis of non-Q-wave MI is ultimately made. A minority of patients who present initially without ST-segment elevation may develop a Q-wave MI. Previously it was believed that transmural MI is present if the ECG demonstrates Q waves or loss of R waves, and nontransmural MI may be present if the ECG shows only transient ST-segment and T-wave changes. However, electrocardiographic-pathologic correlations are far from perfect; and therefore a more rational nomenclature for designating electrocardiographic infarction is now commonly in use, with the terms Q-wave and non-Q-wave MI replacing the terms transmural and nontransmural MI, respectively.

The presentations that comprise the spectrum ranging from unstable angina through non-Q-waveMI to Q-wave MI are called the *acute coronary syndromes* (Fig. 243-1). This classification scheme provides a conceptual framework for interpreting the diagnostic and prognostic information gleaned from serum cardiac marker measurements as well as for planning antithrombotic therapy.

SERUM CARDIAC MARKERS

Certain proteins, called *serum cardiac markers*, are released into the blood in large quantities from necrotic heart muscle afterAMI. The rate of liberation of specific proteins differs depending on their intracellular location and molecular weight, and the local blood and lymphatic flow. The temporal pattern of protein release is of diagnostic importance, but contemporary urgent reperfusion strategies necessitate making a decision (based largely on a combination of clinical andECGfindings) before the results of blood tests have returned from the central laboratory. Rapid whole-blood bedside assays for serum cardiac markers are now available and may facilitate management decisions, particularly in patients with nondiagnostic ECGs.

Creatine phosphokinase (CK) rises within 4 to 8 h and generally returns to normal by 48 to 72 h. An important drawback of total CK measurement is its lack of specificity forAMI, as CK may be elevated with skeletal muscle trauma. A two- to threefold elevation of total CK may follow an intramuscular injection, for example. This ambiguity may lead to the erroneous diagnosis of AMI in a patient who has been given an intramuscular injection of a narcotic for chest pain of noncardiac origin. Other potential sources of total CK elevation are (1) skeletal muscular diseases, including muscular dystrophy, myopathies, and polymyositis; (2) electrical cardioversion; (3) hypothyroidism; (4) stroke; (5) surgery; and (6) skeletal muscle damage secondary to trauma, convulsions, and prolonged immobilization.

The MB isoenzyme ofCK has the advantage over total CK that it is not present in significant concentrations in extracardiac tissue and therefore is considerably more specific. However, cardiac surgery, myocarditis, and electrical cardioversion often result in elevated serum levels of the MB isoenzyme. A ratio (relative index) of CKMB mass:CK activity $^{3}2.5$ suggests but is not diagnostic of a myocardial rather than a skeletal muscle source for the CKMB elevation. This ratio is less useful when levels of total CK are high owing to skeletal muscle injury or when the total CK level is within the normal range but CKMB is elevated.

Rather than attempting to make the diagnosis ofAMI on the basis of a single measurement ofCK and CKMB, clinicians should evaluate a series of measurements obtained over the first 24 h. Skeletal muscle release of CKMB typically produces a "plateau" pattern, whereas AMI produces a CKMB elevation that peaks approximately 20 h after the onset of coronary occlusion. When released into the circulation, the myocardial form of CKMB (CKMB2) is acted on by the enzyme carboxypeptidase, which cleaves a lysine residue from the carboxyl terminus to produce an isoform (CKMB1) with a different electrophoretic mobility. A CKMB2:CKMB1 ratio of>1.5 is highly sensitive for the diagnosis of AMI, particularly 4 to 6 h after the onset of coronary occlusion.

Cardiac-specific troponin T (cTnT) and *cardiac-specific troponin I (cTnI)* have amino acid sequences different from those of the skeletal muscle forms of these proteins. These differences have permitted the development of quantitative assays for cTnT and cTnI with highly specific monoclonal antibodies. Since cTnT and cTnI are not normally detectable in the blood of healthy individuals but may increase afterAMI to levels over 20 times higher than the cutoff value (usually set only slightly above the noise level of the assay), the measurement of cTnT or cTnI is of considerable diagnostic usefulness, and they are now the preferred biochemical markers for MI. The cardiac troponins are particularly valuable when there is clinical suspicion of either skeletal muscle injury or a small MI that may be below the detection limit forCK and CKMB measurements. Levels of cTnI may remain elevated for 7 to 10 days after AMI, and cTnT levels may remain elevated for up to 10 to 14 days. Thus, measurement of cTnT or cTnI has replaced measurement of lactate dehydrogenase (LDH) and its isoenzymes in patients with suspected MI who come to medical attention more than 24 to 48 h after the onset of symptoms.

Myoglobin is released into the blood within only a few hours of the onset ofAMI. Although myoglobin is one of the first serum cardiac markers that rises above the normal range after AMI, it lacks cardiac specificity, and it is rapidly excreted in the urine, so that blood levels return to the normal range within 24 h of the onset of infarction.

Many hospitals are usingcTnT orcTnIrather thanCKMB as the routine serum cardiac marker for diagnosis ofAMI, although any of these analytes remains clinically acceptable. It is not cost-effective to measure both a cardiac-specific troponin and CKMB at all time points in every patient. However, in view of the prolonged elevation of cardiac-specific troponins (>1 week), episodes of recurrent ischemic discomfort and suspected recurrentMI are more readily diagnosed with a serum cardiac marker that remains elevated in the blood more briefly, such as CKMB or myoglobin.

While it has long been recognized that the total quantity of protein released correlates with the size of the infarct, the peak protein concentration correlates only weakly with infarct size. Recanalization of a coronary artery occlusion (either spontaneously or by mechanical or pharmacologic means) in the early hours ofAMIcauses earlier and higher peaking (at about 8 to 12 h after reperfusion) of serum cardiac markers.

Characteristic rises occur in serum cardiac markers in virtually all patients with clinically provenMI.CK and CKMB levels generally do not rise in unstable angina. However, approximately one-third of patients who are considered to have unstable angina on the

basis of a lack of CK or CKMB elevation have elevations of cTnT or cTnI, probably indicating the presence of microinfarction. The finding of an elevated cardiac-specific troponin level, even in the presence of normal CK and CKMB values, is indicative of an adverse prognosis, and such patients should be considered to have sustained MI and managed as described below.

For the purposes of confirming the diagnosis of MI, serum cardiac markers should be measured on admission, 6 to 9 h after admission, and 12 to 24 h after admission if the diagnosis remains uncertain.

The *nonspecific reaction* to myocardial injury is associated with polymorphonuclear leukocytosis, which appears within a few hours after the onset of pain, persists for 3 to 7 days, and often reaches levels of 12,000 to 15,000 leukocytes per microliter. The erythrocyte sedimentation rate rises more slowly than the white blood cell count, peaking during the first week and sometimes remaining elevated for 1 or 2 weeks.

CARDIAC IMAGING

Two-dimensional echocardiography (Chap. 227) is the most frequently employed imaging modality in patients with AMI. Abnormalities of wall motion are almost universally present (Fig. 243-CD3). Even when no ST-segment elevation is seen, echocardiographically detectable wall motion abnormalities may be observed. Although AMI cannot be distinguished from an old myocardial scar or from acute severe ischemia by echocardiography, the ease and safety of the procedure make its use appealing as a screening tool. In the emergency department setting, early detection of the presence or absence of wall motion abnormalities by echocardiography can aid in management decisions, such as whether the patient should receive reperfusion therapy [e.g., thrombolysis or a percutaneous coronary intervention (PCI)]. Echocardiographic estimation of left ventricular (LV) function is useful prognostically; detection of reduced function serves as an indication for therapy with an angiotensin-converting enzyme inhibitor (see "Angiotensin-Converting Enzyme Inhibitors," below). Echocardiography may also identify the presence of right ventricular (RV) infarction, ventricular aneurysm, pericardial effusion, and LV thrombus. In addition, Doppler echocardiography is useful in the detection and quantitation of a ventricular septal defect and mitral regurgitation, two serious complications of AMI (see below).

Several radionuclide imaging techniques are available for evaluating patients with suspected AMI. However, these imaging modalities are used less often than echocardiography because they are more cumbersome and they lack sensitivity and specificity in many clinical circumstances. Myocardial perfusion imaging with ^{201}Tl or ^{99m}Tc-sestamibi, which are distributed in proportion to myocardial blood flow and concentrated by viable myocardium (Chap. 244) reveal a defect ("cold spot") in most patients during the first few hours after development of a transmural infarct. However, although perfusion scanning is extremely sensitive, it cannot distinguish acute infarcts from chronic scars and thus is not specific for the diagnosis of *acute* MI. Radionuclide ventriculography, carried out with ^{99m}Tc-labeled red blood cells, frequently demonstrates wall motion disorders and reduction in the ventricular ejection fraction in patients with AMI. While of value in assessing the hemodynamic consequences of infarction and in aiding in the diagnosis of RV infarction when the RV ejection fraction is depressed, this

technique is also quite nonspecific, as many cardiac abnormalities other than MI alter the radionuclide ventriculogram.

MANAGEMENT (FIG. 243-CD4)

PREHOSPITAL CARE

The prognosis in AMI is largely related to the occurrence of two general classes of complications: (1) electrical complications (arrhythmias) and (2) mechanical problems ("pump failure"). Most out-of-hospital deaths from AMI are due to the sudden development of ventricular fibrillation. The vast majority of deaths due to ventricular fibrillation occur within the first 24 h of the onset of symptoms, and, of these, over half occur in the first hour. Therefore, the major elements of prehospital care of patients with suspected AMI include (1) recognition of symptoms by the patient and prompt seeking of medical attention; (2) rapid deployment of an emergency medical team capable of performing resuscitative maneuvers, including defibrillation; and (3) expeditious transportation of the patient to a hospital facility that is continuously staffed by physicians and nurses skilled in managing arrhythmias, providing advanced cardiac life support, and (4) expeditious implementation of reperfusion therapy. The biggest delay usually occurs not during transportation to the hospital but rather between the onset of pain and the patient's decision to call for help. This delay can best be reduced by education of the public by health care professionals concerning the significance of chest pain and the importance of seeking early medical attention. Increasingly, monitoring and treatment are carried out by trained personnel in the ambulance, further shortening the time between the onset of the infarction and appropriate treatment.

INITIAL MANAGEMENT IN THE EMERGENCY DEPARTMENT

In the emergency department, the goals for the management of patients with suspected AMI include control of cardiac pain, rapid identification of patients who are candidates for urgent reperfusion therapy, triage of lower-risk patients to the appropriate location in the hospital, and avoidance of inappropriate discharge of patients with AMI. Many aspects of the treatment of AMI are initiated in the emergency department and then continued during the in-hospital phase of management.

Aspirin is now considered an essential element in the management of patients with suspected AMI and is effective across the entire spectrum of acute coronary syndromes (Fig. 243-2 and 243-3). Rapid inhibition of cyclooxygenase in platelets followed by a reduction of thromboxane A_2 levels is achieved by buccal absorption of a chewed 160 to 325 mg tablet in the emergency department. This measure should be followed by daily oral administration of aspirin in a dose of 160 to 325 mg.

Since patients with AMI may develop hypoxemia secondary to ventilation-perfusion abnormalities from LV failure and intrinsic pulmonary disease, it has been a common practice to routinely administer *supplemental oxygen*. In patients whose arterial oxygen saturation is normal as estimated by pulse oximetry or measured by an arterial blood gas specimen, supplemental oxygen is of limited if any clinical benefit and therefore is not cost effective. However, when hypoxemia is present, oxygen should be administered by nasal prongs or face mask (2 to 4 L/min) for the first 6 to 12 h after

infarction; the patient should then be reassessed to determine if there is a continued need for such treatment.

CONTROL OF PAIN

Morphine is a very effective analgesic for the pain associated withAMI. However, it may reduce sympathetically mediated arteriolar and venous constriction, and the resulting venous pooling may reduce cardiac output and arterial pressure. This complication does not contraindicate the use of morphine. Hypotension associated with venous pooling usually responds promptly to elevation of the legs, but in some patients volume expansion with intravenous saline is required. The patient may experience diaphoresis and nausea, but these events usually pass and are replaced by a feeling of well-being associated with the relief of pain. Morphine also has a vagotonic effect and may cause bradycardia or advanced degrees of heart block, particularly in patients with posteroinferior infarction. These side effects usually respond to atropine (0.5 mg intravenously). Morphine is routinely administered by repetitive (every 5 min) intravenous injection of small doses (2 to 4 mg) rather than by the subcutaneous administration of a larger quantity, because absorption may be unpredictable by the latter route.

Before morphine is administered, sublingual *nitroglycerin* can be given safely to most patients withAMI. Up to three 0.4-mg doses should be administered at about 5-min intervals. In addition to diminishing or abolishing chest discomfort, nitroglycerin, once considered contraindicated in the setting of AMI, may be capable of both decreasing myocardial oxygen demand (by lowering preload) and increasing myocardial oxygen supply (by dilating infarct-related coronary vessels or collateral vessels). In patients whose initially favorable response to sublingual nitroglycerin is followed by the return of chest pain, particularly if accompanied by other evidence of ongoing ischemia such as further ST-segment or T-wave shifts, the use of intravenous nitroglycerin should be considered. Therapy with nitrates should be avoided in patients who present with low systolic arterial pressure (<100 mmHg) or in whom there is clinical suspicion of right ventricular infarction (inferior infarction on electrocardiogram, elevated jugular venous pressure, clear lungs, and hypotension). Nitrates should not be administered to patients who have taken the phosphodiasterase 5 inhibitor sildenafil for erectile dysfunction within the preceding 24 h since it may potentiate the hypotensive effects of nitrates. An idiosyncratic reaction to nitrates, consisting of sudden marked hypotension, sometimes occurs but can usually be reversed promptly by the rapid administration of intravenous atropine.

Intravenous *beta blockers* are also useful in the control of the pain ofAMI. These drugs control pain effectively in some patients, presumably by diminishing myocardial oxygen demand and hence ischemia. More important, there is evidence that intravenous beta blockers reduce in-hospital mortality, particularly in high-risk patients (see "b-Adrenoceptor Blockers," below). A commonly employed regimen is metoprolol, 5 mg every 2 to 5 min for a total of three doses, provided the patient has a heart rate>60 beats per minute (bpm), systolic pressure>100 mmHg, a PR interval<0.24 s, and rales that are no higher than 10 cm up from the diaphragm. Fifteen minutes after the last intravenous dose, an oral regimen is initiated of 50 mg every 6 h for 48 h followed by 100 mg every 12 h.

Unlike beta blockers, calcium antagonists are of little value in the acute setting, and there is evidence that short-acting dihydropyridines may be associated with an increased mortality risk.

MANAGEMENT STRATEGIES (Figs. 243-2 and243-3)

The primary tool for screening patients and making triage decisions is the initial 12-leadECG. When ST-segment elevation in at least two contiguous leads of at least 2 mm in V1-V3 and 1 mm in other leads is present, a patient should be considered a candidate for *reperfusion therapy* (Fig. 243-2;Fig. 243-CD5). If no contraindications are present (see "Contraindications and Complications," under "Thombolysis," below), thrombolytic therapy should ideally be initiated within 30 min. The process of selecting patients for thrombolysis versus primaryPCI(angioplasty, or stenting) (Chap. 245) is discussed below. In the absence of ST-segment elevation, thrombolysis is not helpful, and evidence exists suggesting that it may be harmful. Pharmacotherapy for patients presenting without ST-segment elevation (Fig. 243-3) typically includes measures to control cardiac pain (as discussed above), aspirin, antithrombin therapy (preferably with low-molecular-weight heparin), and infusion of nitroglycerin as needed to control recurrent ischemia. For high-risk patients an intravenous infusion of a glycoprotein IIb/IIIa inhibitor should be considered. Further management recommendations for patients without ST-segment elevation are outlined inFig. 243-3.

LIMITATION OF INFARCT SIZE

The quantity of myocardium that becomes necrotic as a consequence of a coronary artery occlusion is determined by factors other than just the site of occlusion. While the central zone of the infarct contains necrotic tissue that is irretrievably lost, the fate of the surrounding ischemic myocardium may be improved by timely restoration of coronary perfusion, reduction of myocardial oxygen demands, prevention of the accumulation of noxious metabolites, and blunting of the impact of mediators of reperfusion injury (e.g., calcium overload and oxygen-derived free radicals). Up to one-third of patients withAMI may achieve *spontaneous* reperfusion of the infarct-related coronary artery within 24 h and experience improved healing of infarcted tissue. Reperfusion either pharmacologically (by thrombolysis) or mechanically (by angioplasty and/or stenting) accelerates the process of opening the occluded infarct-related artery in those patients in whom spontaneous thrombolysis ultimately would have occurred and also greatly increases the number of patients in whom restoration of flow in the infarct-related artery is accomplished. Timely restoration of flow in the epicardial infarct-related artery combined with improved perfusion of the downstream zone of infarcted myocardium results in a limitation of infarct size. Protection of the ischemic myocardium by the maintenance of an optimal balance between myocardial oxygen supply and demand through pain control, treatment of congestive heart failure, and minimization of tachycardia and hypertension extends the "window" of time for the salvage of myocardium by reperfusion strategies.

Glucocorticoids and nonsteroidal anti-inflammatory agents, with the exception of aspirin, should be avoided in the setting ofAMI. They can impair infarct healing and increase the risk of myocardial rupture, and their use may result in a larger infarct scar. In addition,

they can increase coronary vascular resistance, thereby potentially reducing flow to ischemic myocardium.

THROMBOLYSIS

The thrombolytic agents tissue plasminogen activator (tPA), streptokinase, anisoylated plasminogen streptokinase activator complex (APSAC) and reteplase (rPA) have been approved by the Food and Drug Administration for intravenous use in the setting ofAMI. These drugs all act by promoting the conversion of plasminogen to plasmin, which subsequently lyses fibrin thrombi. Although considerable emphasis was first placed on a distinction between more fibrin-specific agents, such as tPA, and non-fibrin-specific agents, such as streptokinase, it is now recognized that these differences are only relative, as some degree of systemic fibrinolysis occurs with tPA. The principal goal of thrombolysis is prompt restoration of coronary arterial patency.

When assessed angiographically, flow in the culprit coronary artery is described by a simple qualitative scale called the TIMI grading system: grade 0 indicates complete occlusion of the infarct-related artery; grade 1 indicates some penetration of the contrast material beyond the point of obstruction but without perfusion of the distal coronary bed; grade 2 indicates perfusion of the entire infarct vessel into the distal bed but with flow that is delayed compared with that of a normal artery; and grade 3 indicates full perfusion of the infarct vessel with normal flow. Early reports frequently lumped TIMI grades 2 and 3 under the general category of *patency*, but it is now recognized that grade 3 flow is the goal of reperfusion therapy, because full perfusion of the infarct-related coronary artery yields far better results in terms of infarct size, maintenance ofLVfunction, and reduction of both short- and long-term mortality rates. Relatively new methods of angiographic assessment of the efficacy of thrombolysis include counting the number of frames required on the cine film for dye to flow from the origin of the infarct-related artery to a landmark in the distal vascular bed (TIMI frame count) and determining the rate of entry and exit of contrast dye from the microvasculature in the myocardial infarct zone (TIMI Myocardial Perfusion Grade).

Thrombolytic therapy can reduce the relative risk of in-hospital death by up to 50% when administered within the first hour of the onset of symptoms ofAMI, and much of this benefit is maintained for at least 10 years. Appropriately used thrombolytic therapy appears to reduce infarct size, limitLVdysfunction, and reduce the incidence of serious complications such as septal rupture, cardiogenic shock, and malignant ventricular arrhythmias. Since myocardium can be salvaged only before it has been irreversibly injured, the timing of reperfusion therapy, by thrombolysis or a catheter-based approach, is of extreme importance in achieving maximum benefit. While the upper time limit depends on specific factors in individual patients, it is clear that "every minute counts" and that patients treated within 1 to 3 h of the onset of symptoms generally benefit most. Although reduction of the mortality rate is more modest, the therapy remains of benefit for many patients seen 3 to 6 h after the onset of infarction, and some benefit appears to be possible up to 12 h, especially if chest discomfort is still present and ST segments remain elevated inECGleads that do not yet demonstrate new Q waves. In addition to the possibility of early treatment, clinical factors that favor proceeding with thrombolytic therapy include anterior wall injury, hemodynamically complicated infarction, and widespread ECG evidence of myocardial jeopardy. Although

patients (younger than 65 years) achieve a greater relative reduction in the mortality rate than elderly patients, the higher *absolute* mortality rate (15 to 25%) in elderly patients results in similar absolute reductions in the mortality rates for both age groups.

Intriguing data are accumulating to indicate that improved ventricular function and reduced mortality may also be achieved by *late coronary reperfusion*. The benefits of late reperfusion cannot be attributed to a reduction of infarct size but appear to result from improvement of tissue healing in the infarct zone with prevention of infarct expansion, enhancement of collateral flow, improvement of myocardial contractile performance, and reduction in the tendency to electrical instability. In addition, *hibernating myocardium* (i.e., poorly contractile myocardium in a zone that is supplied by a stenotic infarct-related coronary artery with slow antegrade perfusion,Chap. 244) may show improved contraction after angioplasty to increase coronary blood flow.

tPAis more effective than streptokinase at restoring full perfusion -- i.e., TIMI grade 3 coronary flow -- and has a small edge in improving survival as well. The current recommended regimen of tPA consists of a 15-mg bolus followed by 50 mg intravenously over the first 30 min, followed by 35 mg over the next 60 min. Streptokinase is administered as 1.5 million units (MU) intravenously over 1 h. Reteplase is administered in a double bolus regimen consisting of a 10-MU bolus given over 2 to 3 min followed by a second 10-MU bolus 30 min later.

Promising new pharmacologic regimens for reperfusion combine an intravenous glycoprotein IIb/IIIa inhibitor with a reduced dose of a thrombolytic agent. Such combination reperfusion regimens appear to facilitate the rate and extent of thrombolysis by inhibiting platelet aggregation, weakening the clot structure, and allowing penetration of the thrombolytic agent deeper into the clot.

Contraindications and Complications Clear contraindications to the use of thrombolytic agents include a history of cerebrovascular hemorrhage at any time, a nonhemorrhagic stroke or other cerebrovascular event within the past year, marked hypertension (a reliably determined systolic arterial pressure>180 mmHg and/or a diastolic pressure>110 mmHg) at any time during the acute presentation, suspicion of aortic dissection, and active internal bleeding (excluding menses). While advanced age is associated with an increase in hemorrhagic complications, the benefit of thrombolytic therapy in the elderly appears to justify its use if no other contraindications are present and the amount of myocardium in jeopardy appears to be substantial.

Relative contraindications to thrombolytic therapy, which require careful assessment of the risk:benefit ratio, include current use of anticoagulants (international normalized ratio³2), a recent (<2 weeks) invasive or surgical procedure or prolonged (>10 min) cardiopulmonary resuscitation, known bleeding diasthesis, pregnancy, a hemorrhagic ophthalmic condition (e.g., hemorrhagic diabetic retinopathy), active peptic ulcer disease, and a history of severe hypertension that is currently adequately controlled. Because of the risk of an allergic reaction, patients should not receive streptokinase if that agent had been received within the preceding 5 days to 2 years.

Allergic reactions to streptokinase occur in approximately 2% of patients who receive it. While a minor degree of hypotension occurs in 4 to 10% of patients given this agent,

marked hypotension occurs, although rarely, in association with severe allergic reactions.

Hemorrhage is the most frequent and potentially the most serious complication. Because bleeding episodes that require transfusion are more common when patients require invasive procedures, unnecessary venous or arterial interventions should be avoided in patients receiving thrombolytic agents. Hemorrhagic stroke is the most serious complication and occurs in approximately 0.5 to 0.9% of patients being treated with these agents. This rate increases with advancing age, with patients older than 70 years experiencing roughly twice the rate of intracranial hemorrhage as those younger than 65 years. Large-scale intervention trials have suggested that the rate of intracranial hemorrhage withtPA orrPA is slightly higher than that with streptokinase.

Routine angiography after thrombolysis with the intent of performing aPCI on underlying coronary artery stenoses in the culprit vessel is not recommended. Higher rates of abrupt closure of the infarct-related coronary artery with a need for urgent coronary artery bypass surgery as well as a trend toward an increase in mortality rate have been noted with this approach. Instead, after thrombolytic therapy, cardiac catheterization and coronary angiography should be carried out if there is evidence of either (1) failure of reperfusion (persistent chest pain and ST-segment elevation beyond 90 min) in which case a *rescue PCI* should be considered, or (2) coronary artery reocclusion (reelevation of ST segments and/or recurrent chest pain) or the development of recurrent ischemia (such as recurrent angina in the early hospital course or a positive exercise stress test before discharge), in which case an *elective PCI* should be considered. Coronary artery bypass surgery should be reserved for patients whose coronary anatomy is unsuited to angioplasty but in whom revascularization appears to be advisable because of extensive jeopardized myocardium or recurrent ischemia.

Primary Percutaneous Coronary Intervention (See alsoChap. 245) PCI, usually angioplasty and/or stenting without preceding thrombolysis, is also effective in restoring perfusion inAMI when carried out on an emergency basis in the first few hours ofMI. It has the advantage of being applicable to patients who have contraindications to thrombolytic therapy but otherwise are considered appropriate candidates for reperfusion. It appears to be more effective than thrombolysis in opening occluded coronary arteries and, *when performed by experienced operators in dedicated medical centers*, is associated with better short-term and long-term clinical outcomes. It remains to be determined whether the advantages of primary PCI reported from organized research efforts can be replicated in routine clinical practice. However, PCI is expensive in terms of personnel and facilities, and its applicability is seriously limited by its availability, around the clock, in only a minority of hospitals.

HOSPITAL PHASE MANAGEMENT

CORONARY CARE UNITS

These units are routinely equipped with a system that permits continuous monitoring of the cardiac rhythm of each patient and hemodynamic monitoring in selected patients. Defibrillators, respirators, noninvasive transthoracic pacemakers, and facilities for introducing pacing catheters and flow-directed balloon-tipped catheters are also usually

available. Equally important is the organization of a highly trained team of nurses who can recognize arrhythmias; adjust the dosage of antiarrhythmic, vasoactive, and anticoagulant drugs; and perform cardiac resuscitation, including electroshock, when necessary.

Patients should be admitted to a coronary care unit early in their illness when it is expected that they will derive benefit from the sophisticated and expensive care provided. The availability of electrocardiographic monitoring and trained personnel outside the coronary care unit has made it possible to admit lower-risk patients (e.g., those not hemodynamically compromised and without active arrhythmias) to "intermediate care units."

The duration of stay in the coronary care unit is dictated by the ongoing need for intensive care. IfAMI has been ruled out (ideally within 8 to 12 h) and symptoms are controlled with oral therapy, patients may be transferred out of the coronary care unit. Also, patients who have a confirmed AMI but who are considered to be at low risk (no prior infarction and no persistent chest discomfort, congestive heart failure, hypotension, or cardiac arrhythmias) may be safely transferred out of the coronary care unit in 24 to 36 h.

Activity Factors that increase the work of the heart during the initial hours of infarction may increase the size of the infarct. Therefore, patients withAMIshould be kept at bed rest for the first 12 h. However, in the absence of complications, patients should be encouraged, under supervision, to resume an upright posture by dangling their feet over the side of the bed and sitting in a chair within the first 24 h. This practice is both psychologically beneficial and usually results in a reduction in the pulmonary capillary wedge pressure. In the absence of hypotension and other complications, by the second or third day patients typically are ambulating in their room with increasing duration and frequency, and they may shower or stand at the sink to bathe. By day 3 or 4 after infarction, patients should be increasing their ambulation progressively to a goal of 600 ft at least three times a day.

Diet Because of the risk of emesis and aspiration soon afterMI, patients should receive either nothing or only clear liquids by mouth for the first 4 to 12 h. The typical coronary care unit diet should provide£30% of total calories as fat and have a cholesterol content of £300 mg/d. Complex carbohydrates should make up 50 to 55% of total calories. Portions should not be unusually large, and the menu should be enriched with foods that are high in potassium, magnesium, and fiber but low in sodium. Diabetes mellitus and hypertriglyceridemia are managed by restriction of concentrated sweets in the diet.

Bowels Bed rest and the effect of the narcotics used for the relief of pain often lead to constipation. A bedside commode rather than a bedpan, a diet rich in bulk, and the routine use of a stool softener such as dioctyl sodium sulfosuccinate (200 mg/d) are recommended. If the patient remains constipated despite these measures, a laxative can be prescribed. Contrary to prior belief, it is safe to perform a gentle rectal examination on patients withAMI.

Sedation Many patients require sedation during hospitalization to withstand the period of enforced inactivity with tranquillity. Diazepam (5 mg), oxazepam (15 to 30 mg), or

lorazepam (0.5 to 2 mg), given three or four times daily, is usually effective. An additional dose of any of the above medications may be given at night to ensure adequate sleep. Attention to this problem is especially important during the first few days in the coronary care unit, where the atmosphere of 24-h vigilance may interfere with the patient's sleep. However, sedation is no substitute for reassuring, quiet surroundings. Many drugs used in the coronary care unit, such as atropine, H_2blockers, and narcotics, can produce delirium, particularly in the elderly. This effect should not be confused with agitation, and it is wise to conduct a thorough review of the patient's medications before arbitrarily prescribing additional doses of anxiolytics.

PHARMACOTHERAPY

ANTITHROMBOTIC AGENTS

The use of antiplatelet and antithrombin therapy during the initial phase ofAMI is based on extensive laboratory and clinical evidence that thrombosis plays an important role in the pathogenesis of this condition. The primary goal of treatment with antiplatelet and antithrombin agents is to establish and maintain patency of the infarct-related artery. A secondary goal is to reduce the patient's tendency to thrombosis and thus the likelihood of mural thrombus formation or deep venous thrombosis, either of which could result in pulmonary embolization. The degree to which antiplatelet and antithrombin therapy achieves these goals partly determines how effectively it reduces the risk of mortality from AMI.

As noted previously (see "Initial Management in the Emergency Department," above), aspirin is the standard antiplatelet agent for patients withAMI. The most compelling evidence for the benefits of antiplatelet therapy (mainly with aspirin) in AMI is found in the comprehensive overview by the Antiplatelet Trialists' Collaboration. Data from nearly 20,000 patients with AMI enrolled in nine randomized trials were pooled and revealed a reduction in the mortality rate from 11.7% in control patients to 9.3% in patients receiving antiplatelet agents. This difference corresponds to the prevention of 24 deaths for every 1000 patients treated. Similarly, 2 strokes and 12 recurrent infarctions are prevented for every 1000 patients treated with antiplatelet therapy.

The glycoprotein IIb/IIIa receptor is the focus of intense investigation by basic and clinical scientists (Fig. 243-CD6) (Chap. 116). Because platelet-rich thrombi are more resistant to thrombolytic agents than platelet-poor thrombi and because platelet aggregates appear to play a role in reocclusion after initially successful thrombolysis, glycoprotein IIb/IIIa inhibition may facilitate thrombolysis and reduce the rate of reocclusion of reperfused vessels. Compounds have been developed that block the glycoprotein IIb/IIIa receptor. These drugs appear useful for preventing thrombotic complications in patients withAMIundergoingPCI and reduce the rate of the composite endpoint of death and recurrent AMI in the medical management of patients without ST-segment elevation at presentation.

The standard antithrombin agent used in clinical practice is unfractionated heparin (UFH). Despite numerous clinical trials, the precise role of heparin in patients treated with thrombolytic agents remains uncertain. The available data fail to show any convincing benefit of UFH with respect to either coronary arterial patency or mortality

rate when UFH is added to a regimen of aspirin and a non-fibrin-specific thrombolytic agent such as streptokinase. Although not conclusively proven, it appears that the immediate administration of intravenous UFH, in addition to a regimen of aspirin andtPA, helps to facilitate thrombolysis and to establish and maintain patency of the infarct-related artery. This effect is achieved at the cost of a small increased risk of bleeding. Most clinicians who use tPA also administer a bolus and infusion of UFH, which should be administered as a bolus of 60 U/kg followed by a maintenance infusion of 12 U/kg per hour. The activated partial thromboplastin time during maintenance therapy should be 1.5 to 2 times the control value.

An alternative toUFH for anticoagulation of patients withAMI that is being used with increased frequency are the low-molecular-weight heparin preparations (LMWHs), which are formed by enzymatic or chemical depolymerization to produce saccharide chains of varying length but with a mean molecular weight of about 5000 Da. The LMWHs have several advantages over UFH including an increased anti-factor Xa:IIa ratio, decreased sensitivity to platelet factor IV, a more stable reliable anticoagulant effect, and enhanced bioavailability, thereby permitting administration via the subcutaneous route. Because of the stable anticoagulant effect when LMWHs are used, routine monitoring of hematologic tests such as the activated partial thromboplastin time (aPTT) is not required. Although the LMWHs share many pharmacologic similarities, they also vary in a number of important features; and therefore these agents should be considered individually rather than as members of an interchangeable class of compounds. Of the LMWHs, nadroparin and dalteparin have been found to be similar to UFH in therapeutic effectiveness, while enoxaparin (1 mg/kg subcutaneously every 12 h) appears to be superior to UFH for reducing the mortality rate and cardiac ischemic events in patients with AMI who do not present with ST-segment elevation. Direct comparisons among the LMWHs have not been carried out.

Patients with an anterior location of the infarction, severeLVdysfunction, congestive heart failure, a history of embolism, two-dimensional echocardiographic evidence of mural thorombus, or atrial fibrillation are at increased risk of systemic or pulmonary thromboembolism. Such individuals should receive full therapeutic levels of antithrombin therapy (UFH orLMWHs) while hospitalized, followed by at least 3 months of warfarin therapy.

BETA-ADRENOCEPTOR BLOCKERS

The benefits of beta blockers in patients withAMI can be divided into those that occur immediately when the drug is given acutely and those that accrue over the long term when the drug is given for secondary prevention after an index infarction. Acute intravenous beta blockade improves the myocardial oxygen supply-demand relationship, decreases pain, reduces infarct size, and decreases the incidence of serious ventricular arrhythmias. An overview of the data from 27,000 patients enrolled in nine randomized trials in the prethrombolytic era indicates that intravenous followed by oral beta blockade is associated with a 15% relative reduction in mortality, nonfatal reinfarction, and nonfatal cardiac arrest. In patients who undergo thrombolysis soon after the onset of chest pain, no incremental reduction in mortality rate is seen with beta blockers, but recurrent ischemia and reinfarction are reduced.

Beta blocker therapy afterAMI thus is useful for most patients except those in whom it is specifically contraindicated (patients with heart failure or severely compromisedLVfunction, heart block, orthostatic hypotension, or a history of asthma) and perhaps those whose excellent long-term prognosis (defined as an expected mortality rate of <1% per year) markedly diminishes any potential benefit (patients younger than 55 years with normal ventricular function, no complex ventricular ectopy, and no angina).

Although the data supporting the use of beta blockers in patients withAMI who do not present with ST-segment elevation are limited, the available evidence suggests that even among such patients, the use of beta blockers decreases the rates of cardiovascular mortality and reinfarction, and increases the probability of long-term survival.

ANGIOTENSIN CONVERTING ENZYME INHIBITORS

Angiotensin-converting enzyme (ACE) inhibitors reduce the mortality rate afterAMI, and the mortality benefits are additive to those achieved with aspirin and beta blockers. The maximum benefit is seen in high-risk patients (those who are elderly or have an anterior infarction, a prior infarction, and/or globally depressedLVfunction), but evidence suggests that a short-term benefit occurs when ACE inhibitors are prescribed unselectively to all hemodynamically stable patients with AMI (i.e., those with a systolic pressure >100 mmHg). The mechanism involves a reduction in ventricular remodeling after infarction (see "Ventricular Dysfunction," below) with a subsequent reduction in the risk of congestive heart failure (CHF). The rate of recurrent infarction also may be lower in patients treated chronically with ACE inhibitors after infarction.

ACEinhibitors should be prescribed within 24 h to all patients withAMI and overtCHF as well as to hemodynamically stable patients with ST-segment elevation or left bundle branch block. There is little evidence to support the immediate use of ACE inhibitors in patients with AMI who present without ST-segment changes or only with ST-segment depression without CHF. Before hospital discharge,LVfunction should be assessed with an imaging study. ACE inhibitors should be continued indefinitely in patients who have clinically evident CHF, in patients whom an imaging study shows a reduction in global LV function or a large regional wall motion abnormality, or in those who are hypertensive.

OTHER AGENTS

Although the actual impact on the mortality rate is slight (three to four lives saved per 1000 patients treated), *nitrates* (intravenous or oral) may be useful in the relief of pain associated withAMI. Favorable effects on the ischemic process and ventricular remodeling (see below) have led many physicians to routinely use intravenous nitroglycerin (5 to 10 ug/min initial dose and up to 200 ug/min as long as hemodynamic stability is maintained) for the first 24 to 48 h after the onset of infarction.

Results of multiple trials of different calcium antagonists have failed to establish a role for these agents in the treatment of most patients withAMI, in contrast to the more consistent data that exist for other drugs (e.g., beta blockers, aspirin, thrombolytic

agents). The routine use of calcium antagonists cannot be recommended.

A metabolic supportive measure that has shown promise in several small-scale trials of patients withAMI is the administration of a solution of glucose-insulin-potassium (GIK). A GIK infusion lowers the concentration of plasma free fatty acids and improves ventricular performance. Strict control of blood glucose in diabetic patients with AMI has been shown to reduce the mortality rate. It remains to be determined whether infusions of GIK should be administered to all patients with AMI.

Intracellular *magnesium* levels are frequently reduced in patients withAMI, but this deficit is not adequately reflected in serum measurements, as magnesium is predominantly an intracellular ion and <1% of its total body stores is intravascular. Whether giving routine empirical supplemental infusions of magnesium to high-risk patients with AMI is beneficial remains an open question. At present, serum magnesium should be measured in all patients on admission, and any demonstrated deficits should be corrected to minimize the risk of arrhythmias. There does not appear to be any benefit in the routine use of magnesium when it is administered relatively late (after more than 6 h) or to patients with an uncomplicated AMI who have a low mortality risk. Its role in high-risk patients is under investigation.

COMPLICATIONS AND THEIR TREATMENT

VENTRICULAR DYSFUNCTION

AfterAMI, theLVundergoes a series of changes in shape, size, and thickness in both the infarcted and noninfarcted segments. This process is referred to as *ventricular remodeling* and generally precedes the development of clinically evidentCHF in the months to years after infarction (Fig. 243-CD7). Soon after AMI, the LV begins to dilate. Acutely, this results from expansion of the infarct (i.e., slippage of muscle bundles, disruption of normal myocardial cells, and tissue loss within the necrotic zone, resulting in disproportionate thinning and elongation of the infarct zone). Later, lengthening of the noninfarcted segments occurs as well. The overall chamber enlargement that occurs is related to the size and location of the infarct, with greater dilation following infarction of the apex of the LV and causing more marked hemodynamic impairment, more frequent heart failure, and a poorer prognosis. Progressive dilation and its clinical consequences may be ameliorated by therapy withACEinhibitors and other vasodilators (e.g., nitrates) (Fig. 243-CD8). Thus, in patients with an ejection fraction <40%, regardless of whether or not heart failure is present, ACE inhibitors should be prescribed.

HEMODYNAMIC ASSESSMENT

Pump failure is now the primary cause of in-hospital death fromAMI. The extent of ischemic necrosis correlates well with the degree of pump failure and with mortality, both early (within 10 days of infarction) and later. The most common clinical signs are pulmonary rales and S_3 and S_4gallop rhythms. Pulmonary congestion is also frequently seen on the chest roentgenogram. ElevatedLVfilling pressure and elevated pulmonary artery pressure are the characteristic hemodynamic findings, but these findings may result from a reduction of ventricular compliance (diastolic failure) and/or a reduction of stroke volume with secondary cardiac dilation (systolic failure) (Chap. 231).

A classification originally proposed by Killip divides patients into four groups: class I, no signs of pulmonary or venous congestion; class II, moderate heart failure as evidenced by rales at the lung bases, S_3gallop, tachypnea, or signs of failure of the right side of the heart, including venous and hepatic congestion; class III, severe heart failure, pulmonary edema; and class IV, shock with systolic pressure <90 mmHg and evidence of peripheral vasoconstriction, peripheral cyanosis, mental confusion, and oliguria. When this classification was established in 1967, the expected hospital mortality rate of patients in these classes was as follows: class I, 0 to 5%; class II, 10 to 20%; class III, 35 to 45%; and class IV, 85 to 95%. With advances in management, the mortality rate in each class has fallen, perhaps by as much as one-third to one-half.

Hemodynamic evidence of abnormalLVfunction appears when contraction is seriously impaired in 20 to 25% of the LV. Infarction of ³40% of the LV usually results in cardiogenic shock (see below). Positioning of a balloon flotation catheter in the pulmonary artery permits monitoring of LV filling pressure; this technique is useful in patients who exhibit hypotension and/or clinical evidence ofCHF(Fig. 243-CD9). Cardiac output can also be determined with a pulmonary artery catheter. With the addition of intraarterial pressure monitoring, systemic vascular resistance can be calculated as a guide to adjusting vasopressor and vasodilator therapy. Some patients withAMI have markedly elevated LV filling pressures (>22 mmHg) and normal cardiac indexes [>2.6 and>3.6 L/(min/m_2)], while others have relatively low LV filling pressures (<15 mmHg) and reduced cardiac indexes. The former patients usually benefit from diuresis, while the latter may respond to volume expansion by means of intravenous administration of colloid-containing solutions.

Hypovolemia Hypovolemia is an easily corrected condition that may contribute to the hypotension and vascular collapse associated withAMI in some patients. It may be secondary to previous diuretic use, to reduced fluid intake during the early stages of the illness, and/or to vomiting associated with pain or medications. Consequently, hypovolemia should be identified and corrected in patients with AMI and hypotension before more vigorous forms of therapy are begun. Central venous pressure reflectsRVrather thanLVfilling pressure and is an inadequate guide for adjustment of blood volume, since LV function is almost always affected much more adversely than RV function in patients with AMI. The optimal LV filling or pulmonary artery wedge pressure may vary considerably among patients. Each patient's ideal level (generally ~20 mmHg) is reached by cautious fluid administration during careful monitoring of oxygenation and cardiac output. Eventually, the cardiac output level plateaus, and further increases in LV filling pressure only increase congestive symptoms and decrease systemic oxygenation without raising arterial pressure.

TREATMENT

The management ofCHF in association withAMI is similar to that of acute heart failure secondary to other forms of heart disease (avoidance of hypoxemia, diuresis, afterload reduction, inotropic support) (Chap. 232), except that the benefits of digitalis administration to patients with AMI are unimpressive. By contrast, diuretic agents are extremely effective, as they diminish pulmonary congestion in the presence of systolic and/or diastolic heart failure. Left ventricular filling pressure falls and orthopnea and

dyspnea improve after the intravenous administration of furosemide or other loop diuretics. These drugs should be used with caution, however, as they can result in a massive diuresis with associated decreases in plasma volume, cardiac output, systemic blood pressure, and hence coronary perfusion. Nitrates in various forms may be used to decrease preload and congestive symptoms. Oral isosorbide dinitrate, topical nitroglycerin ointment, or intravenous nitroglycerin all have the advantage over a diuretic of lowering preload through venodilation without decreasing the total plasma volume. In addition, nitrates may improve ventricular compliance if ischemia is present, as ischemia causes an elevation ofLVfilling pressure. The patient with pulmonary edema is treated as described inChap. 232, but vasodilators must be used with caution to prevent serious hypotension. As noted earlier,ACEinhibitors are an ideal class of drugs for management of ventricular dysfunction after AMI, especially for the long term.

CARDIOGENIC SHOCK

In recent years, efforts to reduce infarct size and prompt treatment of ongoing ischemia and other complications ofMIappear to have reduced the incidence of cardiogenic shock from 20% to about 7%. Only 10% of patients with this condition present with it on admission, while 90% develop it during hospitalization. Typically, patients who develop cardiogenic shock have severe multivessel coronary artery disease with evidence of "piecemeal" necrosis extending outward from the original infarct zone (Fig. 243-4).

Cardiogenic shock should be considered to be a form of severeLVfailure. This syndrome is characterized by marked hypotension with systolic arterial pressure of <80 mmHg and a markedly reduced cardiac index [<1.8 L/(min/m_2)] in the face of an elevated LV filling (pulmonary capillary wedge) pressure (>18 mmHg). Hypotension alone is not a basis for the diagnosis of cardiogenic shock, because many patients who make an uneventful recovery have serious hypotension (systolic pressure of<80 mmHg) for several hours. Such patients often have low LV filling pressures, and their hypotension usually resolves with the administration of intravenous fluids. In contrast to hypovolemic hypotension, cardiogenic shock is generally associated with a mortality rate of>70%; however, recent efforts to restore perfusion by coronary angioplasty or surgical revascularization suggest that this high mortality rate can be lowered by as much as one-half.

Risk factors for the in-hospital development of shock include advanced age, a depressedLVejection fraction on admission, a large infarct, previousMI, and a history of diabetes mellitus. Patients with several of these risk factors should be considered for cardiac catheterization and mechanical reperfusion (byPCI or surgery) before the development of shock.

Pathophysiology of Severe Power Failure A marked reduction in the quantity of contracting myocardium is the cause of cardiogenic shock inAMI. The initial insult reduces arterial pressure, and the reduction in coronary perfusion pressure and myocardial blood flow initiates a vicious cycle that impairs myocardial function further and may increase the size of the infarct (Fig. 243-4). Arrhythmias and metabolic acidosis also contribute to this deterioration, because they are the result of inadequate perfusion. This positive feedback loop accounts for the high mortality rate associated with the shock syndrome.

TREATMENT

The physiology and ominous prognosis of cardiogenic shock dictate that all patients with this condition should, if possible, have continuous monitoring of arterial pressure and ofLVfilling pressure (as reflected in the pulmonary capillary wedge pressure measured with a pulmonary artery balloon catheter) as well as frequent determinations of cardiac output. When pulmonary edema coexists, endotracheal intubation may be necessary to ensure oxygenation. The relief of pain is important, as some vasodepressor reflex activity may be a response to severe pain. However, narcotics should be used cautiously, in view of their propensity to lower arterial pressure. The primary objective of treatment is to maintain coronary perfusion by raising the arterial blood pressure with vasopressors (see below), intraaortic balloon counterpulsation, and manipulation of blood volume to a level that ensures an optimum LV filling pressure (~20 mmHg). The latter may require either infusion of crystalloid or diuresis.

Vasopressors Various intravenous drugs may be used to augment arterial pressure and cardiac output in patients with cardiogenic shock. All have important disadvantages or problems, and none has been shown to change the outcome in patients with established shock. *Isoproterenol* is a sympathomimetic amine that is now rarely used in the treatment of shock due toMI. Although this agent increases contractility, it also produces peripheral vasodilation and increases the heart rate. The resulting increase in myocardial oxygen consumption and reduction of coronary perfusion pressure may extend the area of ischemic injury. *Norepinephrine* (Chap. 72) is a potenta-adrenergic agonist with powerful vasoconstrictor properties that also possesses b-adrenergic activity and therefore enhances contractility. Because the increase in afterload and contractility associated with its use causes a marked increase in myocardial oxygen consumption, norepinephrine should be reserved for patients in desperate situations or for those with cardiogenic shock and reduced systemic vascular resistance. It should be started at a dosage of 2 to 4 ug/min. If pressure cannot be maintained with a dosage of 15 ug/min, it is unlikely that a further increase will be beneficial.

Dopamine (Chap. 72) is useful in many patients with severe power failure. At low doses (2 to 10 ug/kg per min), the drug has positive chronotropic and inotropic effects as a consequence ofb receptor stimulation. At higher doses, a vasoconstrictor effect results from a receptor stimulation. At lower doses (£2 ug/kg per min), dopamine also has the unique effect of dilating the renal and splanchnic vascular beds, and it apparently has little effect on myocardial oxygen consumption. Intravenous dopamine is started at an infusion rate of 2 to 5 ug/kg per min, and the dosage is increased every 2 to 5 min up to a maximum of 20 to 50 ug/kg per min. Systolic arterial blood pressure should be maintained at ~90 mmHg. *Dobutamine* is a synthetic sympathomimetic amine with positive inotropic action and minimal positive chronotropic or peripheral vasoconstrictive activity in the usual dosage range of 2.5 to 10 ug/kg per min. It should not be used when a vasoconstrictor effect is required. However, in patients with less profound degrees of hypotension, dobutamine may be an extremely useful agent, particularly if positive chronotropy is to be avoided.

Amrinone and *milrinone* are positive inotropic agents without catecholamine structure or activity that inhibit phosphodiesterase. These drugs resemble dobutamine in

pharmacologic activity, although they have a more potent vasodilating action. For amrinone, an initial loading dose of 0.75 mg/kg is given over 2 to 3 min. If effective, it is followed by an infusion of 5 to 10 ug/kg per min. If necessary, the dose may then be increased up to 15 ug/kg per min for short periods. Milrinone is given as a loading dose of 50 ug/kg over 10 min followed by a maintenance infusion of 0.375 to 0.75 ug/kg per min.

Aortic Counterpulsation In cardiogenic shock, mechanical assistance with an intraaortic balloon pumping (IABP) system capable of augmenting both diastolic pressure and cardiac output may be helpful. A sausage-shaped balloon at the end of a catheter is introduced percutaneously into the aorta via the femoral artery, and the balloon is automatically inflated during early diastole, thereby augmenting coronary blood flow. The balloon collapses in early systole, thereby reducing the afterload against whichLVejection takes place. Improvement in hemodynamic status has been achieved with balloon pumping in a large number of patients. In the absence of early revascularization, however, long-term survival after this mode of therapy in patients with cardiogenic shock is still disappointing. Intraaortic balloon pumping may best be reserved for patients whose condition merits mechanical (surgical or angioplastic) intervention (e.g., patients with continuing ischemia, ventricular septal rupture, or mitral regurgitation) and in whom a successful result is likely to reverse the cardiogenic shock. This technique is contraindicated if aortic regurgitation is present or aortic dissection is suspected.

Therapy for the shock syndrome secondary toMI, while improving gradually as a result of meticulous attention to the details outlined above, continues to be disappointing overall because a large fraction of patients with the syndrome have large areas of infarcted myocardium with severe, diffuse coronary atherosclerosis. The SHOCK trial was a randomized study comparing emergency revascularization (PCI or coronary artery bypass grafting) with initial medical stabilization and delayed revascularization as clinically indicated for patients with cardiogenic shock. Although the 30-day mortality rates in the two groups did not differ significantly, the 6-month and 1-year mortality rates in the emergency revascularization group were significantly lower than the corresponding rates in the stabilization and delayed revascularization group. Patients younger than 75 years showed particular benefit from emergency revascularization. However, few patients developing cardiogenic shock have prompt access to these expensive techniques. It is hoped that the widespread and early application of thrombolytic therapy will reduce the amount of myocardium that becomes necrotic and thereby reduce the incidence of this syndrome.

RIGHT VENTRICULAR INFARCTION

Approximately one-third of patients with inferoposterior infarction demonstrate at least a minor degree ofRVnecrosis. An occasional patient with inferoposteriorLVinfarction also has extensive RV infarction, and rare patients present with infarction limited primarily to the RV. Clinically significant RV infarction causes signs of severe RV failure [jugular venous distention, Kussmaul's sign (Chap. 225), hepatomegaly] with or without hypotension. ST-segment elevations of right-sided precordialECGleads, particularly lead V_4R, are frequently present in the first 24 h in patients with RV infarction. Two-dimensional echocardiography is helpful in determining the degree of RV

dysfunction. Catheterization of the right side of the heart often reveals a distinctive hemodynamic pattern resembling cardiac tamponade or constrictive pericarditis (steep right atrial "y" descent and an early diastolic dip and plateau in right ventricular waveforms) (Chap. 239). Therapy consists of volume expansion to maintain adequate RV preload and efforts to improve LV performance with attendant reduction in pulmonary capillary wedge and pulmonary arterial pressures.

MECHANICAL CAUSES OF HEART FAILURE

Free Wall Rupture Myocardial rupture is a dramatic complication ofAMI that is most likely to occur during the first week after the onset of symptoms; its frequency increases with the age of the patient. First infarction, a history of hypertension, no history of angina pectoris, and a relatively large Q-wave infarct are associated with a higher incidence of cardiac rupture. The clinical presentation typically is a sudden loss of pulse, blood pressure and consciousness while theECGcontinues to show sinus rhythm (apparent electromechanical dissociation or pulseless electrical activity). The myocardium continues to contract, but forward flow is not maintained as blood escapes into the pericardium. Cardiac tamponade (Chap. 239) ensues, and closed-chest massage is ineffective. This condition is almost universally fatal, although dramatic cases of urgent pericardiotensis followed by successful surgical repair have been reported.

Ventricular Septal Defect The pathogenesis of perforation of the ventricular septum is similar to that of free wall rupture, but the chance of successful therapy is greater. Patients with ventricular septal rupture present with sudden, severeLVfailure in association with the appearance of a pansystolic murmur, often accompanied by a parasternal thrill. It is often impossible to differentiate this condition from rupture of a papillary muscle with resulting mitral regurgitation (MR), and the presence in both conditions of a tall "v" wave in the pulmonary capillary wedge pressure further complicates the differentiation. The diagnosis of ventricular septal defect can be established by the demonstration of a left-to-right shunt (i.e., an oxygen step-up at the level of the RV) by means of limited cardiac catheterization performed at the bedside with a flow-directed balloon catheter. Color flow Doppler echocardiography can also be extremely useful for making this diagnosis at the bedside (Fig. 243-CD10). A prolonged period of hemodynamic compromise may produce end-organ damage and other complications that can be avoided by early intervention, including nitroprusside infusion and intraaortic balloon counterpulsation.

The pathophysiology of acuteMR is similar to that of acute ventricular septal perforation in that the level of aortic systolic pressure partly determines the regurgitant volume, the principal difference being the chamber into which the regurgitant fraction is ejected. In septal perforation, a fraction ofLVoutput is ejected into the right ventricle. As in MR, lowering of the aortic systolic pressure by mechanical (intraaortic balloon counterpulsation) and/or pharmacologic (nitroglycerin or nitroprusside) means can decrease the hemodynamic compromise caused by perforation.

Mitral Regurgitation (See alsoChap. 236) The reported incidence of apical systolic murmurs ofMRduring the first few days after the onset ofAMIvaries widely (from 10 to 50% of patients) depending on the population studied and the acumen of the observers. While MR causes acute hemodynamic compromise in only a minority of these patients,

it is a risk factor for late CHF and reduced survival.

The most common cause of MR after AMI is dysfunction of the mitral valve due to ischemia or infarction. Left ventricular dilatation or alteration in the size or shape of the LV due to impaired contractility or to aneurysm formation causes disordered contraction of the papillary muscles and failure of coaptation of the mitral valve leaflets. Rarely, a papillary muscle, or, more commonly, the head of a papillary muscle, may rupture. Then, LV function deteriorates dramatically, with superimposition of severe MR. The major element in the differential diagnosis is perforation of the ventricular septum as discussed above. Surgical repair or replacement of the mitral valve may lead to dramatic improvement in patients in whom acute heart failure results primarily from severe MR due to papillary muscle rupture or dysfunction and in whom global ventricular function is relatively good.

If aortic systolic pressure is lowered in patients with MR, a greater fraction of the LV output will be ejected antegrade, thus lessening the regurgitant fraction. To this end, both intraaortic balloon counterpulsation (IABC), which lowers the aortic systolic pressure mechanically, and the infusion of nitroglycerin or sodium nitroprusside, which reduce systemic vascular resistance, have been used with success in the interim management of patients with severe MR in the presence of AMI. Ideally, definitive operative treatment should be postponed until pulmonary congestion has cleared and the infarct has had time to heal. However, if the patient's hemodynamic and/or clinical condition does not improve or stabilize, surgical treatment should be undertaken, even in the acute stage.

ARRHYTHMIAS (See also Chaps. 229 and 230)

The incidence of arrhythmias after AMI is higher in patients seen early after the onset of symptoms. The mechanisms responsible for infarction-related arrhythmias include autonomic nervous system imbalance, electrolyte disturbances, ischemia, and slowed conduction in zones of ischemic myocardium. An arrhythmia can usually be managed successfully if trained personnel and appropriate equipment are available when it develops. Since most deaths from arrhythmia occur during the first few hours after infarction, the effectiveness of treatment relates directly to the speed with which patients come under medical observation. The prompt management of arrhythmias constitutes a significant advance in the treatment of myocardial infarction.

Ventricular Premature Beats Infrequent, sporadic ventricular premature depolarizations occur in almost all patients with AMI and do not require therapy. Whereas in the past, frequent, multifocal, or early diastolic ventricular extrasystoles (so-called warning arrhythmias) were routinely treated with antiarrhythmic drugs to reduce the risk of development of ventricular tachycardia and ventricular fibrillation, pharmacologic therapy is now reserved for patients with sustained ventricular arrhythmias. Prophylactic antiarrhythmic therapy (either intravenous lidocaine early or oral agents later) is contraindicated for ventricular premature beats in the absence of clinically important ventricular tachyarrhythmias, as such therapy may actually increase the mortality rate. b-Adrenoceptor blocking agents are effective in abolishing ventricular ectopic activity in patients with AMI and in the prevention of ventricular fibrillation. As described above (see "b-Adrenoceptor Blockers"), they should be used routinely in

patients without contraindications. In addition, hypokalemia and hypomagnesemia are risk factors for ventricular fibrillation in patients with AMI; the serum potassium concentration should be adjusted to approximately 4.5 mmol/L and magnesium to about 2.0 mmol/L.

Ventricular Tachycardia and Fibrillation Within the first 24 h of AMI, ventricular tachycardia and fibrillation can occur without prior warning arrhythmias. The occurrence of ventricular fibrillation can be reduced by prophylactic administration of intravenous lidocaine. However, prophylactic use of lidocaine has not been shown to reduce overall mortality from AMI. In fact, in addition to causing possible noncardiac complications, lidocaine may predispose to an excess risk of bradycardia and asystole. For these reasons, and with earlier treatment of active ischemia, more frequent use of beta-blocking agents, and the nearly universal success of electrical cardioversion or defibrillation, routine prophylactic antiarrhythmic drug therapy is no longer recommended. It should be reserved for patients who cannot reach a hospital or for those treated in hospitals that lack the constant presence in the coronary care unit of a physician or nurse trained in the recognition and treatment of ventricular fibrillation.

Sustained ventricular tachycardia that is well tolerated hemodynamically should be treated with an intravenous regimen of lidocaine (bolus of 1.0 to 1.5 mg/kg; infusion of 20 to 50 ug/kg per min), procainamide (bolus of 15 mg/kg over 20 to 30 min; infusion of 1 to 4 mg/min), or amiodarone (bolus of 75 to 150 mg over 10 to 15 min followed by infusion of 1.0 mg/min for 6 h and then 0.5 mg/min); if it does not stop promptly, electroversion should be used (Chap. 230). An unsynchronized discharge of 200 to 300 J (defibrillation) is used immediately in patients with ventricular fibrillation or when ventricular tachycardia causes hemodynamic deterioration. Ventricular tachycardia or fibrillation that is refractory to electroshock may be more responsive after the patient is treated with epinephrine (1 mg intravenously or 10 mL of a 1:10,000 solution via the intracardiac route), bretylium (a 5 mg/kg bolus), or amiodarone (a 75 to 150 mg bolus).

Ventricular arrhythmias, including the unusual form of ventricular tachycardia known as *torsade de pointes* (Chap. 230), may occur in patients with AMI as a consequence of other concurrent problems (such as hypoxia, hypokalemia, or other electrolyte disturbances) or of the toxic effects of an agent being administered to the patient (such as digoxin or quinidine). A search for such secondary causes should always be undertaken.

Although the in-hospital mortality rate is increased, the long-term survival is good in patients who survive to hospital discharge after *primary* ventricular fibrillation, i.e., ventricular fibrillation that is a primary response to acute ischemia and is not associated with predisposing factors such as CHF, shock, bundle branch block, or ventricular aneurysm. This result is in sharp contrast to the poor prognosis for patients who develop ventricular fibrillation *secondary* to severe pump failure. For patients who develop ventricular tachycardia or ventricular fibrillation late in their hospital course (i.e., after the first 48 h), the mortality rate is increased both in-hospital and during long-term follow-up. Such patients should be considered for electrophysiologic study (Chap. 230).

Accelerated Idioventricular Rhythm Accelerated idioventricular rhythm (AIVR, "slow ventricular tachycardia"), a ventricular rhythm with a rate of 60 to 100 beats per minute,

occurs in 25% of patients withAMI. It often occurs transiently during thrombolytic therapy at the time of reperfusion. The rate of AIVR is usually similar to that of the sinus rhythm that precedes and follows it, and this similarity of rate plus the relatively minor hemodynamic effects make this rhythm more difficult to detect except by electrocardiographic monitoring. For the most part, AIVR is benign and does not presage the development of classic ventricular tachycardia. Most episodes of AIVR do not require treatment if the patient is monitored carefully, as degeneration into a more serious arrhythmia is rare, and, if it occurs, AIVR can generally be readily treated with a drug that increases the sinus rate (atropine).

Supraventricular Arrhythmias Sinus tachycardia is the most common supraventricular arrhythmia. If it occurs secondary to another cause (such as anemia, fever, heart failure, or a metabolic derangement), the primary problem should be treated first. However, if it appears to be due to sympathetic overstimulation, for example, as part of a hyperdynamic state, then treatment with a beta blocker is indicated. Other common arrhythmias in this group are atrial flutter and atrial fibrillation, which are often secondary toLVfailure. Digoxin is usually the treatment of choice for supraventricular arrhythmias if heart failure is present. If heart failure is absent, beta blockers, verapamil, or diltiazem are suitable alternatives for controlling the ventricular rate, as they may also help to control ischemia. If the abnormal rhythm persists for >2 h with a ventricular rate in excess of 120 beats per minute, or if tachycardia induces heart failure, shock, or ischemia (as manifested by recurrent pain orECGchanges), a synchronized electroshock (100 to 200 J) should be used.

Accelerated junctional rhythms have diverse causes but may occur in patients with inferoposterior infarction. Digitalis excess must be ruled out. In some patients with severely compromisedLVfunction, the loss of appropriately timed atrial systole results in a marked decrease in cardiac output. Right atrial or coronary sinus pacing is indicated in such instances.

Sinus Bradycardia Treatment of sinus bradycardia is indicated if hemodynamic compromise results from the slow heart rate. Atropine is the most useful drug for increasing heart rate and should be given intravenously in doses of 0.5 mg initially. If the rate remains below 50 to 60 bpm, additional doses of 0.2 mg, up to a total of 2.0 mg, may be given. Persistent bradycardia (<40 bpm) despite atropine may be treated with electrical pacing. Isoproterenol should be avoided.

Atrioventricular and Intraventricular Conduction Disturbances (See alsoChap. 229) Both the in-hospital mortality rate and the post-discharge mortality rate of patients who have complete atrioventricular (AV) block in association with anterior infarction are markedly higher than those of patients who develop AV block with inferior infarction. This difference is related to the fact that heart block in inferior infarction is commonly a result of increased vagal tone and/or the release of adenosine and therefore is transient. In anterior wall infarction, heart block is usually related to ischemic malfunction of the conduction system, which commonly is associated with extensive myocardial necrosis.

Temporary electrical pacing provides an effective means of increasing the heart rate of patients with bradycardia due to AVblock. However, acceleration of the heart rate may have only a limited impact on prognosis in patients with anterior wall infarction and

complete heart block in whom the large size of the infarct is the major factor determining outcome. It should be carried out if it improves hemodynamics, however. Pacing does appear to be beneficial in patients with inferoposterior infarction who have complete heart block associated with heart failure, hypotension, marked bradycardia, or significant ventricular ectopic activity. A subgroup of these patients, those with RVinfarction, often respond poorly to ventricular pacing because of the loss of the atrial contribution to ventricular filling. In such patients, dual-chamber AV sequential pacing may be required.

External noninvasive pacing electrodes should be positioned in a "demand" mode for patients with sinus bradycardia (rate <50 bpm) that is unresponsive to drug therapy, Mobitz II second-degreeAVblock, third-degree heart block, or bilateral bundle branch block (e.g., right bundle branch block plus left anterior fascicular block). Retrospective studies suggest that permanent pacing may reduce the long-term risk of sudden death due to bradyarrhythmias in the rare patient who develops combined persistent bifascicular and transient third-degree heart block during the acute phase ofMI.

OTHER COMPLICATIONS

Recurrent Chest Discomfort Recurrent angina develops in ~25% of patients hospitalized forAMI. This percentage is even higher in patients who undergo successful thrombolysis. Since recurrent or persistent ischemia often heralds extension of the original infarct or reinfarction in a new myocardial zone and is associated with a doubling of risk after AMI, patients with these symptoms should be considered for repeat thrombolysis or referred for prompt coronary arteriography and mechanical revascularization. Repeat administration of a thrombolytic agent is an alternative to early mechanical revascularization.

Pericarditis (See alsoChap. 239) Pericardial friction rubs and/or pericardial pain are frequently encountered in patients with transmuralAMI. This complication can usually be managed with aspirin (650 mg qid). It is important to diagnose the chest pain of pericarditis accurately, since failure to recognize it may lead to the erroneous diagnosis of recurrent ischemic pain and/or infarct extension, with resulting inappropriate use of anticoagulants, nitrates, beta blockers, or coronary arteriography. When it occurs, complaints of pain radiating to either trapezius muscle is helpful since such a pattern of discomfort is typical of pericarditis but rarely occurs with ischemic discomfort. Anticoagulants potentially could cause tamponade in the presence of acute pericarditis (as manifested by either pain or persistent rub) and therefore should not be used unless there is a compelling indication.

Thromboembolism Clinically apparent thromboembolism complicatesAMI in ~10% of cases, but embolic lesions are found in 20% of patients in necropsy series, suggesting that thromboembolism is often clinically silent. Thromboembolism is considered to be at least an important contributing cause of death in 25% of patients with AMI who die after admission to the hospital. Arterial emboli originate fromLV mural thrombi, while most pulmonary emboli arise in the leg veins.

Thromboembolism typically occurs in association with large infarcts (especially anterior),CHF, and a LVthrombus detected by echocardiography. The incidence of

arterial embolism from a clot originating in the ventricle at the site of an infarction is small but real. Two-dimensional echocardiography reveals LV thrombi in about one-third of patients with anterior wall infarction but in few patients with inferior or posterior infarction. Arterial embolism often presents as a major complication, such as hemiparesis when the cerebral circulation is involved or hypertension if the renal circulation is compromised. When a thrombus has been clearly demonstrated by echocardiographic or other techniques or when a large area of regional wall motion abnormality is seen even in the absence of a detectable mural thrombus, systemic anticoagulation should be undertaken (in the absence of contraindications), as the incidence of embolic complications appears to be markedly lowered by such therapy. The appropriate duration of therapy is unknown, but 3 to 6 months is probably prudent.

Left Ventricular Aneurysm The term *ventricular aneurysm* is usually used to describe *dyskinesis* or local expansile paradoxical wall motion. Normally functioning myocardial fibers must shorten more if stroke volume and cardiac output are to be maintained in patients with ventricular aneurysm; if they cannot, overall ventricular function is impaired. True aneurysms are composed of scar tissue and neither predispose to nor are associated with cardiac rupture.

The complications ofLVaneurysm do not usually occur for weeks to months afterAMI; they includeCHF, arterial embolism, and ventricular arrhythmias. Apical aneurysms are the most common and the most easily detected by clinical examination. The physical finding of greatest value is a double, diffuse, or displaced apical impulse. Ventricular aneurysms are readily detected by two-dimensional echocardiography, which may also reveal a mural thrombus in an aneurysm.

Rarely, myocardial rupture may be contained by a local area of pericardium, along with organizing thrombus and hematoma. Over time, this *pseudoaneurysm* enlarges, maintaining communication with theLVcavity through a narrow neck. Because a pseudoaneurysm often ruptures spontaneously, it should be surgically repaired if recognized.

POSTINFARCTION RISK STRATIFICATION AND MANAGEMENT

Many clinical factors have been identified that are associated with an increase in cardiovascular risk after initial recovery fromAMI. Some of the most important factors include persistent ischemia (spontaneous or provoked), depressedLVejection fraction (<40%), rales above the lung bases on physical examination or congestion on chest radiograph, and symptomatic ventricular arrhythmias. Other features associated with increased risk include a history of previous myocardial infarction, age over 70 years, diabetes, prolonged sinus tachycardia, hypotension, ST-segment changes at rest without angina ("silent ischemia"), an abnormal signal-averagedECG, nonpatency of the infarct-related coronary artery (if angiography is undertaken), and persistent advanced heart block or a new intraventricular conduction abnormality on the ECG. Therapy must be individualized on the basis of the relative importance of the risk(s) present.

The goal of preventing reinfarction and death after recovery fromAMI has led to strategies to evaluate risk after infarction. Early after AMI, this evaluation generally involves the use of noninvasive testing. In stable patients, submaximal exercise stress

testing may be carried out before hospital discharge to detect residual ischemia and ventricular ectopy and to provide the patient with a guideline for exercise in the early recovery period. Alternatively, or in addition, a maximal (symptom-limited) exercise stress test may be carried out 4 to 6 weeks after infarction. Evaluation ofLVfunction at rest and during exercise is usually warranted as well. Recognition of a depressed LV ejection fraction by echocardiography or radionuclide ventriculography identifies patients who should receiveACEinhibitors (see "Angiotensin-Converting Enzyme Inhibitors," above). Patients in whom angina is induced at relatively low workloads, those who have a large reversible defect on perfusion imaging or a depressed ejection fraction, those with demonstrable ischemia, and those in whom exercise provokes symptomatic ventricular arrhythmias should be considered at high risk for recurrentMI or death from arrhythmia; and cardiac catheterization with coronary angiography and/or invasive electrophysiologic evaluation is advised.

Exercise tests also aid in formulating an individualized exercise prescription, which can be much more vigorous in patients who tolerate exercise without any of the above-mentioned adverse signs. Additionally, predischarge stress testing may provide an important psychological benefit, building the patient's confidence by demonstrating a reasonable exercise tolerance. Furthermore, particularly when no arrhythmias or signs of ischemia are identified, the patient benefits by the physician's reassurance that objective evidence suggests no immediate jeopardy.

In many hospitals a cardiac rehabilitation program with progressive exercise is initiated in the hospital and continued after discharge. Ideally, such programs should include an educational component that informs patients about their disease and its risk factors.

The usual duration of hospitalization for an uncomplicatedAMI is about 5 days. The remainder of the convalescent phase may be accomplished at home. During the first 2 weeks, the patient should be encouraged to increase activity by walking about the house and outdoors in good weather. Normal sexual activity may be resumed during this period. After 2 weeks, the physician must regulate the patient's activity on the basis of exercise tolerance. Most patients will be able to return to work within 2 to 4 weeks.

SECONDARY PREVENTION OF INFARCTION

Various secondary preventive measures are at least partly responsible for the improvement in the long-term mortality and morbidity rates afterAMI. Long-term treatment with an antiplatelet agent (usually aspirin) after AMI is associated with a 25% reduction in the risk of recurrent infarction, stroke, or cardiovascular mortality (36 fewer events for every 1000 patients treated). In addition, in patients taking aspirin chronically, AMIs tend to be smaller and are more likely to be non-Q-wave in nature. An alternative antiplatelet agent that may be used for secondary prevention in patients intolerant of aspirin is the ADP receptor antagonist clopidogrel (75 mg orally daily).ACEinhibitors should be used indefinitely by patients with clinically evident heart failure, a moderate decrease in global ejection fraction, or a large regional wall motion abnormality to prevent late ventricular remodeling and recurrent ischemic events.

The chronic routine use of oral b-adrenoceptor blockers for at least 2 years afterAMI is supported by well-conducted, placebo-controlled trials that have convincingly

demonstrated reductions in the rates of total mortality, sudden death, and, in some instances, reinfarction. In contrast, calcium antagonists are not recommended for routine secondary prevention.

Evidence suggests that warfarin lowers the risk of late mortality and the incidence of reinfarction afterAMI. Since studies comparing aspirin and warfarin therapy separately or in combination have not yet been completed, most physicians prescribe aspirin routinely for all patients without contraindications and add warfarin for patients at increased risk of embolism (see "Thromboembolism," above).

Finally, risk factors for *atherosclerosis* (Chap. 241) should be discussed with the patient, and, when possible, favorably modified. In particular, efforts should be made to ensure the cessation of smoking and the control of hypertension and hyperlipidemia (the target low-density lipoprotein level is<100 mg/dL). In addition, regular physical exercise and reduction of emotional stress should be encouraged. The benefits of hormone replacement therapy in postmenopausal women recovering fromMIremain controversial. The initiation of a combination of estrogen plus progestin is associated with an increased risk of cardiovascular events within the first year but may reduce events in later years (HERS Trial). Thus, hormone replacement therapy prevention of coronary events should not be given *de novo* to postmenopausal women afterAMI. Postmenopausal women already taking estrogen plus progestin at the time of AMI may continue that therapy.

244. ISCHEMIC HEART DISEASE - *Andrew P. Selwyn*, *Eugene Braunwald*

ETIOLOGY AND PATHOPHYSIOLOGY

Ischemia refers to a lack of oxygen due to inadequate perfusion, which results from an imbalance between oxygen supply and demand. The most common cause of myocardial ischemia is atherosclerotic disease of epicardial coronary arteries. Ischemic heart disease (IHD) is the most common, serious, chronic, life-threatening illness in the United States, where more than 11 million persons have IHD. This condition causes more deaths and disability and incurs greater economic costs than any other illness in the developed world.

By reducing the lumen of the coronary arteries, atherosclerosis reduces myocardial perfusion in the basal state or limits appropriate increases in perfusion when the demand for flow is augmented, as occurs during exertion or excitement. Coronary blood flow can also be limited by spasm (Fig. 244-CD1), arterial thrombi, and, rarely, coronary emboli as well as by ostial narrowing due to luetic aortitis. Congenital abnormalities, such as anomalous origin of the left anterior descending coronary artery from the pulmonary artery, may cause myocardial ischemia and infarction in infancy, but this cause is very rare in adults. Myocardial ischemia can also occur if myocardial oxygen demands are markedly increased, as in severe ventricular hypertrophy due to aortic stenosis. The latter can present with angina that is indistinguishable from that caused by coronary atherosclerosis. A reduction in the oxygen-carrying capacity of the blood, as in extremely severe anemia or in the presence of carboxyhemoglobin, is a rare cause of myocardial ischemia. Not infrequently, two or more causes of ischemia will coexist, such as an increase in oxygen demand due to left ventricular hypertrophy and a reduction in oxygen supply secondary to coronary atherosclerosis and anemia. Often such a combination leads to clinical manifestations of ischemia.

Although the large epicardial coronary arteries are capable of constriction and relaxation, in healthy persons they serve largely as conduits and are referred to as *conductance vessels*, while the intramyocardial arterioles normally exhibit striking changes in tone and are therefore referred to as *resistance vessels*. Abnormal constriction or failure of normal dilation of the coronary resistance vessels can also cause ischemia. When it causes angina this condition is referred to as *microvascular angina*.

The normal coronary circulation is dominated and controlled by the heart's requirements for oxygen. This need is met by the ability of the coronary vascular bed to vary its resistance (and therefore blood flow) considerably while the myocardium extracts a high and relatively fixed percentage of oxygen. Normally, intramyocardial resistance vessels demonstrate an immense capacity for dilation. For example, the changing oxygen needs with exercise and emotional stress affect coronary vascular resistance and in this manner regulate the supply of oxygen and substrate to the myocardium (*metabolic regulation*). The coronary resistance vessels also adapt to physiologic alterations in blood pressure in order to maintain coronary blood flow at levels appropriate to myocardial needs (*autoregulation*).

CORONARY ATHEROSCLEROSIS (See also Chap. 241)

Epicardial coronary arteries are a major site of atherosclerotic disease. The major risk factors for atherosclerosis [high plasma low-density lipoprotein (LDL), low plasma high-density lipoprotein (HDL), cigarette smoking, hypertension, and diabetes mellitus] are thought to disturb the normal functions of the vascular endothelium. These functions include local control of vascular tone, maintenance of an anticoagulant surface, and defense against inflammatory cells. The loss of these defenses leads to inappropriate constriction, luminal clot formation, and abnormal interactions with blood monocytes and platelets. The latter leads to subintimal collections of fat, cells, and debris (i.e., atherosclerotic plaques), which develop at irregular rates in different segments of the epicardial coronary tree and lead eventually to segmental reductions in cross-sectional area (stenosis). The relationship between pulsatile flow and luminal stenosis is complex, but experiments have shown that when a stenosis reduces the cross-sectional area by approximately 75%, a full range of increases in flow to meet increased myocardial demand is not possible. When the luminal area is reduced by more than approximately 80%, blood flow at rest may be reduced, and further minor decreases in the stenotic orifice can reduce coronary flow dramatically and cause myocardial ischemia.

Segmental atherosclerotic narrowing of epicardial coronary arteries is caused most commonly by the formation of a plaque, which is subject to fissuring, hemorrhage, and thrombosis. Any of these events can temporarily worsen the obstruction, reduce coronary blood flow, and cause clinical manifestations of myocardial ischemia, as described below. The location of the obstruction will influence the quantity of myocardium rendered ischemic and thus determine the severity of the clinical manifestations. Severe coronary narrowing and myocardial ischemia are frequently accompanied by the development of collateral vessels, especially when the narrowing develops gradually. When well developed, such vessels can, by themselves, provide sufficient blood flow to sustain the viability of the myocardium at rest but not during conditions of increased demand.

Once stenosis of a proximal epicardial artery has reduced the cross-sectional area by more than approximately 70%, the distal resistance vessels (when they function normally) dilate to reduce vascular resistance and maintain coronary blood flow. A pressure gradient develops across the proximal stenosis, and poststenotic pressure falls. When the resistance vessels are maximally dilated, myocardial blood flow becomes dependent on the pressure in the coronary artery distal to the obstruction. In these circumstances ischemia in the region perfused by the stenotic artery can be precipitated by increases in myocardial oxygen demands caused by physical activity, emotional stress, and/or tachycardia. Changes in the caliber of the stenosed coronary artery due to physiologic vasomotion, loss of endothelial control of dilation, pathologic spasm, or small platelet plugs can all upset the critical balance between oxygen supply and demand and thus precipitate myocardial ischemia.

EFFECTS OF ISCHEMIA

The inadequate perfusion induced by coronary atherosclerosis may cause transient disturbances of the mechanical, biochemical, and electrical functions of the myocardium. The abrupt development of severe ischemia, as occurs with total or subtotal occlusion, is associated with almost instantaneous failure of normal muscle

contraction and relaxation. The relatively poor perfusion of the subendocardium causes more intense ischemia of this portion of the wall. Ischemia of large portions of the ventricle will cause transient left ventricular failure, and if the papillary muscles are involved, mitral regurgitation can complicate this event. When ischemia is transient, it may be associated with angina pectoris; when it is prolonged, it can lead to myocardial necrosis and scarring with or without the clinical picture of acute myocardial infarction (Chap. 243). Coronary atherosclerosis is a focal process that usually causes nonuniform ischemia. Regional disturbances of ventricular contractility cause segmental akinesis or, in severe cases, bulging (dyskinesia), which can greatly reduce myocardial pump function.

Underlying these mechanical disturbances are a wide range of abnormalities in cell metabolism, function, and structure. When oxygenated, the normal myocardium metabolizes fatty acids and glucose to carbon dioxide and water. With severe oxygen deprivation, fatty acids cannot be oxidized, and glucose is broken down to lactate; intracellular pH is reduced, as are the myocardial stores of high-energy phosphates, ATP, and creatine phosphate. Impaired cell membrane function leads to potassium leakage and the uptake of sodium by myocytes. The severity and duration of the imbalance between myocardial oxygen supply and demand will determine whether the damage is reversible (0 to 20 min for total occlusion) or whether it is permanent, with subsequent myocardial necrosis (>20 min).

Ischemia also causes characteristic changes in the electrocardiogram (ECG) such as repolarization abnormalities, as evidenced by inversion of the T wave and, when more severe, by displacement of the ST segment (Chap. 226). Transient ST-segment depression often reflects subendocardial ischemia, while transient ST-segment elevation is thought to be caused by more severe transmural ischemia. Another important consequence of myocardial ischemia is electrical instability, which may lead to ventricular tachycardia or ventricular fibrillation (Chap. 230). Most patients who die suddenly fromIHD do so as a result of ischemia-induced malignant ventricular tachyarrhythmias (Chap. 39).

ASYMPTOMATIC VERSUS SYMPTOMATIC ISCHEMIC HEART DISEASE (IHD)

Postmortem studies on accident victims and military casualties in western countries have shown that coronary atherosclerosis often begins to develop prior to age 20 and is widespread even among adults who were asymptomatic during life. When all age groups are considered, IHD is the most common cause of death not only in men but also in women (Chap. 6). Exercise stress tests in asymptomatic persons may show evidence of silent myocardial ischemia, i.e., exercise-inducedECGchanges not accompanied by angina; coronary angiographic studies of such persons may reveal obstructive [coronary artery disease (CAD) (Chap. 228)]. Postmortem examination of patients with obstructive CAD without a history of any clinical manifestations of myocardial ischemia often shows macroscopic scars secondary to myocardial infarction in regions supplied by diseased coronary arteries. According to population studies, approximately 25% of patients who survive acute myocardial infarction may not reach medical attention, and these patients carry the same adverse prognosis as those who present with the classic clinical syndrome (Chap. 243). Sudden death may be unheralded and is a common presenting manifestation of IHD (Chap. 39). Patients can

also present with cardiomegaly and heart failure secondary to ischemic damage of the left ventricular myocardium that may have caused no symptoms prior to the development of heart failure; this condition is referred to as *ischemic cardiomyopathy*. In contrast to the asymptomatic phase of IHD, the symptomatic phase is characterized by chest discomfort due to either angina pectoris or acute myocardial infarction (Chap. 243). Having entered the symptomatic phase, the patient may exhibit a stable or progressive course, revert to the asymptomatic stage, or suddenly die.

STABLE ANGINA PECTORIS

This episodic clinical syndrome is due to transient myocardial ischemia. Various diseases that cause myocardial ischemia as well as the numerous forms of discomfort with which it may be confused are discussed in Chap. 13. Males constitute approximately 70% of all patients with angina pectoris and an even greater fraction of those younger than 50 years of age.

HISTORY

The typical patient with angina is a 50- to 60-year-old man or 65- to 75-year-old woman who seeks medical help for chest discomfort, usually described as heaviness, pressure, squeezing, smothering, or choking and only rarely as frank pain. When the patient is asked to localize the sensation, he or she will typically press on the sternum, sometimes with a clenched fist, to indicate a squeezing, central, substernal discomfort. This symptom is usually crescendo-decrescendo in nature and lasts 1 to 5 min. Angina can radiate to the left shoulder and to both arms and especially to the ulnar surfaces of the forearm and hand. It can also arise in or radiate to the back, neck, jaw, teeth, and epigastrium.

Although episodes of angina are typically caused by exertion (e.g., exercise, hurrying, or sexual activity) or emotion (e.g., stress, anger, fright, or frustration) and are relieved by rest, they may also occur at rest (see "Unstable Angina Pectoris," p. 1408) and at night while the patient is recumbent (angina decubitus). The patient may be awakened at night distressed by typical chest discomfort and dyspnea. Nocturnal angina may be due to episodic tachycardia or activities such as micturition. It can also be due to the expansion of the intrathoracic blood volume that occurs with recumbency, which causes an increase in cardiac size and myocardial oxygen demand that lead to ischemia and transient left ventricular failure.

The threshold for the development of angina pectoris varies from person to person and may vary by time of day and emotional state. Many patients report a fixed threshold for angina, which occurs predictably at a certain level of activity. In these patients coronary stenosis and myocardial oxygen supply are fixed and ischemia is precipitated by an increase in myocardial oxygen demand. In other patients the threshold for angina may vary considerably within any given day and from day to day. In such patients variations in oxygen supply, most likely due to changes in coronary vascular tone, may play an important role. A patient may report symptoms upon minor exertion in the morning (a short walk or shaving) yet by midday may be capable of much greater effort without symptoms. Angina may also be precipitated by unfamiliar tasks, a heavy meal, or exposure to cold.

Sharp, fleeting chest pain or prolonged, dull aches localized to the left submammary area are rarely due to myocardial ischemia. However, angina pectoris may be atypical in location and may not be strictly related to provoking factors. In addition, this symptom may exacerbate and remit over days, weeks, or months. Its occurrence can be seasonal, being more frequent in the winter in temperate climates. Anginal "equivalents" are symptoms of myocardial ischemia other than angina. These include dyspnea, fatigue, and faintness and are more common in the elderly.

Systematic questioning of the patient with suspectedIHD is important to uncover a positive family history of premature IHD (under the age of 45 years in first-degree male relatives and under 55 in female relatives), diabetes, hyperlipidemia, hypertension, cigarette smoking, and other risk factors for coronary atherosclerosis. The history of typical angina pectoris establishes the diagnosis of IHD until proven otherwise. In patients with atypical angina (Chap. 13), coexistence of advanced age, male sex, the postmenopausal state, and risk factors for atherosclerosis (Chap. 241) increase the likelihood of important coronary disease.

PHYSICAL EXAMINATION

The physical examination is often normal in the patient with stable angina. Rarely, the general examination reveals signs of risk factors associated with coronary atherosclerosis such as xanthelasma, xanthomas (Chap. 241), or diabetic skin lesions. There may also be signs of anemia, thyroid disease, and nicotine stains on the fingertips from cigarette smoking. Palpation can reveal thickened or absent peripheral arteries, signs of cardiac enlargement, and abnormal contraction of the cardiac impulse (left ventricular akinesia or dyskinesia). Examination of the fundi may reveal increased light reflexes and arteriovenous nicking as evidence of hypertension (Table 35-2), while auscultation can uncover arterial bruits, a third and/or fourth heart sound, and, if acute ischemia or previous infarction has impaired papillary muscle function, an apical systolic murmur due to mitral regurgitation. These auscultatory signs are best appreciated with the patient in the left decubitus position. Aortic stenosis, aortic regurgitation (Chap. 236), pulmonary hypertension (Chap. 260), and hypertrophic cardiomyopathy (Chap. 238) must be excluded, since these disorders may cause angina in the absence of coronary atherosclerosis. Examination during an anginal attack is useful, since ischemia can cause transient left ventricular failure with the appearance of a third and/or fourth heart sound, a dyskinetic cardiac apex, mitral regurgitation, and even pulmonary edema.

LABORATORY EXAMINATION

Although the diagnosis ofIHD can be made with confidence from the clinical examination, a number of simple laboratory tests can be helpful. The urine should be examined for evidence of diabetes mellitus and renal disease, since both of these conditions accelerate atherosclerosis. Similarly, examination of the blood should include measurements of lipids (cholesterol -- total, low density, high density -- and triglycerides), glucose, creatinine, hematocrit, and, if indicated based on the physical examination, thyroid function. A chest x-ray is important, since it may show the consequences of IHD, i.e., cardiac enlargement, ventricular aneurysm, or signs of heart failure. These signs can support the diagnosis of IHD and are important in assessing the

degree of cardiac damage and the effects of treatment for heart failure.

Electrocardiogram A 12-leadECGrecorded at rest is normal in about half the patients with typical angina pectoris, but there may be signs of an old myocardial infarction (Chap. 226). Although repolarization abnormalities, i.e., T-wave and ST-segment changes and intraventricular conduction disturbances at rest, are suggestive ofIHD, they are nonspecific, since they can also occur in pericardial, myocardial, and valvular heart disease or transiently with anxiety, changes in posture, drugs, or esophageal disease. Typical ST-segment and T-wave changes that accompany episodes of angina pectoris and disappear thereafter are more specific. The most characteristic changes include displacement of the ST segment that is similar in every way to that induced during a stress test (see below). The ST segment is usually depressed during angina but may be elevated -- sometimes strikingly so -- in Prinzmetal's angina.

Upsloping or junctional ST-segment changes are not considered characteristic of ischemia and do not constitute a positive test. Although T-wave abnormalities, conduction disturbances, and ventricular arrhythmias that develop during exercise should be noted, they are also not diagnostic. Negative exercise tests in which the target heart rate (85% of maximal heart rate for age and sex) is not achieved are considered to be nondiagnostic. When applying and interpreting ECG stress testing, one must first consider the probability thatCADexists in the patient or population under study (i.e., pretest probability). Overall, false-positive or -negative results can occur in one-third of cases. However, a positive result on exercise indicates that the likelihood of CAD is 98% in males over 50 years of age with a history of typical angina pectoris who develop chest discomfort during the test. The likelihood decreases progressively and significantly if the patient has atypical or no chest pain by history and/or during the test. The incidence of false-positive tests is significantly increased in asymptomatic men under the age of 40 or in premenopausal women with no risk factors for premature atherosclerosis. It is also increased in patients taking cardioactive drugs, such as digitalis and quinidine, or in those with intraventricular conduction disturbances, resting abnormalities of the ST segment and T wave, myocardial hypertrophy, or abnormal serum potassium levels. Obstructive disease limited to the circumflex coronary artery may result in a false-negative stress test since the posterior portion of the heart which this vessel supplies is not well represented on the surface 12-lead ECG. Since the overall sensitivity of exercise stress electrocardiography is only about 75%, a negative result does not exclude CAD,

although it makes the likelihood of three-vessel or left main CAD extremely unlikely.

The physician should be present throughout the exercise test, and it is important to measure total duration of exercise, the times to the onset of ischemic ST-segment change and chest discomfort, the external work performed (generally expressed as a stage of exercise), and the internal cardiac work performed; the last is represented by the heart rate-blood pressure product. The depth of the ST-segment depression and the time needed for recovery of theseECGchanges are also important. Because the risks of exercise testing are small but real -- estimated at one fatality and two nonfatal complications per 10,000 tests -- equipment for resuscitation should be available. Modified (heart rate-limited rather than symptom-limited) exercise tests can be performed safely in patients as early as 6 days after myocardial infarction. Contraindications to exercise stress testing include acute myocardial infarction (<4-5 days), rest angina <48 h, unstable rhythm, severe aortic stenosis, acute myocarditis, uncontrolled heart failure, and active infective endocarditis.

The normal response to graded exercise includes a progressive increase in heart rate and blood pressure. Failure of the blood pressure to increase or an actual decrease in blood pressure with signs of ischemia during the test is an important adverse prognostic sign, since it may reflect ischemia-induced global left ventricular dysfunction. The development of angina and/or severe (>0.2 mV) ST-segment depression at a low workload, i.e., before completion of stage II of the Bruce protocol, and ST-segment depression that persists for more than 5 min after the termination of exercise increases the specificity of the test and suggests severe ischemic heart disease and a high risk of future adverse events.

When the restingECG is abnormal (e.g., Wolff-Parkinson-White syndrome, >1 mm of resting ST-segment depression, left bundle branch block, paced ventricular rhythm), information gained from an exercise test can be enhanced by stress myocardial perfusion imaging after the intravenous administration of a radioisotope such as thallium 201 or technetium 99m sestamibi during exercise (or a pharmacologic stress) (Chap. 227); the imaging is carried out both immediately after cessation of exercise to detect reversible ischemia and 4 h later to confirm reversible ischemia and regions of infarction (Fig. 244-2;Fig. 244-CD3).

An important fraction of patients who need noninvasive stress testing to identify myocardial ischemia and increased risk of coronary events cannot exercise because of peripheral vascular or musculoskeletal disease, exertional dyspnea, or deconditioning. In these circumstances intravenous dipyridamole or adenosine can be used in place of exercise. The development of a transient perfusion defect with a tracer such as radioactive thallium or technetium 99m sestamibi is used to detect myocardial ischemia. Ambulatory monitoring of theECG can assess myocardial ischemia as episodes of ST-segment depression. These techniques are sensitive and capable of identifying patients with ischemia who are at increased risk of coronary events (Figs. 244-CD4 and244-CD5).

Two-dimensional echocardiography of the left ventricle can assess both global and regional wall motion abnormalities due to myocardial infarction or persistent ischemia (Chap. 227). Stress (exercise or dobutamine) echocardiography may cause the

emergence of regions of akinesis or dyskinesis not present at rest. Stress echocardiography, like stress myocardial perfusion imaging, is more sensitive than exercise electrocardiography in the diagnosis ofIHD. The relative advantages of stress echocardiography and stress radionuclide perfusion imaging in the diagnosis of IHD are shown inTable 244-1.

Echocardiography or radionuclide angiography should be carried out to assess left ventricular function in patients with chronic stable angina and in patients with a history of a prior myocardial infarction, pathologic Q waves, or clinical evidence of heart failure.

Coronary Arteriography (See also Chap. 228) This diagnostic method outlines the coronary anatomy and can be used to detect important evidence of coronary atherosclerosis or to exclude this condition. By this means, one can assess the severity of obstructive lesions and, when coronary arteriography is combined with left ventricular angiocardiography, can evaluate both global and regional function of the left ventricle.

Indications Coronary arteriography is indicated in (1) patients with chronic stable angina pectoris who are severely symptomatic despite medical therapy and who are being considered for revascularization, i.e., a percutaneous coronary intervention (PCI) or coronary artery bypass grafting (CABG); (2) patients with troublesome symptoms that present diagnostic difficulties in whom there is need to confirm or rule out the diagnosis ofIHD; (3) patients with known or possible angina pectoris who have survived sudden cardiac death; and (4) patients judged to be at high risk of sustaining coronary events based on signs of severe ischemia on noninvasive testing, regardless of the presence or severity of symptoms (see below).

Examples of other clinical situations include:

1. Patients with chest discomfort suggestive of angina pectoris but a negative or nondiagnostic stress test who require a definitive diagnosis for guiding medical management, alleviating psychological stress, career or family planning, or insurance purposes.

2. Patients who have been admitted repeatedly to the hospital for suspected acute myocardial infarction but in whom this diagnosis has not been established and in whom the presence or absence ofCADshould be determined.

3. Patients with careers that involve the safety of others (e.g., airline pilots) who have questionable symptoms, suspicious or positive noninvasive tests, and in whom there are reasonable doubts about the state of the coronary arteries.

4. Patients with aortic stenosis or hypertrophic cardiomyopathy and angina in whom the chest pain could be due toIHD.

5. Male patients aged 45 and females aged 55 years of age or older who are to undergo a cardiac operation, such as valve replacement or repair and who may or may not have clinical evidence of myocardial ischemia.

6. Patients who are at high risk after myocardial infarction because of the recurrence of

angina or the presence of heart failure, frequent ventricular premature contractions, or signs of ischemia in the stress test.

7. Patients with angina pectoris, regardless of severity, in whom noninvasive testing indicates a high risk of coronary events.

8. Patients in whom coronary spasm or another nonatherosclerotic cause of myocardial ischemia (e.g., coronary artery anomaly, Kawasaki's disease) is suspected.

PROGNOSIS

The principal prognostic indicators in patients withIHD are the functional state of the left ventricle, the location and severity of coronary artery narrowing, and the severity or activity of myocardial ischemia. Angina pectoris of recent onset, unstable angina, angina that is unresponsive or poorly responsive to medical therapy or is accompanied by symptoms of congestive heart failure all indicate an increased risk for adverse coronary events. The same is true for the physical signs of heart failure, episodes of pulmonary edema, transient third heart sounds, or mitral regurgitation or for echocardiographic (or roentgenographic) evidence of cardiac enlargement. An abnormal restingECG or positive evidence of myocardial ischemia during a stress test also indicates increased risk. Most importantly, the following signs during noninvasive testing indicate a high risk for coronary events: a strongly positive exercise test showing onset of myocardial ischemia at low workloads [³0.1 mV ST-segment depression before completion of stage II (Bruce protocol) of the exercise test;³0.2 mV ST depression in any stage; ST depression for >5 min following the cessation of exercise; a decline in systolic pressure >10 mmHg during exercise; the development of ventricular tachyarrhythmias during exercise]; the development of large or multiple perfusion defects or increased lung uptake during stress radioisotope perfusion imaging; and a decrease in left ventricular ejection fraction during exercise on radionuclide ventriculography or during stress echocardiography. Conversely, patients who can complete stage III of the Bruce exercise protocol and have a normal stress perfusion scan or negative stress echocardiographic evaluation are at very low risk of future coronary events.

On cardiac catheterization, elevations in left ventricular end-diastolic pressure and ventricular volume and a reduced ejection fraction are the most important signs of left ventricular dysfunction and are associated with a poor prognosis. Patients with chest discomfort but normal left ventricular function and normal coronary arteries have an excellent prognosis. In patients with normal left ventricular function and mild angina but with critical stenoses (³70% luminal diameter) of one, two, or three epicardial coronary arteries, the 5-year mortality rates are approximately 2, 8, and 11 percent, respectively. Obstructive lesions of the left anterior descending coronary artery proximal to the origin of the first septal artery are associated with a greater risk than are lesions of the right or left circumflex coronary artery, since the former vessel usually perfuses a greater quantity of myocardium. Stenosis (>50% luminal diameter) of the left main coronary artery is associated with a mortality rate of about 15% per year. The segmental atherosclerotic plaques in epicardial arteries go through phases of inflammatory cellular activity, degeneration, endothelial instability, abnormal vasomotion, platelet aggregation, and fissuring or hemorrhage. These factors can temporarily worsen the stenosis and cause abnormal reactivity of the vessel wall, thus exacerbating the manifestations of

ischemia. The recent onset of symptoms, the appearance of severe ischemia during stress testing, and unstable angina pectoris (p. 1508) all reflect episodes of rapid progression in coronary lesions.

With any degree of obstructiveCAD, mortality is greatly increased when left ventricular function is impaired; conversely, at any level of left ventricular function, the prognosis is influenced importantly by the quantity of myocardium perfused by the critically obstructed vessels. Therefore, it is useful to collect all the evidence substantiating past myocardial damage (ECG and ventriculographic evidence of myocardial infarction), residual left ventricular function (ejection fraction and wall motion), and risk of future damage from coronary events (extent of coronary disease and severity of ischemia defined by noninvasive stress testing). The larger the amount of established myocardial necrosis, the less the heart is able to withstand additional damage and the poorer the prognosis. All the above signs of past damage plus the risk of future damage should be considered indicators of risk.

TREATMENT

Each patient must be evaluated individually with respect to his or her expectations and goals, control of symptoms, and prevention of adverse clinical outcomes such as myocardial infarction and premature death. The degree of disability as well as the physical and emotional stress that precipitate angina must be carefully recorded in order to set treatment goals. Each management plan should consist of the following: (1) explanation and reassurance, (2) identification and treatment of aggravating conditions, (3) adaptation of activity, (4) treatment of risk factors that will decrease the occurrence of adverse coronary outcomes, (5) drug therapy for angina, and (6) consideration of mechanical revascularization.

Explanation and Reassurance Patients withIHD need to understand their condition as best they can and to realize that a long and useful life is possible even though they suffer from angina pectoris or have experienced and recovered from an acute myocardial infarction. Offering case histories of persons in public life who have lived with coronary disease as well as results of national studies showing improved outcomes can be of great value when encouraging patients to resume or maintain activity and return to their occupation. A planned program of rehabilitation can encourage patients to lose weight, improve exercise tolerance, and control risk factors with more confidence.

Identification and Treatment of Aggravating Conditions A number of conditions may either increase oxygen demand or decrease oxygen supply to the myocardium and may precipitate or exacerbate angina. Aortic valve disease and hypertrophic cardiomyopathy may cause angina and should be excluded or treated. Obesity, hypertension, and hyperthyroidism may be managed successfully in order to reduce the frequency of anginal attacks. Decreased myocardial oxygen supply may be due to reduced oxygenation of the blood (e.g., in pulmonary disease or, when carboxyhemoglobin is present, due to cigarette or cigar smoking) or decreased oxygen-carrying capacity (e.g., in anemia). Correction of these abnormalities, if present, may reduce or even eliminate angina pectoris.

Adaptation of Activity Therapy of angina due to episodes of myocardial ischemia

consists of eliminating the discrepancy between the demand of the heart muscle for oxygen and the ability of the coronary circulation to meet this demand. Most patients can be made to understand this fundamental concept and utilize it in the rational programming of activity. Many tasks that ordinarily evoke angina may be accomplished without symptoms simply by reducing the speed at which they are performed. Patients must appreciate the diurnal variation in their tolerance of certain activities and should reduce their energy requirements in the morning and immediately after meals. Sometimes it is helpful to alter the eating pattern, taking small and more frequent meals.

It may be necessary to recommend a change in employment or residence to avoid physical stress; however, with the exception of manual laborers, most patients withIHD can continue to function merely by allowing more time to complete each task. In some patients, anger and frustration may be the most important factors precipitating myocardial ischemia. If these cannot be avoided, training in stress management may be useful. A treadmill exercise test to determine the approximate heart rate at which ischemicECGchanges or symptoms develop may be helpful in the development of a specific exercise program.

Physical conditioning usually improves the exercise tolerance of patients with angina and exerts substantial psychological benefits. It may also improve the chances of surviving a myocardial infarction. An exercise program within the limits of each patient's threshold for the development of angina pectoris should be encouraged.

Treatment of Risk Factors Although the treatment of risk factors was developed for the primary prevention of coronary atherosclerosis, there is growing evidence that it can reduce the occurrence of angina, myocardial infarction, and death both in subjects without provenIHD as well as in those with a history of chronic angina or an acute coronary syndrome. A *family history* of premature IHD is an important indicator of increased risk and should trigger a search for treatable risk factors such as hyperlipidemia, hypertension, and diabetes. *Obesity* impairs the treatment of other risk factors and increases the risk of adverse coronary events. In addition, obesity is often accompanied by two other risk factors -- hypertension and hyperlipidemia. The treatment of obesity and these accompanying risk factors is an important component of any management plan.

Cigarette smoking accelerates coronary atherosclerosis in both sexes and at all ages and increases the risk of myocardial infarction and death. By increasing myocardial oxygen needs and reducing oxygen supply it aggravates angina. Smoking cessation studies have demonstrated important benefits with a significant decline in the occurrence of these adverse outcomes. The physician's message must be clear and strong and supported by programs that achieve and monitor abstinence (Chap. 390). *Hypertension* (Chaps. 35 and246) is associated with increased risk of adverse clinical events from coronary atherosclerosis as well as stroke. In addition, the left ventricular hypertrophy that results from sustained hypertension aggravates ischemia. There is evidence that long-term, effective treatment of hypertension can decrease the occurrence of adverse coronary events. *Diabetes mellitus* (Chap. 333) accelerates coronary and peripheral atherosclerosis and is frequently associated with dyslipidemias and increases in the risk of angina, myocardial infarction, and sudden coronary death. Strict control of the dyslipidemia that is frequently found in diabetic patients is essential,

as described below.

Treatment of Dyslipidemia The adverse interactions between the atherogenic lipids (LDL, triglycerides, and lipid remnants) play a critical role in the development of atherosclerosis and the ischemic syndromes. The treatment of dyslipidemia is central when aiming for long-term relief from angina, reduced need for revascularization, and reduction in myocardial infarction and death. Epidemiology, angiographic trials, and controlled trails have shown that (1) men over 45 years and women over 55 years with two risk factors (family history of prematureIHD, cigarette smoking, hypertension, diabetes mellitus) or evidence of atherosclerotic disease should have a total cholesterol£ 5.17 mmol/L (£200 mg/dL), LDL£ 2.58 mmol/L (£100 mg/dL), andHDL³ 1.03 mmol/L (³40 mg/dL); and (2) diabetic patients any age need to achieve the same goals as the likelihood of adverse coronary events is so high. The controlled trials have shown equal benefit for women, the elderly, and even smokers. The control of lipids can be achieved by the combination of a diet low in saturated fatty acids, exercise, and weight loss. Frequently, HMG CoA reductase inhibitors (statins) are required and can lower LDL cholesterol (25 to 60%), raise HDL cholesterol (5 to 9%), and lower triglycerides (5 to 45%). Niacinand fibrates can be used to raise HDL cholesterol and lower triglycerides (Chaps. 242 and341).

Risk reduction in women with IHD The incidence of clinical IHD in premenopausal women is very low. However, following the menopause, the atherogenic risk factors increase (e.g., increasedLDL, reducedHDL) and the rate of clinical coronary events accelerates to the levels observed in men. Women have not given up cigarette smoking as effectively as have men. Diabetes mellitus, which is more common in women, greatly increases the occurrence of clinical IHD and amplifies the deleterious effects of hypertension, hyperlipidemia, and smoking. Cardiac catheterization and coronary revascularization are often applied more sparingly in women and at a later, and more severe, stage of the disease than in men. These factors likely explain the modest increase in complications. Although many of the clinical trials to date have not represented women adequately, the evidence is that when cholesterol lowering, beta blockers after myocardial infarction, andCABG are applied in the appropriate patient groups, women enjoy the same benefits of improved outcome as do men.

Drug Therapy The commonly used drugs for angina pectoris are summarized inTable 244-2.

Nitrates This valuable class of drugs in the management of angina pectoris acts by causing systemic venodilation, thereby reducing myocardial wall tension and oxygen requirements, as well as by dilating the epicardial coronary vessels and increasing blood flow in collateral vessels. The absorption of these agents is most rapid and complete through the mucous membranes. For this reason, nitroglycerin is administered sublingually in tablets of 0.4 or 0.6 mg. Patients with angina should be instructed to take the medication both to relieve angina and also in anticipation of stress (exercise or emotional) that is likely to induce an episode. The value of this prophylactic use of the drug cannot be overemphasized.

Headache and a pulsating feeling in the head are the most common side effects of nitroglycerin and fortunately only rarely become disturbing at the doses usually required

to relieve or prevent angina. Nitroglycerin deteriorates with exposure to air, moisture, and sunlight, so that if the drug neither relieves discomfort or headache nor produces a slight sensation of burning at the sublingual site of absorption, the preparation may be inactive and a fresh supply should be obtained. If relief is not achieved after the first dose of nitroglycerin, a second or third dose may be given at 5-min intervals. If discomfort continues despite treatment, the patient should consult a physician or report promptly to a hospital emergency room for evaluation of possible unstable angina or acute myocardial infarction (Chap. 243).

A diary of angina and nitroglycerin use may be valuable for detecting changes in the frequency or severity of discomfort that may signify the development of unstable angina pectoris and/or herald an impending myocardial infarction.

None of the long-acting nitrates is as effective as sublingual nitroglycerin for the acute relief of angina. These preparations can be swallowed, chewed, or administered as a patch or paste by the transdermal route. They can provide effective plasma levels for up to 24 h, but the therapeutic response is highly variable. Different preparations and/or administration during the daytime should be tried only to prevent discomfort in the individual patient while avoiding side effects such as headache and dizziness. Individual dose titration is important in order to prevent side effects. Useful preparations include isosorbide dinitrate (10 to 60 mg PO bid or tid), nitroglycerin ointment (0.5 to 2.0 in. qid), or sustained-release transdermal patches (5 to 25 mg/d). The nitrates likely bind to guanylate cyclase in vascular smooth muscle cells, oxidize sulfhydryl groups, and are converted to *S*-nitrosothiols. This leads to an increase in cyclic guanosine monophosphate which causes relaxation of vascular smooth muscle. Tolerance with loss of efficacy develops with 12 to 24 h of continuous exposure to all of the long-acting nitrates due to depletion of sulfhydryl groups and to counterregulatory alterations in intravascular fluid balance with fluid retention. In order to minimize the effects of tolerance, the minimum effective dose should be used and a minimum of 8 h each day kept free of the drug so as to restore any useful response(s).

Beta Blockers (See also Chap. 72) These drugs represent an important component of the pharmacologic treatment of angina pectoris. They reduce myocardial oxygen demand by inhibiting the increases in heart rate and myocardial contractility caused by adrenergic activation. Beta blockade reduces these variables most strikingly during exercise while causing only small reductions in heart rate, cardiac output, and arterial pressure at rest. Long-acting beta-blocking drugs (atenolol, 50 to 100 mg/d, and nadolol, 40 to 80 mg/d) offer the advantage of once-a-day dosage (Tables 72-1 and244-2). The therapeutic aims include relief of angina and ischemia. These drugs can also reduce mortality and reinfarction when given to patients after myocardial infarction. Relative contraindications to the use of beta blockers include asthma and reversible airway obstruction in patients with chronic lung disease, atrioventricular conduction disturbances, severe bradycardia, Raynaud's phenomenon, and a history of depression. Side effects include fatigue, impotence, cold extremities, intermittent claudication, bradycardia (sometimes severe), impaired atrioventricular conduction, left ventricular failure, bronchial asthma, and intensification of the hypoglycemia produced by oral hypoglycemic agents and insulin. Reducing the dose or even discontinuation of the drug may be necessary if these side effects develop and persist.

Calcium Antagonists Slow-release nifedipine (30 to 90 mg once daily), verapamil (80 to 120 mg tid), diltiazem (30 to 90 mg qid), amlodipine (2.5 to 10 mg daily), and other calcium antagonists are coronary vasodilators that produce variable and dose-dependent reductions in myocardial oxygen demand, contractility, and arterial pressure. These combined pharmacologic effects are advantageous and make these agents effective in the treatment of angina pectoris. They are indicated when beta blockers are contraindicated, poorly tolerated, or ineffective. Verapamil and diltiazem may produce symptomatic disturbances in cardiac conduction and bradyarrhythmias, exert negative inotropic actions, and are more likely to worsen left ventricular failure, particularly when used in patients with left ventricular dysfunction. Although useful effects are usually achieved when calcium antagonists are combined with beta blockers and nitrates, careful individual titration of dose is essential with these potent combinations. Variant (Prinzmetal's) angina responds particularly well to calcium antagonists, supplemented when necessary by nitrates. Nifedipine as well as other calcium antagonists are now formulated as long-acting preparations including diltiazem (60 to 120 mg twice daily) and verapamil (180 to 240 mg once daily).

Verapamil should not ordinarily be combined with beta blockers because of the combined effects on heart rate and contractility. Diltiazem can be combined with beta blockers with caution and only in patients with normal ventricular function and no conduction disturbances. Nifedipine or amlodipine and the beta blockers have complementary actions on coronary blood supply and myocardial oxygen demands. While the former decreases blood pressure and dilates coronary arteries, the latter slows heart rate and decreases contractility. Nifedipine and the other second-generation dihydropyridine calcium antagonists (nicardipine, isradipine, amlodipine, and felodipine) are potent vasodilators and useful in the simultaneous treatment of angina and hypertension. Short-acting dihydropyridines should be avoided because of the risk of precipitating infarction, particularly in the absence of beta blockers.

Choice between Beta Blockers and Calcium Antagonists for Initial Therapy Since beta blockers have been shown to improve life expectancy following myocardial infarction (p. 1393), they may be preferable in patients with chronicIHD. However, calcium antagonists are indicated in patients with the following: (1) angina and a history of asthma or chronic obstructive pulmonary disease; (2) sick-sinus syndrome or significant atrioventricular conduction disturbances; (3) Prinzmetal's angina; (4) symptomatic peripheral vascular disease; and (5) adverse reactions to beta blockers -- depression, sexual disturbances, fatigue. Many patients with angina do well with a combination of a beta blocker and dihydropyridine calcium antagonist.

Antiplatelet Drugs Aspirin is an irreversible inhibitor of platelet cyclooxygenase activity and thereby interferes with platelet activation. Chronic administration of 100 to 325 mg orally per day has been shown to reduce coronary events in asymptomatic adult men, patients with asymptomatic ischemia after myocardial infarction, patients with chronic stable angina, and patients with or who have survived unstable angina and myocardial infarction. Administration of this drug should be considered in all patients withIHD in the absence of side effects such as gastrointestinal bleeding, allergy, or dyspepsia (Fig. 244-CD6). Clopidogrel is an oral agent that blocks ADP receptor-mediated platelet aggregation. It provides the same benefits as aspirin, if not better, particularly if aspirin causes the side effects listed above.

In summary, a regimen of exercise, smoking cessation, treatment of hypertension and dyslipidemia, aspirin, and beta blockers after infarction are medical interventions that reduce angina, the need for revascularization, myocardial infarction and coronary death.

Treatment af Angina and Heart Failure Transient left ventricular failure with angina can be controlled by the use of nitrates. For patients with established congestive heart failure the increased left ventricular wall tension raises myocardial oxygen demand. Treatment of congestive heart failure with angiotensin-converting enzyme inhibitors, diuretics, and digitalis (Chap. 232) will decrease heart size, wall tension, and myocardial oxygen demands, which, in turn, will help to control angina and ischemia. Nocturnal angina can often be relieved by the treatment of heart failure; however, there is no proven benefit when these drugs are used in patients with angina, a normal heart size, and no evidence of heart failure. Nitrates are particularly useful and can simultaneously improve the disturbed hemodynamics of congestive heart failure by vasodilatation, thereby reducing preload, and relieve angina by preventing or reversing myocardial ischemia. There is some evidence that amlodipine is a calcium antagonist that is well tolerated by patients with left ventricular dysfunction and a valuable agent in the treatment of angina in patients with heart failure. The combination of congestive heart failure and angina in patients withIHDusually indicates a poor prognosis and warrants serious consideration of cardiac catheterization and mechanical revascularization.

CORONARY REVASCULARIZATION

While the basic management of patients withCAD, which is a lifelong condition, is medical, as described above, many patients are improved by coronary revascularization procedures, as described below. These interventions should be employed in conjunction with but do not replace the continuing need to modify risk factors.

PERCUTANEOUS CORONARY INTERVENTION (See also Chap. 245)

PCI, most commonly percutaneous transluminal coronary angioplasty (PTCA) or stenting, is a widely used method to achieve revascularization of the myocardium in patients with symptomaticIHD and suitable stenoses of epicardial coronary arteries (Fig. 244-CD7). Whereas patients with stenosis of the left main coronary artery and those with three-vesselCAD(especially with associated impaired left ventricular function) who require revascularization are best treated withCABG, PCI is widely employed in patients with symptoms and evidence of ischemia due to stenoses of one or two vessels, and even selected patients with three-vessel disease, and may offer many advantages over surgery.

Indications and Patient Selection The most common clinical indication forPCI is angina pectoris, stable or unstable, accompanied by evidence of ischemia in an exercise test. PCI is more effective than medical therapy for the relief of angina. The value of this procedure in reducing the occurrence of coronary death and myocardial infarction has not been established, and therefore it is not generally indicated in asymptomatic or mildly symptomatic patients. PCI can be used to treat stenoses in native coronary arteries as well as in bypass grafts in patients who have recurrent angina following coronary artery surgery. This is an important indication when the

technical difficulties and the increased mortality that accompanies reoperation are considered. PCI has also been carried out in patients with recent total occlusion (within 3 months) of a coronary artery and severe angina; in this group the primary success rate is slightly decreased.

Risks When coronary stenoses are discrete and symmetric, two and three vessels can be dilated in sequence. However, case selection is essential in order to avoid a prohibitive risk of complications. Advanced age, stenoses with thrombus, left ventricular dysfunction, stenosis of an artery perfusing a large segment of myocardium without collaterals, long eccentric or irregular stenoses, and calcified plaques all increase the likelihood of complications but are not absolute contraindications, while left main coronary artery stenosis *is* generally regarded as an absolute contraindication. The major complications are usually due to dissection or thrombosis with vessel occlusion, uncontrolled ischemia, and ventricular failure. Oral aspirin and intravenous heparin are always given to reduce coronary thrombus formation. In unstable angina and when intracoronary thrombus is seen, the use of specific platelet glycoprotein receptor antagonists further reduce thrombotic complications and increase success. In experienced hands, the overall mortality rate should be less than 0.5%, the need for emergency coronary surgery less than 1%, and the occurrence of clinical myocardial infarction less than 2%. Minor complications occur in 5 to 10% of patients and include occlusion of a branch of a coronary artery, myocardial infarction with release of CK-MB into the circulation, and complications of arterial catheterization.

Efficacy Primary success, i.e., adequate dilation (an increase in luminal diameter to a residual diameter obstruction <50%) with relief of angina, is achieved in approximately 95% of cases. Recurrent stenosis of the dilated vessels occurs in 30 to 45% of cases within 6 months ofPTCA, and angina will recur within 6 to 12 months in 25% of cases. This recurrence of symptoms and restenosis is more common in patients with diabetes mellitus, unstable angina, incomplete dilation of the stenosis, dilation of the left anterior descending coronary artery, and stenoses containing thrombi. Dilation of arteries that are totally occluded and of stenotic or occluded vein grafts also exhibits a high incidence of restenosis. It is usual clinical practice to administer aspirin for months after the procedure. Although aspirin and the antiplatelet drug Clopidogrel may help prevent acute coronary thrombosis during and shortly followingPCI, there are no controlled clinical trials that have demonstrated that these medications or any other can clearly reduce the incidence of restenosis. Successful deployment of a metal stent lowers the restenosis rate to 10 to 30% at 6 months but initially requires vigorous antiplatelet therapy (aspirin and Clopidogrel). There is early evidence that local radiation can further reduce restenosis.

If patients do not develop restenosis or angina within the first year after angioplasty, the prognosis for maintaining improvement over the subsequent 4 years is excellent. If restenosis occurs,PTCA can be repeated with the same success and risk, but the likelihood of restenosis increases with the third or subsequent attempt.

SuccessfulPCIproduces effective relief of angina in over 95% of cases and has been shown to be more effective than medical therapy for up to 2 years. Between 30 and 50% of patients with symptomaticIHD who require revascularization can be treated by PCI and need not undergoCABG. Successful PCI is less invasive and expensive than

CABG, usually requires only 1 to 2 days in the hospital, and permits considerable savings in the initial cost of care. Successful PCI also allows earlier return to work and the resumption of an active life. However, this economic benefit is reduced over time because of the greater need for follow-up and for repeat procedures.

CORONARY ARTERY BYPASS GRAFTING

InCABG, a section of a vein (usually the saphenous) is used to form a connection between the aorta and the coronary artery distal to the obstructive lesion. Alternatively, anastomosis of one or both of the internal mammary arteries or a radial artery to the coronary artery distal to the obstructive lesion may be employed and is now preferred whenever possible.

Although some indications for coronary artery bypass surgery are controversial, certain areas of agreement exist:

1. The operation is relatively safe, with mortality rates less than 1% in patients without serious comorbid disease and normal left ventricular function, when the procedure is performed by an experienced surgical team.

2. Intraoperative and postoperative mortality increase with the degree of ventricular dysfunction, comorbidities, age above 80 years, and surgical inexperience. The effectiveness and risk ofCABGvary widely depending on case selection and the skill and experience of the surgical team.

3. Occlusion of vein grafts is observed in 10 to 20% during the first postoperative year and in approximately 2% per year during 5- to 7-year follow-up and 4% per year thereafter. Long-term patency rates are considerably higher for internal mammary and radial artery implantations; in patients with left anterior descending coronary artery obstruction, survival is better when coronary bypass involves the internal mammary artery rather than a saphenous vein. Graft patency and outcomes are improved by meticulous treatment of risk factors, particularly dyslipidemia.

4. Angina is abolished or greatly reduced in approximately 90% of patients following complete revascularization. Although this is usually associated with graft patency and restoration of blood flow, the pain may also have been alleviated as a result of infarction of the ischemic segment or a placebo effect. Within 3 years, angina recurs in about one-fourth of patients but is rarely severe.

5. CABGdoes not appear to reduce the incidence of myocardial infarction in patients with chronicIHD; perioperative myocardial infarction occurs in 5 to 10% of cases, but in most instances these infarcts are small and have little effect on left ventricular function.

6. Mortality is reduced by operation in patients with stenosis of the left main coronary artery as well as in patients with three- or two-vessel disease with significant obstruction of the proximal left anterior descending coronary artery. The survival benefit is greater in patients with abnormal left ventricular function (ejection fraction<50%). Mortality *may* also be reduced in the following patients: (1) with one- or two-vesselCADwithout significant proximal left anterior descending artery CAD but with high-risk criteria on

noninvasive testing; (2) with obstructive CAD who have survived sudden cardiac death or sustained ventricular tachycardia; (3) who have undergone previousCABG and who have multiple saphenous vein graft stenoses, especially of a graft supplying the left anterior descending coronary artery; and (4) with prior PCI recurrent stenosis, and high-risk criteria on noninvasive testing.

Indications forCABG are usually based on the severity of symptoms, coronary anatomy, and ventricular function. The ideal candidate is male, less than 75 years of age, has no other complicating disease, has troublesome or disabling symptoms that are not adequately controlled by medical therapy or does not tolerate medical therapy and wishes to lead a more active life, and has severe stenoses of several epicardial coronary arteries with objective evidence of myocardial ischemia as a cause of the chest discomfort. Great symptomatic benefit can be anticipated in such patients.

Congestive heart failure and/or left ventricular dysfunction (ejection fraction<40%), advanced age (>75 years), reoperation, urgent need for surgery, and the presence of diabetes are all associated with higher perioperative mortality.

Left ventricular dysfunction can be due to noncontractile segments that are viable (hibernating myocardium). These can be detected by using radionuclide scans of myocardial perfusion and metabolism, positron emission tomography, or delayed scanning with thallium-201 or by return of contractile function provoked by low-dose dobutamine. Revascularization can return function and improve survival.

The Choice BetweenPCIandCABG(See Table 244-3) A number of randomized trials have comparedPTCA and CABG in patients with multivesselCAD who were suitable technically for both procedures. The redevelopment of angina requiring repeat coronary angiography and repeat revascularization due to restenosis was higher in the PTCA group. However, the occurrence of death or myocardial infarction has been found to be similar between both groups for up to 5 years. In patients with diabetes plus disease of two or more coronary arteries, bypass surgery results in significantly better outcomes and survival and should be the technique of choice. In addition, the recurrence of angina and stenosis and the need for additional revascularization was much higher in the angioplasty group (about 50%) than in the surgery group (about 10%). Based on these trials and observational studies, we now recommend that patients with an unacceptable level of angina despite optimal medical management should be considered for revascularization. Patients with single- or two-vessel disease with normal or slightly depressed global left ventricular function and anatomically suitable lesions are ordinarily advised initially to undergo PCI (Chap. 245). Patients with two- or three-vessel disease and impaired global left ventricular function (left ventricular ejection fraction <45%) or diabetes mellitus or those with left main disease or other lesions unsuitable for catheter-based procedures should be considered for CABG as the initial method of revascularization (Table 244-3).

UNSTABLE ANGINA PECTORIS

The following three patient groups may be said to have unstable angina pectoris: (1) patients with new onset (<2 months) angina that is severe and/or frequent (³3 episodes per day); (2) patients with accelerating angina, i.e., those with chronic stable angina who

develop angina that is distinctly more frequent, severe, prolonged, or precipitated by less exertion than previously; (3) those with angina at rest. Five mechanisms for unstable angina have been described: (1) a nonocclusive thrombus -- often a platelet plug -- overlying a fissured atherosclerotic plaque; (2) dynamic obstruction -- either spasm of an epicardial coronary artery, as in Prinzmetal's variant angina (see below), or abnormal vasoconstriction of the coronary microcirculation, as in microvascular angina; (3) severe, organic luminal narrowing, as in restenosis following aPCI; (4) arterial inflammation leading to thrombosis; and (5) increase in myocardial oxygen demands caused by conditions such as tachycardia, fever, and thyrotoxicosis in the presence of fixed, severe coronary obstruction. More than one of these may be operative.

When unstable angina is accompanied by objectiveECGevidence of transient myocardial ischemia (ST-segment changes and/or T-wave inversions during episodes of chest pain), it is associated with critical stenoses in one or more major epicardial coronary arteries in about 85% of cases.

TREATMENT

The management of unstable angina is outlined inFig. 244-3. The patient is admitted to the hospital, placed at rest, sedated, and reassured. In all instances, concomitant conditions that can intensify ischemia, such as tachycardia, hypertension, diabetes mellitus, cardiomegaly, heart failure, arrhythmias, thyrotoxicosis, and any acute febrile illness, should be sought and vigorously treated. Acute myocardial infarction should be ruled out by means of serialECGs and measurements of plasma cardiac enzyme activity.

ContinuousECGmonitoring should be carried out. Since thrombus formation frequently complicates this condition, intravenous heparin should be given for 3 to 5 days to maintain the partial thromboplastin time at 2 to 2.5 times control, together with or followed by oral aspirin at a dose of 325 mg/d (Fig. 244-CD8). Alternatively, low-molecular-weight heparin (e.g., enoxaparin, 1 mg/kg subcutaneously b.i.d.) may be used. High-risk unstable angina patients, i.e., those with rest pain, and ST-segment deviations and/or release of a marker of myocardial injury (such as troponin I or T) should also receive an intravenous infusion of a platelet GpIIb/IIIa inhibitor. A beta blocker should be administered and a calcium antagonist added if ischemia persists despite the aforementioned therapy, but with caution and an awareness of the possible side effects discussed above. Dosages of these agents should be raised rapidly, but the patient must be observed carefully to avoid bradycardia, heart failure, and hypotension. Nitroglycerin should be given by the sublingual route as needed for symptoms. Intravenous nitroglycerin is quite effective, especially in patients with episodes of ischemia that are particularly severe or prolonged. It is begun at a dosage of 10 ug/min and is raised in 5 ug/min increments to a level at which chest pain is abolished but systolic arterial pressure is maintained or reduced only slightly and other side effects are avoided. After initial stabilization, either an early invasive strategy (coronary angiography and revascularization) or early conservative strategy (continued medical therapy) can be pursued (Fig. 244-3).

The majority of patients (approximately 80%) improve with rest and medical treatment over a 48-h period. If angina at rest and/orECGevidence of ischemia persist despite 24

to 48 h of the comprehensive treatment described above, then cardiac catheterization and coronary arteriography should be performed in patients with no obvious contraindications for revascularization. If the anatomy is suitable,PCI can be performed. If the coronary anatomy is not suitable for PCI,CABGshould be considered to relieve symptoms and myocardial ischemia and as a means of preventing myocardial damage. The factors that influence the choice between catheter-based and surgical revascularization are similar to those in chronic stable angina.

In the early conservative strategy, if the patient's symptoms and signs are controlled on medical therapy, a diagnostic exerciseECG or perfusion scan or, if exercise is not possible, a pharmacologic stress test (p. 1402) should be carried out near the time of hospital discharge. If there is evidence of severe myocardial ischemia and/or evidence of a high risk of coronary events (p. 1402), consideration should be given to catheterization and, depending on the findings, revascularization. Following discharge, patients with unstable angina should be managed similar to chronic angina patients (p. 1404). Severe obstructiveCAD is often present in patients with unstable angina who respond to medical therapy. Many patients in whom the unstable state is controlled are left with severe chronic stable angina and ultimately require mechanical revascularization.

PRINZMETAL'S VARIANT ANGINA

This relatively uncommon form of unstable angina is characterized by recurrent, prolonged attacks of severe ischemia, caused by episodic focal spasm of an epicardial coronary artery. Approximately three-fourths of patients with Prinzmetal's angina exhibit a mild or moderately severe fixed obstruction (with a luminal diameter 50 to 70% of normal) within 1 cm of the site of spasm. Patients with this condition are often smokers and are younger than patients with unstable angina secondary to coronary atherosclerosis. Ischemic pain usually occurs at rest, sometimes awakens the patient from sleep, and is characterized by multilead ST-segment elevation. The diagnosis may be confirmed by detecting transient spasm occurring spontaneously or following a provocative stimulus (intracoronary acetylcholine, hyperventilation) on coronary arteriography. While long-term survival is excellent, complications include episodes of disabling pain, myocardial infarction, serious ventricular arrhythmias, atrioventricular block, and, rarely, sudden death.

TREATMENT

Management of the acute attack consists of multiple doses of sublingual nitroglycerin, an intravenous infusion of nitroglycerin, and short-acting nifedipine (10 to 30 mg); hypotension should be avoided. In chronic management, long-acting nitrates and calcium antagonists are useful. Beta blockers are of little value, while prazosin, a selective alpha-adrenoceptor blocker, may be useful. Occasionally, mechanical revascularization is helpful in patients with accompanying severe discrete obstructive lesions.

ASYMPTOMATIC (SILENT) ISCHEMIA

ObstructiveCAD, acute myocardial infarction, and transient myocardial ischemia are

frequently asymptomatic. During continuous ambulatoryECGmonitoring, the majority of ambulatory patients with typical chronic stable angina are found to have objective evidence of myocardial ischemia (ST-segment depression) during episodes of chest discomfort while they are active outside the hospital, but many of these patients also appear to have more frequent episodes of asymptomatic ischemia. In addition, there is a large (but as yet unknown) number of totally asymptomatic people with severe coronary atherosclerosis who exhibit ST-segment changes during activity. Some of these patients exhibit higher thresholds to electrically induced pain, others show higher endorphin levels, and still others may be diabetic patients with autonomic dysfunction.

Evidence of frequent episodes of ischemia (symptomatic and asymptomatic) during daily life appears to indicate an increased likelihood of adverse coronary events such as death and myocardial infarction. The widespread use of exerciseECGduring routine examinations has also defined some of these heretofore unrecognized patients with asymptomaticCAD. Longitudinal studies have demonstrated an increased incidence of coronary events (sudden death, myocardial infarction, and angina) in asymptomatic patients with positive exercise tests. In addition, patients with asymptomatic ischemia after suffering a myocardial infarction are at greater risk for a second coronary event.

TREATMENT

The management of patients with asymptomatic ischemia must be individualized. Thus, the physician should consider the following: (1) the degree of positivity of the stress test, particularly the stage of exercise at whichECGsigns of ischemia appear, the magnitude and number of the perfusion defect(s) on thallium scintigraphy, and the change in left ventricular ejection fraction which occurs on radionuclide ventriculography or echocardiography during ischemia and/or during exercise; (2) the ECG leads showing a positive response, with changes in the anterior precordial leads indicating a less favorable prognosis than changes in the inferior leads; and (3) the patient's age, occupation, and general medical condition. Most would agree that an asymptomatic 45-year-old commercial airline pilot with 0.4-mV ST-segment depression in leads V_1 to V_4during mild exercise should undergo coronary arteriography, whereas the asymptomatic, sedentary 75-year-old retiree with 0.1-mV ST-segment depression in leads II and III during maximal activity need not. However, there is no consensus about the appropriate procedure in the large majority of patients for whom the situation is less extreme. Patients with evidence of severe ischemia on noninvasive testing (as outlined earlier) should undergo coronary arteriography. Asymptomatic patients with silent ischemia, three-vesselCAD, and impaired left ventricular function may be considered appropriate candidates forCABG.

The treatment of risk factors, particularly lipid lowering as described above, as well as the use of aspirin and beta blockers have been shown to reduce events and improve outcomes in asymptomatic as well as symptomatic patients with ischemia and provenCAD. While the incidence of asymptomatic ischemia can be reduced by treatment with beta blockers, calcium channel antagonists, and long-acting nitrates, it is not clear whether this is necessary or desirable in patients who have not suffered a myocardial infarction. However, there is evidence that beta-adrenoceptor blockade begun 7 to 35 days after acute myocardial infarction improves survival (Chap. 243).

245. PERCUTANEOUS CORONARY REVASCULARIZATION - *Donald S. Baim*

Before 1977, bypass surgery was the only form of revascularization available to treat coronary artery disease. In that year, Andreas Gruntzig performed the first catheter-based coronary revascularization, which he named percutaneous transluminal coronary angioplasty (PTCA). With crude early equipment and limited anatomic capability, fewer than 1000 such procedures were performed worldwide annually until 1981. Through the 1980s and early 1990s, however, progressive improvements in the balloon angioplasty equipment led to improved results, expanded indications for use, and explosive growth in PTCA to the point that in the United States, the annual number of procedures (~300,000) roughly matched the number of surgical bypass operations. This growth has been sustained during the late 1990s with the introduction of a number of newer devices (including stents and atherectomy devices) that further improved the acute success and safety as well as the long-term durability of what is now known more broadly as percutaneous coronary revascularization (PCR) or intervention (PCI). The current annual number of PCRs (~600,000) is thus now greater than the number of coronary bypass operations (~400,000). The dominant role that catheter-based intervention has assumed in the treatment of coronary artery disease has led to definition of the field known as *interventional cardiology*, which now has its own fellowship requirements and Board certification of additional qualifications based on training (a specialized interventional cardiology fellowship beyond basic cardiology training), ongoing experience (75 procedures per year), and a written examination.

All catheter-based coronary interventions are derivatives of diagnostic cardiac catheterization (Chap. 228), in which catheters are introduced into the arterial circulation by needle puncture, advanced into the heart under fluoroscopic guidance, and used for pressure measurements or injections of radio-opaque liquid contrast agents. Interventional procedures differ in that the catheter placed into the ostium of the narrowed coronary artery has a slightly larger diameter, and its lumen is used to convey a flexible, steerable guidewire (diameter <0.5 mm) down the coronary artery lumen, through the narrowing, and into the vessel beyond. This guidewire then serves as the rail over which angioplasty balloons or other therapeutic devices are run to enlarge the narrowed segment of coronary artery (Fig. 245-1). BecausePCR is performed with local anesthesia and requires only a short (1- to 2-day) hospitalization, its use in suitable patients can greatly decrease expense and recovery time compared to those associated with coronary bypass surgery. Not all types of coronary narrowing are well suited to catheter-based intervention, but such intervention is the treatment of choice for roughly 70% of patients with symptomatic single vessel disease and roughly 20% of patients with symptomatic three-vessel disease. Given these anatomic restrictions and the small but definite risk of catheter-based intervention (elective mortality rate 0.4 to 1.0%, compared to a rate of 1 to 3% for elective surgical bypass), PCR should still be viewed as an invasive procedure whose risks and benefits for each individual patient need to be weighed before use. Beyond the decision of which patients should undergo revascularization (versus continued medical management), the selection of which patients should undergo catheter-based rather than surgical revascularization requires detailed understanding of both clinical and coronary angiographic factors, as well as the applicability of various interventional techniques.

INDICATIONS

The main indication forPCRremains the presence of one or more coronary stenoses that are approachable by catheter-based techniques and are thought to be responsible for a clinical syndrome that warrants revascularization. Moreover, the risks and benefits of revascularization by PCR should compare favorably with those of surgery. In patients with significant narrowing of a single coronary artery, the main benefit of revascularization lies in relief of anginal symptoms rather than in increasing their already good prognosis with medical therapy. By contrast, for the patient with significant left main stenosis or multivessel disease, revascularization may both relieve angina *and* improve long-term survival. Most patients with multivessel coronary disease, however, currently undergo surgical rather than catheter-based revascularization, particularly when one or more vessels supplying significant areas of viable myocardium are not well-suited to PCR (owing to chronic total occlusion or other unfavorable anatomic features). In patients for whom either PCR or bypass surgery is a possible treatment for multivessel coronary artery disease, a number of randomized trials have suggested that the two procedures have equivalent in-hospital and 3- to 5-year mortality rates, but that more patients undergoing PCR (40 to 50% versus 7 to 10% surgical patients) will require a second revascularization procedure (generally a repeat PCR to treat restenosis) by 5 years to maintain an equivalent level of symptom relief. One exception may be diabetic patients with multivessel coronary artery disease, for whom some studies have suggested better survival with surgical treatment than with PCR.

The clinical indications forPCRcover the spectrum from patients with unstable angina or acute infarction to patients with silent ischemia, as summarized in the 1999 guidelines. For most patients, PCR is used to treat anatomically approachable lesions that are responsible for the clinical syndrome of *moderately severe, chronic, stable angina*, which persists despite medical antianginal therapy (Chap. 244). Approximately 15% of current patients undergoing PCR, however, have only mild anginal symptoms despite suitable coronary anatomy but have objective evidence of ischemia on noninvasive testing (i.e., an abnormal exercise test). At the other extreme, many patients have more pressing indications for revascularization, including unstable angina or even acute myocardial infarction (with or without prior thrombolytic therapy). An aggressive approach to the treatment of unstable angina involving initial stabilization with beta blockers, nitrates, heparin, and antiplatelet agents (aspirin and frequently a platelet glycoprotein IIb/IIIa receptor blocker), followed by diagnostic catheterization, and same-procedure PCR of the underlying blockage, offers the patient a more rapid return to work, fewer readmissions and late revascularizations, and potentially a reduction in late events compared to prolonged initial trials of medical therapy before proceeding with invasive evaluation and treatment.

In the early 1980s the introduction of intravenous fibrinolytic agents to reopen the occluded infarct-related vessel was a major advance in the treatment of acute myocardial infarction (Chap. 243). It seemed reasonable thatPCRmight further improve the results of thrombolytic therapy by treating the underlying atherosclerotic stenosis, opening those arteries that failed to reperfuse with a thrombolytic alone and preventing the 10 to 20% incidence of in-hospital reocclusion that occurs after even successful thrombolysis. Randomized trials, however, showed that none of the routine PCR strategies tested after thrombolytic administration improved the outcome more than a "watchful waiting" strategy in which PCR was reserved for patients with spontaneous or

exercise-induced ischemia. In contrast, there is evidence that *primary* or direct angioplasty (used instead of thrombolytic therapy) can reduce the in-hospital mortality rate (from roughly 7 to 4%) when performed promptly by a skilled operator (Fig. 245-2). Another advantage of PCR is that it can be performed even in the approximately 30% of patients with acute myocardial infarction with contraindications to thrombolytic therapy.

As the clinical indications forPCR have broadened, so have its anatomic capabilities. PCR thus is no longer restricted to proximal, discrete, subtotal, concentric, noncalcified lesions, as was the case initially. Calcified, complex, or diffuse disease lesions respond well to coronary stent placement, sometimes after pretreatment with rotational atherectomy. Even totally occluded coronary arteries (particularly ones that have been occluded for less than 6 months) can be crossed and dilated effectively, although the success rate remains somewhat lower than for subtotal lesions (60% versus 90% for subtotal stenotic lesions). In addition to lesions in the native coronary tree, obstructions in saphenous vein (Fig. 245-3) or internal mammary artery bypass grafts also can be dilated successfully to treat postbypass angina. If multiple lesions are responsible for the clinical syndrome, they generally can be dilated during a single procedure.

RESULTS

The success rate forPCRexceeds 95% for dilating a target lesion so that its residual diameter stenosis is <50% (<30% when a stent has been used), without producing an associated complication. About half of the failures result from inability to cross the target lesion with the guidewire or balloon catheter, particularly when that target lesion is a chronic total occlusion. With balloon dilatation alone, some local dissection is present in virtually all successful procedures. Before the introduction of stent technology (see below), more extensive dissection (particularly in association with local thrombus formation or vasospasm) led to abrupt closure of the dilated segment soon after withdrawal of the balloon catheter, and necessitated emergency bypass surgery in approximately 3% of angioplasty attempts. However, such dissections are now routinely treated by stent placement, reducing the incidence of emergency bypass surgery to <1%. Other than dissection, the main hazards of PCR concern spasm, thrombosis, and perforation.

Coronary spasm is controlled by the routine use of vasodilators (nitrates and calcium channel antagonists), whereas thrombosis is controlled by systemic anticoagulation (heparin, 7000 to 10,000 units during the procedure to maintain an activated clotting time of 250 to 300 s), and antiplatelet therapy (aspirin, 325 mg/d starting at least 24 h beforePCR and continued for at least 3 to 6 months after the procedure). If a coronary stent has been placed, aspirin is supplemented by a blocker of the platelet ADP receptor (ticlopidine or clopidogrel) to reduce the likelihood of stent thrombosis (see below). Newer potent intravenous antiplatelet agents (blockers of the platelet glycoprotein IIb/IIIa receptors) may reduce further the incidence of ischemic complications within 72 h of PCR, and are used prophylactically in what are perceived to be high-risk interventions or provisionally in interventions that have left behind an imperfect mechanical result (e.g., an unstented distal dissection).

Perforation of a coronary artery was an extremely rare complication of conventional balloon angioplasty but may occur in up to 1% of patients undergoing more aggressive

atherectomy procedures (see below). Even small perforations of the distal vessel by the angioplasty guidewire may lead to significant hemopericardium requiring urgent pericardiocentesis in the setting of intense anticoagulant and antiplatelet therapy. Finally, catheter-based interventions are subject to all of the complications of diagnostic catheterization, including adverse reactions to iodinated contrast agents and groin hematoma. By and large, however, catheter-based coronary revascularization has reached the point of being a safe and effective alternative to surgical revascularization.

FOLLOW-UP

After successfulPCR of all "culprit" lesions, marked improvement or complete resolution of the presenting ischemic syndrome should be evident. In approximately 20% of patients, however, evidence of recurrent ischemia develops within 6 months, due to restenosis of the dilated segment. This restenosis appears to result from excessive local fibrointimal proliferation and vessel constriction, occurring in response to the local injury that is part of enlarging the stenotic lumen. When recurrent ischemia develops more than 6 months after PCR, it usually reflects progression of disease at another site, rather than restenosis. Whether due to restenosis or disease progression, most post-PCR problems can be treated by repeat PCR, so that only about 10% of patients require bypass surgery during the 5 years after a successful procedure. When a patient has provided evidence of severe obstructive coronary atherosclerosis requiring revascularization, either by bypass surgery or PCR, the opportunity to implement an aggressive program to reduce atherosclerotic risk factors and thereby slow the pace of development of new lesions should not be overlooked (Chap. 244).

NONBALLOON TECHNIQUES

Conventional balloon angioplasty(PTCA)was the only catheter-based coronary revascularization technique that was widely available before 1990. Although it offered anatomic versatility and acceptable short- and long-term results, the difficulty of using this technique for certain anatomic lesion types (e.g., calcified eccentric, ostial, thrombus-containing, or bifurcation lesions) and the persistence of problems such as abrupt closure and restenosis fostered the development of a number of newer, nonballoon techniques that include stent placement and atherectomy. These treatments moved from clinical investigation to routine clinical practice during the early 1990s and now account for 70 to 80% of percutaneous coronary interventions. Used appropriately, these new techniques have improved the success, safety, and long-term results (restenosis rate) in most lesion types. Most of these procedures cost more than PTCA, but much of this cost can be recouped by the reduction in long-term expenses for the treatment of restenosis. Given these developments, stand-alone balloon angioplasty is now used in a minority of procedures (20% of allPCRs), although adjunctive balloon angioplasty is still routinely used to pre- or postdilate, before or after a newer interventional device.

STENTS

Stents are metallic scaffolds that are inserted into a diseased vessel segment in their collapsed form and are then expanded (by balloon expansion, or by self-expansion after removal of a constraining membrane) to establish a normal-appearing vessel lumen

(Fig. 245-CD1). Stents overcome two of the principal limitations of balloon dilatation -- the tendency for elastic recoil of the vessel wall and local dissection of the plaque. As such, stents provide a larger acute lumen than does conventional balloon angioplasty, which allows them to reduce the incidence of subsequent restenosis by roughly one-third (e.g., angiographic restenosis rates of 20% versus 33%, and clinical restenosis rates of 10% versus 16 to 20%). When in-stent restenosis does occur, it is almost never the result of stent crush but rather the consequence of excessive neointimal hyperplasia within the stent (Fig. 245-4). In-stent restenosis can be treated by atherectomy to remove the excess tissue (see below), balloon dilatation, and then local delivery of b org radiation to suppress neointimal regrowth.

Two balloon-expandable stent designs were approved by the Food and Drug Administration (FDA) in the early 1990s -- a wire coil design for use in stabilizing actual or threatened abrupt closure and a slotted tube design for elective treatment of native coronary lesions. After their release, the efficacy of the slotted tube design was demonstrated in a variety of other circumstances, including restenotic lesions and saphenous vein grafts (Fig. 245-3). In the late 1990s, a number of second generation stent designs were developed that offer easier delivery to tortuous or distal lesions as well as a wider variety of sizes and lengths. The approval of these devices has allowed them to completely replace the first generation devices in clinical practice (Fig. 245-5). Still further refinements in stent coverings (to seal aneurysms or perforations) and coatings (to suppress stent thrombosis and in-stent proliferation) are in progress.

Early experience suggested that metallic stents were prone to thrombotic occlusion, either acute (<24 h) or subacute (1 to 14 days with a peak at 6 days), and that an aggressive anticoagulation regimen (aspirin, dipyridamole, and warfarin) was needed to prevent such thrombosis. This aggressive anticoagulant regimen reduced the incidence of stent thrombosis to ~3% but led to longer hospitalization and an increased incidence of local vascular complications at the femoral arterial entry site. Subsequent data suggested that many of these thrombotic complications were the result of incomplete stent expansion and that more attention to full initial deployment would allow the same stents to be used with only antiplatelet drugs (aspirin plus the platelet ADP-receptor blockers, ticlopidine or clopidogrel) with more acceptable thrombosis and vascular complication rates (each<1%). This rapid evolution in devices, concomitant medications, and indications has led to the dominance of stent placement in catheter-based coronary revascularization, with placement of one or more stents in 70 to 80% of all procedures.

Atherectomy Whereas both balloon angioplasty and stent placement enlarge the coronary lumen by displacing plaque, atherectomy catheters enlarge the lumen by removing plaque mass from the treated lesion. Directional atherectomy achieves this result by use of a special catheter with a windowed steel cylinder at its tip. Inflation of a low-pressure positioning balloon on the back of the cylinder presses plaque into the window, where it is cut and trapped by a spinning cup-shaped cutter. This device was the first (1990) approved nonballoon technology to reach clinical practice, and it is still the treatment of choice for noncalcified lesions at the origin of the left anterior descending artery or at major coronary bifurcations (Fig. 245-6). Although its efficacy over conventional balloon angioplasty has been demonstrated, the ease and result of stent placement are much greater for most other lesion types. Rotational atherectomy uses burrs of various sizes (diameter 1.25 to 2.50 mm) that are coated on their leading

half with small diamond chips. The burr is spun at 140,000 to 160,000 rpm as it is advanced through a coronary lesion over a leading guidewire. As the burr is advanced, the diamond chips grind through the obstructing plaque, and pulverize it into small (5 to 25 um) particles, which pass through the distal coronary microcirculation. This device has emerged as an effective treatment for long (>20 mm), calcified, ostial lesions or in-stent restenotic lesions, frequently followed by balloon dilation or stent placement. *Extraction* atherectomy uses a combination of distal cutting blades rotating at low speed and continuous vacuum aspiration to remove coronary obstructions. The device has limited cutting efficiency, and its use is now confined to softer lesions (e.g., atherosclerotic saphenous vein grafts) or thrombotic lesions. Newer aspiration devices based on the Bernoulli principle appear better able to remove clot and cause less vessel disruption.

Although it is not mechanical, laser light [at wavelengths from the ultraviolet (308 mm) to the midinfrared (2000 um)] can be delivered to obstructing coronary plaques through bundles of small optical fibers housed in flexible catheters whose outer diameter is between 1.2 and 2.0 mm. When these catheters are pulsed with laser energy as they are advanced through a coronary obstruction over a guidewire, they can ablate noncalcified coronary plaque by a combination of photoacoustic (blast), thermal, and photochemical effects. Although lasers have been used to treat ostial as well as diffuse coronary lesions, acceptance of the technique has been limited by the expense of the device and the fact that these lesions can be treated by other techniques, such as rotational atherectomy.

SUMMARY

With the development of new techniques such as stent placement and atherectomy, new drug regimens, and a preponderance of "evidence-based" practices, over the last 20 years catheter-based revascularization (PCR) has developed from a procedural curiosity to one of the mainstays of coronary revascularization. As short- and long-term results have improved and the number of procedures has continued to grow, the pace of development, if anything, has intensified.

246. HYPERTENSIVE VASCULAR DISEASE - *Gordon H. Williams*

An elevated arterial pressure is probably the most important public health problem in developed countries. It is common, asymptomatic, readily detectable, usually easily treatable, and often leads to lethal complications if left untreated (Chap. 35). As a result of extensive educational programs in the late 1960s and 1970s by both private and government agencies, the number of undiagnosed and/or untreated patients was reduced significantly by the late 1980s to a level of about 25%, with a concomitant decline in cardiovascular mortality. Unfortunately, by the mid-1990s, this beneficial trend began to wane. The number of undiagnosed patients with hypertension increased to nearly 33%, the decline in cardiovascular mortality flattened, and the number of individuals with chronic diseases with untreated or poorly treated hypertension increased. For example, the prevalence of end-stage renal disease per million population increased from <100 in 1982 to>250 in 1995, and the prevalence of congestive heart failure from ages 55 to 75 more than doubled between 1976 to 1980 and 1988 to 1991. Thus, although our understanding of the pathophysiology of elevated arterial pressure has increased, in 90 to 95% of cases the etiology (and thus potentially the means of prevention or cure) is still largely unknown. As a consequence, in most cases the hypertension is treated nonspecifically, resulting in a large number of minor side effects and a relatively high (50 to 60%) noncompliance rate.

PREVALENCE

The prevalence of hypertension depends on both the racial composition of the population studied and the criteria used to define the condition. In a white suburban population like that in the Framingham Study, nearly one-fifth of individuals have blood pressures >160/95, while almost one-half have pressures >140/90. An even higher prevalence has been documented in the nonwhite population. In females the prevalence is closely related to age, with a substantial increase occurring after age 50. This increase is presumably related to the hormonal changes of menopause, although the mechanism is unclear. Thus, the ratio of hypertension frequency in women versus men increases from 0.6 to 0.7 at age 30 to 1.1 to 1.2 at age 65.

The prevalence of various forms of secondary hypertension depends on the nature of the population studied and on how extensive the evaluation is. There are no available data to define the frequency of secondary hypertension in the general population, although in middle-aged males it has been reported to be 6%. On the other hand, in referral centers where patients undergo an extensive evaluation, it has been reported to be as high as 35%. The various forms of hypertension are outlined in Table 246-1, and their relative frequencies are given in Table 246-2.

ESSENTIAL HYPERTENSION

Patients with arterial hypertension and no definable cause are said to have *primary*, *essential*, or *idiopathic hypertension*. Undoubtedly, the primary difficulty in uncovering the mechanism(s) responsible for the hypertension in these patients is attributable to the variety of systems that are involved in the regulation of arterial pressure -- peripheral and/or central adrenergic, renal, hormonal, and vascular -- and to the complexity of the interrelations of these systems. Several abnormalities have been described in patients

with essential hypertension, often with a claim that one or more of them are primarily responsible for the hypertension. While it is still uncertain whether these individual abnormalities are primary or secondary, varying expressions of a single disease process or reflective of separate disease entities, the accumulating data increasingly support the latter hypothesis. Therefore, just as pneumonia is caused by a variety of infectious agents, even though the clinical picture observed may be similar, so essential hypertension likely has a number of distinct causes. Thus, the distinction between primary and secondary hypertension has become blurred, and the approach to both the diagnosis and therapy of hypertensive patients has been modified. For example, when a group of patients with essential hypertension is separated into a distinct subset (e.g., low-renin essential hypertension), the patients have not been reclassified as having a form of secondary hypertension but rather remain in the essential hypertensive group. In this**chapter**, individuals in whom a specific structural organ or gene defect is responsible for hypertension are defined as having a *secondary* form of hypertension. In contrast, individuals in whom generalized or functional abnormalities may be the cause of hypertension, even if the abnormalities are discrete, are defined as having *essential* hypertension.

GENETIC CONSIDERATIONS

Genetic factors have long been assumed to be important in the genesis of hypertension. Data supporting this view can be found in animal studies as well as in population studies in humans. One approach has been to assess the correlation of blood pressure in families (familial aggregation). From these studies, the minimum size of the genetic factor can be expressed by a correlation coefficient of approximately 0.2. However, the variation in the size of the genetic factor in different studies reemphasizes the probably heterogeneous nature of the essential hypertensive population. In addition, most studies support the concept that the inheritance is probably multifactorial or that a number of different genetic defects each have an elevated blood pressure as one of their phenotypic expressions. Finally, both monogenic defects (e.g., glucocorticoid-remediable aldosteronism and Liddle's syndrome) and susceptibility genes (e.g., the angiotensinogen and a adducin genes) have now been reported which have as one of their consequences an increased arterial pressure (see below and Chap. 331). Yet, as can be seen inTable 246-3, most studies of likely genes have failed to document linkage or consistent association with hypertension. However, uncertainty exists as to the validity of these negative conclusions. A positive relationship between hypertension and a gene could be obscured by the high probability of a false-negative result because of the heterogeneity of the hypertensive population. Thus, intermediate phenotypes in the hypertensive population need to be identified to differentiate patients into more homogeneous subgroups; the role of a specific candidate gene can then be more readily assessed. Such an approach is illustrated inTable 246-4.

ENVIRONMENT

A number of environmental factors have been implicated in the development of hypertension, including salt intake, obesity, occupation, alcohol intake, family size, and crowding. These factors have all been assumed to be important in the increase in blood pressure with age in more affluent societies, in contrast to the decline in blood pressure with age in less affluent groups.

SALT SENSITIVITY

The environmental factor that has received the greatest attention is salt intake. Even this factor illustrates the heterogeneous nature of the essential hypertensive population, in that the blood pressure in only approximately 60% of hypertensives is particularly responsive to the level of sodium intake. The cause of this special sensitivity to salt varies, with primary aldosteronism, bilateral renal artery stenosis, renal parenchymal disease, and low-renin essential hypertension accounting for about half the patients. In the remainder, the pathophysiology is still uncertain, but postulated contributing factors include chloride intake, calcium intake, a generalized cellular membrane defect, insulin resistance, and "nonmodulation" (see below).

ROLE OF RENIN

Renin is an enzyme secreted by the juxtaglomerular cell of the kidney and linked with aldosterone in a negative feedback loop (Chap. 331). While a variety of factors can modify its rate of secretion, the primary determinant is the volume status of the individual, particularly as related to changes in dietary sodium intake. The end product of the action of renin on its substrate is the generation of the peptide angiotensin II. The response of target tissues to this peptide is uniquely determined by the prior dietary electrolyte intake. For example, sodium intake normally modulates adrenal and renal vascular responses to angiotensin II. With sodium restriction, adrenal responses are enhanced and the renal vascular responses reduced. Sodium loading has the opposite effect. The range of plasma renin activities observed in hypertensive subjects is broader than in normotensive individuals. In consequence, some hypertensive patients have been defined as having *low-renin* and others as having *high-renin* essential hypertension.

Low-Renin Essential Hypertension Approximately 20% of patients who by all other criteria have essential hypertension have suppressed plasma renin activity. This situation is more common in individuals of African descent than in white patients. Though these patients are not hypokalemic, they have been reported to have expanded extracellular fluid volumes, and it has been suggested but not proved that they have sodium retention and renin suppression due to excessive production of an unidentified mineralocorticoid. On the other hand, some, but not all, studies have suggested that the adrenal cortex of some of these patients has an increased sensitivity to angiotensin II as the underlying mechanism. Not only does this hypothesis potentially explain their low plasma renin activity, it also suggests the cause of their hypertension. On a diet with a normal or high sodium content, aldosterone production will not be suppressed normally, leading to a mild degree of hyperaldosteronism with its resulting increased sodium retention, volume expansion, and increase in blood pressure. Since this altered sensitivity has been reported even in patients with normal-renin hypertension, it is likely that patients with low-renin hypertension are not a distinct subset but rather form part of a continuum of patients with essential hypertension.

Nonmodulating Essential Hypertension Another subset of hypertensive patients has an adrenal defect opposite to that observed in some low-renin patients -- a reduced adrenal response to sodium restriction. In these individuals, sodium intake does not

modulate either adrenal or renal vascular responses to angiotensin II. Hypertensives in this subset have been termed *nonmodulators* because of the absence of the sodium-mediated modulation of target tissue responses to angiotensin II. These individuals make up 25 to 30% of the hypertensive population, have plasma renin activity levels that are normal to high if measured when the patient is on a low-salt diet, and have hypertension that is salt-sensitive because of a defect in the kidney's ability to excrete sodium appropriately. They also are more insulin-resistant than ohter hypertensive patients, and the pathophysiologic characteristics can be corrected by the administration of a converting-enzyme inhibitor. Furthermore, the nonmodulation characteristic appears to be genetically determined (associated with a certain allele of the angiotensinogen gene). Thus, nonmodulators are probably the most completely characterized intermediate phenotype in the hypertensive population.

High-Renin Essential Hypertension Approximately 15% of patients with essential hypertension have plasma renin activity levels above the normal range. It has been suggested that plasma renin plays an important role in the pathogenesis of the elevated arterial pressure in these patients. However, most studies have found that saralasin (a substance that, like losartan, acts as a competitive antagonist of angiotensin II) significantly reduces blood pressure in fewer than half of these patients. This finding has led some investigators to postulate that the elevated renin levels and blood pressure may both be secondary to an increase in adrenergic system activity. It has been proposed that, in patients with angiotensin-dependent high-renin hypertension whose arterial pressures are lowered by an angiotensin II antagonist, the mechanism responsible for the increase in renin and, therefore, for the hypertension is the nonmodulating defect.

SODIUM ION VERSUS CHLORIDE OR CALCIUM

Most studies assessing the role of salt in the hypertensive process have assumed that it is the sodium ion that is important. However, some investigators have suggested that the chloride ion may be equally important. This suggestion is based on the observation that feeding chloride-free sodium salts to salt-sensitive hypertensive animals fails to increase arterial pressure. Calcium has also been implicated in the pathogenesis of some forms of essential hypertension. A low-calcium intake has been associated with an increase in blood pressure in epidemiologic studies; an increase in leukocyte cytosolic calcium levels has been reported in some hypertensives. Finally, calcium entry blockers are effective antihypertensive agents. Several studies have reported a potential link between the salt-sensitive forms of hypertension and calcium. It has been postulated that salt loading in combination with a defect in the kidney's ability to excrete salt may lead to a secondary increase in circulating natriuretic factors. One of these factors, the so-called digitalis-like natriuretic factor, inhibits ouabain-sensitive Na^+, K^+-ATPase and thereby leads to intracellular calcium accumulation and a hyperreactive vascular smooth muscle.

CELL MEMBRANE DEFECT

Another postulated explanation for salt-sensitive hypertension is a generalized cell membrane defect. This hypothesis derives most of its data from studies on circulating blood elements, particularly red blood cells, in which abnormalities in the transport of

sodium across the cell membrane have been documented. Since both increases and decreases in the activity of different transport systems have been reported, it is likely that some abnormalities are primary and some are secondary. It has been assumed that this abnormality in sodium transport reflects an undefined alteration in the cell membrane and that this defect occurs in many, perhaps all, cells of the body, particularly the vascular smooth-muscle cells. The defect leads to an abnormal accumulation of calcium in vascular smooth muscle, resulting in a heightened vascular responsiveness to vasoconstrictor agents. This defect has been proposed to be present in 35 to 50% of essential hypertensive persons on the basis of studies using red cells. Other studies suggest that the abnormality in red cell sodium transport is not fixed but can be modified by environmental factors.

The common final pathway in all these hypotheses is an increase in cytosolic calcium resulting in increased vascular reactivity. However, as described above, several mechanisms might produce this calcium accumulation.

INSULIN RESISTANCE

Insulin resistance and/or hyperinsulinemia have been suggested as being responsible for the increased arterial pressure in some patients with hypertension. While it is clear that a substantial fraction of the hypertensive population has insulin resistance and hyperinsulinemia, it is less certain that this is more than an association. Insulin resistance is common in patients with non-insulin-dependent diabetes mellitus (NIDDM) or obesity. Both obesity and NIDDM are more common in hypertensive than in normotensive subjects. However, several studies have found that hyperinsulinemia and insulin resistance are present even in lean hypertensive patients without NIDDM, suggesting that this relationship is more than a coincidence. As noted earlier, these individuals seem to be concentrated in the nonmodulation phenotype.

Hyperinsulinemia can increase arterial pressure by one or more of four mechanisms. An underlying assumption in each case is that some, but not all, of the target tissues of insulin are resistant to its effects. Specifically, tissues involved in glucose homeostasis are resistant (thereby producing the hyperinsulinemia), while tissues involved in the hypertensive process are not. First, hyperinsulinemia produces renal sodium retention (at least acutely) and increases sympathetic activity. Either or both of these effects could lead to an increase in arterial pressure. Another mechanism is vascular smooth-muscle hypertrophy secondary to the mitogenic action of insulin. Third, insulin also modifies ion transport across the cell membrane, thereby potentially increasing the cytosolic calcium levels of insulin-sensitive vascular or renal tissues. This mechanism would increase arterial pressure for reasons similar to those described above for the membrane-defect hypothesis. Finally, insulin resistance may be a marker for another pathologic process, e.g., nonmodulation, which could be the primary mechanism increasing blood pressure. It is important to point out, however, that the role of insulin in controlling arterial pressure is only vaguely understood, and, therefore, its potential as a pathogenic factor in hypertension remains unclear.

Few of the features of hypertension discussed above remain constant in a given patient. Some may be a reflection of the current metabolic and hormonal status of the patient rather than a permanent feature of the disease process. For example, at one point a

patient might have insulin resistance secondary to obesity, which could lead to sodium retention, intravascular volume expansion, and renin suppression. This patient would be labeled as having "low-renin essential hypertension." If the patient lost weight, however, the salt-retaining tendency would be reversed. If the blood pressure did not normalize, the patient might then have "normal or high-renin essential hypertension." Thus, the features reviewed above should not be considered mutually exclusive or permanent characteristics in a given patient with hypertension.

FACTORS THAT MODIFY THE COURSE OF ESSENTIAL HYPERTENSION

Age, race, sex, smoking, alcohol intake, serum cholesterol, glucose intolerance, and weight may all alter the prognosis of this disease. The younger the patient when hypertension is first noted, the greater is the reduction in life expectancy if the hypertension is left untreated. In the United States, urban blacks have about twice the prevalence of hypertension as whites and more than four times the hypertension-induced morbidity rate. At all ages and in both white and nonwhite populations, females with hypertension fare better than males up to the age of 65, and the prevalence of hypertension in premenopausal females is substantially less than that in age-matched males or postmenopausal women. Yet, compared with their normotensive counterparts, females with hypertension run the same relative risk of a morbid cardiovascular event as males do. Accelerated atherosclerosis is an invariable companion of hypertension. Thus, it is not surprising that independent risk factors associated with the development of atherosclerosis, such as an elevated serum cholesterol, glucose intolerance, and/or cigarette smoking, significantly enhance the effect of hypertension on mortality rate regardless of age, sex, or race (Chap. 241). There also is no question that a positive correlation exists between obesity and arterial pressure. A gain in weight is associated with an increased frequency of hypertension in persons with normal blood pressure, and weight loss in obese persons with hypertension lowers their arterial pressure and, if they are being treated for hypertension, the intensity of therapy required to keep them normotensive. Whether these changes are mediated by changes in insulin resistance is unknown.

NATURAL HISTORY

Because essential hypertension is a heterogeneous disorder, variables other than the arterial pressure modify its course. Thus, the probability of developing a morbid cardiovascular event with a given arterial pressure may vary as much as 20-fold depending on whether associated risk factors are present (Table 246-5). Although exceptions have been reported, most untreated adults with hypertension will develop further increases in arterial pressure with time. Furthermore, it has been demonstrated from both actuarial data and experience in the era prior to effective therapy that untreated hypertension is associated with a shortening of life by 10 to 20 years, usually related to an acceleration of the atherosclerotic process, with the rate of acceleration in part related to the severity of the hypertension. Even individuals who have relatively mild disease -- i.e., without evidence of end organ damage -- that is left untreated for 7 to 10 years have a high risk of developing significant complications. Nearly 30% will exhibit atherosclerotic complications, and more than 50% will have end organ damage related to the hypertension itself, such as cardiomegaly, congestive heart failure, retinopathy, a cerebrovascular accident, and/or renal insufficiency. Thus, even in its mild forms,

hypertension is a progressive and lethal disease if left untreated.

SECONDARY HYPERTENSION

As noted earlier, in only a small minority of patients with elevated arterial pressure can a specific cause be identified. Yet these patients should not be ignored for at least two reasons: (1) correction of the cause may cure their hypertension, and (2) these secondary forms of the disease may provide insight into the etiology of essential hypertension. Nearly all the secondary forms of hypertension are related to an alteration in hormone secretion and/or renal function and are discussed in detail in other chapters.

RENAL HYPERTENSION (See also Chap. 278)

Hypertension produced by renal disease is the result of either (1) a derangement in the renal handling of sodium and fluids leading to volume expansion or (2) an alteration in renal secretion of vasoactive materials resulting in a systemic or local change in arteriolar tone. The main subdivisions of renal hypertension are renovascular hypertension, including preeclampsia and eclampsia, and renal parenchymal hypertension. A simple explanation for *renal vascular hypertension* is that decreased perfusion of renal tissue due to stenosis of a main or branch renal artery activates the renin-angiotensin system, described in Chap. 331. Circulating angiotensin II elevates arterial pressure by directly causing vasoconstriction, by stimulating aldosterone secretion with resulting sodium retention, and/or by stimulating the adrenergic nervous system. In practice, only about one-half of patients with renovascular hypertension have an absolute elevation in renin activity in peripheral plasma, although when renin measurements are referenced against an index of sodium balance, a much higher fraction have inappropriately high values.

Activation of the renin-angiotensin system has also been offered as an explanation for the hypertension in both acute and chronic *renal parenchymal disease*. In this formulation, the only difference between renovascular and renal parenchymal hypertension is that the decreased perfusion of renal tissue in the latter case results from inflammatory and fibrotic changes involving multiple small intrarenal vessels. There are enough differences between the two conditions, however, to suggest that other mechanisms are active in renal parenchymal disease. Specifically, (1) peripheral plasma renin activity is elevated far less frequently in renal parenchymal than in renovascular hypertension; (2) cardiac output is said to be normal in renal parenchymal hypertension (unless uremia and anemia are present) but slightly elevated in renovascular hypertension; (3) circulatory responses to tilting and to the Valsalva maneuver are exaggerated in the latter condition; and (4) blood volume tends to be high in patients with severe renal parenchymal disease and low in patients with severe unilateral renovascular hypertension. Alternative explanations for the hypertension in renal parenchymal disease include the possibilities that the damaged kidneys (1) produce an unidentified vasopressor substance other than renin, (2) fail to produce a necessary humoral vasodilator substance (perhaps prostaglandin or bradykinin), (3) fail to inactivate circulating vasopressor substances, and/or (4) are ineffective in disposing of sodium. In the last case, the retained sodium would be responsible for the hypertension as outlined earlier. Although all these explanations, including participation of the renin-angiotensin system, probably have some validity in individual patients, the

hypothesis involving sodium retention is particularly attractive. It is supported by the observation that those patients with chronic pyelonephritis or polycystic renal disease who are salt wasters do not develop hypertension and by the observation that removal of salt and water by dialysis or diuretics is effective in controlling arterial pressure in most patients with renal parenchymal disease.

A rare form of renal hypertension results from the excess secretion of renin by juxtaglomerular cell tumors or nephroblastomas. The initial presentation is similar to that of hyperaldosteronism, with hypertension, hypokalemia, and overproduction of aldosterone. However, in contrast to primary aldosteronism, peripheral renin activity is *elevated instead of subnormal*. This disease can be distinguished from other forms of secondary aldosteronism by the presence of normal renal function and unilateral increases in renal vein renin concentration without a renal artery lesion.

ENDOCRINE HYPERTENSION

Adrenal Hypertension Hypertension is a feature of a variety of adrenal cortical abnormalities. In *primary aldosteronism* (Chap. 331), there is a clear relationship between the aldosterone-induced sodium retention and the hypertension. Normal individuals given aldosterone develop hypertension only if they also ingest sodium. Since aldosterone causes sodium retention by stimulating renal tubular exchange of sodium for potassium, hypokalemia is a prominent feature in most patients with primary aldosteronism, and, therefore, the measurement of serum potassium provides a simple screening test. The effect of sodium retention and volume expansion in chronically suppressing plasma renin activity is critical for the definitive diagnosis. In most clinical situations, plasma renin activity and plasma or urinary aldosterone levels parallel each other, but in patients with primary aldosteronism, aldosterone levels are high and relatively fixed because of autonomous aldosterone secretion, whereas plasma renin activity levels are suppressed and respond sluggishly to sodium depletion. Primary aldosteronism may be secondary to either a tumor or bilateral adrenal hyperplasia. It is important to distinguish between these two conditions preoperatively, since the hypertension in the latter case is usually not modified by operation.

The sodium-retaining effect of large amounts of glucocorticoids (perhaps resulting in part from saturation of the 11b-hydroxysteroid hydrogenase enzyme system in the kidney by the increased concentration of cortisol) also offers an explanation for the hypertension in severe cases of Cushing's syndrome (Chap. 331). Moreover, increased production of mineralocorticoids has also been documented in some patients with Cushing's syndrome. However, the hypertension in many cases of Cushing's syndrome does not seem volume-dependent, leading investigators to speculate that it may be secondary to glucocorticoid-induced production of renin substrate (angiotensin-mediated hypertension). In the forms of the adrenogenital syndrome due to C-11 or C-17 hydroxylase deficiency (Chap. 331), deoxycorticosterone accounts for the sodium retention and the resulting hypertension, which is accompanied by suppression of plasma renin activity.

In patients with pheochromocytoma (Chap. 332), increased secretion of epinephrine and norepinephrine by a tumor (most often located in the adrenal medulla) causes excessive stimulation of adrenergic receptors, which results in peripheral vasoconstriction and

cardiac stimulation. This diagnosis is confirmed by demonstrating increased urinary excretion of epinephrine and norepinephrine and/or their metabolites.

Acromegaly (See also Chap. 328) Hypertension, coronary atherosclerosis, and cardiac hypertrophy are frequent complications of this condition.

Hypercalcemia (See alsoChap. 340) The hypertension that occurs in up to one-third of patients with hyperparathyroidism ordinarily can be attributed to renal parenchymal damage due to nephrolithiasis and nephrocalcinosis. However, increased calcium levels can also have a direct vasoconstrictive effect. In some cases, the hypertension disappears when the hypercalcemia is corrected. Thus, paradoxically, the increased serum calcium level in hyperparathyroidism raises blood pressure, while epidemiologic studies suggest that a high calcium intake lowers blood pressure. To further confuse the issue, calcium entry-blocking agents are effective antihypertensive agents. Additional studies are needed to resolve these seemingly conflicting observations.

Oral Contraceptives Several years ago, a common cause of endocrine hypertension was the use of estrogen-containing oral contraceptives. However, several studies have since suggested that this is no longer true, probably owing to the lower estrogen content of modern oral contraceptives. In patients receiving these agents who do become hypertensive, the mechanism is likely to be activation of the renin-angiotensin-aldosterone system. Thus, both volume (aldosterone) and vasoconstrictor (angiotensin II) factors are important. The estrogen component of oral contraceptive agents stimulates the hepatic synthesis of the renin substrate angiotensinogen, which in turn favors the increased production of angiotensin II and secondary aldosteronism. Some women taking oral contraceptives have increased plasma concentrations of angiotensin II and aldosterone with some increase in arterial pressure. However, only a small number actually have an increase in arterial pressure to a level>140/90, and, in about half of these, the hypertension will remit within 6 months of stopping the drug.

Why some women taking oral contraceptives develop hypertension and others do not is unclear but may be related to (1) increased vascular sensitivity to angiotensin II, (2) the presence of mild renal disease, (3) familial factors (over one-half have a positive family history for hypertension), (4) age (hypertension is significantly more prevalent in women over age 35), (5) the estrogen content of the contraceptive, and/or (6) obesity. Indeed some investigators have suggested that the oral contraceptives are simply unmasking women with essential hypertension.

COARCTATION OF THE AORTA (See also Chap. 234)

The hypertension associated with coarctation may be caused by the constriction itself or perhaps by the changes in the renal circulation, which result in an unusual form of renal arterial hypertension. The diagnosis of coarctation is usually evident from physical examination and routine x-ray findings.

EFFECTS OF HYPERTENSION

Patients with hypertension die prematurely; the most common cause of death is heart

disease, with stroke and renal failure also frequent, particularly in patients with significant retinopathy.

EFFECTS ON THE HEART

Cardiac compensation for the excessive workload imposed by increased systemic pressure is at first sustained by concentric left ventricular hypertrophy, characterized by an increase in wall thickness. Ultimately, the function of this chamber deteriorates, the cavity dilates, and the symptoms and signs of heart failure appear (Chap. 231). Angina pectoris may also occur because of the combination of accelerated coronary arterial disease and increased myocardial oxygen requirements as a consequence of the increased myocardial mass (Chap. 244). On physical examination, the heart is enlarged and has a prominent left ventricular impulse. The sound of aortic closure is accentuated, and there may be a faint murmur of aortic regurgitation. Presystolic (atrial, fourth) heart sounds appear frequently in hypertensive heart disease, and a protodiastolic (ventricular, third) heart sound or summation gallop rhythm may be present. Electrocardiographic changes of left ventricular hypertrophy (Chap. 226) may occur, but the electrocardiogram substantially underestimates the frequency of cardiac hypertrophy compared with that observed with the echocardiogram. Evidence of ischemia or infarction may be observed late in the disease. Most deaths due to hypertension result from myocardial infarction or congestive heart failure. Recent data suggest that some of the myocardial damage may be mediated by aldosterone in the presence of a normal/high salt intake rather than just the increased blood pressure or an increase in angiotensin II levels per se.

NEUROLOGIC EFFECTS

The neurologic effects of long-standing hypertension may be divided into retinal and central nervous system changes. Because the retina is the only tissue in which the arteries and arterioles can be examined directly, repeated ophthalmoscopic examination provides the opportunity to observe the progress of the vascular effects of hypertension (Table 35-2). The Keith-Wagener-Barker classification of the *retinal changes* in hypertension has provided a simple and excellent means for serial evaluation of hypertensive patients. Increasing severity of hypertension is associated with focal spasm and progressive general narrowing of the arterioles, as well as the appearance of hemorrhages, exudates, and papilledema. These retinal lesions often produce scotomata, blurred vision, and even blindness, especially when there is papilledema or hemorrhages of the macular area. Hypertensive lesions may develop acutely and, if therapy results in significant reduction of blood pressure, may show rapid resolution. Rarely, these lesions resolve without therapy. In contrast, retinal arteriolosclerosis results from endothelial and muscular proliferation, and it accurately reflects similar changes in other organs. Sclerotic changes do not develop as rapidly as hypertensive lesions, nor do they regress appreciably with therapy. As a consequence of increased wall thickness and rigidity, sclerotic arterioles distort and compress the veins where the two vessel types cross in their common fibrous sheath, and the reflected light streak from the arterioles is changed by the increased opacity of the vessel wall.

Central nervous system dysfunction also occurs frequently in patients with hypertension. Occipital headaches, most often occurring in the morning, are among the most

prominent early symptoms of hypertension. Dizziness, light-headedness, vertigo, tinnitus, and dimmed vision or syncope may also be observed, but the more serious manifestations are due to vascular occlusion, hemorrhage, or encephalopathy (Chap. 361). The pathogeneses of the former two disorders are quite different. *Cerebral infarction* is secondary to the increased atherosclerosis observed in hypertensive patients, whereas *cerebral hemorrhage* is the result of both the elevated arterial pressure and the development of cerebral vascular microaneurysms (Charcot-Bouchard aneurysms). Only age and arterial pressure are known to influence the development of the microaneurysms. Thus, it is not surprising that arterial pressure shows a better association with cerebral hemorrhage than with either cerebral or myocardial infarction.

Hypertensive encephalopathy consists of the following symptom complex: severe hypertension, disordered consciousness, increased intracranial pressure, retinopathy with papilledema, and seizures. The pathogenesis is uncertain but is probably not related to arteriolar spasm or cerebral edema. Focal neurologic signs are infrequent and, if present, suggest that infarction, hemorrhage, or transient ischemic attacks are more likely diagnoses. Although some investigators have suggested that prompt lowering of arterial pressure in these patients may adversely affect cerebral blood flow, most studies indicate that this is not the case.

EFFECTS ON THE KIDNEY (See alsoChap. 278)

Arteriosclerotic lesions of the afferent and efferent arterioles and the glomerular capillary tufts are the most common renal vascular lesions in hypertension and result in a decreased glomerular filtration rate and tubular dysfunction. Proteinuria and microscopic hematuria occur because of glomerular lesions, and approximately 10% of the deaths caused by hypertension result from renal failure. Blood loss in hypertension occurs not only from renal lesions; epistaxis, hemoptysis, and metrorrhagia also occur frequently in these patients.

Approach to the Patient

The detailed initial evaluation of the hypertensive patient is outlined inChap. 35. It includes the critical elements of the history, physical examination, and basic laboratory investigation that aid in arriving at appropriate diagnostic and therapeutic decisions (Table 35-2).

DIAGNOSIS OF SECONDARY HYPERTENSION

Certain clues from the history, physical examination, and basic laboratory studies may suggest an unusual cause for the hypertension and dictate the need for special studies. For example, the abrupt onset of severe hypertension and/or the onset of hypertension of any severity in a patient under the age of 25 or over the age of 50 should lead to laboratory tests to exclude renovascular hypertension and pheochromocytoma. A history of headaches, palpitations, anxiety attacks, unusual sweating, hyperglycemia, and weight loss should also lead to tests to exclude pheochromocytoma. The presence of an abdominal bruit should lead to a workup for renovascular hypertension, and the finding on physical examination of bilateral upper abdominal masses consistent with polycystic renal disease should lead to the performance of an abdominal ultrasound

examination or intravenous pyelogram (IVP). An elevated creatinine or blood urea nitrogen level, associated with proteinuria and hematuria, should prompt a detailed workup for renal insufficiency (Chap. 268). Special studies for secondary hypertension are also indicated if there is therapeutic failure with the initial drug program. The specific diagnostic measures depend on the most likely causes of secondary hypertension.

Pheochromocytoma (See also Chap. 332) The easiest and best screening procedure for pheochromocytoma is the measurement of catecholamines and their metabolites in a 24-h urine sample collected while the patient is hypertensive. Measurement of plasma catecholamine levels may also be useful. These tests may be indicated even in patients who do not have episodic hypertension, since over half the patients with pheochromocytoma have fixed hypertension. Provocative tests are seldom, if ever, indicated, although occasionally a suppressive test may be useful.

Cushing's Syndrome (See alsoChap. 331) A 24-h urine test for cortisol and creatinine or the administration of 1 mg of dexamethasone at bedtime, followed by the measurement of plasma cortisol at 7 to 10 A.M., is the best test to screen for the presence of Cushing's syndrome. A urine cortisol level of<2750 nmol (100 ug) or suppression of the plasma cortisol level to <140 nmol/L (5 ug/dL) effectively rules out Cushing's syndrome.

Renovascular Hypertension (See also Chap. 278) Over the past decades the standard approach to screen for renovascular hypertension has progressed from the rapid-sequence IVP to one of three noninvasive techniques: the captopril-enhanced radionuclide renal scan (the preferred choice), a duplex Doppler flow study, or magnetic resonance (MRI) angiography. However, perhaps the most sensitive and specific screening test, the spiral computed tomography (CT) scan, which gives a three-dimensional view, unfortunately also requires giving an intravenous contrast agent.

The definitive test for surgically correctable renal disease is the combination of a renal angiogram and renal vein renin determinations. The renal arteriogram both establishes the presence of a renal arterial lesion and aids in the determination of whether the lesion is due to atherosclerosis or to one of the fibrous or fibromuscular dysplasias. It does not, however, prove that the lesion is responsible for the hypertension, nor does it permit prediction of the chances of surgical cure. It must be noted that (1) renal artery stenosis is a frequent finding by angiography and at postmortem in normotensive individuals, and (2) essential hypertension is a common condition and may occur in combination with renal arterial stenosis that is not responsible for the hypertension. Bilateral renal vein catheterization for measurement of plasma renin activity is therefore used to assess the functional significance of any lesion noted on arteriography. When one kidney is ischemic and the other is normal, all the renin released comes from the involved kidney. In the most straightforward situation, the ischemic kidney has a significantly higher venous plasma renin activity than the normal kidney, by a factor of 1.5 or more. Moreover, the renal venous blood draining the uninvolved kidney exhibits levels similar to those in the inferior vena cava below the entrance of the renal veins.

Significant benefit from operative correction may be anticipated in at least 80% of patients with the findings described above if care is taken to prepare the patient properly

before renal vein blood sampling, i.e., by discontinuing renin-suppressing drugs, such as beta blockers, for at least 10 days; restricting the patient to a low-sodium intake for 4 days; and/or giving a converting-enzyme inhibitor for 24 h. When obstructing lesions in the *branches* of the renal arteries are demonstrated by arteriography, an attempt to obtain blood samples from the main *branches* of the renal vein should be made in an effort to identify a localized intrarenal arterial lesion responsible for the hypertension.

Primary Aldosteronism (See also Chap. 331) These patients usually exhibit hypokalemia. Diuretic therapy often complicates the picture when the hypokalemia is first observed and needs to be assessed. Given the presence of hypokalemia, the relation between plasma renin activity and the aldosterone level becomes the key to the diagnosis of primary aldosteronism. The aldosterone concentration or excretion rate is high and plasma renin activity is low in primary aldosteronism, and these levels are relatively unaffected by changes in sodium balance. Thus, the aldosterone:renin ratio is high. A critical part of the evaluation after primary aldosteronism has been established is to determine whether disease is unilateral or bilateral, because surgical removal of the lesion usually reduces arterial pressure only in patients with unilateral disease.

Plasma Renin Activity Measurements Some studies have suggested that the plasma renin level should be measured in most hypertensive patients and related to a 24-h urine sodium excretion rate to assess whether high, low, or normal renin levels are present. It has been proposed that this information may be important for both therapeutic and prognostic reasons. However, as noted earlier, it is unclear, on the basis of the available data and treatment programs, that these random measurements are really useful except in patients with findings suggestive of renal vascular disease or mineralocorticoid excess in whom lateralizing renal vein renin levels or suppressed peripheral renin levels may be of diagnostic and/or therapeutic significance.

TREATMENT

Indications for Therapy Virtually every patient with a diastolic arterial pressure that persistently exceeds 90 mmHg, or any patient over 65 years of age with a systolic arterial pressure >160 mmHg, is a candidate for diagnostic studies and for subsequent treatment. Furthermore, at any given level of blood pressure elevation, the ultimate risk of developing hypertensive vascular complications is greater in men than in women, in younger than in older persons, and in diabetic than nondiabetic patients. It may be argued, then, that it is hard to justify producing the uncomfortable side effects of therapy in, for example, an asymptomatic woman over 70 years of age with a diastolic pressure of 90 mmHg. On the other hand, it is easy to justify side effects in a man of 30 with a diastolic pressure exceeding 110 mmHg because such a person may be expected to receive the greatest benefit from therapy. Fortunately, the choice of treatment is such that a satisfactory program to control arterial pressure with minimal side effects can be developed for most patients, particularly as more studies assessing the impact of specific therapeutic agents on the patient's quality of life are reported.

A reasonable guideline would be that all patients with a diastolic pressure repeatedly>90 mmHg or systolic pressure>140 mmHg should be treated unless specific contraindications exist. Patients with isolated *systolic* hypertension (levels >160 mmHg with diastolic pressure<89 mmHg) should also be treated if they are over age 65. It is

uncertain that individuals under age 65 who have isolated systolic hypertension will benefit from therapy until the results of a well-controlled, prospective study are completed. Patients with labile hypertension or isolated systolic hypertension who are not treated should have regular follow-up examinations at 6-month intervals because of the frequent development of progressive and/or sustained hypertension. Finally, if coronary artery disease or associated cardiovascular risks are present, then treatment of a patient with a lower blood pressure may be warranted. For example, patients with angina pectoris or diabetes mellitus with diastolic blood pressures between 85 and 90 mmHg may be candidates for antihypertensive therapy.

What should the blood pressure goal be? Previously it was assumed that 140/90 mmHg was the desired level. This still seems reasonable for nondiabetic patients since the Hypertension Optimal Treatment (HOT) study did not detect a significant difference in cardiovascular risk between patients with treatment goal diastolic blood pressures of 90 and 80 mmHg. However, in patients with diabetes this is not the case. In the UK Prospective Diabetes Study (UKPDS), individuals with a blood pressure of 144/82 mmHg had a substantially lower risk compared to those with a blood pressure of 154/87 mmHg. The HOT study investigators documented a similar finding in their diabetic subset. Thus, it seems reasonable to target a blood pressure in the normal range for diabetic patients, i.e., 130/85 mmHg. While not definitively proven, it seems prudent to use the same goal in all young and middle-aged patients depending on what other cardiovascular risk factors are present. For elderly individuals, a goal of 140/90 mmHg is appropriate, although definitive data for lowering systolic blood pressure below 160 mmHg is still lacking. Importantly, how aggressive one should be in achieving these blood pressure goals depends on the number and severity of other risk factors present.

The identification of an operable form of secondary hypertension does not automatically mean that surgical treatment is indicated. The decision depends on the age and general health of the patient, the natural history of the lesion, and the response of the arterial pressure to drug therapy. In patients with renovascular hypertension, the feasibility of renal angioplasty, the advantages of surgical repair versus nephrectomy, and the degree of overall renal functional impairment must be considered. Age and general health are important in patients with renovascular hypertension due to arteriosclerosis, because there is no evidence that repair of the stenosis increases life expectancy in the elderly patient with other evidence of vascular disease. Knowledge of the natural history of the disease is especially important when making a decision in the case of a young patient with renal artery stenosis due to fibrous dysplasia. If the arteriographic appearance suggests that the stenosis is due to intimal or subadventitial fibroplasia, the lesion may be expected to progress, and operation or angioplasty is required. Medial fibroplasia, on the other hand, often remains stable, and operation or angioplasty may not be necessary if pressure can be controlled by drug therapy.

The decision regarding operation should also be considered carefully in patients with primary aldosteronism when neither abdominalCT nor bilateral adrenal venous sampling for aldosterone demonstrates a tumor, because such patients may prove to have multinodular hyperplasia. In that case, bilateral adrenalectomy would be required to eliminate the aldosterone excess, and, even then, hypertension would usually persist. If hypokalemia can be controlled by an aldosterone receptor antagonist, e.g., spironolactone, or other drug therapy and arterial pressure lowered with

antihypertensive agents, then it is reasonable to withhold operative treatment.

GENERAL MEASURES

Nondrug therapeutic intervention is probably indicated in all patients with sustained hypertension and probably in most with labile hypertension. The general measures employed include (1) relief of stress, (2) dietary management, (3) regular aerobic exercise, (4) weight reduction (if needed), and (5) control of other risk factors contributing to the development of arteriosclerosis. Relief of emotional and environmental stress is one of the reasons for the improvement in hypertension that occurs when a patient is hospitalized. Though it is usually impossible to extricate the hypertensive patient from all internal and external stresses, he or she should be advised to avoid unnecessary tensions. In rare instances, it may be appropriate to recommend a change of job or of life-style. It has been suggested that relaxation techniques may also lower arterial pressure. However, it is uncertain that these techniques alone have much long-term effect.

Dietary management has three aspects:

1. Because of the documented efficacy of sodium restriction and volume contraction in lowering blood pressure, patients previously were instructed to curtail sodium intake drastically. Some investigators have suggested that this is not necessary. They base their conclusion on two observations: (1) In many patients the blood pressure is not sensitive to the level of sodium intake, and (2) diuretics provide another method of decreasing body sodium stores in individuals whose blood pressure is sodium-sensitive. However, meta-analyses of previous diet studies have documented a 5-mmHg reduction in systolic pressure and a 2.6-mmHg reduction in diastolic pressure when sodium intake is reduced by approximately 75 meq/d. In addition, several reports have documented that, while mild sodium restriction has little if any direct action on blood pressure, it significantly potentiates the efficacy of nearly all antihypertensive agents. Thus, by making it possible to control blood pressure with lower doses of drugs, sodium restriction leads to a reduction in side effects. In addition, it is quite clear that in some hypertensive patients, as noted above, the level of sodium intake does influence the blood pressure. Thus, since there is no apparent risk to mild sodium restriction, the most practical approach now is to advise mild dietary sodium restriction (up to 5 g NaCl per day), which can be achieved by eliminating all additions of salt to food that is prepared normally. Some studies have also reported a lowering of arterial pressure related to an *increase* in potassium and/or calcium intake. For example, in one meta-analysis, dietary potassium supplements of 50 to 120 meq/d reduced blood pressure by about the same amount as salt restriction (by 6 mmHg systolic and 3.4 mmHg diastolic). While the advisability of these forms of dietary alteration is still controversial, the fact that a moderately high calcium intake (1.5 g elemental calcium daily) probably also reduces the extent of age-related osteoporosis, combined with the results of the potassium supplementation studies, indicate that they are probably useful adjuncts. A particularly useful approach is the DASH (Dietary Approaches to Stop Hypertension) diet, which uses natural foods that are high in potassium and low in saturated and total fat. This diet significantly lowered blood pressure in borderline and stage 1 hypertensive subjects (see Table 35-1 for definitions).

2. Caloric restriction should be urged for patients who are overweight. Some obese patients will show a significant reduction in blood pressure simply as a consequence of weight loss. In the Trial of Antihypertensive Interventions and Management (TAIM) study, weight reduction (average 4.4 kg over 6 months) lowered blood pressure by 2.5 mmHg.

3. A restriction in the intake of cholesterol and saturated fats is recommended, as this diet modification may diminish the incidence of arteriosclerotic complications. Reducing alcohol intake to <15 mL daily is also beneficial. Regular exercise is indicated within the limits of the patient's cardiovascular status. Not only is exercise helpful in controlling weight, but there is also evidence that physical conditioning itself may lower arterial pressure. Isotonic exercises (jogging, swimming) are better than isometric exercises (weight lifting) since the latter, if anything, raises arterial pressure. The dietary management outlined above is aimed at the control of other risk factors. Probably the most significant additional step that could be taken in this area would be to convince the smoker to give up cigarettes.

DRUG THERAPY FOR HYPERTENSION (Table 246-6)

To make rational use of antihypertensive drugs, the sites and mechanisms of their action must be understood. In general, there are six classes of drugs: diuretics, antiadrenergic agents, vasodilators, calcium entry blockers, angiotensin-converting enzyme (ACE) inhibitors, and angiotensin receptor antagonists.

DIURETICS (See alsoChap. 232)

The thiazides are the most frequently used and most extensively investigated members of this group, and their early effect is certainly related to sodium diuresis and volume depletion. A reduction in peripheral vascular resistance has also been reported by some workers to be important in the long term. Traditionally, thiazide diuretics have formed the cornerstone of most therapeutic programs designed to lower arterial pressure, and they are usually effective within 3 to 4 days. Furthermore, they have been shown to reduce mortality and morbidity in long-term trials. However, in recent years there has been increasing resistance to their routine use, primarily because of their adverse metabolic effects, which include hypokalemia due to renal potassium loss, hyperuricemia due to uric acid retention, carbohydrate intolerance, and hyperlipidemia. These effects are minimized if the dose is kept below the equivalent of 25 mg/d of hydrochlorothiazide. The more potent loop-acting diuretics furosemide and bumetanide have also been shown to be antihypertensive but have been used less extensively for this indication, primarily because of their shorter duration of action. Spironolactone causes renal sodium loss by blocking the effect of mineralocorticoids, and, therefore, it may be more effective in patients whose mineralocorticoid levels are excessive, such as patients with primary or secondary aldosteronism. However, a clinical trial in heart failure using low doses of spironolactone achieved a 30% reduction in mortality, suggesting that an aldosterone receptor antagonist may be beneficial even when aldosterone levels are relatively normal. Although they do not compete directly with aldosterone, triamterene and amiloride act at the same site as spironolactone to impede sodium reabsorption. They are effective in the same situations as an aldosterone receptor antagonist, except that triamterene has little intrinsic antihypertensive effect.

Their major disadvantage is that they can produce hyperkalemia, particularly in patients with impaired renal function. Any of these three potassium-sparing diuretics can also be given along with thiazide diuretics to minimize renal potassium loss.

ANTIADRENERGIC AGENTS (See alsoChap. 72)

These drugs act at one or more sites -- centrally on the vasomotor center, in peripheral neurons, where they modify catecholamine release, or in target tissues, where they block adrenergic receptor sites. Drugs that appear to have predominant *central actions* are *clonidine*, *methyldopa*, *guanabenz*, and *guanfacine*. These drugs and their metabolites are predominantly a-receptor agonists. Stimulation of a_2 receptors in the vasomotor centers of the brain *reduces* sympathetic outflow, thereby reducing arterial pressure. Usually a fall in cardiac output and heart rate also occurs, more commonly with clonidine and guanabenz, but the baroreceptor reflex is intact. Thus, postural symptoms are absent. However, rebound hypertension may occur rarely when these drugs, particularly clonidine and guanabenz, are stopped. This effect is probably secondary to an increase in norepinephrine release, which is inhibited by these agents owing their agonist effect on presynaptic a receptors. They are usually not used as first-line therapy.

Another class of antiadrenergic agents consists of the *ganglionic blocking drugs*, which are used infrequently now. Because of their side effects, ganglionic blocking agents are now usually reserved for the rapid lowering of arterial pressure by parenteral administration of the short-acting agent *trimethaphan* in patients with severe hypertension.

Various drugs act at *postganglionic adrenergic nerve endings*, but they are rarely used now because of their side effects. *Guanethidine* and its shorter-acting analogue guanadrel block the release of norepinephrine from adrenergic nerve endings. They usually reduce cardiac output and lower systolic more than diastolic blood pressure. They also produce a greater postural effect than the other drugs that act at the nerve endings, and orthostatic hypotension is a frequent side effect.

The last group of drugs affecting the adrenergic system are those that block the *peripheral adrenergic receptors*, a,b, or both (Chap. 72).

a-Adrenergic Receptor Blockers These agents also usually are not used as first-line therapy. *Phentolamine* and *phenoxybenzamine* block the action of norepinephrine at a-adrenergic receptor sites. These two compounds block both presynaptic (a_2) and postsynaptic (a_1) a receptors, and the former action accounts for the tolerance that develops. *Prazosin* is more effective because it selectively blocks only *postsynaptic* a receptors, i.e., a_1 receptors. Thus, presynaptic a activity remains, suppressing norepinephrine release, and tolerance occurs only infrequently. Accordingly, prazosin produces less tachycardia but more postural hypotension than direct-acting vasodilators, such as hydralazine, and rarely can produce substantial hypotension following the first dose. Its use has decreased with a report of its association with an increase in cardiovascular events.

b-Adrenergic Receptor Blockers (See also Chap. 244) A number of

effective*b-adrenergic receptor blocking agents* are available that block sympathetic effects on the heart and should be most effective in reducing cardiac output and in lowering arterial pressure when there is increased cardiac sympathetic nerve activity. These agents *are* often used as first-line therapy. In addition, they block the adrenergic nerve-mediated release of renin from the renal juxtaglomerular cells. This action may be an important component of their blood pressure-lowering action.b-Adrenergic blockers are particularly useful when employed in conjunction with vascular smooth-muscle relaxants, which tend to evoke a reflex increase in heart rate, and with diuretics, the administration of which often results in an elevation of circulating renin activity. In practice, beta blockers appear to be effective even when there is no evidence of increased sympathetic tone, with about one-half or more of all hypertensive patients showing a fall in pressure. Furthermore, like diuretics, they have been shown to reduce morbidity and mortality in long-term clinical trials. However, these agents can precipitate congestive heart failure and asthma in susceptible individuals, and they must be used with caution in diabetic patients receiving hypoglycemic therapy because they inhibit the usual sympathetic responses to hypoglycemia. Cardioselective beta-blocking agents (so-called $beta_1$blockers, e.g., metoprolol, atenolol) have been developed and may be superior to nonselective beta blockers such as propranolol and timolol in patients with bronchospasm. Nadolol, a nonselective beta blocker, unlike other drugs of this class, is excreted unchanged in the urine and has a half-life of 14 to 20 h; only one dose a day is required. Atenolol also usually needs to be given only once a day. Pindolol and acebutolol are nonselective beta blockers that have partial agonist activity and, therefore, produce less bradycardia. Labetalol exerts both a- andb-adrenergic blocking actions. It is usually not used as first-line therapy as there is no mortality study in which it has been tested. Thus, it lowers arterial pressure not only by the same complex actions as do beta blockers but also directly by reducing systemic vascular resistance. Usually it has a more rapid onset of action but produces more postural symptoms and chronic sexual dysfunction than the other beta blockers.

VASODILATORS

These agents are usually not used for initial therapy. *Hydralazine* is the most versatile of the drugs that cause direct relaxation of vascular smooth muscle; it is effective both orally and parenterally and acts mainly on arterial resistance rather than on venous capacitance vessels, as evidenced by lack of postural effects. Unfortunately, the effect of hydralazine on peripheral resistance is partly negated by a reflex increase in sympathetic discharge that raises heart rate and cardiac output. This response limits the usefulness of hydralazine, especially in patients with severe coronary artery disease. However, the efficacy of hydralazine can be increased if it is given in conjunction with a beta blocker or a drug such as methyldopa or clonidine, all of which block reflex sympathetic stimulation of the heart. A serious side effect of doses of hydralazine exceeding 300 mg/d has been the production of a lupus erythematosus-like syndrome.

Minoxidil is even more potent than hydralazine but unfortunately produces significant hypertrichosis and fluid retention and, therefore, is mainly limited to patients with severe hypertension and renal insufficiency.

Diazoxide, a thiazide derivative, is restricted in its application to acute situations. It is not a diuretic; in fact, it causes sodium retention. However, like other thiazides, it reduces

carbohydrate tolerance. It must be given rapidly intravenously to guarantee an effect. It begins to act immediately to lower blood pressure, and its effects may last for several hours. *Nitroprusside* given intravenously also acts as a direct vasodilator, with onset and offset of actions that are almost immediate. *Nitroglycerin* is a third direct-acting vasodilator useful as an intravenous agent. These latter three drugs are useful only for the treatment of hypertensive emergencies (Table 246-7).

ACE INHIBITORS

Drugs from several of the categories discussed above have been shown to possess an additional action resulting in inhibition of renin secretion. These include clonidine, reserpine, methyldopa, and beta blockers. A second group of drugs inhibit the enzyme converting angiotensin I into angiotensin II -- ACE. These agents are an increasingly popular choice for initial therapy. They are useful because they not only inhibit the generation of a potent vasoconstrictor (angiotensin II) but also may retard the degradation of a potent vasodilator (bradykinin), alter prostaglandin production (an effect most notable with captopril), and can modify the activity of the adrenergic nervous system. They are especially useful in renal or renovascular hypertension and in diabetic patients, as well as in accelerated and malignant hypertension. However, in patients with bilateral renal artery stenosis, rapid deterioration of renal function may occur. They are also as effective in mild, uncomplicated hypertension as beta blockers and thiazides -- and have fewer side effects, particularly ones that adversely affect the patient's quality of life.

These drugs should be used with caution when the renin system is activated (e.g., by severe heart failure, prior diuretic therapy, or substantial salt restriction) to avoid profound hypotension. Usually, diuretics are stopped 2 to 3 days before administration of an ACEinhibitor is begun and are added back later if needed.

ANGIOTENSIN RECEPTOR ANTAGONISTS

These drugs have effects similar to those ofACEinhibitors. However, instead of blocking the production of angiotensin II, they competitively inhibit its binding to the angiotensin II AT_1receptor subtype. Their utility and tolerability are similar to those of the ACE inhibitors, but they do not cause cough or angioedema.

CALCIUM CHANNEL ANTAGONISTS

There are three subclasses of calcium channel antagonists: the phenylalkylamine derivatives (e.g., verapamil), the benzothiazepines (e.g., diltiazem), and the dihydropyridines (e.g., amlodipine). To date, there is only one therapeutic agent in each of the first two classes but a number of agents in the third class. All three subclasses modify calcium entry into cells by interacting with specific binding sites on the$\alpha_1$subunit of the L-type voltage-dependent calcium channel. Thus, since there are other calcium channels (e.g., the T and N types), the actions of these drugs only partially modify total calcium transport into cells. The relative specificity of each agent stems from the fact that each class has a unique binding site on the$\alpha_1$subunit, and these sites are variably expressed in different tissues. Thus, while agents from all three subclasses cause vasodilation, usually only dihydropyridines produce reflex tachycardia. Diltiazem and

verapamil can both slow atrioventricular conduction -- a feature not observed with the dihydropyridines. While calcium channel antagonists are also useful in angina pectoris (Chap. 244), because of their negative inotropic actions, they should be used with caution in hypertensive patients with heart failure. Considerable controversy has surrounded the use of calcium channel antagonists in the treatment of hypertension. In part the controversy was secondary to the inadequacy of the data and the confusion between the use of short-acting agents (e.g., nifedipine) and long-acting agents. Several facts have helped partially to resolve this controversy. First has been the general recognition that despite its previously frequent use as an antihypertensive agent, short-acting nifedipine rarely, if ever, should be used to treat hypertension, since it has been reported to increase the incidence of acute coronary events. Second, the results of the SYST-EUR (Systolic Hypertension in Europe) trial documented that a long-acting calcium channel antagonist reduced mortality to an extent equivalent to that previously reported for diuretics and beta blockers. Thus, long-acting calcium channel antagonists are often used as first-line therapy.

APPROACH TO DRUG THERAPY

The aim of drug therapy is to use the agents just described, alone or in combination, to return arterial pressure to normal levels with minimal side effects. Ideally, one would choose a therapeutic program that specifically corrects the underlying defect resulting in the elevated blood pressure -- for example, treatment with spironolactone for patients with primary aldosteronism. As our knowledge of the mechanisms underlying the hypertension in individual patients increases, more specific drug programs will become available. Such programs presumably will result in normalization of blood pressure with fewer side effects. In the absence of this information, an empirical approach is used, which takes into consideration efficacy, safety, impact on the quality of life, compliance, ease of administration, and cost. When used in combination, drugs are chosen for their different sites of action. However, except for those patients with severe hypertension (average diastolic blood pressure>130 mmHg), in whom intensive therapy with several agents simultaneously is usually required, most patients are treated *initially* with a single agent.

Since many effective antihypertensive agents are available, a number of useful therapeutic regimens have been developed. There are two major authoritative groups who have treatment guidelines when the patient's condition does not require a specific approach: World Health Organization-International Society of Hypertension (WHO-ISH) (Figs. 246-1 and246-2) and the Sixth U.S. Joint National Committee (JNC) on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (JNC VI). In the absence of specific therapy, their approaches are similar in most respects, relying heavily on the results of randomized clinical trials (Table 246-8), except for which drugs should be used to initiate therapy. JNC VI recommends starting with diuretics and/or beta blockers because they are the ones where mortality trials have demonstrated a positive effect of treatment. The WHO-ISH guidelines recommends initiating therapy with any of six classes of agents (Table 246-9). The different recommendations, in part, reflect the fact that the WHO-ISH committee reviewed more recent data from mortality clinical trials that, in one case, documented a reduction in morbidity and mortality with a long-acting calcium channel antagonist versus placebo that was similar to previous reports for diuretics and beta blockers and, in another case, reported thatACEinhibitors

were as effective as beta blockers and diuretics in reducing mortality (Table 246-8).

There are several critical caveats common to both approaches:

1. Start with a low dose of an agent and, if blood pressure is not controlled, increase only moderately.

2. Start with an agent that may also treat and/or not harm a coexisting condition.

3. Add a second agent from a different, complementary class if blood pressure is not controlled with a moderate dose of the first agent.

4. Start with an agent that the patient is likely to tolerate best; long-term compliance is related to tolerability and efficacy of the first agent used.

5. Use a diuretic when two agents are used, in nearly all cases.

6. Use thiazide diuretics only at low doses, i.e., £25 mg/d of hydrochlorothiazide or its equivalent, unless some pressing reason exists.

7. Use low-dose combination therapy when appropriate as initial therapy:

a. A diuretic with a beta blocker, ACE inhibitor, or angiotensin II antagonist;

b. A calcium channel blocker with an ACE inhibitor or a beta blocker

8. One or two agents will control blood pressure in 90% of hypertensive patients; to achieve a diastolic blood pressure of <90 mmHg in the HOTstudy, two agents were required in 70% of cases.

If therapy with two drugs does not achieve blood pressure control, the primary agent should be increased to full dose, e.g., 100 mg of captopril or atenolol, 20 mg of enalapril, or 360 mg of diltiazem. If the blood pressure is still not controlled, then a detailed search for a secondary cause of hypertension, as outlined above, is indicated. If none is found, then a dietary assessment will often reveal a high sodium intake. With reduction in salt intake to 5 g/d or less, blood pressure is often controlled. If the blood pressure is still not controlled, then the primary agent should be switched, maintaining the thiazide. Caution should be used if anACEinhibitor was not the original agent, as administration of such an agent to a patient who is already taking a diuretic occasionally may lead to profound hypotension. If none of these changes produces better control of arterial pressure, then the combination of a calcium channel antagonist and an ACE inhibitor, or triple therapy, usually with a diuretic, ACE inhibitor, and hydralazine, may be effective.

If the blood pressure is controlled, then a stepwise reduction in the dose and/or withdrawal of some of the agents should be carried out to determine the minimal therapeutic program that will maintain the blood pressure at 140/90 mmHg or less. Whether triple or quadruple drug therapy is warranted to lower blood pressure further is uncertain.

Fewer than 5% of patients will still be hypertensive at this point. For these, one first should consider the reasons for therapeutic failure, as shown inTable 246-10. If none can be identified, then one of the other agents, such as one of the vasodilators listed inTable 246-6 (e.g., hydralazine) or an antiadrenergic agent (e.g., prazosin or clonidine), should be added. If blood pressure is controlled, previous drugs are withdrawn sequentially to determine the minimal therapeutic program that will maintain a normal blood pressure.

While the recommendations outlined above are satisfactory for a large majority of patients, it is important to use a flexible approach, because individual patients may respond differently to individual drugs and drug combinations. For those patients requiring multiple drugs, once the appropriate combination has been found, the use of a single formulation with the appropriate combination of drugs may simplify the regimen and thereby increase compliance. Every effort should be made to reduce the number of times each day the patients must interrupt their schedules for the medication. Pharmacologic treatment of essential hypertension is usually lifelong, and since most patients are asymptomatic, compliance with a complex regimen may be a serious problem, particularly if the therapeutic regimen has a negative impact on the quality of the patient's life. Finally, it is uncertain what level of arterial pressure should be accepted as representing adequate control. It is clear that reducing diastolic blood pressure to<90 mmHg is appropriate and reduces morbidity and/or mortality.

Five groups of patients with hypertension require special consideration because of associated conditions. These groups are considered in the following sections.

RENAL DISEASE

Reduction of arterial pressure in hypertensive patients with impaired renal function is often accompanied initially by an increase in serum creatinine. This change does not represent further structural renal damage and should not deter the physician from continuing the therapy, since achievement of blood pressure control may eventually reduce the value toward normal. However, if serum creatinine increases in a patient treated with a converting-enzyme inhibitor, care needs to be exercised, because these patients may have bilateral renal artery disease. Their renal function will continue to deteriorate as long as the converting-enzyme inhibitor is given. Thus, converting-enzyme inhibitors should be used cautiously in patients with impaired renal function, and renal function should be assessed frequently (every 4 to 5 days) for the first 3 weeks. While converting-enzyme inhibitors are contraindicated in patients with bilateral renal artery stenosis, these are the drugs of choice in patients with unilateral renal artery stenosis and a normally functioning contralateral kidney and probably also in patients with chronic renal failure with or without diabetes mellitus.

CORONARY ARTERY DISEASE

In these patients, who also may be taking cardiac glycosides, thiazides should be used judiciously, and a reduction in serum potassium levels should be watched for and, if found, should be corrected rapidly. Beta blockers should be withdrawn carefully, if at all, in these patients. Finally, calcium channel antagonists and converting-enzyme inhibitors

may be useful in these patients because they minimize a number of potential adverse reactions that accompany the use of other therapeutic agents, particularly nonspecific vasodilators.

DIABETES MELLITUS

The diabetic patient with hypertension is particularly challenging to treat because many of the agents used to lower blood pressure can affect glucose metabolism adversely. Converting-enzyme inhibitors may be particularly useful in these individuals. They have no known adverse effects on glucose or lipid metabolism and minimize the development of diabetic nephropathy by reducing renal vascular resistance and renal perfusion pressure -- the primary factor underlying renal deterioration in these patients.

PREGNANCY

The patient who is pregnant and hypertensive or who develops hypertension during pregnancy (pregnancy-induced hypertension, preeclampsia, eclampsia) is particularly difficult to treat. Because it is uncertain whether autoregulation of uterine blood flow occurs, lowering blood pressure in the pregnant hypertensive patient may result in reduced placental and fetal perfusion. Thus, a conservative approach to lowering blood pressure is usually indicated. In the second and third trimesters, antihypertensive agents are often not indicated unless the diastolic pressure exceeds 95 mmHg. In general, severe salt restriction and/or diuretics are not used because of the associated increase in fetal wastage. Beta blockers need to be used cautiously for similar reasons. Methyldopa and hydralazine, and to a lesser extent calcium channel antagonists, are the antihypertensive agents used most often, because they have no known adverse effects on the fetus. Little is known about the safety of other antihypertensive agents in pregnancy, except that nitroprusside and converting-enzyme inhibitors may cause adverse effects on the fetus and are contraindicated.

ELDERLY PATIENTS

Hypertensive patients who are over age 65, and particularly those over age 75, offer substantial challenges to the physician. Several studies have reported that healthy elderly patients, whether male or female, who are treated with relatively modest doses of antihypertensive agents show a substantial reduction in strokes and stroke-related deaths. This is true whether the patient has systolic and diastolic hypertension or isolated systolic hypertension. What is not clear from these studies is how broadly the results can be extrapolated, since the studies were performed in healthy elderly patients, while many such patients have other diseases. Thus, in the elderly hypertensive patient, individualization of therapy still seems warranted.

Probably fewer than one-third of hypertensive patients in the United States are being treated effectively. Only a small number of these failures are related to drug unresponsiveness. Most are related to (1) failure to detect hypertension, (2) failure to institute effective treatment of an asymptomatic hypertensive patient, and (3) failure of the asymptomatic hypertensive patient to adhere to therapy. To help with the latter problem, patients must be educated to continue treatment once an effective regimen has been identified. Side effects and inconveniences of treatment must be minimized or

counteracted in order to obtain the patient's continued cooperation.

MALIGNANT HYPERTENSION

In addition to marked blood pressure elevation in association with papilledema and retinal hemorrhages and exudates, the full-blown picture of malignant hypertension may include manifestations of hypertensive encephalopathy, such as severe headache, vomiting, visual disturbances (including transient blindness), transient paralyses, convulsions, stupor, and coma. These manifestations have been attributed to spasm of cerebral vessels and to cerebral edema. In some patients who have died, multiple small thrombi have been found in the cerebral vessels. Cardiac decompensation and rapidly declining renal function are other critical features of malignant hypertension. Oliguria may, in fact, be the presenting feature. The vascular lesion characteristic of malignant hypertension is fibrinoid necrosis of the walls of small arteries and arterioles, and this development can be reversed by effective antihypertensive therapy.

The pathogenesis of malignant hypertension is unknown. However, at least two independent processes -- dilation of cerebral arteries and generalized arteriolar fibrinoid necrosis -- contribute to the associated signs and symptoms. The cerebral arteries dilate because the normal autoregulation of cerebral blood flow decompensates as a result of the markedly elevated arterial pressure. Cerebral blood flow therefore is excessive, producing the encephalopathy associated with malignant hypertension. Many patients also show evidence of a microangiopathic hemolytic anemia; this secondary phenomenon could contribute to the deterioration of renal function. Most patients also have elevated levels of peripheral plasma renin activity and increased aldosterone production, and these effects may be involved in causing vascular damage.

Perhaps fewer than 1% of hypertensive patients develop the malignant phase, which can occur in the course of both essential and secondary hypertension. Rarely, it is the first recognized manifestation of the blood pressure problem, and it is unusual for it to occur in patients under treatment. The average age at diagnosis is 40, and men are affected more often than women. Prior to the availability of effective therapy, the life expectancy after diagnosis of malignant hypertension was less than 2 years, with most deaths being due to renal failure, cerebral hemorrhage, or congestive heart failure. With the advent of effective antihypertensive therapy, at least half the patients survive for more than 5 years.

TREATMENT

Malignant hypertension is a medical emergency that requires immediate therapy. However, it needs to be distinguished from severe hypertension, since overly aggressive therapy in malignant hypertension could result in a potentially hazardous reduction in myocardial and cerebral perfusion. The initial aims of therapy should be (1) correction of medical complications and (2) reduction of diastolic pressure by one-third, but not to a level <95 mmHg. The drugs available for treatment of malignant hypertension can be divided into two groups on the basis of time of onset of action (Table 246-7). Those in the first group act within a few minutes but are not satisfactory for long-term management. If the patient is having convulsions, and if arterial pressure must be reduced rapidly, then one from the immediate-acting group should be used.

The first three agents in this group require continuous infusion and close monitoring. *Nitroprusside* is given by continuous intravenous infusion at a dose of 0.25 to 8.0 ug/kg per min. It is probably the agent of choice in this condition, since it dilates both arterioles and veins. It has the advantage over the ganglionic blockers of not being associated with the development of tachyphylaxis and can be used for days with few side effects. The dosage must be controlled with an infusion pump. *Nitroglycerin* affects veins more than arterioles and is given by continuous infusion at a rate of 5 to 100 ug/min. It is particularly useful in the treatment of hypertension following coronary bypass surgery, myocardial infarction, left ventricular failure, or unstable angina pectoris. *Diazoxide* is the easiest agent to administer, for no individual titration of dosage is required. However, it is probably less effective than the other agents. It primarily affects arteriolar and not venous tone. A dose of 50 to 100 mg is given rapidly intravenously, and the antihypertensive effect appears in 1 to 5 min. The same dose can be repeated in 5 to 10 min, if necessary, or when the pressure begins to rise, usually after several hours. The total dose should not exceed 600 mg/d. In an occasional patient, pressure may drop below normal levels after diazoxide administration. This drug should not be used in patients in whom aortic dissection or myocardial infarction is suspected. Because it can increase the force of myocardial contraction, often a beta blocker is given concomitantly. *Enalaprilat*, an intravenous form of theACEinhibitor *enalapril*, has also proven effective, particularly in individuals with left heart failure. Finally, intravenous *labetalol* may be particularly useful in patients with a myocardial infarct or angina because it prevents an increase in heart rate. However, it may be ineffective in patients previously treated with beta blockers and is contraindicated in patients with heart failure, asthma, bradycardia, or heart block. It may also serve as an alternative therapy in patients with eclampsia who are unresponsive to hydralazine.

Patients given any of these agents also should receive other medications effective for long-term control. Those in the second group in Table 246-7 require 30 min or more to produce their full effect, but they have the advantage of being satisfactory for subsequent oral administration and for long-term management of the patient's hypertension. If such a delay in the achievement of the full effect is acceptable, intravenous *hydralazine* is effective in many patients within 10 min; an effective protocol involves giving 10-mg doses intravenously every 10 to 15 min until the desired effect has been obtained or until a total of 50 mg has been administered. The total amount required for response may then be repeated intramuscularly or intravenously every 6 h. Hydralazine should be used with caution in patients with significant coronary artery disease and should be avoided in patients manifesting myocardial ischemia or aortic dissection. It is effective in preeclampsia. *Esmolol*, a beta blocker with an onset of action of 1 to 2 min, is particularly useful in aortic dissection and for perioperative hypertensive crisis. Its major disadvantage is that it can have a negative inotropic effect. Its use in individuals with congestive heart failure, obstructive lung disease, or asthma is problematic.

Furosemide is an important adjunct to the therapy just discussed. Given either orally or intravenously, it serves to maintain sodium diuresis in the face of a falling arterial pressure and thus will speed recovery from encephalopathy and congestive heart failure as well as maintain the sensitivity to the primary antihypertensive drug. Digitalis (Chap. 232) may also be indicated if there is evidence of cardiac decompensation.

In patients with malignant hypertension in whom the existence of pheochromocytoma is suspected, urine should be collected for measurement of the products of catecholamine metabolism, and drugs that might release additional catecholamines, such as methyldopa, reserpine, and guanethidine, must be avoided. The parenteral drug of choice in these patients is phentolamine, administered with care to avoid a precipitous reduction in arterial pressure.

There is hope even for patients who fail to respond sufficiently to any of the forms of therapy and who show progressive deterioration in renal function. In some, a period of peritoneal dialysis or hemodialysis to deplete extracellular fluid has resulted in better blood pressure control and eventual improvement in renal function. In other patients with refractory hypertension and renal failure who do not respond to volume depletion or hypotensive therapy, including minoxidil administration -- particularly those with marked elevation of plasma renin activity -- bilateral nephrectomy has resulted in amelioration of hypertension; subsequently, these patients have been maintained on chronic dialysis or have received renal homografts. However, bilateral nephrectomy should be avoided where possible because (1) the loss of renal erythropoietin will contribute to the associated anemia, (2) vitamin D metabolism may be adversely affected, and (3) all residual renal function will be lost.

247. DISEASES OF THE AORTA - *Victor J. Dzau, Mark A. Creager*

The aorta is the conduit through which the blood ejected from the left ventricle is delivered to the systemic arterial bed. In adults, its diameter is approximately 3 cm at the origin, 2.5 cm in the descending portion in the thorax, and 1.8 to 2 cm in the abdomen. The aortic wall consists of a thin intima composed of endothelium, subendothelial connective tissue, and an internal elastic lamina; a thick tunica media composed of smooth-muscle cells and extracellular matrix; and an adventitia composed primarily of connective tissue enclosing the vasa vasorum and nervi vascularis. In addition to its conduit function, the viscoelastic and compliant properties of the aorta also subserve a buffering function. The aorta is distended during systole to enable a portion of the stroke volume to be stored, and it recoils during diastole so that blood continues to flow to the periphery. Because of its continuous exposure to high pulsatile pressure and shear stress, the aorta is particularly prone to injury and disease resulting from mechanical trauma (Table 247-1). The aorta is also more prone to rupture than any other vessel, especially with the development of aneurysmal dilatation, since its wall tension, as governed by Laplace's law (i.e., proportional to the product of pressure and radius), would be increased.

AORTIC ANEURYSM

An *aneurysm* is defined as a pathologic dilatation of a segment of a blood vessel. A *true aneurysm* involves all three layers of the vessel wall and is distinguished from a *pseudoaneurysm*, in which the intimal and medial layers are disrupted and the dilatation is lined by adventitia only and sometimes by perivascular clot. Aneurysms also may be classified accordingly to their gross appearance. A *fusiform aneurysm* affects the entire circumference of a segment of the vessel, resulting in a diffusely dilated lesion. In contrast, a *saccular aneurysm* involves only a portion of the circumference, resulting in an outpouching of the vessel wall. Aortic aneurysms are also classified according to location, i.e., abdominal versus thoracic. Aneurysms of the descending thoracic aorta are usually contiguous with infradiaphragmatic aneurysms and are referred to as *thoracoabdominal aortic aneurysms*.

ETIOLOGY

The most common pathologic condition associated with aortic aneurysm is *atherosclerosis*. It is controversial whether atherosclerosis itself actually causes aortic aneurysms or whether atherosclerosis develops as a secondary event in the dilated aorta. Causality is implied by studies that have shown that many patients with aortic aneurysms have coexisting risk factors for atherosclerosis (Chap. 241), particularly cigarette smoking, as well as atherosclerosis in other blood vessels. Seventy-five percent of atherosclerotic aneurysms are located in the distal abdominal aorta, below the renal arteries.

Cystic medial necrosis is the term used to describe the degeneration of collagen and elastic fibers in the tunica media of the aorta, as well as the loss of medial cells that are replaced by multiple clefts of mucoid material. Cystic medial necrosis characteristically affects the proximal aorta, results in circumferential weakness and dilatation, and leads to development of fusiform aneurysms involving the ascending aorta and the sinuses of

Valsalva. This condition is particularly prevalent in patients with Marfan syndrome and Ehrlers-Danlos syndrome type IV (Chap. 351) but also occurs in pregnant women, in patients with hypertension, and in those with valvular heart disease. Sometimes it appears as an isolated condition in patients without any other apparent disease. Familial clusterings of aortic aneurysms occur in 20% of patients, suggesting a hereditary basis of the disease. A mutation of the gene encoding type III procollagen has been implicated. *Syphilis* (Chap. 172) is a relatively uncommon cause of aortic aneurysm. Syphilitic periaortitis and mesoaortitis damage elastic fibers, resulting in thickening and weakening of the aortic wall. Approximately 90% of syphilitic aneurysms are located in the ascending aorta or aortic arch. *Tuberculous aneurysms* (Chap. 169) typically affect the thoracic aorta and result from direct extension of infection from hilar lymph nodes or contiguous abscesses or from bacterial seeding. Loss of aortic wall elasticity results from granulomatous destruction of the medial layer. A *mycotic aneurysm* is a rare condition that develops as a result of staphylococcal, streptococcal, or salmonella infections of the aorta, usually at an atherosclerotic plaque. These aneurysms are usually saccular. Blood cultures are often positive and reveal the nature of the infecting agent.

Vasculitides associated with aortic aneurysm include Takayasu's arteritis and giant cell arteritis, which may cause aneurysms of the aortic arch and descending thoracic aorta. Spondyloarthropathies such as ankylosing spondylitis, rheumatoid arthritis, psoriatic arthritis, relapsing polychondritis, Behcet's syndrome, and Reiter's syndrome are associated with dilatation of the ascending aorta. *Traumatic aneurysms* may develop after penetrating or non-penetrating chest trauma and most commonly affect the descending thoracic aorta just beyond the site of insertion of the ligamentum arteriosum. *Congenital aortic aneurysms* may be primary or associated with anomalies such as a bicuspid aortic valve or aortic coarctation.

THORACIC AORTIC ANEURYSMS

The clinical manifestations and natural history of thoracic aortic aneurysms depend on their location. Cystic medial necrosis is the most common cause of ascending aortic aneurysms, whereas atherosclerosis is the condition most frequently associated with aneurysms of the aortic arch and descending thoracic aorta. The average growth rate of thoracic aneurysms is 0.1 to 0.4 cm per year. The risk of rupture is related to the size of the aneurysm and the presence of symptoms; it increases substantially for ascending aortic aneurysms>6 cm and descending thoracic aneurysms>7 cm. Most thoracic aortic aneurysms are asymptomatic. However, compression or erosion of adjacent tissue by aneurysms may cause symptoms such as chest pain, shortness of breath, cough, hoarseness, or dysphagia. Aneurysmal dilatation of the ascending aorta may cause congestive heart failure as a consequence of aortic regurgitation; and compression of the superior vena cava may produce congestion of the head, neck, and upper extremities.

A chest x-ray may be the first test to suggest the diagnosis of a thoracic aortic aneurysm. Findings include widening of the mediastinal shadow and displacement or compression of the trachea or left mainstem bronchus. Two-dimensional echocardiography, and particularly transesophageal echocardiography, can be used to assess the proximal ascending aorta and descending thoracic aorta. Both

contrast-enhanced computed tomography (CT) and magnetic resonance imaging (MRI) are sensitive and specific tests for assessment of aneurysms of the thoracic aorta. In asymptomatic patients whose aneurysms are too small to justify surgery, noninvasive testing with either contrast-enhanced CT or MRI should be performed at least every 6 to 12 months to monitor expansion. Contrast aortography is frequently required preoperatively to assess the length of the aneurysm and involvement of branch vessels.

Patients with thoracic aortic aneurysms, and particularly patients with Marfan syndrome who have evidence of aortic root dilatation, should receive long-term beta-blocker therapy. Additional medical therapy should be given, as necessary, to control hypertension. Operative repair with placement of a prosthetic graft is indicated in patients with symptomatic thoracic aortic aneurysms and in those in whom the aortic diameter is >6 cm. In patients with Marfan syndrome, thoracic aortic aneurysms >5 cm should be considered for surgery.

ABDOMINAL AORTIC ANEURYSMS

Abdominal aortic aneurysms occur more frequently in males than in females, and the incidence increases with age. Abdominal aortic aneurysms may affect 1 to 2% of men older than 50 years. At least 90% of all abdominal aortic aneurysms are affected by atherosclerosis, and most of these aneurysms are below the level of the renal arteries. Prognosis is related to both the size of the aneurysm and the severity of coexisting coronary artery and cerebrovascular disease. The risk of rupture increases with the size of the aneurysm. The 5-year risk of rupture for aneurysms<5 cm is 1 to 2%, whereas it is 20 to 40% for aneurysms >5 cm in diameter. The formation of mural thrombi within the aneurysm may predispose to peripheral embolization.

An abdominal aortic aneurysm commonly produces no symptoms. It is usually detected on routine examination as a palpable, pulsatile, and nontender mass, or it is an incidental finding during an abdominal x-ray or ultrasound performed for other reasons. However, as abdominal aortic aneurysms expand, they may become painful. Some patients complain of strong pulsations in the abdomen; others experience pain in the chest, lower back, or scrotum. Aneurysmal pain is usually a harbinger of rupture and represents a medical emergency. More often, acute rupture occurs without any prior warning, and this complication is always life-threatening. Rarely, there is leakage of the aneurysm with severe pain and tenderness. Acute pain and hypotension occur with rupture of the aneurysm, which requires emergency operation.

Abdominal radiography may demonstrate the calcified outline of the aneurysm. However, about 25% of aneurysms are not calcified and cannot be visualized by plain x-ray. An abdominal ultrasound can delineate the transverse and longitudinal dimensions of an abdominal aortic aneurysm and may detect mural thrombus. Abdominal ultrasound in useful for serial documentation of aneurysm size and can be used to screen patients at risk for developing aortic aneurysm, such as those with affected siblings, peripheral atherosclerosis, or peripheral artery aneurysms. CT with contrast and MRI are accurate, noninvasive tests to determine the location and size of abdominal aortic aneurysms. Contrast aortography is used commonly for the evaluation of patients with aneurysms before surgery; but the procedure carries a small risk of complications, such as bleeding, allergic reactions, and atheroembolism. This technique

is useful in documenting the length of the aneurysm, especially its upper and lower limits, and the extent of associated atherosclerotic vascular disease. However, since the presence of mural clots may reduce the luminal size, aortography may underestimate the diameter of an aneurysm.

TREATMENT

Operative repair of the aneurysm and insertion of a prosthetic graft is indicated for abdominal aortic aneurysms of any size that are expanding rapidly or are associated with symptoms. For asymptomatic aneurysms, operation is indicated if the diameter is >5 cm. Operation may be recommended in patients with aneurysm diameters of 4 to 5 cm, except for patients with exceptionally high operative risk. However, in a recent randomized trial of patients with abdominal aortic aneurysms <5.5 cm, there was no difference in the 6-year mortality rate between those followed with ultrasound surveillance and those undergoing elective aneurysm repair. Thus, serial noninvasive follow-up of smaller aneurysms (<5 cm) is an alternative to immediate surgery. Percutaneous placement of endovascular stent grafts (Fig. 247-1) for treatment of infrarenal abdominal aortic aneurysms is currently available for selected patients, and initial reports have been favorable.

In surgical candidates, careful preoperative cardiac and general medical evaluations (followed by appropriate therapy of complicating conditions) are essential. Preexisting coronary artery disease, congestive heart failure, pulmonary disease, diabetes, and advanced age add to the risk of surgery. Perioperative management should include the placement of a Swan-Ganz catheter and arterial line to monitor and optimize left ventricular filling pressure, cardiac output, and arterial pressure, especially during clamping and unclamping of the aorta, as well as during the immediate postoperative period. With careful preoperative cardiac evaluation and postoperative care the operative mortality rate approximates 1 to 2%. After acute rupture, the mortality rate of emergent operation generally exceeds 50%.

AORTIC DISSECTION

Aortic dissection is caused by a circumferential or, less frequently, transverse tear of the intima. It often occurs along the right lateral wall of the ascending aorta where the hydraulic shear stress is high. Another common site is the descending thoracic aorta just below the ligamentum arteriosum. The initiating event is either a primary intimal tear with secondary dissection into the media or a medial hemorrhage that dissects into and disrupts the intima. The pulsatile aortic flow then dissects along the elastic lamellar plates of the aorta and creates a false lumen. The dissection usually propagates distally down the descending aorta and into its major branches, but it also may propagate proximally. In some cases, a secondary distal intimal disruption occurs, resulting in the reentry of blood from the false to the true lumen.

There are at least two important pathologic and radiologic variants: intramural hematoma without an intimal flap and penetrating ulcer. The clinical picture and therapeutic management of intramural hematoma are similar to those for classic aortic dissection. By contrast, penetrating ulcers are usually localized and are not associated with extensive propagation. They are primarily found in the distal portion of the

descending thoracic aorta and are associated with extensive atherosclerotic disease. The ulcer can erode beyond the intimal border, leading to medial hematoma, and may progress to false aneurysm formation or rupture.

DeBakey and coworkers initially classified aortic dissections as type I, in which an intimal tear occurs in the ascending aorta but which involves the descending aorta as well; type II, in which the dissection is limited to the ascending aorta; and type III, in which the intimal tear is located in the descending area with distal propagation of the dissection (Fig. 247-2). Another classification (Stanford) is that of type A, in which the dissection involves the ascending aorta (proximal dissection), and type B, in which it is limited to the descending aorta (distal dissection). From a management standpoint, classification into type A or B is more practical and useful, since DeBakey types I and II are managed in a similar manner.

The factors that predispose to aortic dissection include systemic hypertension, a coexisting condition in 70% of patients, and cystic medial necrosis. Aortic dissection is the major cause of morbidity and mortality in patients with Marfan syndrome (Chap. 351) and similarly may affect patients with Ehlers-Danlos syndrome. The incidence is also increased in patients with inflammatory aortitis (i.e., Takayasu's arteritis, giant cell arteritis), congenital aortic valve anomalies (e.g., bicuspid valve), in those with coarctation of the aorta, and in otherwise normal women during the third trimester of pregnancy.

CLINICAL MANIFESTATIONS

The peak incidence is in the sixth and seventh decades. Men are more affected than women by a ratio of 2:1. The presentations of aortic dissection and its variants are the consequences of intimal tear, dissecting hematoma, occlusion of involved arteries, and compression of adjacent tissues. Acute aortic dissection presents with the sudden onset of pain (Chap. 13), which is often described as very severe and tearing and is associated with diaphoresis. The pain may be localized to the front or back of the chest, often the interscapular region, and typically migrates with propagation of the dissection. Other symptoms include syncope, dyspnea, and weakness. Physical findings may include hypertension or hypotension, loss of pulses, aortic regurgitation, pulmonary edema, and neurologic findings due to carotid artery obstruction (hemiplegia, hemianesthesia) or spinal cord ischemia (paraplegia). Bowel ischemia, hematuria, and myocardial ischemia have all been observed. These clinical manifestations reflect complications resulting from the dissection occluding the major arteries. Furthermore, clinical manifestations may result from the compression of adjacent structures (e.g., superior cervical ganglia, superior vena cava, bronchus, esophagus) by the expanding dissection causing aneursymal dilatation, and include Horner's syndrome, superior vena caval syndrome, hoarseness, dysphagia, and airway compromise. Hemopericardium and cardiac tamponade may complicate a type A lesion with retrograde dissection. Acute aortic regurgitation is an important and common (>50%) complication of proximal dissection. It is the outcome of either a circumferential tear that widens the aortic root or a disruption of the annulus by dissecting hematoma that tears a leaflet(s) or displaces it below the line of closure. Signs of aortic regurgitation include bounding pulses, a wide pulse pressure, a diastolic murmur often radiating along the right sternal border, and evidence of congestive heart failure. The clinical manifestation depends on the severity

of the regurgitation.

In dissections involving the ascending aorta, the chest x-ray often reveals a widened superior mediastinum. A pleural effusion (usually left-sided) also may be present. This effusion is typically serosanguinous and not indicative of rupture unless accompanied by hypotension and falling hematocrit. In dissections of the descending thoracic aorta, a widened mediastinum also may be observed on chest x-ray. In addition, the descending aorta may appear to be wider than the ascending portion. An electrocardiogram that shows no evidence of ischemia is helpful in distinguishing aortic dissection from myocardial infarction. Rarely, the dissection involves the right or left coronary ostium and causes acute myocardial infarction. The diagnosis of aortic dissection can be established by aortography or by the use of noninvasive techniques such as echocardiography,CT, orMRI. Aortography may be used to document the diagnosis; identify the entry point, the intimal flap, and the false and true lumina; and to establish the extent of dissection into the major arteries. Coronary angiography may be performed concomitantly in high-risk patients in the evaluation and preparation for surgery. The sensitivity of aortography is 70% for visualizing an intimal flap, 56% for the site of intimal tear, and 87% for false lumen. It is unable to recognize intramural hemorrhage. Transthoracic echocardiography can be performed simply and rapidly and has an overall sensitivity of 60 to 85%. For diagnosing proximal ascending aortic dissections, its sensitivity exceeds 80%; it is less useful for detecting dissection of the arch and descending thoracic aorta. Transesophageal echocardiography (Fig. 247-3) requires greater skill and patient cooperation but is very accurate in identifying dissections of the ascending and descending thoracic aorta, but not the arch, achieving 98% sensitivity and approximately 90% specificity. CT and MRI are both highly accurate in identifying the intimal flap and the extent of the dissection; each has a sensitivity and specificity exceeding 90%. They are useful in recognizing intramural hemorrhage and penetrating ulcers. MRI also can detect blood flow, which may be useful in characterizing antegrade versus retrograde dissection. These noninvasive tests are now becoming the diagnostic procedures of choice. Their relative utility depends on the availability and expertise in individual institutions as well as on the hemodynamic stability of the patient, with CT and MRI obviously less suitable for more unstable patients.

TREATMENT

Medical therapy should be initiated as soon as the diagnosis is considered. The patient should be admitted to an intensive care unit for monitoring hemodynamics and urine output. Unless hypotension is present, therapy should be aimed at reducing cardiac contractility and systemic arterial pressure, and thereby shear stress. For acute dissection, unless contraindicated,b-adrenergic blockers should be administered parenterally, using intravenous propranolol, metoprolol, or the short-acting esmolol to achieve a heart rate of approximately 60 beats per minute. This should be accompanied by sodium nitroprusside infusion to lower systolic blood pressure to 120 mmHg or less. Labetalol (Chap. 246), a drug with bothb- and a-adrenergic blocking properties, also has been used as a parenteral agent in the acute therapy of dissection.

The calcium channel antagonists, verapamil and diltiazem, may be used intravenously if nitroprusside or labetalol cannot be employed. Experience with calcium antagonists is limited. Direct vasodilators, such as diazoxide and hydralazine, are contraindicated

because these agents can increase hydraulic shear and may propagate dissection.

Emergent or urgent surgical correction is the preferred treatment for ascending aortic dissections (type A) and complicated type B dissections including those characterized by propagation, compromise of major aortic branches, impending rupture, or continued pain. Surgery involves excision of the intimal flap, obliteration of the false lumen, and placement of an interposition graft. A composite valve-graft conduit is used if the aortic valve is disrupted. The overall in-hospital mortality rate after surgical treatment of patients with aortic dissection is reported to be 15 to 20%. The major causes of perioperative mortality and morbidity include myocardial infarction, paraplegia, renal failure, tamponade, hemorrhage, and sepsis. Recent reports of the use of endoluminal stent grafts in selected patients with type B dissection have been encouraging. Other transcatheter techniques, such as fenestration of the intimal flaps and stenting of narrowed branch vessels to increase flow to compromised organs, are also under investigation. For uncomplicated and stable distal dissection (type B), medical therapy is the preferred treatment. The in-hospital mortality rate of medically treated patients with type B dissection is 15 to 20%. Long-term therapy for patients with aortic dissection (with or without surgery) consists of the control of hypertension and reduction of cardiac contractility with the use of beta blockers plus other antihypertensive agents such as angiotensin-converting enzyme inhibitor or calcium antagonist. Patients with chronic type B dissection should be followed on an outpatient basis every 6 to 12 months by contrast-enhancedCT orMRI to detect propagation. Patients with Marfan syndrome are at high risk for postdissection complications. The long-term prognosis for patients with treated dissections is generally good with careful follow-up; the 10-year survival rate is approximately 60%.

AORTIC OCCLUSION

CHRONIC ATHEROSCLEROTIC OCCLUSIVE DISEASE

Atherosclerosis may affect the thoracic and abdominal aorta, but occlusive aortic disease caused by atherosclerosis usually is confined to the distal abdominal aorta below the renal arteries. Frequently the disease extends to the iliac arteries (Chap. 248). Claudication characteristically involves the lower back, buttocks, and thighs and may be associated with impotence in males (Leriche syndrome). The severity of the symptoms depends on the adequacy of collaterals. With sufficient collateral blood flow, a complete occlusion of the abdominal aorta may occur without the development of ischemic symptoms. The physical findings include absence of femoral and other distal pulses bilaterally and the detection of an audible bruit over the abdomen (usually at or below the umbilicus) and the common femoral arteries. Atrophic skin, loss of hair, and coolness of the lower extremities are usually observed. In advanced ischemia, rubor on dependency and pallor on elevation can be seen.

The diagnosis is usually established by the physical examination and noninvasive testing, including leg pressure measurements, Doppler velocity analysis, and pulse volume recordings. The anatomy may be defined by abdominal aortography before revascularization. Operative treatment is indicated in patients with debilitating symptoms and/or with the development of leg ischemia.

ACUTE OCCLUSION

Acute occlusion in the distal abdominal aorta represents a medical emergency because it threatens the viability of the lower extremities. It usually results from an occlusive embolus that almost always originates from the heart. Rarely, acute occlusion may occur as the result of in situ thrombosis in a preexisting severely narrowed segment of the aorta or plaque rupture and hemorrhage into such an area.

The clinical picture is one of acute ischemia of the lower extremities. Severe rest pain, coolness, and pallor of the lower extremities and the absence of distal pulses bilaterally are the usual manifestations. Diagnosis should be established rapidly by aortography. Emergency thrombectomy or revascularization is indicated.

AORTITIS

Aortitis frequently affects the ascending aorta and may result in aneurysmal dilatation and aortic regurgitation; it occasionally obstructs branch vessels of the aorta.

SYPHILITIC AORTITIS

This late manifestation of luetic infection (Chap. 172) usually affects the proximal ascending aorta, particularly the aortic root, resulting in aortic dilatation and aneurysm formation. Syphilitic aortitis may occasionally involve the aortic arch or the descending aorta. The aneurysms may be saccular or fusiform and are usually asymptomatic, but compression of and erosion into adjacent structures may result in symptoms; rupture also may occur.

The initial lesion is an obliterative endarteritis of the vasa vasorum, especially in the adventitia. This is an inflammatory response to the invasion of the adventitia by the spirochetes. Destruction of the aortic media occurs as the spirochetes spread into this layer, usually via the lymphatics accompanying the vasa vasorum. Destruction of collagen and elastic tissues leads to dilation of the aorta, scar formation, and calcification. These changes account for the characteristic radiographic appearance of a calcified ascending aortic aneurysm.

The disease typically presents as an incidental radiographic finding 15 to 30 years after initial infection. Symptoms may result from aortic regurgitation, narrowing of coronary ostia due to syphilitic aortitis, compression of adjacent structures (e.g., esophagus), or rupture. Diagnosis is established by a positive serologic test, i.e., rapid plasmin reagin (RPR) or fluorescent treponemal antibody. Treatment includes penicillin and surgical excision and repair.

RHEUMATIC AORTITIS

Rheumatoid arthritis (Chap. 312), ankylosing spondylitis (Chap. 315), psoriatic arthritis (Chap. 324), Reiter's syndrome (Chap. 315), Behcet's syndrome (Chap. 316), relapsing polychondritis, and inflammatory bowel disorders may all be associated with aortitis involving the ascending aorta. The inflammatory lesions usually involve the ascending aorta and may extend to the sinuses of Valsalva, the mitral valve leaflets, and adjacent

myocardium. The clinical manifestations are aneurysm, aortic regurgitation, and involvement of the cardiac conduction system.

TAKAYASU'S ARTERITIS

Inflammatory diseases of the aortic arch resulting in obstruction of the aorta and its major arteries characterize this major group of diseases. Takayasu's arteritis is also termed *pulseless disease* because of the frequent occlusion of the large arteries originating from the aorta. It also may involve the descending thoracic and abdominal aorta and occlude large branches such as the renal arteries. Aortic aneurysms may also occur. The pathology is a panarteritis, characterized by mononuclear cells and occasionally giant cells, with marked intimal hyperplasia, medial and adventitial thickening, and, in chronic form, fibrotic occlusion. The disease is most prevalent in young females of Asian descent. During the acute stage, fever, malaise, weight loss, and other systemic symptoms may be evident. An elevation of the erythrocyte sedimentation rate is common. The chronic stages of the disease present with symptoms related to large artery occlusion, such as upper extremity claudication, cerebral ischemia, and syncope. The chronic disease is intermittently active. Since the process is progressive and there is no definitive therapy, the prognosis is usually poor. Glucocorticoids and immunosuppressive agents have been reported to be effective in some patients during the acute phase. Occasionally, anticoagulation prevents thrombosis and complete occlusion of a large artery. Surgical bypass of a critically stenotic artery may be necessary.

GIANT CELL ARTERITIS (See also Chap. 317)

This vasculitis occurs in older individuals and affects women more often than men. Primarily large and medium-sized arteries are affected. The pathology is that of focal granulomatous lesions involving the entire arterial wall. It may be associated with polymyalgia rheumatica. Obstruction of medium-sized arteries (e.g., temporal and ophthalmic arteries) and of major branches of the aorta and the development of aortitis and aortic regurgitation are some of the complications of the disease. High-dose glucocorticoid therapy may be effective when given early.

ARTERIAL DISORDERS

PERIPHERAL ARTERIAL DISEASE

Atherosclerosis (arteriosclerosis obliterans) is the leading cause of occlusive arterial disease of the extremities in patients over 40 years old; the highest incidence occurs in the sixth and seventh decades of life. As in patients with atherosclerosis of the coronary and cerebral vasculature, there is an increased prevalence of peripheral atherosclerotic disease in individuals with diabetes mellitus, hypercholesterolemia, hypertension, or hyperhomocysteinemia and in cigarette smokers.

Pathology (See alsoChap. 241) Segmental lesions causing stenosis or occlusion are usually localized in large and medium-sized vessels. The pathology of the lesions includes atherosclerotic plaques with calcium deposition, thinning of the media, patchy destruction of muscle and elastic fibers, fragmentation of the internal elastic lamina, and thrombi composed of platelets and fibrin. The primary sites of involvement are the abdominal aorta and iliac arteries (30% of symptomatic patients), the femoral and popliteal arteries (80 to 90% of patients), and the more distal vessels, including the tibial and peroneal arteries (40 to 50% of patients). Atherosclerotic lesions occur preferentially at arterial branch points, sites of increased turbulence, altered shear stress, and intimal injury. Involvement of the distal vasculature is most common in elderly individuals and patients with diabetes mellitus.

Clinical Evaluation The most common *symptom* is intermittent claudication, which is defined as a pain, ache, cramp, numbness, or a sense of fatigue in the muscles; it occurs during exercise and is relieved by rest. The site of claudication is distal to the location of the occlusive lesion. For example, buttock, hip, and thigh discomfort occurs in patients with aortoiliac disease (Leriche syndrome), whereas calf claudication develops in patients with femoral-popliteal disease. Symptoms are far more common in the lower than in the upper extremities because of the higher incidence of obstructive lesions in the former region. In patients with severe arterial occlusive disease, critical limb ischemia may develop. Patients will complain of rest pain or a feeling of cold or numbness in the foot and toes. Frequently, these symptoms occur at night when the legs are horizontal and improve when the legs are in a dependent position. With severe ischemia, rest pain may be persistent.

Important *physical findings* of peripheral arterial disease include decreased or absent pulses distal to the obstruction, the presence of bruits over the narrowed artery, and muscle atrophy. With more severe disease, hair loss, thickened nails, smooth and shiny skin, reduced skin temperature, and pallor or cyanosis are frequent physical signs. In addition, ulcers or gangrene may occur. Elevation of the legs and repeated flexing of the calf muscles produce pallor of the soles of the feet, whereas rubor, secondary to reactive hyperemia, may develop when the legs are dependent. The time required for rubor to develop or for the veins in the foot to fill when the patient's legs are transferred from an elevated to a dependent position is related to the severity of the ischemia and the presence of collateral vessels. Patients with severe ischemia may develop

peripheral edema because they keep their legs in a dependent position much of the time. Ischemic neuritis can result in numbness and hyporeflexia.

Noninvasive Testing The history and physical examination are usually sufficient to establish the diagnosis of peripheral arterial disease. An objective assessment of the severity of disease is obtained by noninvasive techniques. These include digital pulse volume recordings, Doppler flow velocity waveform analysis, duplex ultrasonography (which combines B-mode imaging and pulse-wave Doppler examination), segmental pressure measurements, transcutaneous oximetry, stress testing (usually using a treadmill), and tests of reactive hyperemia. In the presence of significant peripheral arterial disease, the volume displacement in the leg is decreased with each pulse, and the Doppler velocity contour becomes progressively flatter. Duplex ultrasonography is often useful in detecting stenotic lesions in native arteries and bypass grafts.

Arterial pressure can be recorded noninvasively along the legs by serial placement of sphygmomanometric cuffs and use of a Doppler device to auscultate or record blood flow. Normally, systolic blood pressure in the legs and arms is similar. Indeed, ankle pressure may be slightly higher than arm pressure due to pulse-wave reflection. In the presence of hemodynamically significant stenoses, the systolic blood pressure in the leg is decreased. Thus, if one were to obtain a ratio of the ankle and brachial artery pressures, it would be ≥ 1.0 in normal individuals and <1.0 in patients with peripheral arterial disease. A ratio of <0.5 is consistent with severe ischemia.

Treadmill testing allows the physician to assess functional limitations objectively. Decline of the ankle-brachial systolic pressure ratio immediately after exercise may provide further support for the diagnosis of peripheral arterial disease in patients with equivocal symptoms and findings on examination. Exercise testing also allows simultaneous evaluation for the presence of coronary artery disease.

Contrast angiography should not be used for routine diagnostic testing but is performed prior to potential revascularization. It is useful in defining the anatomy to assist operative planning and is also indicated if nonsurgical interventions are being considered, such as percutaneous transluminal angioplasty (PTA) or thrombolysis. Recent studies have suggested that magnetic resonance angiography has diagnostic accuracy comparable to that of contrast angiography.

Prognosis The natural history of patients with peripheral arterial disease is influenced primarily by the extent of coexisting coronary artery and cerebral vascular disease. Studies using coronary angiography have estimated that approximately one-half of patients with symptomatic peripheral arterial disease also have significant coronary artery disease. Life-table analysis has indicated that patients with claudication have a 70% 5-year and a 50% 10-year survival rate. Most deaths are either sudden or secondary to myocardial infarction. The likelihood of symptomatic progression of peripheral arterial disease appears less than the chance of succumbing to coronary artery disease. Approximately 75% of nondiabetic patients who present with mild to moderate claudication remain symptomatically stable or improve. Deterioration is likely to occur in the remainder, with approximately 5% of the group ultimately undergoing amputation. The prognosis is worse in patients who continue to smoke cigarettes or who have diabetes mellitus.

TREATMENT

Therapeutic options include supportive measures, pharmacologic treatment, nonoperative interventions, and surgery. Supportive measures include meticulous care of the feet, which should be kept clean and protected against excessive drying with moisturizing creams. Well-fitting and protective shoes are advised to reduce trauma. Sandals and shoes made of synthetic materials that do not "breathe" should be avoided. Elastic support hose should be avoided, as they reduce blood flow to the skin. In patients with ischemia at rest, shock blocks under the head of the bed together with a canopy over the feet may improve perfusion pressure and ameliorate some of the rest pain.

Treatment of associated factors that contribute to the development of atherosclerosis should be initiated. The importance of discontinuing cigarette smoking cannot be overemphasized. The physician must assume a major role in this life-style modification. It is important to control blood pressure in hypertensive patients but to avoid hypotensive levels. Treatment of hypercholesterolemia is advocated, although reduction in cholesterol levels has not been shown unequivocally to reverse peripheral atherosclerotic lesions. However, it has been shown to prevent or to slow progression of the disease and to improve survival in patients with coronary atherosclerosis. Patients with claudication should also be encouraged to exercise regularly and at progressively more strenuous levels. Supervised exercise training programs may improve muscle efficiency and prolong walking distance. Patients also should be advised to walk for 30 to 45 min daily, stopping at the onset of claudication and resting until the symptoms resolve before resuming ambulation.

Pharmacologic Management This form of treatment of patients with peripheral arterial disease has not been as successful as the medical treatment of coronary artery disease (Chap. 244). In particular, vasodilators as a class have not proved to be beneficial. During exercise, peripheral vasodilation occurs distal to sites of significant arterial stenoses. As a result, perfusion pressure falls, often to levels less than that generated in the interstitial tissue by the exercising muscle. Drugs such asa-adrenergic blocking agents, calcium channel antagonists, papaverine, and other vasodilators have not been shown to be effective in patients with peripheral arterial disease. Pentoxifylline, a substituted xanthine derivative, has been reported to decrease blood viscosity and to increase red cell flexibility, thereby increasing blood flow to the microcirculation and enhancing tissue oxygenation. Several placebo-controlled studies have reported that pentoxifylline increased the duration of exercise in patients with claudication, but its efficacy has not been confirmed in all clinical trials. Cilostazol, a phosphodiesterase inhibitor with vasodilator and antiplatelet properties, has been reported to increase claudication distance and recently received an indication for treatment of peripheral arterial disease by the U.S. Food and Drug Administration. Other drugs are being studied that potentially may improve claudication, such as L-arginine, which is the precursor of the endothelium-dependent vasodilator, nitric oxide, and vasodilator prostaglandins. Several studies have suggested that long-term parenteral administration of vasodilator prostaglandins decreases pain and facilitates healing of ulcers in patients with severe limb ischemia. Clinical trials with angiogenic growth factors such as vascular endothelial growth factor (VEGF) and basic fibroblast growth factor (bFGF) are

proceeding. A preliminary report suggested that intramuscular gene transfer of DNA encoding VEGF may promote collateral blood vessel growth in patients with critical limb ischemia.

Platelet inhibitors, particularly aspirin, reduce the risk of adverse cardiovascular events in patients with peripheral atherosclerosis. Clopidogril, a drug that inhibits platelet aggregation via its effect on ADP-dependent platelet-fibrinogen binding, appears to be more effective than aspirin in reducing cardiovascular morbidity and mortality in patients with peripheral arterial disease. The anticoagulants heparin and warfarin have not been shown to be effective in patients with chronic peripheral arterial disease but may be useful in acute arterial obstruction secondary to thrombosis or systemic embolism. Similarly, thrombolytic intervention using drugs such as streptokinase, urokinase, or recombinant tissue plasminogen activator (tPA) may have a role in the treatment of acute thrombotic arterial occlusion but is not effective in patients with chronic arterial occlusion secondary to atherosclerosis.

Revascularization Revascularization procedures, including nonoperative as well as operative interventions, are usually reserved for patients with progressive, severe, or disabling symptoms and ischemia at rest, as well as for individuals who must be symptom-free because of their occupation. Angiography should be performed mainly in patients who are being considered for a revascularization procedure. Nonoperative interventions includePTA, stent placement, and atherectomy (Chap. 245). PTA of the iliac artery is associated with a higher success rate than PTA of the femoral and popliteal arteries. Approximately 90 to 95% of iliac PTAs are initially successful, and the 3-year patency rate is in excess of 75%. Patency rates may be higher if a stent is placed in the iliac artery. The initial success rate for femoral-popliteal PTA is approximately 80%, with a 60% 3-year patency rate. Patency rates are influenced by the severity of pretreatment stenoses; the prognosis of total occlusive lesions is worse than that of nonocclusive stenotic lesions.

Several operative procedures are available for treating patients with aortoiliac and femoral-popliteal artery disease. The preferred operative procedure depends on the location and extent of the obstruction(s) and general medical condition of the patient. Operative procedures for aortoiliac disease include aortobifemoral bypass, axillofemoral bypass, femoral-femoral bypass, and aortoiliac endarterectomy. The most frequently used procedure is the aortobifemoral bypass using knitted Dacron grafts. Immediate graft patency approaches 99%, and 5- and 10-year graft patency in survivors is in excess of 90 and 80%, respectively. Operative complications include myocardial infarction and stroke, infection of the graft, peripheral embolization, and sexual dysfunction from interruption of autonomic nerves in the pelvis. Operative mortality ranges from 1 to 3%, mostly due to ischemic heart disease.

Operative therapy for femoral-popliteal artery disease includes in situ and reverse autogenous saphenous vein bypass grafts, placement of polytetrafluoroethylene (PTFE) or other synthetic grafts, and thromboendarterectomy. Operative mortality ranges from 1 to 3%. The long-term patency rate depends on the type of graft used, the location of the distal anastomosis, and the patency of runoff vessels beyond the anastomosis. Patency rates of femoral-popliteal saphenous vein bypass grafts at 1 year approach 90% and at 5 years, 70 to 80%. Five-year patency rates of infrapopliteal saphenous vein bypass

grafts are 60 to 70%. In contrast, 5-year patency rates of infrapopliteal PTFE grafts are less than 30%. Lumbar sympathectomy alone or as an adjunct to aortofemoral reconstruction has fallen into disfavor.

Preoperative cardiac risk assessment may identify individuals especially likely to experience an adverse cardiac event during the perioperative period. Patients with angina, prior myocardial infarction, ventricular ectopy, heart failure, or diabetes are among those at increased risk. Noninvasive tests, such as treadmill testing (if feasible), dipyridamole thallium or sestamibi scintigraphy, dobutamine echocardiography, and ambulatory ischemia monitoring permit further stratification of patient risk (Chap. 245). Patients with abnormal test results require close supervision and adjunctive management with antianginal medications. It is not known whether coronary angiography and coronary arterial revascularization reduce overall perioperative mortality in high-risk patients undergoing peripheral vascular surgery, but cardiac catheterization should be considered in patients suspected of having left main or three-vessel coronary artery disease.

FIBROMUSCULAR DYSPLASIA

This is a hyperplastic disorder affecting medium-sized and small arteries. It occurs predominantly in females and usually involves renal and carotid arteries but can affect extremity vessels such as the iliac and subclavian arteries. The histologic classification includes intimal, medial, and periadventitial dysplasia. Medial dysplasia is the most common type and is characterized by hyperplasia of the media with or without fibrosis of the elastic membrane. It is identified angiographically by a "string of beads" appearance caused by thickened fibromuscular ridges contiguous with thin, less involved portions of the arterial wall. When limb vessels are involved, clinical manifestations are similar to those for atherosclerosis, including claudication and rest pain.PTA and surgical reconstruction have been beneficial in patients with debilitating symptoms or threatened limbs.

THROMBOANGIITIS OBLITERANS

Thromboangiitis obliterans (Buerger's disease) is an inflammatory occlusive vascular disorder involving small and medium-sized arteries and veins in the distal upper and lower extremities. Cerebral, visceral, and coronary vessels may also be affected. This disorder develops most frequently in men under age 40. The prevalence is higher in Asians and individuals of eastern European descent. While the cause of thromboangiitis obliterans is not known, there is a definite relationship to cigarette smoking in patients with this disorder.

In the initial stages of thromboangiitis obliterans, polymorphonuclear leukocytes infiltrate the walls of the small and medium-sized arteries and veins. The internal elastic lamina is preserved, and thrombus may develop in the vascular lumen. As the disease progresses, mononuclear cells, fibroblasts, and giant cells replace the neutrophils. Later stages are characterized by perivascular fibrosis and recanalization.

The clinical features of thromboangiitis obliterans often include a triad of claudication of the affected extremity, Raynaud's phenomenon (p. 1438), and migratory superficial vein

thrombophlebitis. Claudication is usually confined to the calves and feet or the forearms and hands, because this disorder primarily affects distal vessels. In the presence of severe digital ischemia, trophic nail changes, painful ulcerations, and gangrene may develop at the tips of the fingers. The physical examination shows normal brachial and popliteal pulses but reduced or absent radial, ulnar, and/or tibial pulses. Arteriography is helpful in making the diagnosis. Smooth, tapering segmental lesions in the distal vessels are characteristic, as are collateral vessels at sites of vascular occlusion. Proximal atherosclerotic disease is usually absent. The diagnosis can be confirmed by excisional biopsy and pathologic examination of an involved vessel.

There is no specific treatment except abstention from tobacco. The prognosis is worse in individuals who continue to smoke, but results are discouraging even in those who do stop smoking. Arterial bypass of the larger vessels may be used in selected instances, as well as local debridement, depending on the symptoms and severity of ischemia. Antibiotics may be useful; anticoagulants and glucocorticoids are not helpful. If these measures fail, amputation may be required.

VASCULITIS

Other vasculitides may affect the arteries supplying the upper and lower extremities.**Takayasu's arteritis and giant cell (temporal) arteritis are discussed in Chap. 317.*

ACUTE ARTERIAL OCCLUSION

This results in the sudden cessation of blood flow to an extremity. The severity of ischemia and the viability of the extremity depend on the location and extent of the occlusion and the presence and subsequent development of collateral blood vessels. There are two principal causes of acute arterial occlusion: embolism and thrombus in situ.

The most common sources of arterial emboli are the heart, aorta, and large arteries. Cardiac disorders that cause thromboembolism include atrial fibrillation, both chronic and paroxysmal; acute myocardial infarction; ventricular aneurysm; cardiomyopathy; infectious and marantic endocarditis; prosthetic heart valves; and atrial myxoma. Emboli to the distal vessels may also originate from proximal sites of atherosclerosis and aneurysms of the aorta and large vessels. Less frequently, an arterial occlusion results paradoxically from a venous thrombus that has entered the systemic circulation via a patent foramen ovale or other septal defect. Arterial emboli tend to lodge at vessel bifurcations because the vessel caliber decreases at these sites; in the lower extremities, emboli lodge most frequently in the femoral artery, followed by the iliac artery, aorta, and popliteal and tibioperoneal arteries.

Acute arterial thrombosis in situ occurs most frequently in atherosclerotic vessels at the site of a stenosis or aneurysm and in arterial bypass grafts. Trauma to an artery may also result in the formation of an acute arterial thrombus. Arterial occlusion may complicate arterial punctures and placement of catheters. Less frequent causes include the thoracic outlet compression syndrome, which causes subclavian artery occlusion, and entrapment of the popliteal artery by abnormal placement of the medial head of the

gastrocnemius muscle. Polycythemia and hypercoagulable disorders (Chaps. 110 and118) are also associated with acute arterial thrombosis.

Clinical Features The symptoms of an acute arterial occlusion depend on the location, duration, and severity of the obstruction. Often, severe pain, paresthesia, numbness, and coldness develop in the involved extremity within 1 h. Paralysis may occur with severe and persistent ischemia. Physical findings include loss of pulses distal to the occlusion, cyanosis or pallor, mottling, decreased skin temperature, muscle stiffening, loss of sensation, weakness, and/or absent deep tendon reflexes. If acute arterial occlusion occurs in the presence of an adequate collateral circulation, as is often the case in acute graft occlusion, the symptoms and findings may be less impressive. In this situation, the patient complains about an abrupt decrease in the distance walked before claudication occurs or of modest pain and paresthesia. Pallor and coolness are evident, but sensory and motor functions are generally preserved. The diagnosis of acute arterial occlusion is usually apparent from the clinical presentation. Arteriography is useful for confirming the diagnosis and demonstrating the location and extent of occlusion.

TREATMENT

Once the diagnosis is made, the patient should be anticoagulated with intravenous heparin to prevent propagation of the clot. In cases of severe ischemia of recent onset, and particularly when limb viability is jeopardized, immediate intervention to ensure reperfusion is indicated. Surgical thromboembolectomy or arterial bypass procedures are used to restore blood flow to the ischemic extremity promptly, particularly when a large proximal vessel is occluded.

Intraarterial thrombolytic therapy is effective when acute arterial occlusion is caused by a thrombus in an atherosclerotic vessel or arterial bypass graft. Thrombolytic therapy may also be indicated when the patient's overall condition contraindicates surgical intervention or when smaller distal vessels are occluded, thus preventing surgical access. One approach for administering intraarterial urokinase is to give 240,000 IU/h for 4 h, followed by 120,000 IU/h for a maximum of 48 h. Intraarterial recombinanttPA may be administered at infusion rates of 1 mg/h or 0.05 mg/kg per hour. Meticulous observation for hemorrhagic complications is required during intraarterial thrombolytic therapy.

If the limb is not in jeopardy, a more conservative approach that includes observation and administration of anticoagulants may be taken. Anticoagulation prevents recurrent embolism and reduces the likelihood of thrombus propagation. It can be initiated with intravenous heparin and followed by oral warfarin. Recommended dosages are the same as those used for deep vein thrombosis (see below). Emboli resulting from infectious endocarditis, the presence of prosthetic heart valves, or atrial myxoma often require surgical intervention to remove the cause.

ATHEROEMBOLISM

Atheroembolism constitutes a subset of acute arterial occlusion. In this condition, multiple small deposits of fibrin, platelet, and cholesterol debris embolize from proximal atherosclerotic lesions or aneurysmal sites. Atheroembolism may occur after

intraarterial procedures. Since the emboli tend to lodge in the small vessels of the muscle and skin and may not occlude the large vessels, distal pulses usually remain palpable. Patients complain of acute pain and tenderness at the site of embolization. Digital vascular occlusion may result in ischemia and the "blue toe" syndrome; digital necrosis and gangrene may develop. Localized areas of tenderness, pallor, and livedo reticularis (see below) occur at sites of emboli. Skin or muscle biopsy may demonstrate cholesterol crystals.

Ischemia resulting from atheroemboli is notoriously difficult to treat. Usually neither surgical revascularization procedures nor thrombolytic therapy is helpful because of the multiplicity, composition, and distal location of the emboli. Some evidence suggests that platelet inhibitors prevent atheroembolism. Surgical intervention to remove or bypass the atherosclerotic vessel or aneurysm that causes the recurrent atheroemboli may be necessary.

THORACIC OUTLET COMPRESSION SYNDROME

This is a symptom complex resulting from compression of the neurovascular bundle (artery, vein, or nerves) at the thoracic outlet as it courses through the neck and shoulder. Cervical ribs, abnormalities of the scalenus anticus muscle, proximity of the clavicle to the first rib, or abnormal insertion of the pectoralis minor muscle may compress the subclavian artery and brachial plexus as these structures pass from the thorax to the arm. Patients may develop shoulder and arm pain, weakness, paresthesia, claudication, Raynaud's phenomenon, and even ischemic tissue loss and gangrene. Examination is often normal unless provocative maneuvers are performed. Occasionally, distal pulses are decreased or absent and digital cyanosis and ischemia may be evident. Tenderness may be present in the supraclavicular fossa. Abducting the affected arm by 90° and externally rotating the shoulder may precipitate symptoms. Several additional maneuvers are used to confirm the diagnosis of vascular compression and to suggest the location of the abnormality. These include the scalene maneuver (extension of the neck and rotation of the head to the side of the symptoms), the costoclavicular maneuver (posterior rotation of shoulders), and the hyperabduction maneuver (raising the arm 180°), which may cause subclavian bruits and loss of pulses in the arm. A chest x-ray will indicate the presence of cervical ribs. The electromyogram will be abnormal if the brachial plexus is involved.

TREATMENT

Most patients can be managed conservatively. They should be advised to avoid the positions that cause symptoms. Many patients benefit from shoulder girdle exercises. Surgical procedures such as removal of the first rib or resection of the scalenus anticus muscle are necessary occasionally for relief of symptoms or treatment of ischemia.

ARTERIOVENOUS FISTULA

Abnormal communications between an artery and a vein, bypassing the capillary bed, may be congenital or acquired. Congenital arteriovenous fistulas are the result of persistent embryonic vessels that fail to differentiate into arteries and veins; they may be associated with birthmarks, can be located in almost any organ of the body, and

frequently occur in the extremities. Acquired arteriovenous fistulas are either created to provide vascular access for hemodialysis or occur as a result of a penetrating injury such as a gunshot or knife wound or as complications of arterial catheterization or surgical dissection. An infrequent cause of arteriovenous fistula is rupture of an arterial aneurysm into a vein.

The clinical features depend on the location and size of the fistula. Frequently, a pulsatile mass is palpable, and a thrill and bruit lasting throughout systole and diastole are present over the fistula. With long-standing fistulas, clinical manifestations of chronic venous insufficiency, including peripheral edema, large, tortuous varicose veins, and stasis pigmentation become apparent because of the high venous pressure. Evidence of ischemia may occur in the distal portion of the extremity. Skin temperature is higher over the arteriovenous fistula. Large arteriovenous fistulas may result in an increased cardiac output with consequent cardiomegaly and high-output heart failure (Chap. 232).

Diagnosis The diagnosis is often evident from the physical examination. Compression of a large arteriovenous fistula may cause reflex slowing of the heart rate (Nicoladoni-Branham sign). Arteriography can confirm the diagnosis and is useful in demonstrating the site and size of the arteriovenous fistula.

TREATMENT

Management of arteriovenous fistulas may involve surgery, radiotherapy, or embolization. Congenital arteriovenous fistulas are often difficult to treat because the communications may be numerous and extensive, and new ones frequently develop after ligation of the most obvious ones. Many of these lesions are best treated conservatively using elastic support hose to reduce the consequences of venous hypertension. Occasionally, embolization with autologous material, such as fat or muscle, or with hemostatic agents, such as gelatin sponges or silicon spheres, is used to obliterate the fistula. Acquired arteriovenous fistulas are usually amenable to surgical treatment that involves division or excision of the fistula. Occasionally, autogenous or synthetic grafting is necessary to reestablish continuity of the artery and vein.

RAYNAUD'S PHENOMENON

Raynaud's phenomenon is characterized by episodic digital ischemia, manifested clinically by the sequential development of digital blanching, cyanosis, and rubor of the fingers or toes following cold exposure and subsequent rewarming. Emotional stress may also precipitate Raynaud's phenomenon. The color changes are usually well demarcated and are confined to the fingers or toes. Typically, one or more digits will appear white when the patient is exposed to a cold environment or touches a cold object. The blanching, or pallor, represents the ischemic phase of the phenomenon and results from vasospasm of digital arteries. During the ischemic phase, capillaries and venules dilate, and cyanosis results from the deoxygenated blood that is present in these vessels. A sensation of cold or numbness or paresthesia of the digits often accompanies the phases of pallor and cyanosis.

With rewarming, the digital vasospasm resolves, and blood flow into the dilated arterioles and capillaries increases dramatically. This "reactive hyperemia" imparts a

bright red color to the digits. In addition to rubor and warmth, patients often experience a throbbing, painful sensation during the hyperemic phase. Although the triphasic color response is typical of Raynaud's phenomenon, some patients may develop only pallor and cyanosis; others may experience only cyanosis.

Pathophysiology Raynaud originally proposed that cold-induced episodic digital ischemia was secondary to exaggerated reflex sympathetic vasoconstriction. This theory is supported by the fact that a-adrenergic blocking drugs as well as sympathectomy decrease the frequency and severity of Raynaud's phenomenon in some patients. An alternative hypothesis is that the digital vascular responsiveness to cold or to normal sympathetic stimuli is enhanced. It is also possible that normal reflex sympathetic vasoconstriction is superimposed on local digital vascular disease or that there is enhanced adrenergic neuroeffector activity.

Raynaud's phenomenon is broadly separated into two categories: the idiopathic variety, termed *Raynaud's disease*, and the secondary variety, which is associated with other disease states or known causes of vasospasm (Table 248-1).

Raynaud's Disease This appellation is applied when the secondary causes of Raynaud's phenomenon have been excluded. Over 50% of patients with Raynaud's phenomenon have Raynaud's disease. Women are affected about five times more often than men, and the age of presentation is usually between 20 and 40 years. The fingers are involved more frequently than the toes. Initial episodes may involve only one or two fingertips, but subsequent attacks may involve the entire finger and may include all the fingers. The toes are affected in 40% of patients. Although vasospasm of the toes usually occurs in patients with symptoms in the fingers, it may happen alone. Rarely, the earlobes and the tip of the nose are involved. Raynaud's phenomenon occurs frequently in patients who also have migraine headaches or variant angina. These associations suggest that there may be a common predisposing cause for the vasospasm.

Results of physical examination often are entirely normal; the radial, ulnar, and pedal pulses are normal. The fingers and toes may be cool between attacks and may perspire excessively. Thickening and tightening of the digital subcutaneous tissue (*sclerodactyly*) develop in 10% of patients. Angiography of the digits for diagnostic purposes is not indicated.

In general, patients with Raynaud's disease appear to have the milder forms of Raynaud's phenomenon. Fewer than 1% of these patients lose a part of a digit. After the diagnosis is made, the disease improves spontaneously in approximately 15% of patients and progresses in about 30%.

Secondary Causes of Raynaud's Phenomenon Raynaud's phenomenon occurs in 80 to 90% of patients with systemic sclerosis (scleroderma) and is the presenting symptom in 30% (Chap. 313). It may be the only symptom of scleroderma for many years. Abnormalities of the digital vessels may contribute to the development of Raynaud's phenomenon in this disorder. Ischemic fingertip ulcers may develop and progress to gangrene and autoamputation. About 20% of patients with systemic lupus erythematosus (SLE) have Raynaud's phenomenon (Chap. 311). Occasionally, persistent digital ischemia develops and may result in ulcers or gangrene. In most

severe cases, the small vessels are occluded by a proliferative endarteritis. Raynaud's phenomenon occurs in about 30% of patients with dermatomyositis or polymyositis (Chap. 382). It frequently develops in patients with rheumatoid arthritis and may be related to the intimal proliferation that occurs in the digital arteries.

Atherosclerosis of the extremities is a frequent cause of Raynaud's phenomenon in men over age 50. Thromboangiitis obliterans is an uncommon cause of Raynaud's phenomenon but should be considered in young men, particularly in those who are cigarette smokers. The development of cold-induced pallor in these disorders may be confined to one or two digits of the involved extremity. Occasionally, Raynaud's phenomenon may follow acute occlusion of large and medium-sized arteries by a thrombus or embolus. Embolization of atheroembolic debris may cause digital ischemia. The latter situation often involves one or two digits and should not be confused with Raynaud's phenomenon. In patients with the thoracic outlet syndrome, Raynaud's phenomenon may result from diminished intravascular pressure, stimulation of sympathetic fibers in the brachial plexus, or a combination of both. Raynaud's phenomenon occurs in patients with primary pulmonary hypertension (Chap. 260); this is more than coincidental and may reflect a neurohumoral abnormality that affects both the pulmonary and digital circulations.

A variety of blood dyscrasias may be associated with Raynaud's phenomenon. Cold-induced precipitation of plasma proteins, hyperviscosity, and aggregation of red cells and platelets may occur in patients with cold agglutinins, cryoglobulinemia, or cryofibrinogenemia. Hyperviscosity syndromes that accompany myeloproliferative disorders and Waldenstrom's macroglobulinemia should also be considered in the initial evaluation of patients with Raynaud's phenomenon.

Raynaud's phenomenon occurs often in patients whose vocations require the use of vibrating hand tools, such as chain saws or jackhammers. The frequency of Raynaud's phenomenon also seems to be increased in pianists and typists. Electric shock injury to the hands or frostbite may lead to the later development of Raynaud's phenomenon.

Several drugs have been causally implicated in Raynaud's phenomenon. These include ergot preparations, methysergide, b-adrenergic receptor antagonists, and the chemotherapeutic agents bleomycin, vinblastine, and cisplatin.

TREATMENT

Most patients with Raynaud's phenomenon experience only mild and infrequent episodes. These patients need reassurance and should be instructed to dress warmly and avoid unnecessary cold exposure. In addition to gloves and mittens, patients should protect the trunk, head, and feet with warm clothing to prevent cold-induced reflex vasoconstriction. Tobacco use is contraindicated.

Drug treatment should be reserved for the severe cases. The calcium channel antagonists, especially nifedipine and diltiazem, decrease the frequency and severity of Raynaud's phenomenon. Adrenergic blocking agents, such as reserpine, have been shown to increase nutritional blood flow to the fingers. Some, but not all, patients achieve satisfactory results with long-term reserpine therapy. Moreover, systemic use of

this drug is limited by side effects of hypotension, nasal stuffiness, lethargy, and depression. The postsynaptica$_1$-adrenergic antagonist prazosin has been used with favorable responses. Doxazosin and terazosin may also be effective. Other sympatholytic agents, such as methyldopa, guanethidine, and phenoxybenzamine, may be useful in some patients. Surgical sympathectomy is helpful in some patients who are unresponsive to medical therapy, but benefit is often transient.

ACROCYANOSIS

In this condition, there is arterial vasoconstriction and secondary dilation of the capillaries and venules with resulting persistent cyanosis of the hands and, less frequently, the feet. Cyanosis may be intensified by exposure to a cold environment. Women are affected much more frequently than men, and the age of onset is usually less than 30 years. Generally, patients are asymptomatic but seek medical attention because of the discoloration. Examination reveals normal pulses, peripheral cyanosis, and moist palms. Trophic skin changes and ulcerations do *not* occur. The disorder can be distinguished from Raynaud's phenomenon because it is persistent and not episodic, the discoloration extends proximally from the digits, and blanching does not occur. Ischemia secondary to arterial occlusive disease can usually be excluded by the presence of normal pulses. Central cyanosis and decreased arterial oxygen saturation are not present. Patients should be reassured and advised to dress warmly and avoid cold exposure. Pharmacologic intervention is not indicated.

LIVEDO RETICULARIS

In this condition, localized areas of the extremities develop a mottled or netlike appearance of reddish to blue discoloration. The mottled appearance may be more prominent following cold exposure. The idiopathic form of this disorder occurs equally in men and women, and the most common age of onset is in the third decade. Patients with the idiopathic form are usually asymptomatic and seek attention for cosmetic reasons. Livedo reticularis can also occur following atheroembolism (see above). Rarely, skin ulcerations develop. Patients should be reassured and advised to avoid cold environments. No drug treatment is indicated.

PERNIO (CHILBLAINS)

This is a vasculitic disorder associated with exposure to cold; acute forms have been described. Raised erythematous lesions develop on the lower part of the legs and feet in cold weather. These are associated with pruritus and a burning sensation, and they may blister and ulcerate. Pathologic examination demonstrates angiitis characterized by intimal proliferation and perivascular infiltration of mononuclear and polymorphonuclear leukocytes. Giant cells may be present in the subcutaneous tissue. Patients should avoid exposure to cold, and ulcers should be kept clean and protected with sterile dressings. Sympatholytic drugs may be effective in some patients.

ERYTHROMELALGIA (ERYTHERMALGIA)

This disorder is characterized by burning pain and erythema of the extremities. The feet are involved more frequently than the hands, and males are affected more frequently

than females. Erythromelalgia may occur at any age but is most common in middle age. It may be primary or secondary to myeloproliferative disorders such as polycythemia vera and essential thrombocytosis, or it may occur as an adverse effect of drugs such as nifedipine or bromocriptine. Patients complain of burning in the extremities that is precipitated by exposure to a warm environment and aggravated by a dependent position. The symptoms are relieved by exposing the affected area to cool air or water or by elevation. Erythromelalgia can be distinguished from ischemia secondary to peripheral arterial disorders and peripheral neuropathy because the peripheral pulses are present and the neurologic examination is normal. There is no specific treatment; aspirin may produce relief in patients with erythromelalgia secondary to myeloproliferative disease. Treatment of associated disorders in secondary erythromelalgia may be helpful.

FROSTBITE

In this condition, tissue damage results from severe environmental cold exposure or from direct contact with a very cold object. Tissue injury results from both freezing and vasoconstriction. Frostbite usually affects the distal aspects of the extremities or exposed parts of the face, such as the ears, nose, chin, and cheeks. Superficial frostbite involves the skin and subcutaneous tissue. Patients experience pain or paresthesia, and the skin appears white and waxy. After rewarming, there is cyanosis and erythema, wheal- and-flare formation, edema, and superficial blisters. Deep frostbite involves muscle, nerves, and deeper blood vessels. It may result in edema of the hand or foot, vesicles and bullae, tissue necrosis, and gangrene.

Initial treatment is rewarming, performed in an environment where reexposure to freezing conditions will not occur. Rewarming is accomplished by immersion of the affected part in a water bath at temperatures of 40 to 44°C (104 to 111°F). Massage, application of ice water, and extreme heat are contraindicated. The injured area should be cleansed with soap or antiseptic and sterile dressings applied. Analgesics are often required during rewarming. Antibiotics are used if there is evidence of infection. The efficacy of sympathetic blocking drugs is not established. Following recovery, the affected extremity may exhibit increased sensitivity to cold.

VENOUS DISORDERS

Veins in the extremities can be broadly classified as either superficial or deep. In the lower extremity, the superficial venous system includes the greater and lesser saphenous veins and their tributaries. The deep veins of the leg accompany the major arteries. Perforating veins connect the superficial and deep systems at multiple locations. Bicuspid valves are present throughout the venous system to direct the flow of venous blood centrally.

VENOUS THROMBOSIS

The presence of thrombus within a superficial or deep vein and the accompanying inflammatory response in the vessel wall is termed *venous thrombosis* or *thrombophlebitis*. Initially, the thrombus is composed principally of platelets and fibrin. Red cells become interspersed with fibrin, and the thrombus tends to propagate in the

direction of blood flow. The inflammatory response in the vessel wall may be minimal or characterized by granulocyte infiltration, loss of endothelium, and edema.

The factors that predispose to venous thrombosis were initially described by Virchow in 1856 and include stasis, vascular damage, and hypercoagulability. Accordingly, a variety of clinical situations are associated with increased risk of venous thrombosis (Table 248-2). Venous thrombosis may occur in more than 50% of patients having orthopedic surgical procedures, particularly those involving the hip or knee, and in 10 to 40% of patients who undergo abdominal or thoracic operations. The prevalence of venous thrombosis is particularly high in patients with cancer of the pancreas, lungs, genitourinary tract, stomach, and breast. Approximately 10 to 20% of patients with idiopathic deep vein thrombosis have or develop clinically overt cancer; there is no consensus on whether these individuals should be subjected to intensive diagnostic workup to search for occult malignancy. Risk of thrombosis is increased following trauma, such as fractures of the spine, pelvis, femur, and tibia. Immobilization, regardless of the underlying disease, is a major predisposing cause of venous thrombosis. This fact may account for the relatively high incidence in patients with acute myocardial infarction or congestive heart failure. The incidence of venous thrombosis is increased during pregnancy, particularly in the third trimester and in the first month postpartum, and in individuals who use oral contraceptives or receive postmenopausal hormone replacement therapy. A variety of clinical disorders that produce systemic hypercoagulability, including resistance to activated protein C (factor V Leiden); antithrombin III, protein C, and protein S deficiencies; antiphospholipid syndrome;SLE; myeloproliferative diseases; dysfibrinogenemia; and disseminated intravascular coagulation, are associated with venous thrombosis. Venulitis occurring in thromboangiitis obliterans, Behcet's disease, and homocysteinuria may also cause venous thrombosis.

DEEP VENOUS THROMBOSIS

The most important consequences of this disorder are pulmonary embolism (Chap. 261) and the syndrome of chronic venous insufficiency. Deep venous thrombosis of the iliac, femoral, or popliteal veins is suggested by unilateral leg swelling, warmth, and erythema. Tenderness may be present along the course of the involved veins, and a cord may be palpable. There may be increased tissue turgor, distention of superficial veins, and the appearance of prominent venous collaterals. In some patients, deoxygenated hemoglobin in stagnant veins imparts a cyanotic hue to the limb, a condition called *phlegmasia cerulea dolens*. In markedly edematous legs, the interstitial tissue pressure may exceed the capillary perfusion pressure, causing pallor, a condition designated *phlegmasia alba dolens*.

The diagnosis of deep venous thrombosis of the calf is often difficult to make at the bedside. This is so because only one of multiple veins may be involved, allowing adequate venous return through the remaining patent vessels. The most common complaint is calf pain. Examination may reveal posterior calf tenderness, warmth, increased tissue turgor or modest swelling, and, rarely, a cord. Increased resistance or pain during dorsiflexion of the foot (Homans' sign) is an unreliable diagnostic sign.

Deep venous thrombosis occurs less frequently in the upper extremity than in the lower

extremity, but the incidence is increasing because of greater utilization of indwelling central venous catheters. The clinical features and complications are similar to those described for the leg.

Diagnosis The noninvasive test used most often to diagnose deep venous thrombosis is duplex venous ultrasonography (B-mode, i.e., two-dimensional, imaging, and pulse-wave Doppler interrogation). By imaging the deep veins, thrombus can be detected either by direct visualization or by inference when the vein does not collapse on compressive maneuvers. The Doppler ultrasound measures the velocity of blood flow in veins. This velocity is normally affected by respiration and by manual compression of the foot or calf. Flow abnormalities occur when deep venous obstruction is present. The positive predictive value of duplex venous ultrasonography approaches 95% for proximal deep vein thrombosis. In the calf, because calf veins are more difficult to visualize than proximal veins, the sensitivity of this technique is only 50 to 75%, although its specificity is 95%.

Impedance plethysmography measures changes in venous capacitance during physiologic maneuvers. Venous obstruction blunts the normal changes in venous capacitance that occur following inflation and deflation of a thigh cuff. The predictive value of this test for detecting occlusive thrombi in proximal veins is approximately 90%. However, it is much less sensitive for diagnosing deep venous thrombosis of the calves.

Magnetic resonance imaging (MRI) is another noninvasive means to detect deep vein thrombosis. Its diagnostic accuracy for assessing proximal deep vein thrombosis is similar to that of duplex ultrasonography. It is useful in patients with suspected thrombosis of the superior and inferior venae cavae or pelvic veins.

Deep venous thrombosis can also be diagnosed by venography. Contrast medium is injected into a superficial vein of the foot and directed to the deep system by the application of tourniquets. The presence of a filling defect or absence of filling of the deep veins is required to make the diagnosis.

Deep vein thrombosis must be differentiated from a variety of disorders that cause unilateral leg pain or swelling, including muscle rupture, trauma, or hemorrhage; a ruptured popliteal cyst; and lymphedema. It may be difficult to distinguish swelling caused by the postphlebitic syndrome from that due to acute recurrent deep venous thrombosis. Leg pain may also result from nerve compression, arthritis, tendinitis, fractures, and arterial occlusive disorders. A careful history and physical examination can usually determine the cause of these symptoms.

TREATMENT

Anticoagulants (See also Chap. 261) Prevention of pulmonary embolism is the most important reason for treating patients with deep vein thrombosis, since in the early stages the thrombus may be loose and poorly adherent to the vessel wall. Patients should be placed in bed, and the affected extremity should be elevated above the level of the heart until the edema and tenderness subside. Anticoagulants prevent thrombus propagation and allow the endogenous lytic system to operate. Initial therapy should include either unfractionated heparin or low-molecular-weight heparin. Unfractionated

heparin should be administered intravenously as an initial bolus of 7500 to 10,000 IU, followed by a continuous infusion of 1000 to 1500 IU/h. The rate of the heparin infusion should be adjusted so that the activated partial thromboplastin time (aPTT) is approximately twice the control value. Subcutaneous injection of heparin has been used as an alternative form of therapy. In fewer than 5% of patients, heparin therapy may cause thrombocytopenia. Infrequently, these patients develop arterial thrombosis and ischemia. Low-molecular-weight (4000 to 6000 Da) heparins are reported to be as effective as or better than conventional, unfractionated heparin in preventing extension or recurrence of venous thrombosis. Depending on the specific preparation, low-molecular-weight heparin is administered subcutaneously, in fixed doses, once or twice daily; for example, the dose of enoxaparin is 1 mg/kg subcutaneously bid. The incidence of thrombocytopenia is less with low-molecular-weight heparin than with conventional preparations. Hirudin, a direct thrombin inhibitor, may be used as initial anticoagulant therapy for patients in whom heparin is contraindicated because of heparin-induced thrombocytopenia. Warfarin is administered during the first week of treatment with heparin and may be started as early as the first day of heparin treatment if the aPTT is therapeutic. It is important to overlap heparin treatment with oral anticoagulant therapy for at least 4 to 5 days because the full anticoagulant effect of warfarin is delayed. The dose of warfarin should be adjusted to maintain the prothrombin time at an international normalized ratio (INR) of 2.0 to 3.0.

Anticoagulant treatment is indicated for patients with proximal deep vein thrombosis, since pulmonary embolism may occur in approximately 50% of untreated individuals. The use of anticoagulants for isolated deep vein thrombosis of the calf is controversial. However, approximately 20 to 30% of calf thrombi propagate to the thigh, thereby increasing the risk of pulmonary embolism. The overall incidence of pulmonary embolism in patients presenting initially with deep calf vein thrombosis is 5 to 20%. Also, isolated calf vein thrombosis has been identified as a cause of embolic stroke via a patent foramen ovale. Therefore, patients with calf vein thrombosis should either receive anticoagulants or be followed with serial noninvasive tests to determine whether proximal propagation has occurred. Anticoagulant treatment should be continued for at least 3 to 6 months for patients with acute idiopathic deep vein thrombosis and for those with a temporary risk factor for venous thrombosis to decrease the chance of recurrence. The duration of treatment is indefinite for patients with recurrent deep vein thrombosis and for those in whom associated causes, such as malignancy or hypercoagulability, have not been eliminated. If treatment with anticoagulants is contraindicated because of a bleeding diathesis or risk of hemorrhage, protection from pulmonary embolism can be achieved by mechanically interrupting the flow of blood through the inferior vena cava. Inferior vena cava plication generally has been replaced by percutaneous insertion of a filter.

Thrombolytics Thrombolytic drugs such as streptokinase, urokinase, and tPA may also be used, but there is no evidence that thrombolytic therapy is more effective than anticoagulants in preventing pulmonary embolism. However, early administration of thrombolytic drugs may accelerate clot lysis, preserve venous valves, and decrease the potential for developing postphlebitic syndrome.

Prophylaxis Prophylaxis should be considered in clinical situations where the risk of deep vein thrombosis is high. Low-dose unfractionated heparin (5000 units 2 h prior to

surgery and then 5000 units every 8 to 12 h postoperatively), warfarin, and external pneumatic compression are all useful. Low-dose heparin reduces the risk of deep vein thrombosis associated with thoracic and abdominal surgery and with prolonged bed rest. Low-molecular-weight heparins have been shown to prevent deep vein thrombosis in patients undergoing general or orthopedic surgery and in acutely ill medical patients. They are said to be more effective than conventional heparin and to cause an equal or lower incidence of bleeding. Danaparoid, a low-molecular-weight heparinoid, may be used for prophylaxis in patients undergoing hip surgery. Warfarin in a dose that yields a prothrombin time equivalent to anINR of 2.0 to 3.0 is effective in preventing deep vein thrombosis associated with bone fractures and orthopedic surgery. Warfarin is started the night before surgery and continued throughout the convalescent period. External pneumatic compression devices applied to the legs are used to prevent deep vein thrombosis when even low doses of heparin or warfarin might cause serious bleeding, as during neurosurgery or transurethral resection of the prostate.

SUPERFICIAL VEIN THROMBOSIS

Thrombosis of the greater or lesser saphenous veins or their tributaries -- i.e., superficial vein thrombosis -- does not result in pulmonary embolism. It is associated with intravenous catheters and infusions, occurs in varicose veins, and may develop in association with deep vein thrombosis. Migrating superficial vein thrombosis is often a marker for a carcinoma and may also occur in patients with vasculitides, such as thromboangiitis obliterans. The clinical features of superficial vein thrombosis are easily distinguished from those of deep vein thrombosis. Patients complain of pain localized to the site of the thrombus. Examination reveals a reddened, warm, and tender cord extending along a superficial vein. The surrounding area may be red and edematous.

TREATMENT

Treatment is primarily supportive. Initially, patients can be placed at bed rest with leg elevation and application of warm compresses. Nonsteroidal antiinflammatory drugs may provide analgesia but may also obscure clinical evidence of thrombus propagation. If a thrombosis of the greater saphenous vein develops in the thigh and extends toward the saphenofemoral vein junction, it is reasonable to consider anticoagulant therapy to prevent extension of the thrombus into the deep system and a possible pulmonary embolism.

VARICOSE VEINS

Varicose veins are dilated, tortuous superficial veins that result from defective structure and function of the valves of the saphenous veins, from intrinsic weakness of the vein wall, from high intraluminal pressure, or, rarely, from arteriovenous fistulas. Varicose veins can be categorized as primary or secondary. Primary varicose veins originate in the superficial system and occur two to three times as frequently in women as in men. Approximately half of patients have a family history of varicose veins. Secondary varicose veins result from deep venous insufficiency and incompetent perforating veins or from deep venous occlusion causing enlargement of superficial veins that are serving as collaterals.

Patients with venous varicosities are often concerned about the cosmetic appearance of their legs. Symptoms consist of a dull ache or pressure sensation in the legs after prolonged standing; it is relieved with leg elevation. The legs feel heavy, and mild ankle edema develops occasionally. Extensive venous varicosities may cause skin ulcerations near the ankle. Superficial venous thrombosis may be a recurring problem, and, rarely, a varicosity ruptures and bleeds. Visual inspection of the legs in the dependent position usually confirms the presence of varicose veins.

Varicose veins can usually be treated with conservative measures. Symptoms often decrease when the legs are elevated periodically, when prolonged standing is avoided, and when elastic support hose are worn. External compression stockings provide a counterbalance to the hydrostatic pressure in the veins. Small symptomatic varicose veins can be treated with sclerotherapy, in which a sclerosing solution is injected into the involved varicose vein and a compression bandage is applied. Surgical therapy usually involves extensive ligation and stripping of the greater and lesser saphenous veins and should be reserved for patients who are very symptomatic, suffer recurrent superficial vein thrombosis, and/or develop skin ulceration. Surgical therapy may also be indicated for cosmetic reasons.

CHRONIC VENOUS INSUFFICIENCY

Chronic venous insufficiency may result from deep vein thrombosis and/or valvular incompetence. Following deep vein thrombosis, the delicate valve leaflets become thickened and contracted so that they cannot prevent retrograde flow of blood; the vein becomes rigid and thick-walled. Although most veins recanalize after an episode of thrombosis, the large proximal veins may remain occluded. Secondary incompetence develops in distal valves because high pressures distend the vein and separate the leaflets. Primary deep venous valvular dysfunction may also occur without previous thrombosis. Patients with venous insufficiency often complain of a dull ache in the leg that worsens with prolonged standing and resolves with leg elevation. Examination demonstrates increased leg circumference, edema, and superficial varicose veins. Erythema, dermatitis, and hyperpigmentation develop along the distal aspect of the leg, and skin ulceration may occur near the medial and lateral malleoli. Cellulitis may be a recurring problem. Patients should be advised to avoid prolonged standing or sitting; frequent leg elevation is helpful. Graduated compression stockings should be worn during the day. These efforts should be intensified if skin ulcers develop. Ulcers should be treated with applications of wet to dry dressings and, occasionally, dilute topical antibiotic solutions. Commercially available dressings comprising antiseptic solutions and compressive bandages may be applied and should be changed weekly until healing occurs. Recurrent ulceration and severe edema may be treated by surgical interruption of incompetent communicating veins. Rarely, surgical valvuloplasty and bypass of venous occlusions are employed.

LYMPHATIC DISORDERS

Lymphatic capillaries are blind-ended tubes formed by a single layer of endothelial cells. The absent or widely fenestrated basement membrane of lymphatic capillaries allows access to interstitial proteins and particles. Lymphatic capillaries merge to form larger vessels which contain smooth muscle and are capable of vasomotion. Small and

medium-sized lymphatic vessels empty into progressively larger channels, most of which drain into the thoracic duct. The lymphatic circulation is involved in the absorption of interstitial fluid and in the response to infection.

LYMPHEDEMA

Lymphedema may be categorized as primary or secondary (Table 248-3). The prevalence of primary lymphedema is approximately 1 per 10,000 individuals. Primary lymphedema may be secondary to agenesis, hypoplasia, or obstruction of the lymphatic vessels. It may be associated with Turner syndrome, Klinefelter syndrome, Noonan syndrome, the yellow nail syndrome, the intestinal lymphangiectasia syndrome, and lymphangiomyomatosis. Women are affected more frequently than men. There are three clinical subtypes: congenital lymphedema, which appears shortly after birth; lymphedema praecox, which has its onset at the time of puberty; and lymphedema tarda, which usually begins after age 35. Familial forms of congenital lymphedema (Milroy's disease) and lymphedema praecox (Meige's disease) may be inherited in an autosomal dominant manner with variable penetrance; autosomal or sex-linked recessive forms are less common.

Secondary lymphedema is an acquired condition resulting from damage to or obstruction of previously normal lymphatic channels (Table 248-3). Recurrent episodes of bacterial lymphangitis, usually caused by streptococci, are a very common cause of lymphedema. The most common cause of secondary lymphedema worldwide is filariasis (Chap. 221). Tumors, such as prostate cancer and lymphoma, can also obstruct lymphatic vessels. Both surgery and radiation therapy for breast carcinoma may cause lymphedema of the upper extremity. Less common causes include tuberculosis, contact dermatitis, lymphogranuloma venereum, rheumatoid arthritis, pregnancy, and self-induced or factitious lymphedema following application of tourniquets.

Lymphedema is generally a painless condition, but patients may experience a chronic dull, heavy sensation in the leg, and most often they are concerned about the appearance of the leg. Lymphedema of the lower extremity, initially involving the foot, gradually progresses up the leg so that the entire limb becomes edematous. In the early stages, the edema is soft and pits easily with pressure. In the chronic stages, the limb has a woody texture, and the tissues become indurated and fibrotic. At this point the edema may no longer be pitting. The limb loses its normal contour, and the toes appear square. Lymphedema should be distinguished from other disorders that cause unilateral leg swelling, such as deep vein thrombosis and chronic venous insufficiency. In the latter condition, the edema is softer, and there is often evidence of a stasis dermatitis, hyperpigmentation, and superficial venous varicosities.

The evaluation of patients with lymphedema should include diagnostic studies to clarify the cause. Abdominal and pelvic ultrasound and computed tomography can be used to detect obstructing lesions such as neoplasms.MRI may reveal edema in the epifascial compartment and identify lymph nodes and enlarged lymphatic channels. Lymphoscintigraphy and lymphangiography are rarely indicated, but either can be used to confirm the diagnosis or to differentiate primary from secondary lymphedema. Lymphoscintigraphy involves the injection of radioactively labeled technetium-containing

colloid into the distal subcutaneous tissue of the affected extremity. In lymphangiography, contrast material is injected into a distal lymphatic vessel that has been isolated and cannulated. In primary lymphedema, lymphatic channels are absent, hypoplastic, or ectatic. In secondary lymphedema, lymphatic channels are usually dilated, and it may be possible to determine the level of obstruction.

TREATMENT

Patients with lymphedema of the lower extremities must be instructed to take meticulous care of their feet to prevent recurrent lymphangitis. Skin hygiene is important, and emollients can be used to prevent drying. Prophylactic antibiotics are often helpful, and fungal infection should be treated aggressively. Patients should be encouraged to participate in physical activity; frequent leg elevation can reduce the amount of edema. Physical therapy, including massage to facilitate lymphatic drainage, may be helpful. Patients can be fitted with graduated compression hose to reduce the amount of lymphedema that develops with upright posture. Occasionally, intermittent pneumatic compression devices can be applied at home to facilitate reduction of the edema. Diuretics are contraindicated and may cause depletion of intravascular volume and metabolic abnormalities. Recently, microsurgical lymphatico-venous anastomotic procedures have been performed to rechannel lymph flow from obstructed lymphatic vessels into the venous system.

PART NINE -DISORDERS OF THE RESPIRATORY SYSTEM

SECTION 1 -DIAGNOSIS

249. APPROACH TO THE PATIENT WITH DISEASE OF THE RESPIRATORY SYSTEM - *Jeffrey M. Drazen*, *Steven E. Weinberger*

Patients with disease of the respiratory system generally present because of symptoms, an abnormality on a chest radiograph, or both. A set of diagnostic possibilities is often suggested by the initial problems at presentation, including the particular symptom(s) and the appearance of any radiographic abnormalities. The differential diagnosis is then refined on the basis of additional information gleaned from physical examination, pulmonary function testing, additional imaging studies, and bronchoscopic examination. This**chapter**will consider the approach to the patient based on the major patterns of presentation, focusing on the history, the physical examination, and the chest radiograph.**For further discussion of pulmonary function testing, see Chap. 250, and of other diagnostic studies, see Chap. 251.*

CLINICAL PRESENTATION

HISTORY

Dyspnea (shortness of breath) and cough are the primary presenting symptoms for patients with respiratory system disease. Less common symptoms include hemoptysis (the coughing up of blood) and chest pain, often with a pleuritic quality.

Dyspnea (See alsoChap. 32) When evaluating a patient with shortness of breath, one should first determine the time course over which the symptom has become manifest. Patients who were well previously and developed *acute* shortness of breath (over a period of hours to days) can have acute disease affecting the airways (an acute attack of asthma), the pulmonary parenchyma (acute pulmonary edema or an acute infectious process such as a bacterial pneumonia), the pleural space (a pneumothorax), or the pulmonary vasculature (a pulmonary embolus). A *subacute* presentation (over days to weeks) can suggest an exacerbation of preexisting airways disease (asthma or chronic bronchitis), a parenchymal infection or a noninfectious inflammatory process that proceeds at a relatively slow pace (*Pneumocystis carinii* pneumonia in a patient with AIDS, mycobacterial or fungal pneumonia, Wegener's granulomatosis, eosinophilic pneumonia, bronchiolitis obliterans with organizing pneumonia, and many others), neuromuscular disease (Guillain-Barre syndrome, myasthenia gravis), pleural disease (pleural effusion from a variety of possible causes), or chronic cardiac disease (congestive heart failure). A *chronic* presentation (over months to years) often indicates chronic obstructive lung disease, chronic interstitial lung disease, or chronic cardiac disease. Chronic diseases of airways (not only chronic obstructive lung disease but also asthma) are characterized by exacerbations and remissions. Patients often have periods when they are severely limited by shortness of breath, but these may be interspersed with periods in which symptoms are minimal or absent. In contrast, many of the diseases of pulmonary parenchyma are characterized by a slow but inexorable progression.

Other Respiratory Symptoms *Cough* (Chap. 33) may indicate the presence of lung disease, but cough per se is not useful for the differential diagnosis. The presence of sputum accompanying the cough often suggests airway disease and may be seen in asthma, chronic bronchitis, or bronchiectasis.

Hemoptysis (Chap. 33) can originate from disease of the airways, the pulmonary parenchyma, or the vasculature. Diseases of the airways can be inflammatory (acute or chronic bronchitis, bronchiectasis, or cystic fibrosis) or neoplastic (bronchogenic carcinoma or bronchial carcinoid tumors). Parenchymal diseases causing hemoptysis may be either localized (pneumonia, lung abscess, tuberculosis, or infection with *Aspergillus*) or diffuse (Goodpasture's syndrome, idiopathic pulmonary hemosiderosis). Vascular diseases potentially associated with hemoptysis include pulmonary thromboembolic disease and pulmonary arteriovenous malformations.

Chest pain (Chap. 13) caused by diseases of the respiratory system usually originates from involvement of the parietal pleura. As a result, the pain is accentuated by respiratory motion and is often referred to as *pleuritic*. Common examples include primary pleural disorders, such as neoplasm or inflammatory disorders involving the pleura, or pulmonary parenchymal disorders that extend to the pleural surface, such as pneumonia or pulmonary infarction.

Additional Historic Information Information about risk factors for lung disease should be explicitly explored to assure a complete basis of historic data. A history of current and past smoking, especially of cigarettes, should be sought from all patients. The smoking history should include the number of years of smoking, the intensity (i.e., number of packs per day), and, if the patient no longer smokes, the interval since smoking cessation. The risk of lung cancer falls progressively with the interval following discontinuation of smoking, and loss of lung function above the expected age-related decline ceases with the discontinuation of smoking. Even though chronic obstructive lung disease and neoplasia are the two most important respiratory complications of smoking, other respiratory disorders (e.g., spontaneous pneumothorax, respiratory bronchiolitis-interstitial lung disease, eosinophilic granuloma of the lung, and pulmonary hemorrhage with Goodpasture's syndrome) are also associated with smoking. A history of significant secondhand (passive) exposure to smoke, whether in the home or at the workplace, should also be sought as it may be a risk factor for neoplasia or an exacerbating factor for airways disease.

The patient may have been exposed to other inhaled agents associated with lung disease, which act either via direct toxicity or through immune mechanisms (Chaps. 253 and254). Such exposures can be either occupational or avocational, indicating the importance of detailed occupational and personal histories, the latter stressing exposures related to hobbies or the home environment. Important agents include the inorganic dusts associated with pneumoconiosis (especially asbestos and silica dusts) and organic antigens associated with hypersensitivity pneumonitis (especially antigens from molds and animal proteins). Asthma, which is more common in women than men, is often exacerbated by exposure to environmental allergens (dust mites, pet dander, or cockroach allergens in the home or allergens in the outdoor environment such as pollen and ragweed) or may be caused by occupational exposures (diisocyanates). Exposure to particular infectious agents can be suggested by contacts with individuals with known

respiratory infections (especially tuberculosis) or by residence in an area with endemic pathogens (histoplasmosis, coccidioidomycosis, blastomycosis).

A history of coexisting nonrespiratory disease or of risk factors for or previous treatment of such diseases should be sought, as they may predispose a patient to both infectious and noninfectious respiratory system complications. Common examples include systemic rheumatic diseases that are associated with pleural or parenchymal lung disease (Chap. 312), metastatic neoplastic disease in the lung, or impaired host defense mechanisms and secondary infection, which occur in the case of hematologic and lymph node malignancies. Risk factors for AIDS should be sought, as the lungs are not only the most common site of AIDS-defining infection but also can be involved by nonfectious complications of AIDS (Chap. 309). Treatment of nonrespiratory disease can be associated with respiratory complications, either because of effects on host defense mechanisms (immunosuppressive agents, cancer chemotherapy) with resulting infection or because of direct effects on the pulmonary parenchyma (cancer chemotherapy, radiation therapy, or treatment with other agents, such as amiodarone) or on the airways (beta-blocking agents causing airflow obstruction, angiotensin-converting enzyme inhibitors causing cough) (Chap. 253).

Family history is important for evaluating diseases that have a genetic component. These include disorders such as cystic fibrosis,a_1-antitrypsin deficiency, and asthma.

PHYSICAL EXAMINATION

The general principles of inspection, palpation, percussion, and auscultation apply to the examination of the respiratory system. However, the physical examination should be directed not only toward ascertaining abnormalities of the lungs and thorax but also toward recognizing other findings that may reflect underlying lung disease.

On *inspection*, the rate and pattern of breathing as well as the depth and symmetry of lung expansion are observed. Breathing that is unusually rapid, labored, or associated with the use of accessory muscles of respiration generally indicates either augmented respiratory demands or an increased work of breathing. Asymmetric expansion of the chest is usually due to an asymmetric process affecting the lungs, such as endobronchial obstruction of a large airway, unilateral parenchymal or pleural disease, or unilateral phrenic nerve paralysis. Visible abnormalities of the thoracic cage include kyphoscoliosis and ankylosing spondylitis, either of which can alter compliance of the thorax, increase the work of breathing, and cause dyspnea.

On *palpation*, the symmetry of lung expansion can be assessed, generally confirming the findings observed by inspection. Vibration produced by spoken sounds is transmitted to the chest wall and is assessed by the presence or absence and symmetry of tactile fremitus. Transmission of vibration is decreased or absent if pleural liquid is interposed between the lung and the chest wall or if an endobronchial obstruction alters sound transmission. In contrast, transmitted vibration may increase over an area of underlying pulmonary consolidation.

The relative resonance or dullness of the tissue underlying the chest wall is assessed by *percussion*. The normal sound of underlying air-containing lung is resonant. In contrast,

consolidated lung or a pleural effusion sounds dull, while emphysema or air in the pleural space results in a hyperresonant percussion note.

On *auscultation* of the lungs, the examiner listens for both the quality and intensity of the breath sounds and for the presence of extra, or adventitious, sounds. Normal breath sounds heard through the stethoscope at the periphery of the lung are described as *vesicular breath sounds*, in which inspiration is louder and longer than expiration. If sound transmission is impaired by endobronchial obstruction or by air or liquid in the pleural space, breath sounds are diminished in intensity or absent. When sound transmission is improved through consolidated lung, the resulting *bronchial breath sounds* have a more tubular quality and a more pronounced expiratory phase. Sound transmission can also be assessed by listening to spoken or whispered sounds; when these are transmitted through consolidated lung, *bronchophony* and *whispered pectoriloquy*, respectively, are present. The sound of a spoken E becomes more like an A, though with a nasal or bleating quality, a finding that is termed *egophony*.

The primary adventitious (abnormal) sounds that can be heard include crackles (rales), wheezes, and rhonchi. *Crackles* represent the typically inspiratory sound created when alveoli and small airways open and close with respiration, and they are often associated with interstitial lung disease, microatelectasis, or filling of alveoli by liquid. *Wheezes*, which are generally more prominent during expiration than inspiration, reflect the oscillation of airway walls that occurs when there is airflow limitation, as may be produced by bronchospasm, airway edema or collapse, or intraluminal obstruction by neoplasm or secretions. *Rhonchi* is the term applied to the sounds created when there is free liquid in the airway lumen; the viscous interaction between the free liquid and the moving air creates a low-pitched vibratory sound. Other adventitious sounds include pleural friction rubs and stridor. The gritty sound of a *pleural friction rub* indicates inflamed pleural surfaces rubbing against each other, often during both inspiratory and expiratory phases of the respiratory cycle. *Stridor*, which occurs primarily during inspiration, represents flow through a narrowed upper airway, as occurs in an infant with croup.

A summary of the patterns of physical findings on pulmonary examination in common types of respiratory system disease is shown in Table 249-1.

A meticulous *general physical examination* is mandatory in patients with disorders of the respiratory system. Enlarged lymph nodes in the cervical and supraclavicular regions should be sought. Disturbances of mentation or even coma can occur in patients with acute carbon dioxide retention and hypoxemia. Telltale stains on the fingers point to heavy cigarette smoking; infected teeth and gums may occur in patients with aspiration pneumonitis and lung abscess.

Clubbing of the digits can be found in lung cancer, interstitial lung disease, and chronic infections in the thorax, such as bronchiectasis, lung abscess, and empyema. Clubbing can also be seen with congenital heart disease associated with right-to-left shunting and with a variety of chronic inflammatory or infectious diseases, such as inflammatory bowel disease and endocarditis. A number of systemic diseases, such as systemic lupus erythematosus, scleroderma, and rheumatoid arthritis, may be associated with pulmonary complications, even though their primary clinical manifestations and physical

findings are not primarily related to the lungs. Conversely, other diseases that most commonly affect the respiratory system, such as sarcoidosis, can have findings on physical examination not related to the respiratory system, including ocular findings (uveitis, conjunctival granulomas) and skin findings (erythema nodosum, cutaneous granulomas).

CHEST RADIOGRAPHY

Chest radiography is often the initial diagnostic study performed to evaluate patients with respiratory symptoms, but it can also provide the initial evidence of disease in patients who are free of symptoms. Perhaps the most common example of the latter situation is the finding of one or more nodules or masses when the radiograph is performed for a reason other than evaluation of respiratory symptoms.

A number of diagnostic possibilities are often suggested by the radiographic pattern (Figs. 249-1 and249-2). A localized region of opacification involving the pulmonary parenchyma can be described as a nodule (usually <6 cm in diameter), a mass (usually ^{3} 6 cm in diameter), or an infiltrate. Diffuse disease with increased opacification is usually characterized as having an alveolar, an interstitial, or a nodular pattern. In contrast, increased radiolucency can be localized, as seen with a cyst or bulla, or generalized, as occurs with emphysema. The chest radiograph is also particularly useful for the detection of pleural disease, especially if manifested by the presence of air or liquid in the pleural space. An abnormal appearance of the hila and/or the mediastinum can suggest a mass or enlargement of lymph nodes.

A summary of representative diagnoses suggested by these common radiographic patterns is presented inTable 249-2.

Additional Diagnostic Evaluation Further information for clarification of radiographic abnormalities is frequently obtained with computed tomographic scanning of the chest (Chap. 251; seeFig. 265-2). This technique is more sensitive than plain radiography in detecting subtle abnormalities and can suggest specific diagnoses based on the pattern of abnormality.**For further discussion of the use of other imaging studies, including magnetic resonance imaging, scintigraphic studies, ultrasound, and angiography, see Chap. 251.*

Alteration in the function of the lungs as a result of respiratory system disease is assessed objectively by pulmonary function tests, and effects on gas exchange are evaluated by measurement of arterial blood gases or by oximetry (Chap. 250). As part of pulmonary function testing, quantitation of forced expiratory flow assesses the presence of obstructive physiology, which is consistent with diseases affecting the structure or function of the airways, such as asthma and chronic obstructive lung disease. Measurement of lung volumes assesses the presence of restrictive disorders, seen with diseases of the pulmonary parenchyma or respiratory pump and with space-occupying processes within the pleura.

Bronchoscopy is useful in some settings for visualizing abnormalities of the airways and for obtaining a variety of samples from either the airway or the pulmonary parenchyma (Chap. 251).

INTEGRATION OF THE PRESENTING CLINICAL PATTERN AND DIAGNOSTIC STUDIES

Patients with respiratory symptoms but a normal chest radiograph most commonly have diseases affecting the airways, such as asthma or chronic obstructive pulmonary disease. However, the latter diagnosis is also commonly associated with radiographic abnormalities, such as diaphragmatic flattening and attenuation of vascular markings. Other disorders of the respiratory system for which the chest radiograph is normal include disorders of the respiratory pump (either the chest wall or the neuromuscular apparatus controlling the chest wall) or pulmonary circulation and occasionally interstitial lung disease. Chest examination and pulmonary function tests are generally helpful in sorting out these diagnostic possibilities. Obstructive diseases associated with a normal or relatively normal chest radiograph are often characterized by findings on physical examination and pulmonary function testing that are typical for these conditions. Similarly, diseases of the respiratory pump or interstitial diseases may also be suggested by findings on physical examination or by particular patterns of restrictive disease seen on pulmonary function testing.

When respiratory symptoms are accompanied by radiographic abnormalities, diseases of the pulmonary parenchyma or the pleura are usually present. Either diffuse or localized parenchymal lung disease is generally visualized well on the radiograph, and both air and liquid in the pleural space (pneumothorax and pleural effusion, respectively) are usually readily detected by radiography.

Radiographic findings in the absence of respiratory symptoms often indicate localized disease affecting the airways or the pulmonary parenchyma. One or more nodules or masses can suggest intrathoracic malignancy, but they also can be the manifestation of a current or previous infectious process. Patients with diffuse parenchymal lung disease on radiographic examination may be free of symptoms, as is sometimes the case with pulmonary sarcoidosis.

In approaching the patient with pulmonary disease, consideration must be given to the observation that substantial changes in the relative incidence of diseases affecting the respiratory system have taken place in the United States during the past four decades. The prevalence of chronic infectious disorders such as lung abscess and bronchiectasis has decreased. Tuberculosis declined only to undergo resurgence when two susceptible populations, patients with AIDS and immigrants from Southeast Asia, increased in number. Patients with chronic bronchitis and with emphysema now survive longer and form an increasing fraction of patients with chronic respiratory disease, as do patients with environmental lung disease and with drug-induced pulmonary disease. Modern intercontinental travel has increased the appearance in the western world of parasitic infestations of the lung. Also, the reduction of immune competence that occurs in patients with AIDS and in those with diabetes as well as in patients being treated for a variety of malignancies and those receiving immunosuppressive drugs has led to an increasing incidence of opportunistic infections of the lungs with a variety of microorganisms that were rarely pathogenic in the past.

250. DISTURBANCES OF RESPIRATORY FUNCTION - *Steven E. Weinberger, Jeffrey M. Drazen*

The respiratory system includes the lungs, the central nervous system (CNS), the chest wall (with the diaphragm and intercostal muscles), and the pulmonary circulation. The CNS controls the activity of the muscles of the chest wall, which constitute the pump of the respiratory system. Because these components of the respiratory system act in concert to achieve gas exchange, malfunction of an individual component or alteration of the relationships among components can lead to disturbances in function. In this **chapter** we consider three major aspects of disturbed respiratory function: (1) disturbances in ventilatory function, (2) disturbances in the pulmonary circulation, and (3) disturbances in gas exchange. **For further discussion of disorders relating to CNS control of ventilation, see Chap. 263.*

DISTURBANCES IN VENTILATORY FUNCTION

Ventilation is the process whereby the lungs replenish the gas in the alveoli. Measurements of ventilatory function in common diagnostic use consist of quantification of the gas volume contained in the lungs under certain circumstances and the rate at which gas can be expelled from the lungs. Two measurements of lung volume commonly used for respiratory diagnosis are total lung capacity (TLC) and residual volume (RV). The former is the volume of gas contained in the lungs after a maximal inspiration, whereas the latter is the volume of gas remaining in the lungs at the end of a maximal expiration. The volume of gas that is exhaled from the lungs in going from TLC to RV is called the *vital capacity* (VC) (Fig. 250-1).

Common clinical measurements of airflow are obtained from maneuvers in which the subject inspires to TLC and then forcibly exhales to RV. Three measurements are commonly made from a recording of exhaled volume versus time -- i.e., a spirogram -- obtained during such a forced expiratory maneuver: (1) the volume of gas exhaled during the first second of expiration [forced expiratory volume (FEV) in 1 s, or FEV_1], (2) the total volume exhaled [forced vital capacity (FVC)], and (3) the average expiratory flow rate during the middle 50% of the VC [forced expiratory flow (FEF) between 25 and 75% of the VC, or $FEF_{25-75\%}$, also called the maximal midexpiratory flow rate (MMFR)] (Fig. 250-2).

PHYSIOLOGIC FEATURES

The lungs are elastic structures, containing collagen and elastic fibers that resist expansion. For normal lungs to contain air, they must be distended either by a positive internal pressure -- i.e., by a pressure in the airways and alveolar spaces -- or by a negative external pressure -- i.e., by a pressure outside the lung. The relationship between the volume of gas contained in the lungs and the distending pressure (the *transpulmonary pressure*, or P_{TP}, defined as internal pressure minus external pressure) is described by the pressure-volume curve of the lungs (Fig. 250-3*A*).

The chest wall is also an elastic structure, with properties similar to those of an expandable and compressible spring. The relationship between the volume enclosed by the chest wall and the distending pressure for the chest wall is described by the

pressure-volume curve of the chest wall (Fig. 250-3*B*). For the chest wall to assume a volume different from its resting volume, the internal or external pressures acting on it must be altered.

At functional residual capacity (FRC), defined as the volume of gas in the lungs at the end of a normal exhalation, the lungs are partially inflated, so their elastic recoil exerts a force tending to empty the lungs. At the same time, chest wall volume is such that its elastic recoil promotes outward expansion. FRC occurs at the lung volume at which the tendency of the lungs to contract is opposed by the equal and opposite tendency of the chest wall to expand (Fig. 250-3*C*).

For the lungs and the chest wall to achieve a volume other than the resting volume (FRC), either the pressures acting on them must be changed passively -- e.g., by a mechanical ventilator that delivers positive pressure to the airways and alveoli -- or the respiratory muscles must actively oppose the tendency of the lungs and the chest wall to return to FRC. During inhalation to volumes above FRC, the inspiratory muscles actively overcome the tendency of the respiratory system to decrease volume back to FRC. During active exhalation to volumes below FRC, expiratory muscle activity must overcome the tendency of the respiratory system to increase volume back to FRC.

AtTLC, the maximal force applied by the inspiratory muscles to expand the lungs is opposed mainly by the inward recoil of the lungs. As a consequence, the major determinants of TLC are the stiffness of the lungs and inspiratory muscle strength. If the lungs become stiffer -- i.e., less compliant -- TLC is decreased. If the lungs become less stiff (more compliant), TLC is increased. If the inspiratory muscles are significantly weakened, they are less able to overcome the inward elastic recoil of the lungs, and TLC is lowered.

AtRV, the force exerted by the expiratory muscles to decrease lung volume further is balanced by the outward recoil of the chest wall, which becomes extremely stiff at low lung volumes. Two factors influence the volume of gas contained in the lungs at RV. The first is the ability of the subject to exert a prolonged expiratory effort, which is related to muscle strength and the ability to overcome sensory stimuli from the chest wall. The second is the ability of the lungs to empty to a small volume. In normal lungs, as P_{TP} is lowered, lung volume decreases. In lungs with diseased airways, as P_{TP} is lowered, flow limitation or airway closure may limit the amount of gas that can be expired. Consequently, either weak expiratory muscles or intrinsic airways disease can result in an elevation in measured RV.

Dynamic measurements of ventilatory function are made by having the subject inhale toTLC and then perform a forced expiration toRV. If a subject performs a series of such expiratory maneuvers using increasing muscular intensity, expiratory flow rates will increase until a certain level of effort is reached. Beyond this level, additional effort at any given lung volume will not increase the forced expiratory flow rate; this phenomenon is known as the *effort independence* of forced expiratory flow. The physiologic mechanisms determining the flow rates during this effort-independent phase of FEF have been shown to be the elastic recoil of the lung, the airflow resistance of the airways between the alveolar zone and the physical site of flow limitation, and the airway wall compliance at the site of flow limitation. Physical processes that decrease

elastic recoil, increase airflow resistance, or increase airway wall compliance decrease the flow rate that can be achieved at any given lung volume. Conversely, processes that increase elastic recoil, decrease resistance, or stiffen airway walls increase the flow rate that can be achieved at any given lung volume.

MEASUREMENT OF VENTILATORY FUNCTION

Ventilatory function is measured under static conditions for determination of lung volumes and under dynamic conditions for determination of forced expiratory flow rates.VC, expiratory reserve volume (ERV), and inspiratory capacity (IC) (Fig. 250-1) are measured by having the patient breathe into and out of a spirometer, a device capable of measuring expired or inspired gas volume while plotting volume as a function of time. Other volumes -- specifically,RV,FRC, andTLC -- cannot be measured in this way because they include the volume of gas present in the lungs even after a maximal expiration. Two techniques are commonly used to measure these volumes: helium dilution and body plethysmography. In the helium dilution method, the subject repeatedly breathes in and out from a reservoir with a known volume of gas containing a trace amount of helium. The helium is diluted by the gas previously present in the lungs and very little is absorbed into the pulmonary circulation. From knowledge of the reservoir volume and the initial and final helium concentrations, the volume of gas present in the lungs can be calculated. The helium dilution method may underestimate the volume of gas in the lungs if there are slowly communicating airspaces, such as bullae. In this situation, lung volumes can be measured more accurately with a body plethysmograph, a sealed box in which the patient sits while panting against a closed mouthpiece. Because there is no airflow into or out of the plethysmograph, the pressure changes in the thorax during panting cause compression and rarefaction of gas in the lungs and simultaneous rarefaction and compression of gas in the plethysmograph. By measuring the pressure changes in the plethysmograph and at the mouthpiece, the volume of gas in the thorax can be calculated using Boyle's law.

Lung volumes and measurements made during forced expiration are interpreted by comparing the values measured with the values expected given the age, height, sex, and race of the patient (Appendix A). Regression curves have been constructed on the basis of data obtained from large numbers of normal, nonsmoking individuals without evidence of lung disease. Predicted values for a given patient can then be obtained by using the patient's age and height in the appropriate regression equation; different equations are used depending on the patient's race and gender. Because there is some variability among normal individuals, values between 80 and 120% of the predicted value have traditionally been considered normal. Increasingly, calculated percentiles are used in determining normality. Specifically, values of individual measurements falling below the fifth percentile are considered to be below normal.

The normal value for the ratioFEV_1/FVCis approximately 0.75 to 0.80, although this value does fall somewhat with advancing age. The$FEF_{25-75\%}$is often considered a more sensitive measurement of early airflow obstruction, particularly in small airways. However, this measurement must be interpreted cautiously in patients with abnormally small lungs (lowTLC andVC). These patients exhale less air during forced expiration, and the $FEF_{25-75\%}$may appear abnormal relative to the usual predicted value, even though it is normal relative to the size of the patient's lungs.

It is also a common practice to plot expiratory flow rates against lung volume (rather than against time); the close linkage of flow rates to lung volumes produces a typical *flow-volume curve* (Fig. 250-4). In addition, the spirometric values mentioned above can be calculated from the flow-volume curve. Commonly, flow rates during a maximal inspiratory effort performed as rapidly as possible are plotted as well, making the flow-volume curve into a *flow-volume loop*. AtTLC, before expiratory flow starts, the flow rate is zero; once forced expiration has begun, a high peak flow rate is rapidly achieved. As expiration continues and lung volume approachesRV, the flow rate falls progressively, in a nearly linear fashion as a function of lung volume for a person with normal lung function. During maximal inspiration from RV to TLC, inspiratory flow is most rapid at the midpoint of inspiration, so the inspiratory portion of the loop is U-shaped or saddle-shaped. The flow rates achieved during maximal expiration can be analyzed quantitatively by comparing the flow rates at specified lung volumes with the predicted values or qualitatively by analyzing the shape of the descending limb of the expiratory curve.

Assessing the strength of respiratory muscles is an additional part of the overall evaluation of some patients with respiratory dysfunction. When a patient exhales completely toRV and then tries to inspire maximally against an occluded airway, the pressure that can be generated is called the *maximal inspiratory pressure* (MIP). On the other hand, when a patient inhales toTLC and then tries to expire maximally against an occluded airway, the pressure generated is called the *maximal expiratory pressure* (MEP). In the proper clinical setting, these studies may provide useful information regarding the cause of abnormal lung volumes and the possibility that respiratory muscle weakness may be causally related to the lung volume abnormalities.

PATTERNS OF ABNORMAL FUNCTION

The two major patterns of abnormal ventilatory function, as measured by static lung volumes and spirometry, are restrictive and obstructive patterns. In the *obstructive pattern*, the hallmark is a decrease in expiratory flow rates. With fully established disease, the ratioFEV_1/FVCis decreased, as is the$FEF_{25-75\%}$(Fig. 250-2, line *B*). The expiratory portion of the flow-volume loop demonstrates decreased flow rates for any given lung volume. Nonuniform emptying of airways is reflected by a coved (concave upward) configuration of the curve (Fig. 250-4). With early obstructive disease, which originates in the small airways, FEV_1/FVC may be normal; the only abnormalities noted on routine testing of pulmonary function may be a depression in $FEF_{25-75\%}$and an abnormal, i.e., coved, configuration in the terminal portion of the forced expiratory flow-volume curve.

In *obstructive* disease, theTLC is normal or increased. When helium equilibration tests are used to measure lung volumes, the measured volume may be less than the actual volume if helium was not well distributed to all regions of the lung. Residual volume is elevated as a result of airway closure during expiration, and the ratioRV/TLC is increased.VC is frequently decreased in obstructive disease because of the striking elevations in RV with only minor changes in TLC.

A *restrictive pattern* can be broadly divided into two subgroups, depending on the

location of the pathology: pulmonary parenchymal and extraparenchymal. For extraparenchymal disease, dysfunction can be predominantly in inspiration or in both inspiration and expiration (Table 250-1). The hallmark of a restrictive pattern, found in all these subcategories, is a decrease in lung volumes, primarilyTLC andVC. In pulmonary parenchymal disease,RV is also generally decreased, and forced expiratory flow rates are preserved. In fact, when$FEV_1$is considered as a percentage of theFVC, the flow rates are often supranormal, i.e., disproportionately high relative to the size of the lungs (Fig. 250-2, line *C*). The flow-volume curve may graphically demonstrate this disproportionate relationship between flow rates and lung volumes, since the expiratory portion of the curve appears relatively tall (preserved flow rates) but narrow (decreased lung volumes), as shown inFig. 250-4.

In the extraparenchymal pattern characterized by *inspiratory dysfunction*, caused by either inspiratory muscle weakness or a stiff chest wall, inadequate distending forces are exerted on an otherwise normal lung. As a result,TLCvalues are less than predicted,RV is often not significantly affected, and expiratory flow rates are preserved. If inspiratory muscle weakness is the cause of this pattern, thenMIP is decreased. In the extraparenchymal pattern characterized by *inspiratory and expiratory dysfunction*, the ability to expire to a normal RV is also limited, because of either expiratory muscle weakness or a deformed chest wall that is abnormally rigid at volumes belowFRC. Consequently, RV is often elevated, unlike the pattern observed in the other restrictive subcategories. The ratioFEV_1/FVCis variable and depends on expiratory muscle strength. If expiratory muscle strength is significantly decreased, thenMEP is decreased, the ability to expire rapidly is impaired, and FEV_1/FVC may be decreased even though there is no airflow obstruction. If expiratory muscle strength is normal but the chest wall is abnormally stiff below FRC, then FEV_1/FVC is normal or increased.

CLINICAL CORRELATIONS

Table 250-1 summarizes the expected alterations in ventilatory function as indicated by pulmonary function testing. One reason to establish a ventilatory diagnosis is to categorize the functional disorder. This information can be useful in diagnosis, as outlined inTable 250-2. Note that lung disease such as pulmonary vascular disease or lung nodules can be present without abnormal ventilatory function, but the presence of specific diagnostic findings is an aid in differential diagnosis.

DISTURBANCES IN THE PULMONARY CIRCULATION

PHYSIOLOGIC FEATURES

The pulmonary vasculature must handle the entire output of the right ventricle, approximately 5 L/min in a normal adult at rest. The comparatively thin-walled vessels of the pulmonary arterial system provide relatively little resistance to flow and are capable of handling this large volume of blood at perfusion pressures that are low compared with those of the systemic circulation. The normal mean pulmonary artery pressure is 15 mmHg, as compared to approximately 95 mmHg for the normal mean aortic pressure. Regional blood flow in the lung is dependent on hydrostatic forces. In an upright person, pulmonary arterial pressure (PAP) is lowest at the apex of the lung and highest at the lung base. As a result, in the upright position, perfusion is least at the apex and greatest

at the base. When cardiac output increases, as occurs during exercise, the pulmonary vasculature is capable of recruiting previously unperfused vessels and distending underperfused vessels, thus responding to the increase in flow with a decrease in pulmonary vascular resistance. In consequence, the increase in mean PAP, even with a three- to fourfold increase in cardiac output, is small.

METHODS OF MEASUREMENT

Assessment of circulatory function in the pulmonary vasculature depends on measuring pulmonary vascular pressures and cardiac output. Clinically, these measurements are commonly made in intensive care units capable of invasive monitoring and in cardiac catheterization laboratories. With a flow-directed pulmonary arterial (Swan-Ganz) catheter,PAP and pulmonary capillary wedge pressure can be measured directly, and cardiac output can be obtained by the thermodilution method. Pulmonary vascular resistance (PVR) can then be calculated according to the equation

where PVR= pulmonary vascular resistance (dyn×s/cm^5); PAP = mean pulmonary arterial pressure (mmHg); PCW= pulmonary capillary wedge pressure (mmHg); and CO= cardiac output (L/min).

The normal value for pulmonary vascular resistance is approximately 50 to 150 dyn×s/cm^5.

MECHANISMS OF ABNORMAL FUNCTION (See alsoChap. 260)

PVRmay increase by a variety of mechanisms. Pulmonary arterial and arteriolar vasoconstriction is a prominent response to alveolar hypoxia. PVR also increases if intraluminal thrombi or proliferation of smooth muscle in vessel walls diminishes the luminal cross-sectional area. If small pulmonary vessels are destroyed, either by scarring or by loss of alveolar walls, the total cross-sectional area of the pulmonary vascular bed diminishes, and PVR increases. When PVR is elevated, eitherPAPrises to maintain normal cardiac output or cardiac output falls if PAP does not increase.

CLINICAL CORRELATIONS

Disturbances in the function of the pulmonary vasculature as a result of primary cardiac disease, either congenital heart disease or conditions that elevate left atrial pressure, such as mitral stenosis, are beyond the scope of this**chapter**and are discussed in Chaps. 234 and236, respectively. Instead, the focus will be on the pulmonary vasculature as its function is affected by diseases primarily involving the respiratory system, including the pulmonary vessels themselves.

All diseases of the respiratory system causing hypoxemia are potentially capable of increasingPVR, since alveolar hypoxia is a very potent stimulus for pulmonary vasoconstriction. The more prolonged and intense the hypoxic stimulus, the more likely it is that a significant increase in PVR producing pulmonary hypertension will result. In practice, patients with hypoxemia caused by chronic obstructive lung disease, interstitial

lung disease, chest wall disease, and the obesity hypoventilation-sleep apnea syndrome are particularly prone to developing pulmonary hypertension. If there are additional structural changes in the pulmonary vasculature secondary to the underlying process, these will increase the likelihood of developing pulmonary hypertension.

With diseases directly affecting the pulmonary vessels, a decrease in the cross-sectional area of the pulmonary vascular bed is primarily responsible for increasedPVR, while hypoxemia generally plays a lesser role. In the case of recurrent pulmonary emboli, parts of the pulmonary arterial system are occluded by intraluminal thrombi originating in the systemic venous system. With primary pulmonary hypertension (Chap. 260) or with pulmonary vascular disease secondary to scleroderma, the small pulmonary arteries and arterioles are affected by a generalized obliterative process that narrows and occludes these vessels. PVR increases, and significant pulmonary hypertension often results.

DISTURBANCES IN GAS EXCHANGE

PHYSIOLOGIC FEATURES

The primary functions of the respiratory system are to remove the appropriate amount of CO_2 from blood entering the pulmonary circulation and to provide adequate O_2 to blood leaving the pulmonary circulation. For these functions to be carried out properly, there must be adequate provision of fresh air to the alveoli for delivery of O_2 and removal of CO_2(ventilation), adequate circulation of blood through the pulmonary vasculature (perfusion), adequate movement of gas between alveoli and pulmonary capillaries (diffusion), and appropriate contact between alveolar gas and pulmonary capillary blood (ventilation-perfusion matching).

A normal individual at rest inspires approximately 12 to 16 times per minute, each breath having a tidal volume of approximately 500 mL. A portion (approximately 30%) of the fresh air inspired with each breath does not reach the alveoli but remains in the conducting airways of the lung. This component of each breath, which is not generally available for gas exchange, is called the *anatomic dead space component*. The remaining 70% reaches the alveolar zone, mixes rapidly with the gas already there, and can participate in gas exchange. In this example, the total ventilation each minute is approximately 7 L, composed of 2 L/min of dead space ventilation and 5 L/min of alveolar ventilation. In certain diseases, some alveoli are ventilated but not perfused, so that some ventilation in addition to the anatomic dead space component is wasted. If total dead space ventilation is increased but total minute ventilation is unchanged, then alveolar ventilation must fall correspondingly.

Gas exchange is dependent on alveolar ventilation rather than total minute ventilation, as outlined below. The partial pressure of CO_2 in arterial blood (Pa_{CO_2}) is directly proportional to the amount of CO_2produced per minute ($_{CO_2}$) and inversely proportional to alveolar ventilation (A), according to the relationship

where$_{CO_2}$ is expressed in mL/min, A in L/min, and Pa_{CO_2} in mmHg. At fixed$_{CO_2}$, when

alveolar ventilation increases, Pa_{CO_2} falls, and when alveolar ventilation decreases, Pa_{CO_2} rises. Maintaining a normal level of O_2 in the alveoli (and consequently in arterial blood) also depends on provision of adequate alveolar ventilation to replenish alveolar O_2. This principle will become more apparent from consideration of the alveolar gas equation below.

Diffusion of O_2 and CO_2 Both O_2 and CO_2 diffuse readily down their respective concentration gradients through the alveolar wall and pulmonary capillary endothelium. Under normal circumstances, this process is rapid, and equilibration of both gases is complete within one-third of the transit time of erythrocytes through the pulmonary capillary bed. Even in disease states in which diffusion of gases is impaired, the impairment is unlikely to be severe enough to prevent equilibration of CO_2 and O_2. Consequently, a diffusion abnormality rarely results in arterial hypoxemia at rest. If erythrocyte transit time in the pulmonary circulation is shortened, as occurs with exercise, and diffusion is impaired, then diffusion limitation may contribute to hypoxemia. Exercise testing can often demonstrate such physiologically significant abnormalities due to impaired diffusion. Even though diffusion limitation rarely makes a clinically significant contribution to resting hypoxemia, clinical measurements of what is known as *diffusing capacity* (see below) can be a useful measure of the integrity of the alveolar-capillary membrane.

Ventilation-Perfusion Matching In addition to the absolute levels of alveolar ventilation and perfusion, gas exchange depends critically on the proper matching of ventilation and perfusion. The spectrum of possible ventilation-perfusion (/) ratios in an alveolar-capillary unit ranges from zero, in which ventilation is totally absent and the unit behaves as a shunt, to infinity, in which perfusion is totally absent and the unit behaves as dead space. The P_{O_2} and P_{CO_2} of blood leaving each alveolar-capillary unit depend on the gas tension (of blood and air) entering that unit and on the particular / ratio of the unit. At one extreme, when an alveolar-capillary unit has a / ratio of 0 and behaves as a shunt, blood leaving the unit has the composition of mixed venous blood entering the pulmonary capillaries, i.e., P_{O_2}» 40 mmHg and P_{CO_2}» 46 mmHg. At the other extreme, when an alveolar-capillary unit has a high / ratio, it behaves almost like dead space, and the small amount of blood leaving the unit has partial pressures of O_2 and CO_2 (P_{O_2}» 150 mmHg, P_{CO_2}» 0 mmHg while breathing room air) approaching the composition of inspired gas.

In the ideal situation, all alveolar-capillary units have equal matching of ventilation and perfusion, i.e., a ratio of approximately 1 when each is expressed in L/min. However, even in the normal individual, some / mismatching is present, since there is normally a gradient of blood flow from the apices to the bases of the lungs. There is a similar gradient of ventilation from the apices to the bases, but it is less marked than the perfusion gradient. As a result, ventilation-perfusion ratios are higher at the lung apices than at the lung bases. Therefore, blood coming from the apices has a higher P_{O_2} and lower P_{CO_2} than blood coming from the bases. The net P_{O_2} and P_{CO_2} of the blood mixture coming from all areas of the lung is a flow-weighted average of the individual components, which reflects both the relative amount of blood from each unit and the O_2 and CO_2 *content* of the blood coming from each unit. Because of the sigmoid shape of the oxyhemoglobin dissociation curve (see Fig. 106-2), it is important to distinguish between the partial pressure and the content of O_2 in blood. Hemoglobin is almost fully

(~90%) saturated at a P_{O_2} of 60 mmHg, and little additional O_2 is carried by hemoglobin even with a substantial elevation of P_{O_2}above 60 mmHg. On the other hand, significant O_2desaturation of hemoglobin occurs once P_{O_2}falls below 60 mmHg and onto the steep descending limb of the curve. As a result, blood coming from regions of the lung with a high / ratio and a high P_{O_2} has only a small elevation in O_2content and cannot compensate for blood coming from regions with a low / ratio and a low P_{O_2}, which has a significantly decreased O_2content. Although / mismatching can influence P_{CO_2}, this effect is less marked and is often overcome by an increase in overall minute ventilation.

MEASUREMENT OF GAS EXCHANGE

Arterial Blood Gases The most commonly used measures of gas exchange are the partial pressures of O_2 and CO_2 in arterial blood, i.e., Pa_{O_2} and Pa_{CO_2}, respectively. These partial pressures do not measure directly the quantity of O_2 and CO_2 in blood but rather the driving pressure for the gas in blood. The actual quantity or content of a gas in blood also depends on the solubility of the gas in plasma and the ability of any component of blood to react with or bind the gas of interest. Since hemoglobin is capable of binding large amounts of O_2, oxygenated hemoglobin is the primary form in which O_2 is transported in blood. The actual content of O_2 in blood therefore depends both on the hemoglobin concentration and on the Pa_{O_2}. The Pa_{O_2}determines what percentage of hemoglobin is saturated with O_2, based on the position on the oxyhemoglobin dissociation curve. Oxygen content in normal blood (at 37°C, pH 7.4) can be determined by adding the amount of O_2dissolved in plasma to the amount bound to hemoglobin, according to the equation

since each gram of hemoglobin is capable of carrying 1.34 mL O_2 when fully saturated, and the amount of O_2 that can be dissolved in plasma is proportional to the P_{O_2}, with 0.0031 mL O_2dissolved per deciliter of blood per mmHg P_{O_2}. In arterial blood, the amount of O_2transported dissolved in plasma (approximately 0.3 mL O_2 per deciliter of blood) is trivial compared with the amount bound to hemoglobin (approximately 20 mL O_2 per deciliter of blood).

Most commonly, P_{O_2} is the measurement used to assess the effect of respiratory disease on the oxygenation of arterial blood. Direct measurement of O_2saturation in arterial blood by oximetry is also important in selected clinical conditions. For example, in patients with carbon monoxide intoxication, carbon monoxide preferentially displaces O_2 from hemoglobin, essentially making a portion of hemoglobin unavailable for binding to O_2. In this circumstance, carbon monoxide saturation is high and O_2saturation is low, even though the driving pressure for O_2 to bind to hemoglobin, reflected by P_{O_2}, is normal. Measurement of O_2saturation is also important for the determination of O_2content when mixed venous blood is sampled from a pulmonary arterial catheter to calculate cardiac output by the Fick technique. In mixed venous blood, the P_{O_2} is normally about 40 mmHg, but small changes in P_{O_2} may reflect relatively large changes in O_2saturation.

A useful calculation in the assessment of oxygenation is the alveolar-arterial O_2difference (PA_{O_2}-Pa_{O_2}), commonly called the *alveolar-arterial O_2gradient* (or A - a

gradient). This calculation takes into account the fact that alveolar and, hence, arterial P_{O_2} can be expected to change depending on the level of alveolar ventilation, reflected by the arterial P_{CO_2}. When a patient hyperventilates and has a low P_{CO_2} in arterial blood and alveolar gas, alveolar and arterial P_{O_2} will rise; conversely, hypoventilation and a high P_{CO_2} are accompanied by a decrease in alveolar and arterial P_{O_2}. These changes in arterial P_{O_2} are independent of abnormalities in O_2transfer at the alveolar-capillary level and reflect only the dependence of alveolar P_{O_2} on the level of alveolar ventilation.

In order to determine the alveolar-arterial O_2difference, the alveolar P_{O_2}(PA_{O_2}) must first be calculated. The equation most commonly used for this purpose, a simplified form of the alveolar gas equation, is

where FI_{O_2}= fractional concentration of inspired O_2(»0.21 when breathing room air); P_B= barometric pressure (approximately 760 mmHg at sea level); P_{H_2O}= water vapor pressure (47 mmHg when air is fully saturated at 37°C); and R= respiratory quotient (the ratio of CO_2production to O_2consumption, usually assumed to be 0.8). If the preceding values are substituted into the equation for the patient breathing air at sea level, the equation becomes

The alveolar-arterial O_2difference can then be calculated by subtracting measured $Pa_{O_2}$from calculated PA_{O_2}. In a healthy young person breathing room air, the PA_{O_2}-Pa_{O_2} is normally less than 15 mmHg; this value increases with age and may be as high as 30 mmHg in elderly patients.

The adequacy of CO_2elimination is measured by the partial pressure of CO_2 in arterial blood, i.e., Pa_{CO_2}. A more complete understanding of the mechanisms and chronicity of abnormal levels of P_{CO_2}also requires measurement of pH and/or bicarbonate (HCO_3^-), since P_{CO_2} and the patient's acid-base status are so closely intertwined (Chap. 50).

Pulse Oximetry Because measurement of Pa_{O_2}requires arterial puncture, it is not ideal either for office use or for routine or frequent measurement in the inpatient setting. Additionally, because it provides intermittent rather than continuous data about the patient's oxygenation, it is not ideal for close monitoring of unstable patients. Pulse oximetry, an alternative method for assessing oxygenation, is readily available in many clinical settings. Using a probe usually clipped over a patient's finger, the pulse oximeter calculates oxygen saturation (rather than Pa_{O_2}) based on measurements of absorption of two wavelengths of light by hemoglobin in pulsatile, cutaneous arterial blood. Because of differential absorption of the two wavelengths of light by oxygenated and nonoxygenated hemoglobin, the percentage of hemoglobin that is saturated with oxygen, i.e., the Sa_{O_2}, can be calculated and displayed instantaneously.

Although the pulse oximeter has been a major advance in the noninvasive, continuous monitoring of oxygenation, there are several issues and potential problems concerning its use. First, the clinician must be aware of the relationship between oxygen saturation and tension as shown by the oxyhemoglobin dissociation curve (Fig. 106-2). Because

the curve becomes relatively flat above an arterial P_{O_2} of 60 mmHg (corresponding to Sa_{O_2}= 90%), the oximeter is relatively insensitive to changes in Pa_{O_2}above this level. In addition, the position of the curve and therefore the specific relationship between Pa_{O_2} and Sa_{O_2} may change depending on factors such as temperature, pH, and the erythrocyte concentration of 2,3-diphosphoglycerate. Second, when cutaneous perfusion is decreased, e.g., owing to low cardiac output or the use of vasoconstrictors, the signal from the oximeter may be less reliable or even unobtainable. Third, other forms of hemoglobin, such as carboxyhemoglobin and methemoglobin, are not distinguishable from oxyhemoglobin when only two wavelengths of light are used. The Sa_{O_2}values reported by the pulse oximeter are not reliable in the presence of significant amounts of either of these forms of hemoglobin. In contrast, the device used to measure oxygen saturation in samples of arterial blood, called the CO-oximeter, uses at least four wavelengths of light and is capable of distinguishing oxyhemoglobin, deoxygenated hemoglobin, carboxyhemoglobin, and methemoglobin. Finally, the clinician must remember that the often-used goal of Sa_{O_2}[3] 90% does not indicate anything about CO_2elimination and therefore does not ensure a clinically acceptable P_{CO_2}.

Diffusing Capacity The ability of gas to diffuse across the alveolar-capillary membrane is ordinarily assessed by the diffusing capacity of the lung for carbon monoxide (DL_{CO}). In this test, a small concentration of carbon monoxide (0.3%) is inhaled, usually in a single breath that is held for approximately 10 s. The carbon monoxide is diluted by the gas already present in the alveoli and is also taken up by hemoglobin as the erythrocytes course through the pulmonary capillary system. The concentration of carbon monoxide in exhaled gas is measured, and DL_{CO} is calculated as the quantity of carbon monoxide absorbed per minute per mmHg pressure gradient from the alveoli to the pulmonary capillaries. The value obtained for DL_{CO}depends on the alveolar-capillary surface area available for gas exchange and on the pulmonary capillary blood volume. In addition, the thickness of the alveolar-capillary membrane, the degree of / mismatching, and the patient's hemoglobin level will affect the measurement. Because of this effect of hemoglobin levels on DL_{CO}, the measured DL_{CO} is frequently corrected to take the patient's hemoglobin level into account. The value for DL_{CO}, ideally corrected for hemoglobin, can then be compared with a predicted value, based either on age, height, and gender or on the alveolar volume (VA) at which the value was obtained. Alternatively, the DL_{CO} can be divided by VA and the resulting value for DL_{CO}/VA compared with a predicted value.

Approach to the Patient

Arterial Blood Gases Hypoxemia is a common manifestation of a variety of diseases affecting the lungs or other parts of the respiratory system. The broad clinical problem of hypoxemia is often best characterized according to the underlying mechanism. The four basic, and not mutually exclusive, mechanisms of hypoxemia are (1) a decrease in inspired P_{O_2}, (2) hypoventilation, (3) shunting, and (4) / mismatching. Hypoxemia due to decreased diffusion occurs only under selected clinical circumstances and is not usually included among the general categories of hypoxemia. Determining the underlying mechanism for hypoxemia depends on measurement of the Pa_{CO_2}, calculation of PA_{O_2}-Pa_{O_2}, and knowledge of the response to supplemental O_2. A flowchart summarizing the approach to the hypoxemic patient is given inFig. 250-5.

A decrease in the inspired P_{O_2} and hypoventilation both cause hypoxemia by lowering $P_{A_{O_2}}$ and therefore $P_{a_{O_2}}$. In each case, gas exchange at the alveolar-capillary level occurs normally, and $P_{A_{O_2}}$-$P_{a_{O_2}}$ is not elevated. Hypoxemia due to decreased inspired P_{O_2} can be diagnosed from knowledge of the clinical situation. Inspired P_{O_2} is lowered either because the patient is at a high altitude, where barometric pressure is low, or, much less commonly, because the patient is breathing a gas mixture containing less than 21% O_2. The hallmark of hypoventilation as a cause of hypoxemia is an elevation in $P_{a_{CO_2}}$. This is associated with an increase in $P_{A_{CO_2}}$and a fall in $P_{A_{O_2}}$. When hypoxemia is due purely to a low inspired P_{O_2} or to alveolar hypoventilation, $P_{A_{O_2}}$-$P_{a_{O_2}}$ is normal. If $P_{A_{O_2}}$-$P_{a_{O_2}}$ and $P_{a_{CO_2}}$are both elevated, then an additional mechanism, such as / mismatching or shunting, is contributing to hypoxemia.

Shunting is a cause of hypoxemia when desaturated blood effectively bypasses oxygenation at the alveolar-capillary level. This situation occurs either because a structural problem allows desaturated blood to bypass the normal site of gas exchange or because perfused alveoli are not ventilated. Shunting is associated with an elevation in the $P_{A_{O_2}}$-$P_{a_{O_2}}$value. When shunting is an important contributing factor to hypoxemia, the lowered $P_{a_{O_2}}$ is relatively refractory to improvement by supplemental O_2.

Finally, the largest clinical category of hypoxemia is / mismatching. With / mismatching, regions with low / ratios contribute blood with a low P_{O_2} and a low O_2content. Corresponding regions with high / ratios contribute blood with a high P_{O_2}. However, because blood is already almost fully saturated at a normal P_{O_2}, elevation of the P_{O_2} to a high value does not significantly increase O_2saturation or content and therefore cannot compensate for the reduction of O_2saturation and content in blood coming from regions with a low / ratio. When / mismatch is the primary cause of hypoxemia, $P_{A_{O_2}}$-$P_{a_{O_2}}$ is elevated, and P_{CO_2}generally is normal. Supplemental O_2corrects the hypoxemia by raising the P_{O_2} in blood coming from regions with a low / ratio; this response distinguishes hypoxemia due to / mismatching from that due to true shunt.

The essential mechanism underlying all cases of hypercapnia is alveolar ventilation that is inadequate for the amount of CO_2produced. It is conceptually useful to characterize CO_2retention further, based on a more detailed examination of the potential contributing factors. These include (1) increased CO_2production; (2) decreased ventilatory drive ("won't breathe"); (3) malfunction of the respiratory pump or increased airways resistance, which makes it more difficult to sustain adequate ventilation ("can't breathe"); and (4) inefficiency of gas exchange (increased dead space or / mismatch) necessitating a compensatory increase in overall minute ventilation. In practice, more than one of these mechanisms is commonly responsible for hypercapnia, since increased minute ventilation is capable of compensating for increased CO_2production and for inefficiencies of gas exchange.

Diffusing Capacity Although abnormalities in diffusion are rarely responsible for hypoxemia, clinical measurement of diffusing capacity is frequently used to assess the functional integrity of the alveolar-capillary membrane, which includes the pulmonary capillary bed. Diseases that affect solely the airways generally do not lower DL_{CO}, whereas diseases that affect the alveolar walls or the pulmonary capillary bed will have an effect on DL_{CO}. Even though DL_{CO} is a useful marker for assessing whether disease affecting the alveolar-capillary bed is present, an abnormal DL_{CO}does not necessarily

imply that diffusion limitation is responsible for hypoxemia in a particular patient.

CLINICAL CORRELATIONS

Useful clinical correlations can be made with the mechanisms underlying hypoxemia (Fig. 250-5). A lowered inspired P_{O_2} contributes to hypoxemia if either the patient is at high altitude or if the concentration of inspired O_2 is less than 21%. The latter problem occurs if a patient receiving anesthesia or ventilatory support is inadvertently given a gas mixture to breathe containing less than 21% O_2 or if O_2 is consumed from the ambient gas, as can occur during smoke inhalation from a fire. The primary feature of hypoventilation as a cause of hypoxemia is an elevation in arterial P_{CO_2}. *For further discussion of the clinical correlations with hypoventilation, see Chap. 263.*

Shunting as a cause of hypoxemia can reflect transfer of blood from the right to the left side of the heart without passage through the pulmonary circulation, as occurs with an intracardiac shunt. This problem is most common in the setting of cyanotic congenital heart disease, when an interatrial or interventricular septal defect is associated with pulmonary hypertension so that shunting is in the right-to-left rather than the left-to-right direction. Shunting of blood through the pulmonary parenchyma is most frequently due to disease causing absence of ventilation to perfused alveoli. This can occur if the alveoli are atelectatic or if they are filled with fluid, as in pulmonary edema (both cardiogenic and noncardiogenic), or with extensive intraalveolar exudation of fluid due to pneumonia. Less commonly, vascular anomalies with arteriovenous shunting in the lung can cause hypoxemia. These anomalies can be hereditary, as found with hereditary hemorrhagic telangiectasia (Osler-Rendu-Weber syndrome), or acquired, as in pulmonary vascular malformations secondary to hepatic cirrhosis, which are similar to the commonly recognized cutaneous vascular malformations ("spider hemangiomas").

Ventilation-perfusion mismatch is the most common cause of hypoxemia clinically. Most of the processes affecting either the airways or the pulmonary parenchyma are distributed unevenly throughout the lungs and do not necessarily affect ventilation and perfusion equally. Some areas of lung may have good perfusion and poor ventilation, whereas others may have poor perfusion and relatively good ventilation. Important examples of airways diseases in which / mismatch causes hypoxemia are asthma and chronic obstructive lung disease. Parenchymal lung diseases causing / mismatch and hypoxemia include interstitial lung disease and pneumonia.

Clinically important alterations in CO_2 elimination range from excessive ventilation and hypocapnia to inadequate CO_2 elimination and hypercapnia. *For further discussion of these clinical problems, see Chap. 263.*

Diffusing Capacity Measurement of DL_{CO} may be useful for assessing disease affecting the alveolar-capillary bed or the pulmonary vasculature. In practice, three main categories of disease are associated with lowered DL_{CO}: interstitial lung disease, emphysema, and pulmonary vascular disease. With interstitial lung disease, scarring of alveolar-capillary units diminishes the area of the alveolar-capillary bed as well as pulmonary blood volume. With emphysema, alveolar walls are destroyed, so the surface area of the alveolar-capillary bed is again diminished. In patients with disease causing a decrease in the cross-sectional area and volume of the pulmonary vascular bed, such

as recurrent pulmonary emboli or primary pulmonary hypertension, DL_{CO} is commonly diminished.

Diffusing capacity may be elevated if pulmonary blood volume is increased, as may be seen in congestive heart failure. However, once interstitial and alveolar edema ensue, the net DL_{CO}depends on the opposing influences of increased pulmonary capillary blood volume elevating DL_{CO} and pulmonary edema decreasing it. Finding an elevated DL_{CO} may be useful in the diagnosis of alveolar hemorrhage, as in Goodpasture's syndrome. Hemoglobin contained in erythrocytes in the alveolar lumen is capable of binding carbon monoxide, so the exhaled carbon monoxide concentration is diminished and the measured DL_{CO} is increased.

251. DIAGNOSTIC PROCEDURES IN RESPIRATORY DISEASE - *Steven E. Weinberger*, *Jeffrey M. Drazen*

The diagnostic modalities available for assessing the patient with suspected or known respiratory system disease include imaging studies and techniques for acquiring biologic specimens, some of which involve direct visualization of part of the respiratory system.*Methods used to characterize the functional changes developing as a result of disease, including pulmonary function tests and measurements of gas exchange, are discussed in Chap. 250.*

IMAGING STUDIES

ROUTINE RADIOGRAPHY

Routine chest radiography, which generally includes both posteroanterior and lateral views, is an integral part of the diagnostic evaluation of diseases involving the pulmonary parenchyma, the pleura, and, to a lesser extent, the airways and the mediastinum (see Figs. 249-1 and249-2). Lateral decubitus views are often useful for determining whether pleural abnormalities represent freely flowing fluid, whereas apical lordotic views can often visualize disease at the lung apices better than the standard posteroanterior view. Portable equipment, which is often used for acutely ill patients who either cannot be transported to a radiology suite or cannot stand up for posteroanterior and lateral views, generally yields just a single radiograph taken in the anteroposterior direction.**Common radiographic patterns and their clinical correlates are reviewed in Chap. 249.*

COMPUTED TOMOGRAPHY

Computed tomography (CT) offers several advantages over routine chest radiography. First, the use of cross-sectional images often makes it possible to distinguish between densities that would be superimposed on plain radiographs. Second, CT is far better than routine radiographic studies at characterizing tissue density, distinguishing subtle differences in density between adjacent structures, and providing accurate size assessment of lesions. As a result, CT is particularly valuable in assessing hilar and mediastinal disease (which is often poorly characterized by plain radiography), in identifying and characterizing disease adjacent to the chest wall or spine (including pleural disease), and in identifying areas of fat density or calcification in pulmonary nodules (Fig. 251-1). Its utility in the assessment of mediastinal disease has made CT an important tool in the staging of lung cancer (Chap. 88), as an assessment of tumor involvement of mediastinal lymph nodes is critical to proper staging. With the additional use of contrast material, CT also makes it possible to distinguish vascular from nonvascular structures, which is particularly important in distinguishing lymph nodes and masses from vascular structures.

HelicalCTscanning allows the collection of continuous data over a larger volume of lung during a single breath-holding maneuver than is possible with conventional CT. With CT angiography, in which intravenous contrast is administered and images are acquired rapidly by helical scanning, pulmonary emboli can be detected in segmental and larger pulmonary arteries. With high-resolution CT (HRCT), the thickness of individual

cross-sectional images is approximately 1 to 2 mm, rather than the usual 10 mm, and the images are reconstructed with high-spatial-resolution algorithms. The detail that can be seen on HRCT scans allows better recognition of subtle parenchymal and airway disease, such as bronchiectasis, emphysema, and diffuse parenchymal disease (Fig. 251-2). Certain nearly pathognomonic patterns have now been recognized for many of the interstitial lung diseases, such as lymphangitic carcinoma, idiopathic pulmonary fibrosis, sarcoidosis, and eosinophilic granuloma; at present it is not yet clear in what settings these patterns will obviate the need for obtaining lung tissue.

MAGNETIC RESONANCE IMAGING

The role of magnetic resonance imaging (MRI) in the evaluation of respiratory system disease is less well defined than that ofCT. Because MRI generally provides a less detailed view of the pulmonary parenchyma as well as poorer spatial resolution, its usefulness in the evaluation of parenchymal lung disease is limited at present. However, MRI has advantages over CT in certain clinical settings. Because its images can be reconstructed in sagittal and coronal as well as transverse planes, MRI may be better for imaging abnormalities near the lung apex, the spine, and the thoracoabdominal junction. In addition, vascular structures can be distinguished from nonvascular structures without the need for contrast. Flowing blood does not produce a signal on MRI, so vessels appear as hollow tubular structures. This feature can be useful in determining whether abnormal hilar or mediastinal densities are vascular in origin and in defining aortic lesions such as aneurysms or dissection.

SCINTIGRAPHIC IMAGING

Radioactive isotopes, administered by either intravenous or inhaled routes, allow the lungs to be imaged with a gamma camera. The most common use of such imaging is ventilation-perfusion lung scanning performed for evaluation of pulmonary embolism. When injected intravenously, albumin macroaggregates labeled with technetium 99m become lodged in pulmonary capillaries; therefore, the distribution of the trapped radioisotope follows the distribution of blood flow. When inhaled, radiolabeled xenon gas can be used to demonstrate the distribution of ventilation. For example, pulmonary thromboembolism usually produces one or more regions of ventilation-perfusion mismatch -- that is, regions in which there is a defect in perfusion that follows the distribution of a vessel and that is not accompanied by a corresponding defect in ventilation (Chap. 261). Another common use of such radioisotope scans is in a patient with impaired lung function who is being considered for lung resection. The distribution of the isotope(s) can be used to assess the regional distribution of blood flow and ventilation, allowing the physician to estimate the level of postoperative lung function.

Another scintigraphic imaging technique, gallium imaging, has been of diagnostic value in patients with *Pneumocystis carinii* pneumonia and other opportunistic infections. Use of gallium imaging may provide clues to sort out the differential diagnosis of pulmonary infiltrates in immunosuppressed patients, especially patients with AIDS.

PULMONARY ANGIOGRAPHY

The pulmonary arterial system can be visualized by pulmonary angiography, in which

radiopaque contrast medium is injected through a catheter previously threaded into the pulmonary artery. When performed in cases of pulmonary embolism, pulmonary angiography demonstrates the consequences of an intravascular clot -- either a defect in the lumen of a vessel (a "filling defect") or an abrupt termination ("cutoff") of the vessel. Other, less common indications for pulmonary angiography include visualization of a suspected pulmonary arteriovenous malformation and assessment of pulmonary arterial invasion by a neoplasm.

ULTRASOUND

Because ultrasound energy is rapidly dissipated in air, ultrasound imaging is not useful for evaluation of the pulmonary parenchyma. However, it is helpful in the detection and localization of pleural abnormalities and is often used as a guide to placement of a needle for sampling of pleural liquid (i.e., for thoracentesis).

TECHNIQUES FOR OBTAINING BIOLOGIC SPECIMENS

COLLECTION OF SPUTUM

Sputum can be collected either by spontaneous expectoration or after inhalation of an irritating aerosol, such as hypertonic saline. The latter method, called *sputum induction*, is commonly used to obtain sputum for diagnostic studies, either because sputum is not spontaneously being produced or because of an expected higher yield of certain types of findings. Knowledge of the appearance and quality of the sputum specimen obtained is especially important when one is interested in Gram's staining and culture. Because sputum consists mainly of secretions from the tracheobronchial tree rather than the upper airway, the finding of alveolar macrophages and other inflammatory cells is consistent with a lower respiratory tract origin of the sample, whereas the presence of squamous epithelial cells in a "sputum" sample indicates contamination by secretions from the upper airways.

Besides processing for routine bacterial pathogens by Gram's staining and culture, sputum can be processed for a variety of other pathogens, including staining and culture for mycobacteria or fungi, culture for viruses, and staining for *P. carinii*. In the specific case of sputum obtained for evaluation of *P. carinii* pneumonia in a patient infected with HIV, for example, sputum should be collected by induction, rather than spontaneous expectoration, and an immunofluorescent stain should be used to detect the organisms. Cytologic staining of sputum for malignant cells, using the traditional Papanicolaou method, allows noninvasive evaluation for suspected lung cancer. Traditional stains and cultures are now also being supplemented in some cases by immunologic techniques and by molecular biologic methods, including the use of polymerase chain reaction amplification and DNA probes.

PERCUTANEOUS NEEDLE ASPIRATION

A needle can be inserted through the chest wall into a pulmonary lesion for the purpose of aspirating material for analysis by cytologic or microbiologic techniques. The procedure is usually carried out underCTguidance, which assists in the positioning of the needle and assures that it is localized in the lesion. Although the potential risks of

this procedure include intrapulmonary bleeding and creation of a pneumothorax with collapse of the underlying lung, the low risk of complication in experienced hands is usually worth the information obtained. However, a limitation of the technique is sampling error due to the small amount of material obtained. Thus, findings other than a specific cytologic or microbiologic diagnosis are of limited clinical value.

THORACENTESIS

Sampling of pleural liquid by thoracentesis is commonly performed for diagnostic purposes or, in the case of a large effusion, for palliation of dyspnea. Diagnostic sampling, either by blind needle aspiration or after localization by ultrasound, allows the collection of liquid for microbiologic and cytologic studies. Analysis of the fluid obtained for its cellular composition and chemical constituents, including glucose, protein, and lactate dehydrogenase, allows the effusion to be classified as either exudative or transudative (Chap. 262). In some cases, particularly in the setting of possible tuberculous involvement of the pleura (tuberculous pleuritis), closed biopsy of the parietal pleura is also performed, using a cutting needle (either an Abrams or a Cope biopsy needle) to sample tissue for histopathologic examination and culture.

BRONCHOSCOPY

Bronchoscopy is the process of direct visualization of the tracheobronchial tree. Bronchoscopy with a rigid bronchoscope is generally performed in an operating room on a patient under general anesthesia. The development of a flexible fiberoptic bronchoscope has revolutionized the diagnostic use of bronchoscopy. Although bronchoscopy is now performed almost exclusively with fiberoptic instruments, rigid bronchoscopes still have a role in selected circumstances, primarily because of their larger suction channel and the fact that the patient can be ventilated through the bronchoscope channel. These situations include the retrieval of a foreign body and the suctioning of a massive hemorrhage, for which the small suction channel of the bronchoscope may be insufficient.

Flexible Fiberoptic Bronchoscopy This is an outpatient procedure that is usually performed in an awake but sedated patient. The bronchoscope is passed through either the mouth or the nose, between the vocal cords, and into the trachea. The ability to flex the scope makes it possible to visualize virtually all airways to the level of subsegmental bronchi. The bronchoscopist is able to identify endobronchial pathology, including tumors, granulomas, bronchitis, foreign bodies, and sites of bleeding. Samples from airway lesions can be taken by several methods, including washing, brushing, and biopsy. Washing involves instillation of sterile saline through a channel of the bronchoscope and onto the surface of a lesion. A portion of the liquid is collected by suctioning through the bronchoscope, and the recovered material can be analyzed for cells (cytology) or organisms (by standard stains and cultures). Brushing or biopsy of the surface of the lesion, using a small brush or biopsy forceps at the end of a long cable inserted through a channel of the bronchoscope, allows recovery of cellular material or tissue for analysis by standard cytologic and histopathologic methods.

The bronchoscope can be used to sample material not only from the regions that can be directly visualized (i.e., the airways) but also from the more distal pulmonary

parenchyma. With the bronchoscope wedged into a subsegmental airway, aliquots of sterile saline can be instilled through the scope, allowing sampling of cells and organisms even from alveolar spaces. This procedure, called *bronchoalveolar lavage*, has been particularly useful for the recovery of organisms such as *P. carinii* in patients with HIV infection.

Brushing and biopsy of the distal lung parenchyma can also be performed with the same instruments that are used for endobronchial sampling. These instruments can be passed through the scope into small airways, where they penetrate the airway wall, allowing biopsy of peribronchial alveolar tissue. This procedure, called *transbronchial biopsy*, is used when there is either relatively diffuse disease or a localized lesion of adequate size. With the aid of fluoroscopic imaging, the bronchoscopist is able to determine not only whether and when the instrument is in the area of abnormality, but also the proximity of the instrument to the pleural surface. If the forceps are too close to the pleural surface, there is a risk of violating the visceral pleura and creating a pneumothorax; the other potential complication of transbronchial biopsy is pulmonary hemorrhage. The incidence of these complications is less than several percent.

Another procedure involves use of a hollow-bore needle passed through the bronchoscope for sampling of tissue adjacent to the trachea or a large bronchus. The needle is passed through the airway wall, and cellular material can be aspirated from mass lesions or enlarged lymph nodes, generally in a search for malignant cells. This procedure can facilitate the staging of lung cancer by identifying mediastinal lymph node involvement and in some cases obviates the need for a more invasive procedure.

The bronchoscope may provide the opportunity for treatment as well as diagnosis. For example, an aspirated foreign body may be retrieved with an instrument passed through the scope, and bleeding may be controlled with a balloon catheter similarly introduced. Newer interventional techniques performed through a bronchoscope include methods for achieving and maintaining patency of airways that are partially or completely occluded, especially by tumors. These techniques include laser therapy, cryotherapy, electrocautery, and stent placement.

VIDEO-ASSISTED THORACIC SURGERY

Recent advances in video technology have allowed the development of thoracoscopy, or video-assisted thoracic surgery (VATS), for the diagnosis and management of pleural as well as parenchymal lung disease. This procedure, done under general anesthesia, involves the passage of a rigid scope with a distal lens through a trocar inserted into the pleura. A high-quality image is shown on a monitor screen, allowing the operator to manipulate instruments passed into the pleural space through separate small intercostal incisions. With these instruments, the operator can biopsy lesions of the pleura under direct vision, which provides an obvious advantage over closed pleural biopsy. In addition, this procedure is now used commonly to biopsy peripheral lung tissue or to remove peripheral nodules, for both diagnostic and therapeutic purposes. Because this procedure is much less invasive than the traditional thoracotomy performed for lung biopsy, it has largely supplanted "open lung biopsy."

THORACOTOMY

Although frequently replaced byVATS, thoracotomy remains an option for the diagnostic sampling of lung tissue. It provides the largest amount of material, and it can be used to biopsy and/or excise lesions that are too deep or too close to vital structures for removal by VATS. The choice between VATS and thoracotomy needs to be made on a case-by-case basis, and the relative indications for each are still evolving as more experience is being gained with VATS.

MEDIASTINOSCOPY AND MEDIASTINOTOMY

Tissue biopsy is often critical for the diagnosis of mediastinal masses or enlarged mediastinal lymph nodes. AlthoughCT is useful for determining the size of mediastinal lymph nodes as part of the staging of lung cancer, confirmation that enlarged lymph nodes are actually involved with tumor generally requires biopsy and histopathologic examination. The two major procedures used to obtain specimens from masses or nodes in the mediastinum are mediastinoscopy (via a suprasternal approach) and mediastinotomy (via a parasternal approach). Both procedures are performed under general anesthesia by a qualified surgeon. In the case of suprasternal mediastinoscopy, a rigid mediastinoscope is inserted at the suprasternal notch and passed into the mediastinum along a pathway just anterior to the trachea. Tissue can be obtained with biopsy forceps passed through the scope, sampling masses or nodes that are in a paratracheal or pretracheal position. Left paratracheal and aortopulmonary lymph nodes are not accessible by this route and thus are commonly sampled by parasternal mediastinotomy (the Chamberlain procedure). This approach involves either a right or left parasternal incision and dissection directly down to a mass or node that requires biopsy.

SECTION 2 -DISEASES OF THE RESPIRATORY SYSTEM

252. ASTHMA - *E. R. McFadden, Jr.*

DEFINITION

Asthma is defined as a chronic inflammatory disease of airways that is characterized by increased responsiveness of the tracheobronchial tree to a multiplicity of stimuli. It is manifested physiologically by a widespread narrowing of the air passages, which may be relieved spontaneously or as a result of therapy, and clinically by paroxysms of dyspnea, cough, and wheezing. Asthma is an episodic disease, with acute exacerbations interspersed with symptom-free periods. Typically, most attacks are short-lived, lasting minutes to hours, and clinically the patient seems to recover completely after an attack. However, there can be a phase in which the patient experiences some degree of airway obstruction daily. This phase can be mild, with or without superimposed severe episodes, or much more serious, with severe obstruction persisting for days or weeks; the latter condition is known as *status asthmaticus*. In unusual circumstances, acute episodes can cause death.

PREVALENCE AND ETIOLOGY

Asthma is very common; it is estimated that 4 to 5% of the population of the United States is affected. Similar figures have been reported from other countries. Bronchial asthma occurs at all ages but predominantly in early life. About one-half of cases develop before age 10, and another third occur before age 40. In childhood, there is a 2:1 male/female preponderance, but the sex ratio equalizes by age 30.

From an etiologic standpoint, asthma is a heterogeneous disease. It is useful for epidemiologic and clinical purposes to classify asthma by the principal stimuli that incite or are associated with acute episodes. However, it is important to emphasize that this distinction may often be artificial, and the response of a given subclassification usually can be initiated by more than one type of stimulus. Furthermore, the application of molecular and cell biologic techniques to asthma pathogenesis is also beginning to blur this type of classification. With these reservations in mind, one can describe two broad types of asthma: allergic and idiosyncratic.

Atopy is the single largest risk factor for the development of asthma. *Allergic asthma* is often associated with a personal and/or family history of allergic diseases such as rhinitis, urticaria, and eczema, with positive wheal-and-flare skin reactions to intradermal injection of extracts of airborne antigens, with increased levels of IgE in the serum, and/or with a positive response to provocation tests involving the inhalation of specific antigen.

A significant fraction of patients with asthma present with no personal or family history of allergy, with negative skin tests, and with normal serum levels of IgE, and therefore have disease that cannot be classified on the basis of defined immunologic mechanisms. These patients are said to have *idiosyncratic asthma*. Many develop a typical symptom complex on contracting an upper respiratory illness. The initial insult may be little more than a common cold, but after several days the patient begins to

develop paroxysms of wheezing and dyspnea that can last for days to months. These individuals should not be confused with persons in whom the symptoms of bronchospasm are superimposed on chronic bronchitis or bronchiectasis (Chaps. 256 and258).

Many patients have disease that does not fit clearly into either of the preceding categories but instead falls into a mixed group with features of each. In general, asthma that has its onset in early life tends to have a strong allergic component, whereas asthma that develops late tends to be nonallergic or to have a mixed etiology.

PATHOGENESIS OF ASTHMA

The common denominator underlying the asthmatic diathesis is a nonspecific hyperirritability of the tracheobronchial tree. When airway reactivity is high, symptoms are more severe and persistent, and the amount of therapy required to control the patient's complaints is greater. In addition, the magnitude of diurnal fluctuations in lung function is greater, and the patient tends to awaken at night or in the early morning with breathlessness.

In both normal and asthmatic individuals, airway reactivity rises after viral infections of the respiratory tract and exposure to oxidant air pollutants such as ozone and nitrogen dioxide (but not sulfur dioxide). Viral infections have more profound consequences, and airway responsiveness may remain elevated for many weeks after a seemingly trivial upper respiratory tract infection. In contrast, airway reactivity remains high for only a few days after exposure to ozone. Allergens can cause airway responsiveness to rise within minutes and to remain elevated for weeks. If the dose of antigen is high enough, acute episodes of obstruction may occur daily for a prolonged period after a single exposure.

The most popular hypothesis at present for the pathogenesis of asthma is that it derives from a state of persistent subacute inflammation of the airways. An active inflammatory process is frequently observed in endobronchial biopsy specimens even from asymptomatic patients. The airways can be edematous and infiltrated with eosinophils, neutrophils, and lymphocytes, with or without an increase in the collagen content of the epithelial basement membrane. There may also be glandular hypertrophy. The most ubiquitous finding is a generalized increase in cellularity associated with an elevated capillary density. Occasionally, denudation of the epithelium may also be observed.

Although the translation of these histologic observations into a disease process is still incomplete, it is widely believed that the physiologic and clinical features of asthma derive from an interaction among the resident and infiltrating inflammatory cells in the airway surface epithelium, inflammatory mediators, and cytokines. The cells thought to play important parts in the inflammatory response are mast cells, eosinophils, lymphocytes, and epithelial cells. The roles of neutrophils and macrophages are less well defined. Each of these cell types can contribute mediators and cytokines to initiate and amplify both acute inflammation and the long-term pathologic changes described above. The mediators released -- histamine; bradykinin; the leukotrienes C, D, and E; platelet-activating factor; and prostaglandins (PGs) E_2, F_2a, and D_2 -- produce an intense, immediate inflammatory reaction involving bronchoconstriction, vascular congestion, and edema formation. In addition to their ability to evoke prolonged

contraction of airway smooth muscle and mucosal edema, the leukotrienes may also account for some of the other pathophysiologic features of asthma, such as increased mucus production and impaired mucociliary transport. This intense local event can then be followed by a more chronic one. The chemotactic factors elaborated (eosinophil and neutrophil chemotactic factors of anaphylaxis and leukotriene B_4) bring eosinophils, platelets, and polymorphonuclear leukocytes to the site of the reaction. These infiltrating cells as well as resident macrophages and the airway epithelium itself potentially are an additional source of mediators to enhance both the immediate and the cellular phase. The airway epithelium is both the target of, and a contributor to, the inflammatory cascade. These cells amplify bronchoconstriction by elaborating endothelin-1 and promoting vasodilatation through the release of nitric oxide,PG$E_2$and the 15-hydroxyeicosatetraenoic acid (15-HETE) products of arachidonic acid metabolism. They also generate cytokines such as granulocyte-macrophage colony stimulating factor (GM-CSF), interleukin (IL)8, Rantes, and eotaxin.

Like the mast cell in the early reaction, the eosinophil appears to play an important part in the infiltrative component. The granular proteins in this cell (major basic protein and eosinophilic cationic protein) and oxygen-derived free radical are capable of destroying the airway epithelium, which then is sloughed into the bronchial lumen in the form of Creola bodies. Besides resulting in a loss of barrier and secretory function, such damage elicits the production of chemotactic cytokines, leading to further inflammation. In theory, it also can expose sensory nerve endings, thus initiating neurogenic inflammatory pathways. That, in turn, could convert a primary local event into a generalized reaction via a reflex mechanism.

T lymphocytes also appear to be important in the inflammatory response. These cells are present in increased numbers in asthmatic airways and produce cytokines that activate cell-mediated immunity, as well as humoral (IgE) immune responses. Activated T cells recovered from the lungs of persons with asthma express messenger RNA for the cytokines known to play a part in the recruitment and activation of mast cells and eosinophils. Furthermore, the T_H1 and T_H2 lymphocyte subtypes have functions that may influence the asthmatic response. The T_H1 cytokinesIL-2 and interferon (IFN) g can promote the growth and differentiation of B cells and the activation of macrophages, respectively. The T_H2 cytokines IL-4 and IL-5 stimulate B-cell growth and immunoglobulin secretion, and IL-5 promotes eosinophil proliferation, differentiation, and activation. It can also facilitate granule release from basophils.

Cytokine production is another central component of the inflammation of asthma. Cytokines are synthesized and released from many of the inflammatory cells mentioned above, as well as from epithelial cells, fibroblasts, endothelial cells, and airway smooth muscle. Cytokines activate specific cell-surface receptors that are coupled to signal transduction pathways, which often result in alterations of gene regulation and enzyme production. The cytokines that are particularly relevant to asthma are secreted by T lymphocytes and includeIL-3 enhanced (mast cell survival), IL-4 and IL-13 (switching of B lymphocytes to IgE production and expression of adhesion molecules), and IL-5 (differentiation and enhanced survival of eosinophils). Other cytokines, such as IL-1B, IL-6, IL-11, tumor necrosis factor a(TNF-a) andGM-CSF, are proinflammatory and may amplify the inflammatory response.

The relative roles of each of the above elements in the production of heightened airway reactivity and clinical asthma have yet to be determined. Although inflammation is clearly important, recent evidence indicates that the intensity of the cellular infiltrate in the airways is not related either to the severity of the disease state or to the level of airway reactivity. Furthermore, it is unlikely that any one cell type or mediator accounts for every feature. For example, mast cell-derived mediators cannot explain the whole picture, for they have been found in the blood of individuals with mast cell-related diseases such as cold-induced and cholinergic-induced urticaria and in the airways of atopic individuals without asthma. Since these individuals had no lower respiratory illness or complaints, these alleged mediators of asthma would appear to need a unique background from which to exhibit their effects. Similarly, the inflammatory cells believed to be relevant to asthma are also found in the airways of atopic individuals without asthma, raising the possibility that they are merely nonspecific markers of atopy rather than specific indexes of asthma. Finally, the therapeutic administration ofIL-2 andGM-CSFto patients with cancer results in eosinophilia with cell activation but not in asthma.

GENETIC CONSIDERATIONS

Although there is little doubt that asthma has a strong familial component, the identification of the genetic mechanisms underlying the illness has proven difficult for multiple reasons, including such fundamental issues as a lack of uniform agreement on the definition of the disease, the inability to define a single phenotype, non-Mendelian modes of inheritance, and an incomplete understanding of how environmental factors modify genetic expression. Screening families for candidate genes has identified multiple chromosomal regions that relate to atopy, elevated IgE levels, and airway hyperresponsiveness. Evidence for genetic linkage of high total serum IgE levels and atopy has been observed on chromosomes 5q, 11q, and 12q in a number of populations scattered throughout the world. Regions of the genome demonstrating evidence for linkage to bronchial hyperreactivity also typically show evidence for linkage to elevated total serum IgE levels. Excellent candidate genes exist for specific abnormalities in asthma within the regions that were identified in the linkage studies. For example, chromosome 5q contains cytokine clusters includingIL-4, IL-5, IL-9, and IL-13. Other regions on chromosome 5q also contain the beta-adrenergic receptors and the glucocorticoid receptors. Chromosome 6p contains regions that are important in antigen presentation and mediation of the inflammatory response. Chromosome 12q contains two genes that could influence atopy and airway hyperresponsiveness, including nitric oxide synthase.

The stimuli that interact with airway responsiveness and incite acute episodes of asthma can be grouped into seven major categories: allergenic, pharmacologic, environmental, occupational, infectious, exercise-related, and emotional.

Allergens Allergic asthma is dependent on an IgE response controlled by T and B lymphocytes and activated by the interaction of antigen with mast cell-bound IgE molecules. The airway epithelium and submucosa contain dendritic cells that capture and process antigen. After taking up an immunogen, these cells migrate to the local lymph nodes where they present the material to T cell receptors. In the appropriate genetic setting, the interaction of antigen with a naive T cell T_H0 in the presence of IL-4

leads to the differentiation of the cell to a T_H2 subset. This process not only helps facilitate the inflammation of asthma but also causes B lymphocytes to switch their antibody production from IgG and IgM to IgE. Most of the allergens that provoke asthma are airborne, and to induce a state of sensitivity they must be reasonably abundant for considerable periods of time. Once sensitization has occurred, however, the patient can exhibit exquisite responsivity, so that minute amounts of the offending agent can produce significant exacerbations of the disease. Immune mechanisms appear to be causally related to the development of asthma in 25 to 35% of all cases and to be contributory in perhaps another third. Higher prevalences have been suggested, but it is difficult to know how to interpret the data because of confounding factors. Allergic asthma is frequently seasonal, and it is most often observed in children and young adults. A nonseasonal form may result from allergy to feathers, animal danders, dust mites, molds, and other antigens that are present continuously in the environment. Exposure to antigen typically produces an immediate response in which airway obstruction develops in minutes and then resolves. In 30 to 50% of patients, a second wave of bronchoconstriction, the so-called late reaction, develops 6 to 10 h later. In a minority, only a late reaction occurs. It was formerly thought that the late reaction was essential to the development of the increase in airway reactivity that follows antigen exposure. Recent data show that not to be the case.

The mechanism by which an inhaled allergen provokes an acute episode of asthma depends in part on antigen-antibody interactions on the surface of pulmonary mast cells, with the subsequent generation and release of the mediators of immediate hypersensitivity. Current hypotheses hold that very small antigenic particles penetrate the lung's defenses and come in contact with mast cells that interdigitate with the epithelium at the luminal surface of the central airways. The subsequent elaboration of mediators and cytokines then produces the sequence outlined above.

Pharmacologic Stimuli The drugs most commonly associated with the induction of acute episodes of asthma are aspirin, coloring agents such as tartrazine,b-adrenergic antagonists, and sulfiting agents. It is important to recognize drug-induced bronchial narrowing because its presence is often associated with great morbidity. Furthermore, death sometimes has followed the ingestion of aspirin (or other nonsteroidal anti-inflammatory agents) orb-adrenergic antagonists. The typical aspirin-sensitive respiratory syndrome primarily affects adults, although the condition may occur in childhood. This problem usually begins with perennial vasomotor rhinitis that is followed by a hyperplastic rhinosinusitis with nasal polyps. Progressive asthma then appears. On exposure to even very small quantities of aspirin, affected individuals typically develop ocular and nasal congestion and acute, often severe episodes of airways obstruction. The prevalence of aspirin sensitivity in patients with asthma varies from study to study, but many authorities feel that 10% is a reasonable figure. There is a great deal of cross reactivity between aspirin and other nonsteroidal anti-inflammatory compounds that inhibit prostaglandin G/H synthase 1 (cyclooxygenase type 1). Indomethacin, fenoprofen, naproxen, zomepirac sodium, ibuprofen, mefenamic acid, and phenylbutazone are particularly important in this regard. However, acetaminophen, sodium salicylate, choline salicylate, salicylamide, and propoxyphene are well tolerated. The exact frequency of cross reactivity to tartrazine and other dyes in aspirin-sensitive individuals with asthma is also controversial; again, 10% is the commonly accepted figure. This peculiar complication of aspirin-sensitive asthma is particularly insidious,

however, in that tartrazine and other potentially troublesome dyes are widely present in the environment and may be unknowingly ingested by sensitive patients.

Patients with aspirin sensitivity can be desensitized by daily administration of the drug. After this form of therapy, cross tolerance also develops to other nonsteroidal anti-inflammatory agents. The mechanism by which aspirin and other such drugs produce bronchospasm appears to be a chronic overexcretion of cysteinyl leukotrienes, which activate mast cells. The adverse reaction to aspirin can be inhibited with the use of leukotriene synthesis blockers or receptor antagonists.

Beta-adrenergic antagonists regularly obstruct the airways in individuals with asthma as well as in others with heightened airway reactivity and should be avoided by such individuals. Even the selective $beta_1$agents have this propensity, particularly at higher doses. In fact, the local use of $beta_1$blockers in the eye for the treatment of glaucoma has been associated with worsening asthma.

Sulfiting agents, such as potassium metabisulfite, potassium and sodium bisulfite, sodium sulfite, and sulfur dioxide, which are widely used in the food and pharmaceutical industries as sanitizing and preserving agents, also can produce acute airway obstruction in sensitive individuals. Exposure usually follows ingestion of food or beverages containing these compounds, e.g., salads, fresh fruit, potatoes, shellfish, and wine. Exacerbation of asthma has been reported after the use of sulfite-containing topical ophthalmic solutions, intravenous glucocorticoids, and some inhalational bronchodilator solutions. The incidence and mechanism of action of this phenomenon are unknown. When suspected, the diagnosis can be confirmed by either oral or inhalational provocations.

Environment and Air Pollution (See also Chap. 254) Environmental causes of asthma are usually related to climatic conditions that promote the concentration of atmospheric pollutants and antigens. These conditions tend to develop in heavily industrial or densely populated urban areas and are frequently associated with thermal inversions or other situations creating stagnant air masses. In these circumstances, although the general population can develop respiratory symptoms, patients with asthma and other respiratory diseases tend to be more severely affected. The air pollutants known to have this effect are ozone, nitrogen dioxide, and sulfur dioxide. Sulfur dioxide needs to be present in high concentrations and produces its greatest effects during periods of high ventilation. In some regions of North America, seasonal concentrations of airborne antigens such as pollen can rise high enough to result in epidemics of asthma admissions to hospitals and an increase in the death rate. These events may be ameliorated by treating patients prophylactically with anti-inflammatory drugs before the allergy season begins.

Occupational Factors (See alsoChap. 254) Occupation-related asthma is a significant health problem, and acute and chronic airway obstruction has been reported to follow exposure to a large number of compounds used in many types of industrial processes. Bronchoconstriction can result from working with or being exposed to *metal salts* (e.g., platinum, chrome, and nickel), *wood and vegetable dusts* (e.g., those of oak, western red cedar, grain, flour, castor bean, green coffee bean, mako, gum acacia, karay gum, and tragacanth), *pharmaceutical agents* (e.g., antibiotics, piperazine, and cimetidine),

industrial chemicals and plastics (e.g., toluene diisocyanate, phthalic acid anhydride, trimellitic anhydride, persulfates, ethylenediamine, *p*-phenylenediamine, and various dyes), *biologic enzymes* (e.g., laundry detergents and pancreatic enzymes), and *animal and insect dusts, serums, and secretions*. It is important to recognize that exposure to sensitizing chemicals, particularly those used in paints, solvents, and plastics, also can occur during leisure or non-work-related activities.

There seem to be three underlying mechanisms for this airway obstruction: (1) In some cases, the offending agent results in the formation of a specific IgE, and the cause seems immunologic (the immunologic reaction can be immediate, late, or dual); (2) in other cases, the substance causes a direct liberation of bronchoconstrictor substances; and (3) in other instances, the substance causes direct or reflex stimulation of the airways of individuals with either latent or frank asthma. If the occupational agent causes an immediate or dual immunologic reaction, the history is similar to that which occurs with exposure to other antigens. Often, however, patients will give a characteristic cyclic history. They are well when they arrive at work, and symptoms develop toward the end of the shift, progress after the work site is left, and then regress. Absence from work during weekends or vacations brings about remission. Frequently, there are similar symptoms in fellow employees.

Infections Respiratory infections are the most common of the stimuli that evoke acute exacerbations of asthma. Well-controlled investigations have demonstrated that respiratory viruses and not bacteria or allergy to microorganisms are the major etiologic factors. In young children, the most important infectious agents are respiratory syncytial virus and parainfluenza virus. In older children and adults, rhinovirus and influenza virus predominate as pathogens. Simple colonization of the tracheobronchial tree is insufficient to evoke acute episodes of bronchospasm, and attacks of asthma occur only when symptoms of an ongoing respiratory tract infection are, or have been, present. Viral infections can actively and chronically destabilize asthma, and they are perhaps the only stimuli that can produce constant symptoms for weeks. The mechanism by which viruses induce exacerbations of asthma may be related to the production of T cell-derived cytokines that potentiate the infiltration of inflammatory cells into already susceptible airways.

Exercise Exercise is a very common precipitant of acute episodes of asthma. This stimulus differs from other naturally occurring provocations, such as antigens, viral infections, and air pollutants, in that it does not evoke any long-term sequelae, nor does it increase airway reactivity. Exercise can be made to provoke bronchospasm in every patient with asthma, and in some it is the only trigger that produces symptoms. When such patients are followed for sufficient periods, however, they often develop recurring episodes of airway obstruction independent of exercise; thus, the onset of this problem frequently is the first manifestation of the full-blown asthmatic syndrome. The critical variables that determine the severity of the postexertional airway obstruction are the levels of ventilation achieved and the temperature and humidity of the inspired air. The higher the ventilation and the lower the heat content of the air, the greater the response. For the same inspired air conditions, running produces a more severe attack of asthma than walking. Conversely, for a given task, the inhalation of cold air markedly enhances the response, while warm, humid air blunts or abolishes it. Consequently, activities such as ice hockey, cross-country skiing, and ice skating are more provocative than is

swimming in an indoor, heated pool. The mechanism by which exercise produces obstruction may be related to a thermally produced hyperemia and engorgement of the microvasculature of the bronchial wall and does not appear to involve smooth-muscle contraction.

Emotional Stress Abundant objective data demonstrate that psychological factors can interact with the asthmatic diathesis to worsen or ameliorate the disease process. The pathways and nature of the interactions are complex but are operational to some extent in almost half the patients studied. Changes in airway caliber seem to be mediated through modification of vagal efferent activity, but endorphins also may play a role. The most frequently studied variable has been that of suggestion, and the weight of current evidence indicates that it can be quite important in selected individuals with asthma. When psychically responsive individuals are given the appropriate suggestion, they can actually decrease or increase the pharmacologic effects of adrenergic and cholinergic stimuli on their airways. The extent to which psychological factors participate in the induction and/or continuation of any given acute exacerbation is not established but probably varies from patient to patient and in the same patient from episode to episode.

PATHOLOGY

In a patient who has died of acute asthma, the most striking feature of the lungs at necropsy is their gross overdistention and failure to collapse when the pleural cavities are opened. When the lungs are cut, numerous gelatinous plugs of exudate are found in most of the bronchial branches down to the terminal bronchioles. Histologic examination shows hypertrophy of the bronchial smooth muscle, hyperplasia of mucosal and submucosal vessels, mucosal edema, denudation of the surface epithelium, pronounced thickening of the basement membrane, and eosinophilic infiltrates in the bronchial wall. There is an absence of any of the well-recognized forms of destructive emphysema.

PATHOPHYSIOLOGY

The pathophysiologic hallmark of asthma is a reduction in airway diameter brought about by contraction of smooth muscle, vascular congestion, edema of the bronchial wall, and thick, tenacious secretions. The net result is an increase in airway resistance, a decrease in forced expiratory volumes and flow rates, hyperinflation of the lungs and thorax, increased work of breathing, alterations in respiratory muscle function, changes in elastic recoil, abnormal distribution of both ventilation and pulmonary blood flow with mismatched ratios, and altered arterial blood gas concentrations. Thus, although asthma is considered to be primarily a disease of airways, virtually all aspects of pulmonary function are compromised during an acute attack. In addition, in very symptomatic patients there frequently is electrocardiographic evidence of right ventricular hypertrophy and pulmonary hypertension. When a patient presents for therapy, his or her forced vital capacity tends to be £50% of normal. The 1-s forced expiratory volume (FEV_1) averages 30% or less of predicted, while the maximum and minimum midexpiratory flow rates are reduced to 20% or less of expected. In keeping with the alterations in mechanics, the associated air trapping is substantial. In acutely ill patients, residual volume (RV) frequently approaches 400% of normal, while functional residual capacity doubles. The patient tends to report that the attack has ended clinically

when the RV has fallen to 200% of its predicted value and the FEV_1 reaches 50% of the predicted level.

Hypoxia is a universal finding during acute exacerbations, but frank ventilatory failure is relatively uncommon, being observed in 10 to 15% of patients presenting for therapy. Most individuals with asthma have hypocapnia and a respiratory alkalosis. In acutely ill patients, the finding of a normal arterial carbon dioxide tension tends to be associated with quite severe levels of obstruction. Consequently, when found in a symptomatic individual, it should be viewed as representing impending respiratory failure, and the patient should be treated accordingly. Equally, the presence of metabolic acidosis in the setting of acute asthma signifies severe obstruction. Usually, there are no clinical counterparts to the derangements in blood gases. Cyanosis is a very late sign. Hence, a dangerous level of hypoxia can go undetected. Likewise, signs attributable to carbon dioxide retention, such as sweating, tachycardia, and wide pulse pressure, or to acidosis, such as tachypnea, tend not to be of great value in predicting the presence of hypercapnia or hydrogen ion excess in individual patients, because they are too frequently seen in anxious patients with more moderate disease. Trying to judge the state of an acutely ill patient's ventilatory status on clinical grounds alone can be extremely hazardous, and clinical indicators should not be relied on with any confidence. Therefore, in patients with suspected alveolar hypoventilation, arterial blood gas tensions must be measured.

CLINICAL FEATURES

The symptoms of asthma consist of a triad of dyspnea, cough, and wheezing, the last often being regarded as the *sine qua non*. In its most typical form, asthma is an episodic disease, and all three symptoms coexist. At the onset of an attack, patients experience a sense of constriction in the chest, often with a nonproductive cough. Respiration becomes audibly harsh, wheezing in both phases of respiration becomes prominent, expiration becomes prolonged, and patients frequently have tachypnea, tachycardia, and mild systolic hypertension. The lungs rapidly become overinflated, and the anteroposterior diameter of the thorax increases. If the attack is severe or prolonged, there may be a loss of adventitial breath sounds, and wheezing becomes very high pitched. Furthermore, the accessory muscles become visibly active, and a paradoxical pulse often develops. These two signs are extremely valuable in indicating the severity of the obstruction. In the presence of either, pulmonary function tends to be significantly more impaired than in their absence. It is important to note that the development of a paradoxical pulse depends on the generation of large negative intrathoracic pressures. Thus, if the patient's breathing is shallow, this sign and/or the use of accessory muscles could be absent even though obstruction is quite severe. The other signs and symptoms of asthma only imperfectly reflect the physiologic alterations that are present. Indeed, if the disappearance of subjective complaints or even of wheezing is used as the end point at which therapy for an acute attack is terminated, an enormous reservoir of residual disease will be missed.

The end of an episode is frequently marked by a cough that produces thick, stringy mucus, which often takes the form of casts of the distal airways (Curschmann's spirals) and, when examined microscopically, often shows eosinophils and Charcot-Leyden crystals. In extreme situations, wheezing may lessen markedly or even disappear,

cough may become extremely ineffective, and the patient may begin a gasping type of respiratory pattern. These findings imply extensive mucus plugging and impending suffocation. Ventilatory assistance by mechanical means may be required. Atelectasis due to inspissated secretions occasionally occurs with asthmatic attacks. Spontaneous pneumothorax and/or pneumomediastinum occur but are rare.

Less typically, a patient with asthma may complain of intermittent episodes of nonproductive cough or exertional dyspnea. Unlike other individuals with asthma, when these patients are examined during symptomatic periods, they tend to have normal breath sounds but may wheeze after repeated forced exhalations and/or may show ventilatory impairments when tested in the laboratory. In the absence of both these signs, a bronchoprovocation test may be required to make the diagnosis.

DIFFERENTIAL DIAGNOSIS

The differentiation of asthma from other diseases associated with dyspnea and wheezing is usually not difficult, particularly if the patient is seen during an acute episode. The physical findings and symptoms listed above and the history of periodic attacks are quite characteristic. A personal or family history of allergic diseases such as eczema, rhinitis, or urticaria is valuable contributory evidence. An extremely common feature of asthma is nocturnal awakening with dyspnea and/or wheezing. In fact, this phenomenon is so prevalent that its absence raises doubt about the diagnosis. *Upper airway obstruction by tumor* or *laryngeal edema* can occasionally be confused with asthma. Typically, a patient with such a condition will present with stridor, and the harsh respiratory sounds can be localized to the area of the trachea. Diffuse wheezing throughout both lung fields is usually absent. However, differentiation can sometimes be difficult, and indirect laryngoscopy or bronchoscopy may be required. Asthma-like symptoms have been described in patients with glottic dysfunction. These individuals narrow their glottis during inspiration and expiration, producing episodic attacks of severe airway obstruction. Occasionally, carbon dioxide retention develops. However, unlike asthma, the arterial oxygen tension is well preserved, and the alveolar-arterial gradient for oxygen narrows during the episode, instead of widening as with lower airway obstruction. To establish the diagnosis of glottic dysfunction, the glottis should be examined when the patient is symptomatic. Normal findings at such a time exclude the diagnosis; normal findings during asymptomatic periods do not.

Persistent wheezing localized to one area of the chest in association with paroxysms of coughing indicates *endobronchial disease* such as foreign-body aspiration, a neoplasm, or bronchial stenosis.

The signs and symptoms of *acute left ventricular failure* occasionally mimic asthma, but the findings of moist basilar rales, gallop rhythms, blood-tinged sputum, and other signs of heart failure (Chap. 232) allow the appropriate diagnosis to be reached.

Recurrent episodes of bronchospasm can occur with *carcinoid tumors* (Chap. 93), *recurrent pulmonary emboli* (Chap. 261), and *chronic bronchitis* (Chap. 258). In chronic bronchitis there are no true symptom-free periods, and one can usually obtain a history of chronic cough and sputum production as a background on which acute attacks of wheezing are superimposed. Recurrent emboli can be very difficult to separate from

asthma. Frequently, patients with this condition present with episodes of breathlessness, particularly on exertion, and they sometimes wheeze. Pulmonary function studies may show evidence of peripheral airway obstruction (Chap. 250); when these changes are present, lung scans also may be abnormal. The therapeutic response to bronchodilators and to the institution of anticoagulant therapy may be helpful, but pulmonary angiography may be necessary to establish the correct diagnosis.

Eosinophilic pneumonias (Chap. 253) are often associated with asthmatic symptoms, as are various chemical pneumonias and exposures to insecticides and cholinergic drugs. Bronchospasm occasionally is a manifestation of *systemic vasculitis* with pulmonary involvement.

DIAGNOSIS

The diagnosis of asthma is established by demonstrating reversible airway obstruction. *Reversibility* is traditionally defined as a 15% or greater increase in FEV_1after two puffs of a b-adrenergic agonist. When the spirometry results are normal at presentation, the diagnosis can be made by showing heightened airway responsiveness to challenges with histamine, methacholine, or isocapnic hyperventilation of cold air. Once the diagnosis is confirmed, the course of the illness and the effectiveness of therapy can be followed by measuring peak expiratory flow rates (PEFRs) at home and/or the FEV_1 in the laboratory. Positive wheal-and-flare reactions to skin tests can be demonstrated to various allergens, but such findings do not necessarily correlate with the intrapulmonary events. Sputum and blood eosinophilia and measurement of serum IgE levels are also helpful but are not specific for asthma. Chest roentgenograms showing hyperinflation are also nondiagnostic.

TREATMENT

Elimination of the causative agent(s) from the environment of an allergic individual with asthma is the most successful means available for treating this condition (for details on avoidance, see Chap. 310). Desensitization or immunotherapy with extracts of the suspected allergens has enjoyed widespread favor, but controlled studies are limited and have not proved it to be highly effective.

Drug Treatment The available agents for treating asthma can be divided into two general categories: drugs that inhibit smooth muscle contraction, i.e., the so-called "quick relief medications" (beta-adrenergic agonists, methylxanthines, and anticholinergics) and agents that prevent and/or reverse inflammation, i.e., the "long-term control medications" (glucocorticoids, leukotriene inhibitors and receptor antagonists, and mast cell-stabilizing agents).

Adrenergic Stimulants The drugs in this category consist of the catecholamines, resorcinols, and saligenins. These agents are analogues and produce airway dilation through stimulation of beta-adrenergic receptors and activation of G proteins with the resultant formation of cyclic adenosine monophosphate (AMP). They also decrease release of mediators and improve mucociliary transport. The catecholamines available for clinical use are epinephrine, isoproterenol, and isoetharine. As a group, these

compounds are short-acting (30 to 90 min) and are effective only when administered by inhalational or parenteral routes. Epinephrine and isoproterenol are notb_2-selective and have considerable chronotropic and inotropic cardiac effects. Epinephrine also has substantial alpha-stimulating effects. The usual dose is 0.3 to 0.5 mL of a 1:1000 solution administered subcutaneously. Isoproterenol is devoid of alpha activity and is the most potent agent of this group. It is usually administered in a 1:200 solution by inhalation. Isoetharine is the mostb_2-selective compound of this class, but it is a relatively weak bronchodilator. It is employed as an aerosol and supplied as a 1% solution. The use of these agents in treating asthma has been superceded by longer acting selective$b_2$agonists.

The commonly used resorcinols are metaproterenol, terbutaline, and fenoterol, and the most widely known saligenin is albuterol (salbutamol). With the exception of metaproterenol, these drugs are highly selective for the respiratory tract and virtually devoid of significant cardiac effects except at high doses. Their major side effect is tremor. They are active by all routes of administration, and because their chemical structures allow them to bypass the metabolic processes used to degrade the catecholamines, their effects are relatively long-lasting (4 to 6 h). Differences in potency and duration among agents can be eliminated by adjusting doses and/or administration schedules.

Inhalation is the preferred route of administration because it allows maximal bronchodilation with fewer side effects. In the past it was fashionable to treat episodes of severe asthma with intravenous sympathomimetics such as isoproterenol. This approach no longer appears justifiable. Isoproterenol infusions clearly can induce myocardial damage, and even for theb_2-selective agents such as terbutaline and albuterol, intravenous administration offers no advantages over the inhaled route.

Salmeterol is a very long-lasting (9 to 12 h) congener of albuterol. When given every 12 h, it is effective in providing sustained symptomatic relief. It is particularly helpful for conditions such as nocturnal and exercise-induced asthma. It is not recommended for the treatment of acute episodes because of its relatively slow onset of action (approximately 30 min), nor is it intended as a rescue drug for breakthrough symptoms. In addition, its long half-life means that administration of extra doses can cause cumulative side effects.

Methylxanthines Theophylline and its various salts are medium-potency bronchodilators that work by increasing cyclicAMP by the inhibition of phosphodiesterase. The therapeutic plasma concentrations of theophylline traditionally have been thought to lie between 10 and 20 ug/mL. Some sources, however, recommend a lower target range between 5 and 15 ug/mL to avoid toxicity. The dose required to achieve the desired level varies widely from patient to patient owing to differences in the metabolism of the drug. Theophylline clearance, and thus the dosage requirement, is decreased substantially in neonates and the elderly and those with acute and chronic hepatic dysfunction, cardiac decompensation, and cor pulmonale. Clearance is also decreased during febrile illnesses. Clearance is increased in children. In addition, a number of important drug interactions can alter theophylline metabolism. Clearance falls with the concurrent use of erythromycin and other macrolide antibiotics, the quinolone antibiotics, and troleandomycin, allopurinol, cimetidine, and propranolol. It

rises with use of cigarettes, marijuana, phenobarbital, phenytoin, or any other drug that is capable of inducing hepatic microsomal enzymes.

For maintenance therapy, long-acting theophylline compounds are available and are usually given once or twice daily. The dose is adjusted on the basis of the clinical response with the aid of serum theophylline measurements. Single-dose administration in the evening reduces nocturnal symptoms and helps keep the patient complaint-free during the day. Aminophylline and theophylline are available for intravenous use. The recommendations for intravenous therapy in children aged 9 to 16 and in young adult smokers not currently receiving theophylline products are a loading dose of 6 mg/kg followed by an infusion of 1 mg/kg per hour for the next 12 h and then 0.8 mg/kg per hour thereafter. In nonsmoking adults, older patients, and those with cor pulmonale, congestive heart failure, and liver disease, the loading dose remains the same, but the maintenance dose is reduced to between 0.1 and 0.5 mg/kg per hour. In patients already receiving theophylline, the loading dose is frequently withheld or, in extreme situations, reduced to 0.5 mg/kg.

The most common side effects of theophylline are nervousness, nausea, vomiting, anorexia, and headache. At plasma levels greater than 30 ug/mL there is a risk of seizures and cardiac arrhythmias.

Anticholinergics Anticholinergic drugs such as atropine sulfate produce bronchodilation in patients with asthma, but their use is limited by systemic side effects. Nonabsorbable quaternary ammonium congeners (atropine methylnitrate and ipratropium bromide) have been found to be both effective and free of untoward effects. They may be of particular benefit for patients with coexistent heart disease, in whom the use of methylxanthines andb-adrenergic stimulants may be dangerous. The major disadvantages of the anticholinergics are that they are slow to act (60 to 90 min may be required before peak bronchodilation is achieved) and they are only of modest potency.

Glucocorticoids Glucocorticoids are the most potent and most effective anti-inflammatory medications available. Systemic or oral steroids are most beneficial in acute illness when severe airway obstruction is not resolving or is worsening despite intense optimal bronchodilator therapy, and in chronic disease when there has been failure of a previously optimal regimen with frequent recurrences of symptoms of increasing severity. Inhaled glucocorticoids are used in the long-term control of asthma.

Glucocorticoids are not bronchodilators and the correct dose to use in acute situations is a matter of debate. The available data indicate that very high doses do not offer any advantage over more conventional amounts. In the United States, a usual starting dose is 40 to 60 mg of methylprednisolone intravenously every 6 h. Since intravenous and oral administration produce the same effects, prednisone, 60 mg every 6 h, can be substituted. Clinical impressions suggest that smaller quantities may work as effectively, but there are no confirmatory data. In the United Kingdom and elsewhere, acute asthma both in and out of hospital is frequently treated with doses of prednisolone ranging from 30 to 40 mg given once daily. It should be emphasized that the effects of steroids in acute asthma are not immediate and may not be seen for 6 h or more after the initial administration. Consequently, it is mandatory to continue vigorous bronchodilator therapy during this interval. Irrespective of the regimen chosen, it is important to

appreciate that rapid tapering of glucocorticoids frequently results in recurrent obstruction. Most authorities recommend reducing the dose by one-half every third to fifth day after an acute episode. In situations in which it appears that continued steroid therapy will be needed, an alternate-day schedule should be instituted to minimize side effects. This is particularly important in children, since continuous glucocorticoid administration interrupts growth. Long-acting preparations such as dexamethasone should not be used in this approach, for they defeat the purpose of alternate-day schedules by causing prolonged suppression of the pituitary-adrenal axis. The availability of inhaled agents has all but eliminated the need for this form of therapy.

INHALED GLUCOCORTICOIDS These drugs are indicated in patients with persistent symptoms. The agents currently available in the United States are beclomethasone, budesonide, flunisolide, fluticasone propionate, and triamcinolone acetonide. Each has relative advantages and disadvantages, and they are not absolutely interchangeable on either a microgram or a per puff basis. However, all of these drugs share the ability to control inflammation, facilitate the long-term prevention of symptoms, and reduce the need for oral glucocorticoids.

There is no fixed dose of inhaled steroid that works for all patients. Requirements are dictated by the response of the individual and wax and wane in concert with progression of the disease. Generally, the worse the patient's condition, the more inhaled steroid is needed to gain control. Once achieved, however, remission can often be maintained with quantities as low as one or two puffs/day. Inhaled steroids can take up to a week or more to produce improvements; consequently, in rapidly deteriorating situations, it is best to prescribe oral preparations and initiate inhaled drugs as the dose of the former is reduced. In less emergent circumstances, the quantity of inhaled drug can be increased up to 2 to 2.5 times the recommended starting doses. It is critical to remember that the side effects increase in proportion to the dose-time product. In addition to thrush and dysphonia, the increased systemic absorption that accompanies larger doses of inhaled steroids has been reported to produce adrenal suppression, cataract formation, decreased growth in children, interference with bone metabolism, and purpura. As is the case with oral agents, suppression of inflammation, per se, cannot be relied upon to provide optimal results. It is essential to continue adrenergic or methylxanthine bronchodilators if the patient's disease is unstable.

Mast Cell-Stabilizing Agents Cromolyn sodium and nedocromil sodium do not influence airway tone. Their major therapeutic effect is to inhibit the degranulation of mast cells, thereby preventing the release of the chemical mediators of anaphylaxis.

Cromolyn sodium and nedocromil, like the inhaled steroids, improve lung function, reduce symptoms, and lower airway reactivity in persons with asthma. They are most effective in atopic patients who have either seasonal disease or perennial airway stimulation. A therapeutic trial of two puffs four times daily for 4 to 6 weeks frequently is necessary before the beneficial effects of the drug appear. Unlike steroids, nedocromil and cromolyn sodium, when given prophylactically, block the acute obstructive effects of exposure to antigen, industrial chemicals, exercise, or cold air. With antigen, the late response is also abolished. Therefore, a patient who has intermittent exposure to either antigenic or nonantigenic stimuli that provoke acute episodes of asthma need not use these drugs continuously but instead can obtain protection by taking the drug only 15 to

20 min before contact with the precipitant.

Leukotriene Modifiers As mentioned earlier, the cysteinyl leukotrienes (LTC_4, LTD_4, and LTE_4) produce many of the critical elements of asthma, and drugs have been developed to either reduce the synthesis of all of the leukotrienes by inhibiting 5-lipoxygenase (5-LO), the enzyme involved in their production, or competitively antagonizing the principal moiety (LTD_4). Zileuton is the only 5-lipoxygenase synthesis inhibitor that is available in the United States. It is a modest bronchodilator that reduces asthma morbidity, provides protection against exercise-induced asthma, and diminishes nocturnal symptoms, but it has limited effectiveness against allergens. Hepatic enzyme levels can be elevated after its use, and there are significant interactions with other drugs metabolized in the liver. The LTD_4receptor antagonists (zafirlukast and montelukast) have therapeutic and toxicologic profiles similar to that of zileuton but are long acting and permit twice to single daily dose schedules.

This class of drugs does not appear to be uniformly effective in all patients with asthma. Although precise figures are lacking, most authorities put the number of positive responders at less than 50%. As yet, there is no way of determining prospectively who will benefit, so clinical trials are required. Typically, if there is no improvement after one month, treatment can be discontinued.

Miscellaneous Agents It has been suggested that steroid-dependent patients might benefit from the use of immunosuppressant agents such as methotrexate or gold salts. The effects of these agents on steroid dosage and disease activity are minor, and side effects can be considerable. Consequently, this form of treatment can be viewed only as experimental. Opiates, sedatives, and tranquilizers should be absolutely avoided in the acutely ill patient with asthma because the risk of depressing alveolar ventilation is great, and respiratory arrest has been reported to occur shortly after their use. Admittedly, most individuals are anxious and frightened, but experience has shown that they can be calmed equally well by the physician's presence and reassurances. b-Adrenergic blockers and parasympathetic agonists are contraindicated because they can cause marked deterioration in lung function.

Expectorants and mucolytic agents have enjoyed great vogue in the past, but they do not add significantly to the treatment of the acute or chronic phases of this disease. Mucolytic agents such as acetylcysteine may actually produce bronchospasm when administered to susceptible patients with asthma. This effect can be overcome by aerosolizing them in solution with a b-adrenergic agent. The use of intravenous fluids in the treatment of acute asthma also has been advocated. There is little evidence that this adjunct hastens recovery. Nonstandard bronchodilators, such as intravenous magnesium sulfate, for the treatment of acute asthma attacks are not yet warranted in clinical practice because of the controversy surrounding their efficacy.

Special Instructions The treatment of patients with asthma who have coexisting conditions such as heart disease or pregnancy does not differ materially from that outlined above. Therapy with inhaledb_2-selective and anti-inflammatory agents is the mainstay. The lowest doses of adrenergics that produce the desired effects should be used.

FRAMEWORK FOR MANAGEMENT

Emergency Situations The most effective treatment for acute episodes of asthma requires a systematic approach based on the aggressive use of sympathomimetic agents and serial monitoring of key indices of improvement. Reliance on empirism and subjective assessment is no longer acceptable. Multiple inhalations of a short-acting sympathomimetic, such as albuterol, are the cornerstone of most regimens. These drugs provide three to four times more relief than does intravenous aminophylline. Anticholinergic drugs are not first-line therapy because of their long lag time to onset (~ 30 to 40 min) and their relatively modest bronchodilator properties. In emergency situations,$b_2$agonists can be given every 20 min by handheld nebulizer for 2 to 3 doses. The optimum cumulative dose of albuterol appears to lie between 5 and 10 mg. It does not matter how the adrenergic agonists are inhaled. Treatment with albuterol administered by jet nebulizer, metered dose inhaler, or dry powder inhaler all provide equal resolution in acute situations. Aminophylline or ipratropium can be added to the regimen after the first hour in an attempt to speed resolution. Recent studies in a large series of patients demonstrate that$b_2$agonists alone terminate attacks in approximately two-thirds of patients, and that another 5 to 10% benefit from a methylxanthine or ipratropium in combination with a sympathomimetic. The remainder have a poor acute response to all forms of therapy.

Acute episodes of bronchial asthma are one of the most common respiratory emergencies seen in the practice of medicine, and it is essential that the physician recognize which episodes of airway obstruction are life-threatening and which patients demand what level of care. These distinctions can be made readily by assessing selected clinical parameters in combination with measures of expiratory flow and gas exchange. The presence of a paradoxical pulse, use of accessory muscles, and marked hyperinflation of the thorax signify severe airways obstruction, and failure of these signs to remit promptly after aggressive therapy mandates objective monitoring of the patient with measurements of arterial blood gases and the peak expiratory flow rate (PEFR) or FEV_1.

In general, there is a correlation between the severity of the obstruction with which the patient presents and the time it takes to resolve it. Those individuals with the most impairment typically require the most extensive therapy for resolution. If thePEFR or FEV_1 is equal to or less than 20% of predicted on presentation and does not double within an hour of receiving the preceding therapy, the patient is likely to require extensive treatment including glucocorticoids before the obstruction dissipates. This group represents approximately 20% of all the patients who present for acute care. They generally require 3 to 4 days of inpatient treatment before becoming asymptomatic. In such individuals, if the clinical signs of a paradoxical pulse and accessory muscle use are diminishing, and/or if PEFR is increasing, there is no need to change medications or doses; the patient need only be followed. However, if the PEFR falls by more than 20% of its previous value or if the magnitude of the pulsus paradoxicus is increasing, serial measures of arterial blood gases are required, as well as a reconsideration of the therapeutic modalities being employed. If the patient has hypocarbia, one can afford to continue the current approaches a while longer. On the other hand, if the Pa_{CO_2} is within the normal range or is elevated, the patient should be monitored in an intensive care setting, and therapy should be intensified to reverse or

arrest the patient's respiratory failure.

Chronic Treatment The goal of chronic therapy is to achieve a stable, asymptomatic state with the best pulmonary function possible using the least amount of medication. The first step is to educate patients to function as partners in their management. The severity of the illness needs to be assessed and monitored with objective measures of lung function. Asthma triggers should be avoided or controlled, and plans should be made for both chronic management and treatment of exacerbations. Regular follow-up care is mandatory. With respect to pharmacologic interventions, in general, the simplest approach works best. Infrequent symptoms require only the use of an inhaled sympathomimetic on an "as needed" basis. When the disease worsens, as manifested by nocturnal awakenings and daytime symptoms, inhaled steroids and/or mast cell-stabilizing agents should be added. If symptoms do not abate, the dose of inhaled steroids can be increased. An upper limit has not yet been established, but side effects of glucocorticoid excess begin to appear more frequently when the dose exceeds 2.0 mg/d. Persistent asthma complaints can be treated with long-acting inhaled$b_2$agonists, sustained-release theophylline, and/or parasympatholytics. In patients with recurrent or perennial symptoms and unstable lung function, oral steroids in a single daily dose are added to the regimen. Once control is reached and sustained for several weeks, a step-down reduction in therapy should be undertaken, beginning with the most toxic drug, to find the minimum amount of medication required to keep the patient well. During this process, thePEFRshould be monitored and medication adjustments should be based on objective changes in lung function as well as on the patient's symptoms.

PROGNOSIS AND CLINICAL COURSE

The mortality rate from asthma is small. The most recent figures indicate fewer than 5000 deaths per year out of a population of approximately 10 million patients at risk. Death rates, however, appear to be rising in inner-city areas where there is limited availability of health care.

Information on the clinical course of asthma suggests a good prognosis particularly for those whose disease is mild and develops in childhood. The number of children who still have asthma 7 to 10 years after the initial diagnosis varies from 26 to 78%, averaging 46%; however, the percentage who continue to have severe disease is relatively low (6 to 19%).

Although there are reports of patients with asthma developing irreversible changes in lung function, these individuals frequently have comorbid stimuli such as cigarette smoking that could account for these findings. Even when untreated, individuals with asthma do not continuously move from mild to severe disease with time. Rather, their clinical course is characterized by exacerbations and remissions. Some studies suggest that spontaneous remissions occur in approximately 20% of those who develop the disease as adults and that 40% or so can be expected to experience improvement, with less frequent and severe attacks, as they grow older.

253. HYPERSENSITIVITY PNEUMONITIS AND PULMONARY INFILTRATES WITH EOSINOPHILIA - *Joel N. Kline*, *Gary W. Hunninghake*

HYPERSENSITIVITY PNEUMONITIS

Hypersensitivity pneumonitis (HP), or extrinsic allergic alveolitis, is an immunologically induced inflammatory disorder of the lung parenchyma, involving alveolar walls and terminal airways, secondary to repeated inhalation of a variety of organic agents by a susceptible host. Causes of HP are typically designated with colorful names denoting the occupational or avocational risk associated with the disease; "farmer's lung" is the term most commonly used for HP due to inhalation of antigens present in moldy hay, such as thermophilic actinomyces, *Micropolyspora faeni*, and *Aspergillus* species. The prevalence of HP is unknown but varies with the environmental exposure and the specific antigen involved. The prevalence of farmer's lung among Wisconsin dairy farmers has been reported as 4.2 per 1000. The diagnosis of HP requires a constellation of clinical, radiographic, physiologic, pathologic, and immunologic criteria, each of which is rarely pathognomonic alone; and the preferred treatment is avoidance of the causative antigen when practical.

ETIOLOGY

Agents implicated as causes ofHPinclude those listed in Table 253-1. Many cases of HP occurring in various occupations involve exposure to similar agents, particularly the thermophilic actinomycetes. In the United States, the most common types of HP are farmer's lung, bird fancier's lung, and chemical worker's lung. In *farmer's lung*, inhalation of proteins such as thermophilic bacteria and fungal spores that are present in moldy bedding and feed are most commonly responsible for the development of HP. These antigens are probably also responsible for the etiology of *mushroom worker's disease* (moldy composted growth medium is the source of the proteins) and *bagassosis* (moldy sugar cane is the source). *Bird fancier's lung* (and the related disorders of duck fever, turkey handler's lung, and dove pillow's lung) is a response to inhalation of bird proteins from feathers and droppings. *Chemical worker's lung* is an example of how simple chemicals, such as isocyanates, may also cause immune-mediated diseases. In this case, antihapten antibodies may be responsible for the development of HP.

PATHOGENESIS

The finding that precipitating antibodies against extracts of moldy hay were demonstrable in most patients with farmer's lung led to the early conclusion that HPwas an immune-complex-mediated reaction. Subsequent investigations of HP in humans and animal models provided evidence for the importance of cell-mediated hypersensitivity. The very early (acute) reaction is characterized by an increase in polymorphonuclear leukocytes in the alveoli and small airways. This early lesion is followed by an influx of mononuclear cells into the lung and the formation of granulomas that appear to be the result of a classic delayed (T cell mediated) hypersensitivity reaction to repeated inhalation of antigen and adjuvant-active materials. Recent studies in animal models suggest that the disease is mediated as a classic T_H1 cell-mediated immune response to antigen.

Bronchoalveolar lavage in patients with HPconsistently demonstrates an increase in the number of T lymphocytes in lavage fluid (a finding that is also observed in patients with other granulomatous lung disorders). Patients with recent or continual exposure to antigen may have an increase in the number of polymorphonuclear leukocytes in lavage fluid. Increased numbers of mast cells have also been reported. In most patients examined during recovery from acute disease, the T lymphocytes in lavage fluid are predominantly the CD8+ T cell subset. In patients with very recent exposure to antigen, however, the numbers of CD4+ T cells may increase in lavage fluid. Similar findings may be present in similarly exposed, asymptomatic individuals. These observations and others in animal models suggest that there is an active modulation of granuloma formation in the lung by immunoregulatory T cells and associated cytokines in this disorder.

CLINICAL PRESENTATION

The clinical picture is that of an interstitial pneumonitis, although it varies from patient to patient and seems related to the frequency and intensity of exposure to the causative antigen and perhaps other host factors. The presentation can be *acute, subacute*, or *chronic*. In the *acute form*, symptoms such as cough, fever, chills, malaise, and dyspnea may occur 6 to 8 h after exposure to the antigen and usually clear within a few days if there is no further exposure to antigen. The *subacute form* often appears insidiously over a period of weeks marked by cough and dyspnea and may progress to cyanosis and severe dyspnea requiring hospitalization. In some patients, a subacute form of the disease may persist after an acute presentation of the disorder, especially if there is continued exposure to antigen. In most patients with the acute or subacute form ofHP, the symptoms, signs, and other manifestations of HP disappear within days, weeks, or months if the causative agent is no longer inhaled. Transformation to a chronic form of the disease may occur in patients with continued antigen exposure, but the frequency of such progression is uncertain. The *chronic form* of HP may be clinically indistinguishable from pulmonary fibrosis due to a wide variety of causes. Physical examination may reveal clubbing. This stage may progressively worsen, resulting in dependence on supplemental O_2, pulmonary hypertension, and death from respiratory failure. An indolent gradually progressive form of the disease can be associated with cough and exertional dyspnea without a prior history consistent with acute or subacute manifestations. Such a gradual onset frequently occurs with low-dose exposure to the antigen.

Because strict definitions of acute, subacute, and chronic stages ofHP have not been generally agreed on, interpretation of epidemiologic and clinical studies can be difficult. Therefore, it has been proposed that HP be described as recently diagnosed, recurrent or progressive, or residual disease. For these categories, required diagnostic criteria include the presence of an appropriate exposure; exertional dyspnea; inspiratory crackles; and, if performed, lymphocytic alveolitis on bronchoalveolar lavage. Supportive criteria include recurrent febrile episodes, radiographic infiltrates, diminished pulmonary diffusing capacity, precipitating antibodies to appropriate antigens, histopathologic demonstration of granulomas, and improvement in symptoms with avoidance of exposure.

DIAGNOSIS

After acute exposure to antigen, neutrophilia and lymphopenia are frequently present. Eosinophilia is not a feature. All forms of the disease may be associated with elevations in erythrocyte sedimentation rate, C-reactive protein, rheumatoid factor, and serum immunoglobulins. Antinuclear antibodies are rarely present and appear to have no pathogenic role. Examination for *serum precipitins* against suspected antigens, such as those listed inTable 253-1, is an important part of the diagnostic workup and should be performed on any patient with interstitial lung disease, especially if a suggestive exposure history is elicited. If found, precipitins indicate sufficient exposure to the causative agent for generation of an immunologic response. The diagnosis ofHP is not established solely by the presence of precipitins, however, as precipitins are found in sera of many individuals exposed to appropriate antigens who demonstrate no other evidence of HP. False-negative results may occur because of poor-quality antigens or an inappropriate choice of antigens. Extraction of antigens from the suspected source may at times be helpful.

No specific or distinctive *chest roentgenogram* occurs inHP. It can be normal even in symptomatic patients. The acute or subacute phase may be associated with poorly defined, patchy, or diffuse infiltrates or with discrete, nodular infiltrates (Fig. 253-1). In the chronic phase, the chest x-ray usually shows a diffuse reticulonodular infiltrate. Honeycombing may eventually develop as the condition progresses. Apical sparing is common, suggesting that disease severity correlates with inhaled antigen load, but no particular distribution or pattern is classic for HP. Abnormalities rarely seen in HP include pleural effusion or thickening, and hilar adenopathy. High-resolution chest computed tomography (CT) has been reported to show a characteristic constellation of abnormalities, including (1) global lung involvement with increased lung density, (2) prominence of medium-sized bronchial walls, (3) patchy air space opacification with reticular and nodular patterns and midzone prominence, and (4) absence of hilar lymph node enlargement. No pathognomonic CT features of HP have been described (Fig. 253-2).

Pulmonary function studies in all forms ofHP may show a restrictive or obstructive pattern with loss of lung volumes, impaired diffusion capacity, decreased compliance, and an exercise-induced hypoxemia. Resting hypoxemia may also be found. Bronchospasm and bronchial hyperreactivity are sometimes found in acute HP. With antigen avoidance, the pulmonary function abnormalities are usually reversible, but they may gradually increase in severity or may occur rapidly after acute or subacute exposure to antigen.

Bronchoalveolar lavage is used in some centers to aid in diagnostic evaluation. A marked lymphocytic alveolitis on bronchoalveolar lavage is almost universal, although not pathognomonic. Lymphocytes typically have a decreased helper/suppressor ratio and are activated. Alveolar neutrophilia is also prominent acutely but tends to fade in the absence of recurrent exposure. Bronchoalveolar mastocytosis may correlate with disease activity. *Lung biopsy*, obtained through flexible bronchoscopy, open-lung procedures, or thoracoscopy, may be diagnostic. Although the histopathology is distinctive, it may not be pathognomonic ofHP. When the biopsy is taken during the active phase of disease, typical findings include an interstitial alveolar infiltrate consisting of plasma cells, lymphocytes, and occasional eosinophils and neutrophils,

usually with accompanying granulomas. Interstitial fibrosis may be present but most often is mild in earlier stages of the disease. Some degree of bronchiolitis is found in about half the cases, whereas vasculitis is not a feature of the disorder. The triad of mononuclear bronchiolitis; interstitial infiltrates of lymphocytes and plasma cells; and single, nonnecrotizing, and randomly scattered parenchymal granulomas without mural vascular involvement is consistent with but not specific for HP.

Inhalation challenge studies have been described as useful to differentiate betweenHP and other interstitial lung diseases. These tests should be performed in a center that specializes in provocation testing for reasons of both safety and accuracy. Moveover, because the antigens used for provocation testing are not standardized, interpretation of these tests is difficult. In general, these tests may be used to support a diagnosis of HP, but they are not sufficiently accepted to either confirm or deny the diagnosis. The lack of standardized, nonirritating antigens and of proven controlled protocols makes *skin testing* useful only for research purposes. Similarly, in vitro tests of cell-mediated (delayed) hypersensitivity have not consistently been shown to correlate with clinical HP and have no place in the routine diagnostic workup.

In summary, the diagnosis in most cases is established by (1) consistent history, physical findings, pulmonary function tests, and chest x-ray; (2) exposure to a recognized antigen; and (3) finding an antibody to that antigen. In a few circumstances, bronchoalveolar lavage and/or lung biopsy may be needed. Provocation tests may be useful but are not essential for the diagnosis.

DIFFERENTIAL DIAGNOSIS

ChronicHP may often be difficult to distinguish from a number of other interstitial lung disorders such as idiopathic pulmonary fibrosis, sarcoidosis, interstitial lung disease associated with a collagen vascular disorder, and drug-induced lung diseases. A negative history for use of relevant drugs and no evidence of a systemic disorder usually exclude the presence of drug-induced lung disease or a collagen vascular disorder. Bronchoalveolar lavage often shows predominance of neutrophils in idiopathic pulmonary fibrosis and a predominance of CD4+ lymphocytes in sarcoidosis. Hilar/paratracheal lymphadenopathy or evidence of multisystem involvement also favors the diagnosis of sarcoidosis. In some patients, a lung biopsy may be required to differentiate chronic HP from other interstitial diseases. The lung disease associated with acute or subacute HP may clinically resemble other disorders that present with systemic symptoms and recurrent pulmonary infiltrates, including the allergic bronchopulmonary mycoses and other eosinophilic pneumonias.

Eosinophilic pneumonia is often associated with asthma and is typified by peripheral eosinophilia; neither of these is a feature ofHP. Allergic bronchopulmonary aspergillosis (ABPA) is the most common example of the allergic bronchopulmonary mycoses and is sometimes confused with HP because of the presence of precipitating antibodies to *A. fumigatus*. ABPA is associated with allergic (atopic) asthma. Acute HP may be confused with *organic dust toxic syndrome* (ODTS), a condition that is more common than HP. ODTS follows heavy exposure to organic dusts and is characterized by transient fever and muscle aches, with or without dyspnea and cough. Serum precipitins are absent, and the chest x-ray is usually normal. Studies have shown no immunologic basis for

ODTS, and endotoxin is suspected to be involved in its pathogenesis. This distinction is important, as ODTS is a self-limited disorder without significant long-term sequellae, whereas continued antigen exposure in HP can result in permanent disability. Massive exposure to moldy silage may result in a syndrome termed *pulmonary mycotoxicosis*, or *atypical farmer's lung*, with fever, chills, and cough and the presence of pulmonary infiltrates within a few hours of exposure. No previous sensitization is required, and precipitins are absent to *Aspergillus*, the suspected causative agent.

TREATMENT

Because effective treatment depends largely on avoiding the antigen, identification of the causative agent and its source is essential. This identification is usually possible if the physician takes a careful environmental and occupational history or, if necessary, visits the patient's environment. The simplest way to avoid the incriminated agent is to remove the patient from the environment or the source of the agent from the patient's environment. This recommendation cannot be taken lightly when it completely changes the life-style or livelihood of the patient. In many cases, however, the source of exposure (birds, humidifiers) can easily be removed. If occupational exposure is involved, an initial attempt can be made at antigen avoidance maneuvers that are least disruptive to the patient's livelihood, which usually means avoiding areas associated with heavy exposure and wearing an appropriate mask. This will not protect against small-molecular-weight agents such as isocyanates, which require more elaborate respiratory systems. Pollen masks, personal dust respirators, airstream helmets, and ventilated helmets with a supply of fresh air are increasingly efficient means of purifying inhaled air. If symptoms recur or physiologic abnormalities progress in spite of these measures, then more effective measures to avoid antigen exposure must be pursued. Compromises with environmental control pertain primarily to the acute, recurrent, transient clinical form ofHP and must be accompanied by careful follow-up. Subacute forms are ordinarily the result of a heavy, sustained exposure. The chronic form typically results from low-grade or recurrent exposure over many months or years, and the lung disease may already be partially irreversible. These patients are usually advised to avoid completely all possible contact with the offending agent, although follow-up studies of individuals with farmer's lung and bird fancier's lung have found resolution of the disease despite continued exposure in some patients.

Patients with the *acute*, recurrent form ofHPusually recover without need for glucocorticoids. *Subacute* HP may be associated with severe symptoms and marked physiologic impairment and may continue to progress for several days despite hospitalization. Urgent establishment of the diagnosis and prompt institution of glucocorticoid treatment are indicated in such patients. Such therapy may also hasten recovery in patients with lesser involvement. Prednisone at a dosage of 1 mg/kg per day or its equivalent is continued for 7 to 14 days and then tapered over the ensuing 2 to 6 weeks at a rate that depends on the patient's clinical status. Patients with *chronic* HP may gradually recover without therapy after the institution of environmental control. In many patients, however, a trial of prednisone may be useful to obtain maximal reversibility of the lung disease. After initial prednisone therapy (1 mg/kg per day for 2 to 4 weeks), the drug is tapered to the lowest dosage that will maintain the functional status of the patient. Many patients will not require or benefit from long-term therapy if there is no further exposure to antigen. Available studies report no effect of

glucocorticoid therapy on long-term prognosis of farmer's lung.

PULMONARY INFILTRATES WITH EOSINOPHILIA

Pulmonary infiltrates with eosinophilia (PIE, eosinophilic pneumonias) include distinct individual syndromes characterized by eosinophilic pulmonary infiltrates and, commonly, peripheral blood eosinophilia. Since Loeffler's initial description of a transient, benign syndrome of migratory pulmonary infiltrates and peripheral blood eosinophilia of unknown cause, this group of disorders has been enlarged to include several diseases of both known and unknown etiology (Table 253-2). These diseases may be considered as putative hypersensitivity lung diseases but are not to be confused withHP(extrinsic allergic alveolitis), in which eosinophilia is not a feature. When an eosinophilic pneumonia is associated with bronchial asthma, it is important to determine if the patient has atopic asthma and has wheal-and-flare skin reactivity to *Aspergillus* or other relevant fungal antigens. If so, other criteria should be sought for diagnosis ofABPA(Table 253-3) or other, rarer examples of allergic bronchopulmonary mycosis such as those caused by *Penicillium*, *Candida*, *Curvularia*, or *Helminthosporium* spp. *A. fumigatus* is the most common cause of ABPA, although other *Aspergillus* species have also been implicated. ABPA has been reported to complicate cystic fibrosis. The chest roentgenogram in ABPA may show transient, recurrent infiltrates or may suggest the presence of proximal bronchiectasis. High-resolution chestCT is a sensitive, noninvasive technique for the recognition of proximal bronchiectasis. The bronchial asthma of ABPA likely involves an IgE-mediated hypersensitivity, whereas the bronchiectasis associated with this disorder is thought to result from a deposition of immune complexes in proximal airways. Treatment usually requires the long-term use of systemic glucocorticoids.

Tropical eosinophilia is usually caused by filarial infection; however, eosinophilic pneumonias also occur with other parasites such as *Ascaris*, *Ancyclostoma* sp., *Toxocara* sp., and *Strongyloides stercoralis*. Tropical eosinophilia due to *Wuchereria bancrofti* or *W. malayi* occurs most commonly in southern Asia, Africa, and South America, and is treated successfully with diethylcarbamazine.

Drug-induced eosinophilic pneumonias are exemplified by acute reactions to nitrofurantoin, which may begin 2 h to 10 days after nitrofurantoin is started, with symptoms of dry cough, fever, chills, and dyspnea; an eosinophilic pleural effusion accompanying patchy or diffuse pulmonary infiltrates may also occur. Other drugs associated with eosinophilic pneumonias include sulfonamides, penicillin, chlorpropamide, thiazides, tricyclic antidepressants, hydralazine, mephenesin, mecamylamine, nickel carbonyl vapor, gold salts, isoniazid, para-aminosalicylic acid, and others. Treatment consists of withdrawal of the incriminated drugs and the use of glucocorticoids, if necessary. The eosinophilia-myalgia syndrome, caused by dietary supplements of L-tryptophan, is occasionally associated with pulmonary infiltrates.

The group of idiopathic eosinophilic pneumonias consists of diseases of varying severity. *Loeffler's syndrome* was originally reported as a benign, acute eosinophilic pneumonia of unknown cause characterized by migrating pulmonary infiltrates and minimal clinical manifestations. In some patients, these clinical characteristics may prove to be secondary to parasites or drugs. *Acute eosinophilic pneumonia* has been

described recently as an idiopathic acute febrile illness lasting less than 7 days with severe hypoxemia, pulmonary infiltrates, and no history of asthma. *Chronic eosinophilic pneumonia* presents with significant systemic symptoms including fever, chills, night sweats, cough, anorexia, and weight loss lasting for several weeks to months. The chest x-ray classically shows peripheral infiltrates resembling a photographic negative of pulmonary edema. Some patients also have bronchial asthma of the intrinsic or nonallergic type. Dramatic clearing of symptoms and chest x-rays is often noted within 48 h after initiation of glucocorticoid therapy.

Allergic angiitis and granulomatosis of Churg and Strauss is a multisystem vasculitic disorder that frequently involves the skin, kidney, and nervous system in addition to the lung. The disorder may occur at any age and favors persons with a history of bronchial asthma. The asthma often is progressive until the onset of fever and exaggerated eosinophilia, at which time the symptoms of asthma may ease. The illness may be fulminating and the prognosis grave unless treated aggressively with glucocorticoids and, at times, immunosuppressive therapy. The recent introduction of leukotriene-modifying agents (zafirlukast, zyleuton, and montelukast) has unmasked a number of cases of unrecognized Churg-Strauss syndrome when individuals with asthma have been weaned from glucocorticoids with the use of these antigens.

The *hypereosinophilic syndrome* is characterized by the presence of more than 1500 eosinophils per microliter of peripheral blood for 6 months or longer; lack of evidence for parasitic, allergic, or other known causes of eosinophilia; and signs or symptoms of multisystem organ dysfunction. Consistent features are blood and bone marrow eosinophilia with tissue infiltration by relatively mature eosinophils. The heart may be involved with tricuspid valve abnormalities or endomyocardial fibrosis and a restrictive, biventricular cardiomyopathy. Other organs affected typically include the lungs, liver, spleen, skin, and nervous system. Treatment consists of glucocorticoids and/or hydroxyurea, plus treatment as needed for cardiac dysfunction, which is frequently responsible for much of the morbidity and mortality in this syndrome.

254. ENVIRONMENTAL LUNG DISEASES - *Frank E. Speizer*

This**chapter**provides perspectives on ways to assess pulmonary diseases for which environmental causes are suspected. This assessment is important because removal of the patient from a harmful environment is often the only intervention that might prevent further significant deterioration or lead to improvement in a patient's condition. Furthermore, the identification of an environment-associated disease in a single patient may lead to primary preventive strategies affecting other similarly exposed people who have not yet developed disease.

The exact magnitude of the problem is unknown, but there is no question that large numbers of people are at risk for developing serious respiratory disease as a result of occupational or environmental exposures. For example, recent estimates suggest that approximately 2.4 million workers in the United States have been exposed to crystalline silica or asbestos dust in mining and nonmining industries. Even if only 5% of these workers (a conservative estimate) are to suffer from respiratory disease as a result of their exposure, this figure represents more than 100,000 individuals.

Although industries are required to spend substantial amounts of capital in efforts to protect their workers, occupationally related respiratory diseases continue to occur. These diseases are often attributed to exposures in the past, at a time when we were not aware of the risk incurred and the need for worker protection to the degree that we are today.

HISTORY AND PHYSICAL EXAMINATION

The patient's history is of paramount importance in assessing any potential occupational or environmental exposure, and the physician must ask the patient to describe a suspected environmental exposure in detail.

Inquiry into specific work practices should include questions about specific contaminants involved, the availability and use of personal respiratory protection devices, the size and ventilation of workspaces, and whether coworkers have similar complaints. In addition, the patient must be questioned about alternative sources for potentially toxic exposures, including hobbies or other environmental exposures at home. Short-term exposures to potential toxic agents in the distant past must also be considered (Chap. 391).

Many people are aware of the potential hazards in their workplaces, and many states require that employees be informed about potentially hazardous exposures. These requirements include the provision of specific educational materials (including Material Safety Data Sheets), personal protective equipment and instructions in its use, and information on environmental control procedures. Reminders posted in the workplace may warn workers about hazardous substances. Protective clothing, lockers, and shower facilities may be considered necessary parts of the job. However, even in these more progressive industries, the introduction of new processes, particularly when related to the use of new chemical compounds, may change exposure significantly, and often only the employee on the production line is aware of the change. For the physician who regularly sees patients from a particular industry, a visit to the work site can be very instructive. Alternatively, physicians can request inspections by appropriate federal

and/or state authorities.

The physical examination of patients with environment-related lung diseases may help to determine the nature and severity of the pulmonary condition. Unfortunately, the pulmonary response to most injurious agents is the development of a limited number of nonspecific physical signs. These findings do not point to the specific causative agent, and other types of information must be used to arrive at an etiologic diagnosis.

PULMONARY FUNCTION TESTS AND CHEST RADIOGRAPHY

Many mineral dusts produce characteristic alterations in the mechanics of breathing and lung volumes that clearly indicate a restrictive pattern (Chaps. 250 and259). Exposures to a number of organic dusts or chemical agents capable of producing occupational asthma result in pronounced obstructive patterns of pulmonary dysfunction that may be reversible (Chap. 252). Measurement of change in forced expiratory volume (FEV_1) before and after a working shift can be used to detect an acute inflammatory or bronchoconstrictive response. An acute decrement of FEV_1over the first work shift of the week is a characteristic feature of cotton textile workers with byssinosis.

The chest radiograph is useful in detecting and monitoring the pulmonary response to mineral dusts. The International Labour Organization (ILO) International Classification of Radiographs of Pneumoconioses classifies chest radiographs according to the nature and size of opacities seen and the extent of involvement of the parenchyma. In general, opacities may be round or irregular, small (<10 mm in diameter) or large. They may be few in number, with visible normal lung markings, partially obscure normal markings, or totally obscure normal markings. Although useful for screening large numbers of workers, the ILO system lacks specificity and may over- or underestimate the functional impact of pneumoconiosis. With dusts causing rounded, regular opacities like those evident in coal worker's pneumoconiosis, the degree of involvement on the chest radiograph may be extensive, while pulmonary function may be only minimally impaired.

In contrast, in pneumoconiosis causing linear, irregular opacities like those seen in asbestosis, the radiograph may lead to underestimation of the severity of the impairment. It is possible for a patient to have a history of exposure, a moderately reduced forced vital capacity (FVC), and a reduced diffusion capacity in asbestosis with a relatively normal chest radiograph. The radiographic findings of irregular or linear opacities are simply more difficult to separate from normal markings until relatively late in the disease. When shadows become large, as shown in Fig. 254-1, the condition is termed *complicated pneumoconiosis*, sometimes called progressive massive fibrosis (PMF). For the individual patient with a history of exposure, conventional computed tomography (CT) and high-resolution computed tomography (HRCT) have improved the sensitivity of identifying diffuse parenchymal abnormalities of the lung. The procedures have been shown to provide earlier detection of silicosis and asbestosis.

Other diagnostic procedures of use in identifying environment-induced lung disease include evaluation of heavy metal concentrations in urine (arsenic in smelter workers, cadmium in battery plant workers); bacteriologic studies (tuberculosis in medical care personnel, anthrax in wool sorters); fungal studies (coccidioidomycosis in southwestern farm workers, histoplasmosis in poultry or pigeon handlers); and serologic studies

(psittacosis in pet shop workers or owners of sick birds, Q fever in tanners or slaughterhouse workers). Ultimately, a lung biopsy may be required both for morphologic diagnosis of the underlying pulmonary disease and for attempted identification of the specific etiologic agent.

MEASUREMENT OF EXPOSURE

If reliable environmental sampling data are available, this information should be used in assessing a patient's exposure. Since many of the chronic diseases result from exposure over many years, current environmental measurements should be combined with work histories to arrive at estimates of past exposure. Even in acute conditions, when monitoring of exposure may be possible, little may be known about the actual dose received by the lung. Most of the research on health effects of air pollutants (discussed later in this**chapter**) has relied on fixed-station monitoring of outdoor air, often at locations somewhat distant from the residences of the people being studied. In addition, most people spend less than 20% of their time outdoors. Therefore, outdoor measurements can be used only in a relative sense, and they cannot be relied on to estimate actual dose.

In situations where individual exposure to specific agents -- either in a work setting or via ambient air pollutants -- has been determined, transport of these agents through the airways may be an important factor affecting dose. Highly soluble gases such as sulfur dioxide are absorbed in the upper airway and presumably produce their effects by reflex response of sensitive neural fibrils in the trachea or larger airways. In contrast, nitrogen dioxide, which is less soluble, may reach the bronchioles and alveoli in sufficient quantities to result in an acute life-threatening disease in farmers exposed even briefly to the gas evolved from moldy hay in silos (silo-filler's disease).

Particle size and chemistry of air contaminants also must be considered. Particles above 10 to 15 um in diameter, because of their settling velocities in air, do not penetrate beyond the upper airways. These larger particles are often referred to as "fugitive dusts" and include pollens, other windblown dusts, and dusts resulting from mechanical industrial processes. They have little or no role in chronic respiratory disease except perhaps as related to cancer (see below).

Particles below 10 um in size are created by the burning of fossil fuels or high-temperature industrial processes resulting in condensation products from gases, fumes, or vapors. These particles are divided into two size fractions on the basis of their chemical characteristics. Particles of approximately 2.5 to 10 um (coarse-mode fraction) contain crustal elements, such as silica, aluminum, and iron. These particles mostly deposit relatively high in the tracheobronchial tree. Although the total mass of an ambient sample is dominated by these larger respirable particles, the number of particles, and therefore the surface area on which potential toxic agents can deposit and be carried to the lower airways, is dominated by particles smaller than 2.5 um (fine-mode fraction or accumulation mode). The smallest particles, those less than 0.1 um in size, remain in the airstream and deposit in the lung only on a random basis as they come into contact with the alveolar walls.

Besides the size characteristics of particles and the solubility of gases, the actual

chemical composition, mechanical properties, and immunogenicity or infectivity of inhaled material determine in large part the nature of the diseases found among exposed persons. Few studies to date have directly measured those characteristics. However, they are of increasing concern as management strategies for environmental and occupational exposures are developed.

OCCUPATIONAL EXPOSURES AND PULMONARY DISEASE

ASBESTOSIS

Except in localized regions with single industrial exposures, such as coal-mining or granite-quarrying regions, the most frequent inorganic dust-related chronic pulmonary diseases are associated with industries using *asbestiform fibers*. *Asbestos* is a generic term for several different mineral silicates, including chrysolite, amosite, anthophyllite, and crocidolite. Besides workers involved in the mining, milling, and manufacturing of asbestos products, workers in the building trades, including pipe fitters and boilermakers, were exposed to asbestos, which was widely used in construction because of its exceptional thermal and electric insulation properties. In addition, asbestos was used in the manufacture of fire-smothering blankets and safety garments, as filler for plastic materials, in cement and floor tiles, and in friction materials, such as brake and clutch linings.

Exposure to asbestos is not limited to persons who directly handle the material. Cases of asbestos-related diseases have been encountered in individuals with only moderate exposure, such as the painter or electrician who works alongside the insulation worker in a shipyard or the housewife who does no more than shake out and wash her husband's work clothes. Community exposure has probably resulted from the use of asbestos-containing material sprayed on steel girders in many large buildings as a safety feature to prevent buckling in case of fire.

Asbestos was first used extensively in the 1940s. Starting in 1975 it was mostly replaced with synthetic mineral fibers, such as fiberglass or slag wool. However, asbestos is still used in the manufacture of brake linings and remains as pipe and boiler insulation in hundreds of thousands of workplaces and homes. Despite current regulations mandating adequate training for any worker potentially exposed to asbestos, exposure probably continues among inexperienced demolition workers. The major health effects from exposure to asbestos are pulmonary fibrosis (asbestosis) and cancers of the respiratory tract, the pleura, and (in rare cases) the peritoneum.

Asbestosis is a diffuse interstitial fibrosing disease of the lung that is directly related to the intensity and duration of exposure. Except for its association with a history of exposure to asbestos (generally in a work setting), asbestosis resembles the other forms of diffuse interstitial fibrosis (Chap. 259). Usually, moderate to severe exposure has taken place for at least 10 years before the disease becomes manifest.

Physiologic studies reveal a restrictive pattern with a decrease in lung volumes. Flow rates are commonly reduced less than would be predicted on the basis of the volume reduction. An early sign of severe disease may be a reduction in diffusing capacity.

Pulmonary fibrosis may occur following sufficient exposure to any of the asbestiform fiber types. The fibrotic lesions do not appear to relate to either shape or chemical composition of any fiber type. During phagocytosis of the asbestos fiber, the membrane of the macrophage is damaged and this damage results in the release of lysosomes containing enzymes that may act to damage the lung parenchyma. The clinical manifestations are typical of those physical findings in any patient with pulmonary fibrosis (Chap. 259).

Diagnosis The chest radiograph can be used to detect a number of manifestations of asbestos exposure as well as to identify specific lesions. Past exposure is specifically indicated by pleural plaques, which are characterized by either thickening or calcification along the parietal pleura, particularly along the lower lung fields, the diaphragm, and the cardiac border. Without additional manifestations, pleural plaques imply only exposure, not pulmonary impairment. Benign pleural effusions may occur, particularly in patients with asbestosis, but are not necessarily restricted to those with overt disease. The fluid is sterile but may be a serous or blood-stained exudate and may occur bilaterally. The effusion may be slowly progressive or may resolve spontaneously.

The radiographic diagnosis of asbestosis depends on the presence of irregular or linear opacities, usually first noted in the lower lung fields and spreading into the middle and upper lung fields as the disease progresses. An indistinct heart border or a "ground glass" appearance in the lung fields is seen in some cases. As the fibrotic changes in the parenchyma begin to coalesce, the patient develops obliteration of entire acinar units, with eventual formation of the classical honeycombed lung, which appears on chest radiographs as coarse infiltrates with small (about 7- to 10-um) air spaces. In cases in which the x-ray changes are less obvious,HRCT may show distinct changes of subpleural curvilinear lines 5 to 10 cm in length that appear to be parallel to the pleural surface; these alterations increase the positive predictive value of radiographic evidence from approximately 85% to about 100%.

In general, newly diagnosed cases will have resulted from exposure levels that were present many years before and, in spite of the patients' having left the industry, are attributable to that former exposure. Since the patient may be eligible for compensation within a specific time frame after the diagnosis of an asbestos-related disease is made, the physician making the diagnosis should be certain to inform the patient promptly. On occasion, the physician may have reason to suspect ongoing exposure from a patient's current job description or actual monitoring data. In such cases, federal or state health authorities may need to be notified. Present-day occupational safety and health regulations, if followed properly, protect workers from exposure.

Casual, nonoccupational exposure to undisturbed sources of asbestos-containing materials -- e.g., in walls of schools or other buildings -- represents little if any hazard to people who inhabit or work in such buildings. Because the association of smoking and asbestos exposure increases the risk of developing lung cancer (see below), it is extremely important to advise patients with a history of exposure to asbestos to stop smoking. No specific therapy is available in the management of patients with asbestosis. The supportive care is the same as that given to any patient with diffuse interstitial fibrosis from any cause.

Lung cancer (Chap. 88), either squamous cell carcinoma or adenocarcinoma, is the most frequent cancer associated with asbestos exposure. The excess frequency of lung cancer in asbestos workers is associated with a minimum lapse of 15 to 19 years between first exposure and development of the disease. Persons with more exposure are at greater risk of disease. In addition, there appears to be a significant multiplicative effect that leads to a far greater risk of lung cancer in persons who are cigarette smokers and have asbestos exposure than would be expected from the additive risk of each factor. To date, efforts to consider these high-risk individuals for special surveillance studies, including sputum cytologic examinations and repeated chest x-rays as frequently as every 4 to 6 months, have resulted in neither significant early detection nor prolonged survival once the lung cancer is found.

Mesotheliomas (Chap. 262), both pleural and peritoneal, are also associated with asbestos exposure. In contrast to lung cancers, these tumors do not appear to be associated with smoking. Relatively short-term asbestos exposures of 1 to 2 years or less occurring some 20 to 25 years in the past have been associated with the development of mesotheliomas (an observation that emphasizes the importance of obtaining a complete environmental exposure history). The risk for this type of tumor peaks 30 to 35 years after initial exposure. Since maximum exposure took place in the United States between 1930 and 1960, peak incidence of disease in men occurred in 1997, with a total of 2300 cases. Incidence is expected to decline over the next 30+ years to about 500 cases per year.

Although approximately 50% of mesotheliomas metastasize, the tumor generally is locally invasive, and death usually results from local extension. Most patients present with effusions that may obscure the underlying pleural tumor. In contrast to the findings in effusion due to other causes, because of the restriction placed on the chest wall, no shift of mediastinal structures toward the opposite side of the chest will be seen. The major diagnostic problem is differentiation from peripherally spreading pulmonary adenocarcinoma or from adenocarcinoma metastasized to pleura from an extrathoracic primary site. Although a needle biopsy may be diagnostic, an open biopsy is often necessary, and even the latter procedure may not provide a definitive diagnosis of the origin of the tumor.

Since epidemiologic studies have shown that more than 80% of mesotheliomas may be associated with asbestos exposure, documented mesothelioma in a worker with occupational exposure to asbestos may be compensable in many parts of the United States.

SILICOSIS

In spite of the technical adequacy of existing protective equipment, *free silica* (SiO_2), or crystalline quartz, is still a major occupational hazard. In the United States, estimates of potential numbers of exposed workers range between 1.2 and 3 million people. The major occupational exposures include: mining; stonecutting; employment in abrasive industries, such as stone, clay, glass, and cement manufacturing; foundry work; packing of silica flour; and quarrying, particularly of granite. Most often, progressive pulmonary fibrosis (silicosis) occurs in a dose-response fashion after many years of exposure.

Workers exposed through sandblasting in confined spaces, tunneling through rock with high quartz content (15 to 25%), or the manufacture of abrasive soaps may develop acute silicosis with as little as 10 months' exposure. The disease may be rapidly fatal in less than 2 years, despite the discontinuation of exposure. A radiographic picture of profuse miliary infiltration or consolidation is characteristic of acute silicosis.

In long-term, less intense exposure, small rounded opacities in the upper lobes, with retraction and hilar adenopathy, classically appear on the radiograph after 15 to 20 years. Calcification of hilar nodes may occur in as many as 20% of cases and produces the characteristic "eggshell" pattern. These changes may be preceded by or associated with a reticular pattern of irregular densities that are uniformly present throughout the upper lung zones.

The nodular fibrosis may be progressive in the absence of further exposure, with coalescence and formation of nonsegmental conglomerates of irregular masses in excess of 1 cm in diameter. These masses become quite large and are characteristic ofPMF(Figure 254-1). Significant functional impairment with both restrictive and obstructive components may be associated with this form of silicosis. In the late stages of the disease, ventilatory failure may develop. In more subtle cases,CT may be helpful both in identifying nodules, which are preferentially located in the posterior aspect of the upper lobes, as well as in identifying larger opacities and more coalescence than might be noted on regular chest x-rays. Patients with silicosis are at greater risk of acquiring *Mycobacterium tuberculosis* infections (silicotuberculosis) and atypical mycobacterial infections. Because the frequency with which tuberculosis has been found at autopsy in patients with PMF exceeds considerably the frequency of premorbid diagnosis, treatment for tuberculosis is indicated in any patient with silicosis and a positive tuberculin test.

Other less hazardous silicates include Fuller's earth, kaolin, mica, diatomaceous earths, silica gel, soapstone, carbonate dusts, and cement dusts. The production of fibrosis in workers exposed to these agents is believed to be related either to the free silica content of these dusts or, for substances that contain no free silica, to the potentially large dust loads to which these workers may be exposed.

Other silicates, including *talc dusts*, may be contaminated with asbestos and/or free silica. Accidental exposure to significant quantities of talc may result in an acute syndrome with cough, cyanosis, and labored breathing (acute talcosis). Severe progressive fibrosis with respiratory failure may ensue within a few years. Far more common is the fibrosis and/or pleural or lung cancer associated with chronic exposure in rubber workers who use commercial talc as a lubricant in tire molds. Pure talc does not produce fibrosis; thus, it is difficult to sort out whether the effects are due to the contamination of commercial talc by asbestos or by free silica.

COAL WORKER'S PNEUMOCONIOSIS (CWP)

Coal dust is associated with CWP, which has enormous social, economic, and medical significance in every nation in which coal mining is an important industry. Simple radiographically identified CWP is seen in 12% of all miners and in as many as 50% of anthracite miners with more than 20 years' work on the coal face. The prevalence of

disease is lower in workers in bituminous coal mines. Since much western U.S. coal is bituminous, CWP is less prevalent in that region.

Much of the symptomatology associated with simpleCWPappears to be similar and additive to the effects of cigarette smoking on the development of chronic bronchitis and obstructive lung disease (Chap. 258). In the early stages of simple CWP, radiographic abnormalities consist of small, irregular opacities (reticular pattern). With prolonged exposure, one sees small, rounded, regular opacities, 1 to 5 mm in diameter (nodular pattern). Calcification is generally not seen, although approximately 10% of older anthracite miners have calcified nodules.

ComplicatedCWP is manifested by the appearance on the chest radiograph of nodules ranging from 1 cm in diameter to the size of an entire lobe, generally confined to the upper half of the lungs. This condition, considered a form ofPMF, is accompanied by a significant reduction in diffusing capacity and is associated with premature mortality. In contrast to patients with silicosis, underground miners with simple CWP develop PMF at a rate of only 5 to 15%, depending on the type of coal.

The mechanism whereby PMFoccurs inCWP is not fully understood. Several hypotheses have been proposed, including: (1) sufficient free silica is present in the dust; (2) normal clearance mechanisms are unable to clear the excessive dust loads; and (3) atypical reactions to *M. tuberculosis* occur. As previously described, PMF in silicosis is associated with prolonged duration and high intensity of exposure to free silica. Heavy exposure to carbon particles free of silica occurs in carbon black, graphite, and charcoal workers. The prolonged exposure of these workers may result in sufficient accumulation of carbon in the lung to produce PMF. The mechanism appears to relate to a breakdown of the clearance capacity of the airways.

Caplan's syndrome (Chap. 312), first described in coal miners but subsequently found in patients with a variety of pneumoconioses, includes seropositive rheumatoid arthritis with characteristicPMF. The syndrome suggests an immunopathologic mechanism. Over the last decade, the mechanisms by which the chronic inhalation of mineral dusts produce an increase in inflammatory cells (including macrophages and neutrophils), which in turn causes PMF, have been explored. Coal dust can: (1) be a source of reactive oxygen species causing lung injury; (2) result in stimulation of macrophages to produce cytokines and enhance production of (anti)fibrogenic factors such as TNF-a; (3) increase protease activity; and (4) increase inactivation of a_1-antitrypsin and leukocyte elastase activity. The final pathologic pathway may be fibrosis resulting from the interactions of a variety of these mechanisms.

BERYLLIOSIS

Beryllium may produce an acute pneumonitis or, far more commonly, a chronic interstitial pneumonitis. Unless one inquires specifically about occupational exposures to beryllium in the manufacture of alloys, ceramics, high-technology electronics, and (before the 1950s) the production of fluorescent lights, one may miss entirely the etiologic relationship to an occupational exposure. Nonspecific pulmonary function tests may be normal or may indicate evidence of restrictive disease. Between 2 and 15 years of exposure, depending on its intensity, are required for the disease to become

manifest. On open lung biopsy, granulomatous formation similar to that seen in sarcoidosis (Chap. 318) may make differentiation impossible unless tissue levels of beryllium are measured.

Other hard metals, including aluminum powders, chromium, cobalt, titanium dioxide, and tungsten, may produce an interstitial pneumonitis, but this is rare.

OTHER INORGANIC DUSTS

Other dusts are considered *nuisance dusts* because their major environmental and health effects seem to be reduction in visibility and irritation of eyes, ears, nasal passages, and other mucous membranes, respectively. If they penetrate to the lower airways, these dusts do not affect the architecture of the terminal bronchioles or acinar spaces nor do they destroy collagen. Generally, clinical effects are reversible. Pulmonary function tests are usually normal unless another disease process coexists. If the dusts are radiodense, macular collections may produce striking radiographic pictures that are so characteristic that patients with a history of significant exposure are easily diagnosed as having the condition that bears the name reflecting the nature of the dust. Examples of radiodense dusts include iron and iron oxides from welding or silver finishing (*siderosis*); tin oxide used in metallurgy, color stabilization, printing, and the manufacture of porcelain, glass, and fabric (*stannosis*); and barium sulfate used as a catalyst for organic reactions, drilling mud components, and electroplating (*baritosis*). Other metal dusts producing similar radiodense pictures include *cerium dioxide* and *antimony salts*.

Most of the inorganic dusts discussed thus far are associated with the production of either dust macules or interstitial fibrotic changes in the lung. Another set of dusts (Table 254-1), along with some of the dusts previously discussed, is associated with chronic mucous hypersecretion (chronic bronchitis), with or without reduction of expiratory flow rates. These conditions are caused by cigarette smoking, and any effort to attribute some component of the disease to occupational and environmental exposures must take cigarette smoking into account. Most studies suggest an additive effect of dust exposure and smoking. The pattern of the effect is similar to that of cigarette smoking, suggesting that small airway inflammation may be the initial site of pathologic response in those cases associated with the development of obstructive lung disease. Cigarette smoke is usually the more noxious agent, and dust effects may be discernible only in nonsmokers.

ORGANIC DUSTS

Some of the specific diseases associated with organic dusts are discussed in detail in the chapters on asthma (Chap. 252) and hypersensitivity pneumonitis (Chap. 253). Many of these diseases are named for the specific setting in which they are found, e.g., farmer's lung, malt worker's disease, or mushroom worker's disease. Occupational and other environmental exposures must be sought when these conditions are suspected. Often the temporal relation of symptoms to exposure furnishes the best evidence for the diagnosis. Three occupational groups are singled out for discussion because they represent the largest proportion of people affected by the diseases resulting from organic dusts.

Cotton Dust (Byssinosis) Estimates of the number of exposed persons in the United States vary, but probably over 800,000 persons are exposed occupationally to cotton, flax, or hemp in the production of yarns for cotton, linen, and rope making. Although this discussion focuses on cotton, the same syndrome -- albeit somewhat less severe -- has been reported in association with exposure to flax, hemp, and jute.

Exposure occurs throughout the manufacturing process but is most pronounced in those portions of the factory involved with the treatment of the cotton prior to spinning -- i.e., blowing, mixing, and carding (straightening of fibers). Attempts to control dust levels by use of exhaust hoods, general increases in ventilation, and wetting procedures in some settings have been highly successful. However, respiratory protective equipment appears to be required during certain operations to prevent workers from being exposed to levels of dust that exceed the current U.S. cotton dust standard.

Byssinosis is characterized clinically as occasional (early stage) and then regular (late stage) chest tightness toward the end of the first day of the workweek ("Monday chest tightness"). In epidemiologic studies, depending on the level of exposure via the carding room air, up to 80% of employees may show a significant drop in theirFEV_1over the course of a Monday shift.

Initially the symptoms do not recur on subsequent days of the week. However, in 10 to 25% of workers, the disease may be progressive, with chest tightness recurring or persisting throughout the workweek. After more than 10 years of exposure, workers with recurrent symptoms are more likely to have an obstructive pattern on pulmonary function testing. These higher grades of impairment are seen in workers exposed both to high levels of dust and for greater durations. There is an additive effect of cotton dust exposure plus cigarette smoking. The highest grades of impairment are generally seen in smokers.

Treatment in the early stages of the disease is directed toward reversing the bronchospasm with bronchodilators; however, the chest tightness appears to relate, at least in part, to histamine release, and antihistamines have been shown to lessen the anticipated fall in$FEV_1$the first day of the week. Clearly, reduction of dust exposure is of primary importance. All workers with persistent symptoms or significantly reduced levels of pulmonary function should be moved to areas of lower risk of exposure. Regular surveillance of pulmonary function in the industry has made it easier to identify affected persons. Persons with reduced pulmonary function, a personal history of respiratory allergy, and a history of continued cigarette smoking should be considered at increased risk of developing byssinosis in association with work in the cotton industry.

Grain Dust Although the exact number of workers at risk in the United States is not known, at least 500,000 people work in grain elevators, and over 2 million farmers are potentially exposed to grain dust. The presentation of disease in grain elevator employees or in workers in flour or feed mills is virtually identical to the characteristic findings in cigarette smokers, i.e., persistent cough, mucous hypersecretion, wheeze and dyspnea on exertion, and reduced$FEV_1$and FEV_1/FVCratio (Chap. 250).

Dust concentrations in grain elevators vary greatly but appear to be in excess of 10,000

ug/m3; approximately one-third of the particles, by weight, are in the respirable range. The effect of grain dust exposure is additive to that of cigarette smoking, with approximately 50% of workers who smoke having symptoms. Among nonsmoking grain elevator operators, approximately one-quarter have mucous hypersecretion, about five times the number that would be expected in unexposed nonsmokers. However, evidence of obstruction on pulmonary function studies is observed only in workers who smoke. It is not clear whether the reason is an enhancement of the cigarette smoking effect in exposed workers or a greater susceptibility of smokers to the effects of grain dust.

Farmer's Lung This condition results from exposure to moldy hay containing spores of thermophilic actinomycetes that produce a hypersensitivity pneumonitis (Chap. 253). There are few good population-based estimates of the frequency of occurrence of this condition in the United States. However, among farmers in Great Britain, the rate of disease ranges from approximately 10 to 50 per 1000. The prevalence of disease varies in association with rainfall, which determines the amount of fungal growth, and with differences in agricultural practices related to turning and stacking hay.

The patient with acute farmer's lung presents 4 to 8 h after exposure with fever, chills, malaise, cough, and dyspnea without wheezing. The history of exposure is obviously essential to distinguish this disease from influenza or pneumonia with similar symptoms. In the chronic form of the disease, the history of repeated attacks after similar exposure is important in differentiating this syndrome from other causes of patchy fibrosis (e.g., sarcoidosis).

A wide variety of other organic dusts are associated with the occurrence of hypersensitivity pneumonitis (Chap. 253). For those patients who present with hypersensitivity pneumonitis, specific and careful inquiry about occupations, hobbies, or other home environmental exposures will, in most cases, reveal the source of the etiologic agent.

ASSESSMENT OF DISABILITY

Significant reduction of dust levels in coal mines has resulted from federal legislation, enacted in the United States in 1969, that requires that respirable dust levels in underground mines be reduced to less than 2000 ug/m3. This same legislation authorizes payment to coal miners (or their survivors) totally disabled byCWP. The criteria for disability from CWP remain unclear and arbitrary. It is critical that physicians involved in occupational lung disease claim cases be aware of detailed exposure histories of their patients, in terms of both occupational exposures and other environmental exposures (cigarette smoking). To assess disability properly may require input not only from physicians but also from experts in ergonomics and vocational rehabilitation, lawyers, and employer and employee representatives.

Most commonly, the patient presents with asthma, and it is the physician's task to decide whether the asthma is occupation-induced or work-aggravated asthma. The distinction is important not only because of the implications for disability compensation but also because the longer one is exposed to an inciting agent, the worse the prognosis for recovery from occupation-induced asthma. The clinical evaluation of such

a patient requires adherence to a prescribed protocol that may include not only the components of the evaluation previously described but also rechallenge of the patient in a controlled setting or under a carefully monitored program in a work setting.

TOXIC CHEMICALS

Exposure to toxic chemicals affecting the lung generally involves gases and vapors. A common accident is one in which the victim is trapped in a confined space where the chemicals have accumulated to toxic levels. In addition to the specific toxic effects of the chemical, the victim will often sustain considerable anoxia, which can play a dominant role in determining whether the individual survives.

Table 254-2 lists a variety of toxic agents that can produce acute and sometimes life-threatening reactions in the lung. All these agents in sufficient concentrations have been demonstrated, at least in animal studies, to affect the lower airways and disrupt alveolar architecture, either acutely or as a result of chronic exposure. Some of these agents may be generated acutely in the environment. For example, when plastics burn, a number of compounds, including hydrogen cyanide and hydrochloric acid, may be formed and released.**The effects and treatment of exposure to these toxic gases are discussed in Chap. 391.*

Firefighters and fire victims are at risk of *smoke inhalation*, a numerically important cause of acute cardiorespiratory failure. Smoke inhalation kills more fire victims than does thermal injury. Carbon monoxide poisoning with resulting significant hypoxemia can be life-threatening (Chap. 396). Firefighters may inappropriately use the "blackness" of the smoke to indicate the degree of incomplete combustion and thus of carbon monoxide elevation. The use of synthetic materials (plastic, polyurethanes), which, when burned, may release a variety of other toxic agents, must be considered when evaluating smoke inhalation victims. Exposed victims may suffer some degree of lower respiratory tract inflammation, similar to that seen with exposure to other irritant gases (e.g., chlorine). Severe cases may include pulmonary edema.

Firefighters and victims also may be exposed to large quantities of particulate smoke. Significant long-term effects are not clearly associated with this particulate exposure except as related to the production of irritating effects on the upper airways; however, increased airway responsiveness in firefighters with repeated episodes of smoke inhalation has been demonstrated.

Some agents used in the manufacture of synthetic materials such as plastics, polyurethanes, and other polymers have resulted in some workers' being sensitized to extremely low levels of *isocyanates*, *aromatic amines*, or *aldehydes*. Repeated exposure to these agents causes some workers to develop chronic cough and sputum production, asthma, or episodes of low-grade fever and malaise.

Exposure occurs by an unusual route in *polymer fume fever*. Polymers, notably fluorocarbons, which at normal temperatures produce no reaction, may be transmitted from a worker's hands to his or her cigarettes. As the cigarette burns, the polymer is volatilized, and the inhaled agent causes a characteristic syndrome of fever, chills, malaise, and occasionally mild wheezing. The same scenario applies when workers are

exposed to heated polymers without cigarette use -- *meat wrappers' asthma*. A similar self-limited, influenza-like syndrome -- *metal fume fever* -- results from acute exposure to fumes or smoke of zinc, copper, magnesium, and other volatilized metals. The syndrome may begin several hours after work and resolves within 24 h, only to return on repeated exposure. A proper occupational history should make the diagnosis evident.

ENVIRONMENTAL RESPIRATORY CARCINOGENS

Historically, it has been the astute clinician who has recognized a higher incidence of malignant tumors associated with certain environmental exposures. When these observations are linked to an occupational setting, they must be pursued by epidemiologic studies of relatively large groups of both current and former workers. Often the concentration and/or exact nature of the substances involved in the putative exposures cannot be determined. Rarely, the possibility that a substance can play an etiologic role in cancer is supported by observing that a few cases of a very rare tumor in a particular group represent "an epidemic." Examples are nasal sinus and lung cancer in nickel workers, angiosarcomas of the liver in vinyl chloride workers, and adenocarcinomas of the nose in woodworkers.

Only in those few cases in which animal studies have been carried out can one confirm that a given suspected agent is really a carcinogen. For example, bis(chloromethyl)ether (BCME) has been shown to produce tumors in animals and oat cell cancer of the lung in humans. In this particular case, BCME, used as a chemical intermediary in the manufacture of a number of organic compounds, was found to produce tumors in animals at about the same time as the substance was introduced into industry.

In addition to asbestos exposures, other occupational exposures associated with either proven or suspected respiratory carcinogens include those to acrylonitrile, arsenic compounds, beryllium (animal studies only),BCME, chromium, polycyclic hydrocarbons (through coke oven emissions), iron oxide, isopropyl oil (nasal sinuses), mustard gas, the various ores used to produce pure nickel, talc (possible asbestos contamination in both mining and milling), vinyl chloride, welding materials, wood used in woodworking (nasal cancer only), and uranium. The occurrence of excess cancers in uranium miners raises the possibility that a large number of workers are at risk by virtue of exposure to similar radiation hazards. This number includes not only workers involved in processing uranium but also workers exposed in underground mining operations where radon daughters may be emitted from rock formations.

GENERAL ENVIRONMENTAL EXPOSURES

AIR POLLUTION

Dramatic and disastrous episodes of air pollution inversion have been documented in many industrialized centers in the world. Each of these episodes has been associated with excess acute mortality in the very old, the very young, and those with chronic cardiopulmonary diseases. The most dramatic event was the London fog of 1952, in which approximately 4000 excess deaths occurred over a 2-week period following 5 days of severe cold and dense fog. Similar episodes in the United States, although less dramatic in terms of total deaths, occurred in Donora, Pennsylvania, in 1948 and in New

York City in the 1960s. In these episodes, which were generally associated with cold temperature and air stagnation, patients with underlying cardiopulmonary disease were most severely affected.

In addition to significant excess mortality during these episodes, a large number of people required medical care for cardiorespiratory complaints. Subsequent follow-up studies failed to implicate these episodic disasters in the etiology of chronic respiratory disease in adults. On the other hand, many epidemiologic studies of both international and regional differences in the prevalences of chronic respiratory disease suggest that long-term exposures in polluted areas in the early to middle part of the twentieth century were associated with excess chronic respiratory disease.

In 1970, the U.S. government established air quality standards for several pollutants believed to be responsible for excess cardiorespiratory diseases. Primary standards regulated by the Environmental Protection Agency (EPA) designed to protect the public health with an adequate margin of safety exist for sulfur dioxide, particulates <10 um in size, nitrogen dioxide, ozone, lead, and carbon monoxide. Standards for each of these pollutants are updated regularly through an extensive review process conducted by the EPA. In 1997, a new standard was added for particles less than 2.5 um; however, the standard does not become effective until year 2002.

Pollutants are generated from both stationary sources (power plants and industrial complexes) and mobile sources (automobiles), and none of the pollutants occurs in isolation. Thus, except for the change in carboxyhemoglobin from carbon monoxide exposure, it becomes extremely difficult to relate any specific health effect to any single pollutant. Furthermore, pollutants may be changed by chemical reactions after being emitted. For example, reducing agents, such as sulfur dioxide and particulate matter from a power plant stack, may react in air to produce acid sulfates and aerosols, the precursors of acid rain, which can be transported long distances in the atmosphere. Oxidizing substances, such as oxides of nitrogen and oxidants from automobile exhaust, may react with sunlight to produce ozone. Although originally a problem confined to the southwestern part of the United States, in recent years, at least during the summertime, elevated ozone and acid aerosol levels have been documented throughout the United States. Both acute and chronic effects of these exposures are currently under investigation.

The symptoms and diseases associated with air pollution are the same as the nononcogenic conditions commonly associated with cigarette smoking. In addition, respiratory illness in early childhood has been associated with chronic exposure to only modestly elevated levels of SO_2 and respirable particles. Recent population-based studies comparing cities that have relatively high levels of particulate exposures with less polluted communities suggest excess morbidity and mortality from cardiorespiratory conditions in long-term residents of the former communities. This finding, in part, has led to greater emphasis on publicizing pollution alert levels. One can only advise individuals with significant cardiopulmonary impairment to stay indoors during periods when pollution exceeds current standards.

INDOOR EXPOSURE

Because of increased concern about energy costs, efforts to become energy efficient have led to reduced air-exchange rates in indoor environments. The unintentional effect of these efforts has been to increase exposures to a variety of air contaminants heretofore not considered important.

Until relatively recently, little attention was given to the effects of *passive cigarette smoking* (Chap. 390). Several studies have shown that the respirable particulate load in any household is directly proportional to the number of cigarette smokers living in the home. Increases in prevalence of respiratory illnesses and reduced levels of pulmonary function measured with simple spirometry have been found in children of smoking parents in a number of studies.

Evidence from numerous case-control and cohort studies shows modest excess disease associations for cardiopulmonary diseases and lung cancer. Because most of these excess relative risks appear to be below 50%, it is virtually impossible for any one of the studies to be considered definitive. Thus, the techniques of meta-analysis have been used effectively to combine data from the best of these studies. The most recent meta-analyses for lung cancer, cardiac disease, and respiratory disease in terms of excess mortality suggest an approximately 25% increase for each condition, even after adjustment for major potential confounders. According to measures of plasma cotinine, a metabolite of nicotine, a nonsmoker living with a smoker is exposed to approximately 1% of the level of tobacco smoke to which a smoker of 20 cigarettes a day is exposed. In spite of some prominent detractors, these combined relative risks appear to be consistent with the estimated exposure levels and suggest a consensus that the associations are causal.

Radon gas is believed to be a risk factor for lung cancer. The main radon product (radon 222) is a gas that results from the decay series of uranium 238, with the immediate precursor being radium 226. The amount of radium in earth materials determines how much radon gas will be emitted. Outdoors, the concentrations are trivial. Indoors, levels are dependent on the ventilation rate and the size of the space into which the gas is emitted. Levels associated with excess lung cancer risk may be present in as many as 10% of the houses in the United States. When smokers reside in the household, the problem is potentially greater, since the molecular size of radon particles allows them to readily attach to smoke particles that are inhaled. Fortunately, technology is available for assessing and reducing the level of exposure.

Other indoor exposures associated with an increased risk of atopy and asthma include those to such specific recognized putative biologic agents as cockroach antigen, dust mites, and pet danders. Other indoor chemical agents include formaldehyde, perfumes, and latex particles. Of recent interest are the nonspecific responses associated with "tight-building syndrome," in which no particular agent has been implicated; the affected individuals suffer from a wide variety of complaints, including respiratory symptoms, that are relieved only by avoiding exposure in the building in question. The degree to which "smells" or other sensory stimuli are involved in the triggering of potentially incapacitating psychological or physical responses has yet to be determined, and the long-term consequences of such environmental exposures are as yet unknown.

PORTAL OF ENTRY

The lung is a primary point of entry into the body for a number of toxic agents that affect other organ systems. For example, the lung is a route of entry for benzene (bone marrow), carbon disulfide (cardiovascular and nervous systems), cadmium (kidney), and metallic mercury (kidney, central nervous system). Thus, in any disease state of obscure origin, it is important to consider the possibility of inhaled environmental agents. Such consideration can sometimes furnish the clue needed to identify a specific external cause for a disorder that might otherwise be labeled "idiopathic."

255. PNEUMONIA, INCLUDING NECROTIZING PULMONARY INFECTIONS (LUNG ABSCESS) - *Matthew E. Levison*

Pneumonia is an infection of the pulmonary parenchyma that can be caused by various bacterial species, including mycoplasmas, chlamydiae, and rickettsiae; viruses; fungi; and parasites (Table 255-1). Thus pneumonia is not a single disease but a group of specific infections, each with a different epidemiology, pathogenesis, clinical presentation, and clinical course. Identification of the etiologic microorganism is of primary importance, since this is the key to appropriate antimicrobial therapy. However, because of the serious nature of the infection, antimicrobial therapy generally needs to be started immediately, often before laboratory confirmation of the causative agent. The specific microbial etiology remains elusive in more than one-third of cases -- e.g., when no sputum is available for examination, blood cultures are sterile, and there is no pleural fluid. Serologic confirmation requires weeks because of the late formation of specific antibody.

Thus initial antimicrobial therapy is often empirical and is based on the setting in which the infection was acquired, the clinical presentation, patterns of abnormality on chest radiography, results of staining of sputum or other infected body fluids, and current patterns of susceptibility of the suspected pathogens to antimicrobial agents. After the etiologic agent is identified, specific antimicrobial therapy can be chosen.

DEFENSE MECHANISMS

The lung is a complex structure composed of aggregates of units that are formed by the progressive branching of the airways. Approximately 80% of the cells lining the central airways are ciliated, pseudostratified, columnar epithelial cells; the percentage decreases in the peripheral airways. Each ciliated cell contains about 200 cilia that beat in coordinated waves ~1000 times per minute, with a fast forward stroke and a slower backward recovery. Ciliary motion is also coordinated between adjacent cells so that each wave is propagated toward the oropharynx. The cilia are covered by a liquid film that is ~5 to 10 um thick and is composed of two layers. The outer, or gel, layer is viscous and traps deposited particles. The cilia beat in the less viscous inner, or sol, layer. During the forward stroke, the tips of the cilia just touch the viscous gel and propel it toward the oropharynx. During recovery, the cilia move entirely within the low-resistance sol layer. Ciliated cells are interspersed with mucus-secreting cells in the trachea and bronchi but not in the bronchioles.

The alveolar walls, from blood to air, consist of the endothelium that lines the network of anastomotic capillaries, the capillary basement membrane, the interstitial tissue, the alveolar basement membrane, the alveolar lining epithelial cells (which are either flattened type I pneumocytes that cover 95% of the alveolar surface or rounded, granular, surfactant-producing type II pneumocytes), and epithelial lining fluid. The epithelial lining fluid contains surfactant, fibronectin, and immunoglobulin, which may opsonize or -- in the presence of complement -- lyse microbial pathogens deposited on the alveolar surface. Loosely attached to the lining cells or lying free within the lumen are the alveolar macrophages, lymphocytes, and a few polymorphonuclear leukocytes.

The lower respiratory tract is normally sterile, despite being adjacent to enormous

numbers of microorganisms that reside in the oropharynx and being exposed to environmental microorganisms in inhaled air. This sterility is the result of efficient filtering and clearance mechanisms.

Infectious particles deposited on the squamous epithelium of distal nasal surfaces normally are removed by sneezing, while those deposited on the more proximal ciliated surfaces are swept posteriorly in the mucus lining into the nasopharynx, where they are swallowed or expectorated. Reflex closure of the glottis and cough protect the lower respiratory tract. Those particles deposited on the tracheobronchial surface are swept by ciliary motion toward the oropharynx. Infectious particles that bypass defenses in the airways and are deposited on the alveolar surface are cleared by phagocytic cells and humoral factors. Alveolar macrophages are the major phagocytes in the lower respiratory tract. Some phagocytosed microorganisms are killed by the phagocyte's oxygen-dependent systems, lysosomal enzymes, and cationic proteins. Other microorganisms can evade microbicidal mechanisms and persist within the macrophage. For example, *Mycobacterium tuberculosis* persists within the lysosome, while *Legionella* resides within intracellular inclusions that fail to fuse with lysosomes. Intracellular pathogens can then be transported to the ciliated surfaces and into the oropharynx or via the lymphatics to regional lymph nodes. The alveolar macrophages process and present microbial antigens to the lymphocyte and also secrete cytokines (e.g., tumor necrosis factor and interleukin 1) that modulate the immune process in T and B lymphocytes. Cytokines facilitate the generation of an inflammatory response, activate alveolar macrophages, and recruit additional phagocytes and other immunologic factors from plasma. The inflammatory exudate is responsible for many of the local signs of pulmonary consolidation and for the systemic manifestations of pneumonia, such as fever, chills, myalgias, and malaise.

TRANSMISSION

Microbial pathogens may enter the lung by one of several routes.

Aspiration of Organisms That Colonize the Oropharynx Most pulmonary pathogens originate in the oropharyngeal flora. Aspiration of these pathogens is the most common mechanism for the production of pneumonia. At various times during the year, healthy individuals transiently carry common pulmonary pathogens in the nasopharynx; these pathogens include *Streptococcus pneumoniae*, *S. pyogenes*, *Mycoplasma pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. The sources of anaerobic pulmonary pathogens, such as *Porphyromonas gingivalis*, *Prevotella melaninogenica*, *Fusobacterium nucleatum*, *Actinomyces* spp., spirochetes, and anaerobic streptococci, are the gingival crevice and dental plaque, which contain more than 10^{11}colony-forming units (CFU) of microorganisms per gram. The frequency of aerobic gram-negative bacillary colonization of the oropharyngeal mucosa, which is unusual in healthy persons (<2%), increases with hospitalization, worsening debility, severe underlying illness, alcoholism, diabetes, and advanced age. This change may be a consequence of increased salivary proteolytic activity, which destroys fibronectin, a glycoprotein coating the surface of the mucosa. Fibronectin is the receptor for the normal gram-positive flora of the oropharynx. Loss of fibronectin exposes the receptors for aerobic gram-negative bacilli on the epithelial cell surface. The source of aerobic gram-negative bacilli may be the patient's own stomach (which can become colonized with these organisms as the

result of an increase in gastric pH with atrophic gastritis or after the use of H_2-blocking agents or antacids), contaminated respiratory equipment, hands of health care workers, or contaminated food and water. Nasogastric tubes can facilitate the transfer of gastric bacteria to the pharynx.

About 50% of healthy adults aspirate oropharyngeal secretions into the lower respiratory tract during sleep. Aspiration occurs more frequently and may be more pronounced in individuals with an impaired level of consciousness (e.g., alcoholics; drug abusers; and patients who have had seizures, strokes, or general anesthesia), neurologic dysfunction of the oropharynx, and swallowing disorders or mechanical impediments (e.g., nasogastric or endotracheal tubes). Pneumonia due to anaerobes is an especially likely outcome if the aspirated material is large in volume or contains virulent components of the anaerobic microbial flora or foreign bodies, such as aspirated food or necrotic tissue. Impairment of the cough reflex increases the risk of pneumonia, as does mucociliary or alveolar macrophage dysfunction.

Inhalation of Infectious Aerosols Deposition of inhaled particles within the respiratory tract is determined primarily by particle size. Particles>10 um in diameter are deposited mostly in the nose and upper airways. Particles <5 um in diameter (also called *airborne droplet nuclei*) and containing one or perhaps two microorganisms fail to settle out by gravity but rather remain suspended in the atmosphere for long periods unless removed by ventilation or by filtration in the lungs of the individual breathing the contaminated air. Transmission of an infectious agent in the form of an aerosol is particularly efficient. These infectious aerosols are small enough to bypass host defenses in the upper respiratory tract and airways. A greater percentage of particles are deposited in small bronchioles and alveoli as particle size decreases below 5 um. One inhaled particle of appropriate size may be sufficient to reach the alveolus and initiate infection. The etiologies of pneumonia typically acquired by inhalation of infectious aerosols include tuberculosis, influenza, legionellosis, psittacosis, histoplasmosis, Q fever, and hantavirus pulmonary syndrome (HPS).

Hematogenous Dissemination from an Extrapulmonary Site Infection, usually with *Staphylococcus aureus*, disseminates hematogenously to the lungs in patients (such as intravenous drug users) who have either right- or left-sided bacterial endocarditis and in patients with intravenous catheter infections. *Fusobacterium* infections of the retropharyngeal tissues (Lemierre's syndrome -- i.e., retropharyngeal abscess and jugular venous thrombophlebitis) also disseminate hematogenously to the lungs.

Direct Inoculation and Contiguous Spread Two additional routes of transmission of bacteria to the lungs are direct inoculation (as a result of either tracheal intubation or stab wounds to the chest) and contiguous spread from an adjacent site of infection.

PATHOLOGY

The pneumonic process may involve primarily the interstitium or the alveoli. Involvement of an entire lobe is called *lobar pneumonia*. When the process is restricted to alveoli contiguous to bronchi, it is called *bronchopneumonia*. Confluent bronchopneumonia may be indistinguishable from lobar pneumonia. Cavities develop when necrotic lung tissue is discharged into communicating airways, resulting in either necrotizing

pneumonia (multiple small cavities, each <2 cm in diameter, in one or more bronchopulmonary segments or lobes) or lung abscess (one or more cavities>2 cm in diameter). The classification of pneumonia is best based upon the causative microorganism rather than upon these anatomic characteristics (the criteria used in the past).

EPIDEMIOLOGY

The patient's living circumstances, occupation, travel history, pet or animal exposure history, and contacts with other ill individuals as well as the physician's knowledge of the epidemic curve of community outbreaks provide clues to the microbial etiology of a given case of pneumonia (Table 255-1). The relative frequency of various pulmonary pathogens varies with the setting in which the infection was acquired -- e.g., community, nursing home, or hospital. In patients hospitalized with community-acquired pneumonia, the most frequent pathogens are *S. pneumoniae*, *H. influenzae*, *Chlamydia pneumoniae*, and *Legionella pneumophila*. *C. pneumoniae* is often found in association with other pathogens, including *S. pneumoniae*, and the associated pathogen appears to influence the course of the pneumonia. *M. pneumoniae*, which usually causes mild illness, is common among outpatients with community-acquired pneumonia, but may also be an underappreciated cause in all age groups of severe pneumonia that requires hospitalization. In contrast, enteric aerobic gram-negative bacilli and *Pseudomonas aeruginosa*, uncommon causes of community-acquired pneumonia, are estimated to account for>50% of cases of hospital-acquired pneumonia, while *S. aureus* is responsible for >10%. The relative frequencies of pathogens in pneumonia acquired in nursing homes fall somewhere between those of community- and hospital-acquired pneumonia. Enteric aerobic gram-negative bacilli and *P. aeruginosa* are more common among nursing home residents than among patients who acquire pneumonia in noninstitutional settings.

The season of the year and the geographic location are other predictors of etiology. The frequency of influenza virus as a cause of both community-acquired and institutionally acquired pneumonia increases during the winter months. Moreover, influenza virus infection causes an increase in the frequency of secondary bacterial pneumonia due to *S. pneumoniae*, *S. aureus*, and *H. influenzae*. Outbreaks of influenza in a community tend to be explosive and widespread, with many secondary cases resulting from the short incubation period of several days and the high degree of communicability. *Legionella* colonizes hot-water storage systems that provide favorable conditions for its proliferation, such as warm temperature, stagnation, and sediment accumulation. Acquisition of *Legionella* pneumonia requires exposure to aerosols generated from these contaminated water supplies -- e.g., during an overnight stay in a hotel with a faulty air-handling system or after repair of domestic plumbing in buildings with contaminated water supplies. Legionellosis also occurs in explosive outbreaks when large numbers of susceptible people are exposed to an infectious aerosol; however, no secondary cases occur because of the low level of communicability of *L. pneumophila*. *Mycoplasma* causes outbreaks, usually in relatively closed populations such as those at military bases, at colleges, or in households; however, because of its long incubation period (2 to 3 weeks) and its relatively low degree of communicability, *Mycoplasma* infection moves through the community slowly, affecting another person as the first is recovering. In communities where infection with HIV type 1 is endemic, *Pneumocystis*

carinii and *M. tuberculosis* are more prominent causes of community-acquired pneumonia. *Chlamydia psittaci* produces illness in bird handlers. Histoplasmosis, blastomycosis, and coccidioidomycosis are causes of pneumonia that have specific geographic distributions.

HPSis a newly described, frequently fatal disease caused by one of several hantaviruses. Most cases in the United States have been reported from the Four Corners area (New Mexico, Arizona, Utah, and Colorado), where the pathogen is the Sin Nombre virus. The primary hosts are rodents, which apparently remain healthy but excrete the virus in urine, feces, and saliva. Hantavirus infection is acquired by inhalation of infectious aerosols when rodent nests are disturbed by human domestic, occupational, or recreational activities. The appearance of HPS in the southwestern United States is thought to have occurred because of increased rainfall in the region, which increased the rodent food supply and thus the rodent population. No person-to-person transmission of HPS is thought to have taken place, except perhaps in an outbreak in southern Argentina in 1996.

AGE AND COMORBIDITY

Age is an important predictor of the infecting agent in pneumonia. *Chlamydia trachomatis* and respiratory syncytial virus are common among infants< 6 months of age; *H. influenzae* among children 6 months to 5 years of age; *M. pneumoniae*, *C. pneumoniae,* and hantavirus among young adults; *H. influenzae* and *M. catarrhalis* among elderly individuals with chronic lung disease; and *L. pneumophila* among elderly persons, smokers, and persons with compromised cell-mediated immunity (e.g., transplant recipients), renal or hepatic failure, diabetes, or systemic malignancy.

Oral anaerobes, frequently in combination with aerobic bacterial components of the human flora (e.g., viridans streptococci), are causes of community-acquired pneumonia and anaerobic lung abscess in patients who are prone to aspiration. Edentulous persons, who have lower numbers of oral anaerobes, are less likely to develop pneumonia due to anaerobes. When the etiology of community-acquired pneumonia in unselected hospitalized patients has been studied by methods that entail strict anaerobic bacteriology and that avoid contamination of lower respiratory tract secretions by the oral flora, anaerobic bacteria have been found to account for as many as 20 to 30% of cases. In hospital-acquired pneumonia, anaerobes are the pathogens -- with or without aerobic copathogens -- in about one-third of cases. However, the aerobic copathogens in hospital-acquired pneumonia are frequently virulent microorganisms in their own right (e.g., enteric aerobic gram-negative bacilli, *P. aeruginosa*, and *S. aureus*).

The patient's underlying disease may be characterized by specific immunologic or inflammatory defects that predispose to pneumonia due to specific pathogens (Table 255-2). For example, immunoglobulin deficiencies -- especially those involving IgG subtypes 2 and 4, which are important in the immune response to encapsulated organisms (e.g., *S. pneumoniae* and *H. influenzae*) -- may be associated with recurrent sinopulmonary infections. Immunoglobulin deficiencies may be inherited, or they may be acquired (i.e., as a result of either decreased production, as in lymphoproliferative malignancies, or excessive protein loss, as in nephrosis or protein-losing enteropathy).

Inherited immunoglobulin deficiencies may be global or selective. Patients with recurrent sinopulmonary infections and a selective deficiency of IgG2 and/or IgG4 may have a total plasma IgG level within the normal range, as these particular IgG subtypes constitute only 25% of total IgG. HIV-infected patients may also exhibit ineffective antibody formation, which predisposes to infection with these encapsulated bacteria. Severe neutropenia (<500 neutrophils/uL) increases the risk of infections due to *P. aeruginosa*, Enterobacteriaceae, *S. aureus*, and (if neutropenia is prolonged) *Aspergillus*. The risk is unusually high for infections due to *M. tuberculosis* among HIV-infected patients with circulating CD4+ lymphocyte counts of<500/uL; for infections due to *P. carinii*, *Histoplasma capsulatum*, and *Cryptococcus neoformans* among those with CD4+ counts of<200/uL; and for infections due to *M. avium-intracellulare* and cytomegalovirus among those with counts of<50/uL. Long-term glucocorticoid therapy increases the risk of tuberculosis and nocardiosis.

CLINICAL MANIFESTATIONS

Community-Acquired Pneumonia Community-acquired pneumonia has traditionally been thought to present as either of two syndromes: the typical presentation or the atypical presentation. Although current data suggest that these two syndromes may be less distinct than was once thought, the characteristics of the clinical presentation may nevertheless have some diagnostic value.

The "typical" pneumonia syndrome is characterized by the sudden onset of fever, cough productive of purulent sputum, shortness of breath, and (in some cases) pleuritic chest pain; signs of pulmonary consolidation (dullness, increased fremitus, egophony, bronchial breath sounds, and rales) may be found on physical examination in areas of radiographic abnormality. The typical pneumonia syndrome is usually caused by the most common bacterial pathogen in community-acquired pneumonia, *S. pneumoniae*, but can also be due to other bacterial pathogens, such as *H. influenzae* and mixed anaerobic and aerobic components of the oral flora.

The "atypical" pneumonia syndrome is characterized by a more gradual onset, a dry cough, shortness of breath, a prominence of extrapulmonary symptoms (such as headache, myalgias, fatigue, sore throat, nausea, vomiting, and diarrhea), and abnormalities on chest radiographs despite minimal signs of pulmonary involvement (other than rales) on physical examination. Atypical pneumonia is classically produced by *M. pneumoniae* but can also be caused by *L. pneumophila*, *C. pneumoniae*, oral anaerobes, and *P. carinii* as well as by *S. pneumoniae* and the less frequently encountered pathogens *C. psittaci*, *Coxiella burnetii*, *Francisella tularensis*, *H. capsulatum*, and *Coccidioides immitis*. *Mycoplasma* pneumonia (Chap. 178) may be complicated by erythema multiforme, hemolytic anemia, bullous myringitis, encephalitis, and transverse myelitis. *Legionella* pneumonia (Chap. 151) is frequently associated with deterioration in mental status, renal and hepatic abnormalities, and marked hyponatremia; pneumonia due to *H. capsulatum* (Chap. 201) or *C. immitis* (Chap. 202) is often accompanied by erythema nodosum. In *C. pneumoniae* pneumonia (Chap. 179), sore throat, hoarseness, and wheezing are relatively common. The atypical pneumonia syndrome in patients whose behavioral history places them at risk of HIV infection suggests *Pneumocystis* infection. These patients may have concurrent infections caused by other opportunistic pathogens, such as pulmonary (and frequently

extrapulmonary) tuberculosis, oral thrush due to *Candida albicans*, or extensive perineal ulcers due to herpes simplex virus.

Certain viruses also produce pneumonia that is usually characterized by an atypical presentation -- i.e., chills, fever, shortness of breath, dry nonproductive cough, and predominance of extrapulmonary symptoms. Primary viral pneumonia can be caused by influenza virus (usually as part of a community outbreak in winter), by respiratory syncytial virus (in children and immunosuppressed individuals), by measles or varicella-zoster virus (accompanied by the characteristic rash), and by cytomegalovirus (in patients immunocompromised by HIV infection or by therapy given in association with organ transplantation). Hantavirus causes an initial nonspecific febrile prodrome, after which the patient develops rapidly progressive respiratory failure and diffuse pulmonary infiltrates on chest radiographs as a result of exudation into the pulmonary interstitium and alveoli, with thrombocytopenia, neutrophilic leukocytosis, circulating immunoblasts, and laboratory evidence of hemoconcentration. In addition, influenza and measles can predispose to secondary bacterial pneumonia as a result of the destruction of the mucociliary barrier of the airways. Secondary bacterial infection may either follow the viral infection without interruption or be separated from the viral infection by several days of transient relief of symptoms. Bacterial infection may be heralded by sudden worsening of the patient's clinical condition, with persisting or renewed chills, fever, and cough productive of purulent sputum, possibly accompanied by pleuritic chest pain.

Patients with hematogenous *S. aureus* pneumonia may present with fever and dyspnea only. In these cases the inflammatory response is initially confined to the pulmonary interstitium. Cough, sputum production, and signs of pulmonary consolidation develop only after the infection extends into the bronchi. These patients are usually gravely ill, with intravascular infection as well as pneumonia, and may have signs of endocarditis (Chap. 126).

Nocardiosis (Chap. 165) is frequently complicated by metastasis of lesions to the skin and central nervous system. Signs of pulmonary consolidation, cough, and sputum production may be lacking in patients who are unable to mount an inflammatory response, such as those with agranulocytosis. The major manifestations in these patients may be limited to fever, tachypnea, agitation, and altered mental status. Elderly or severely ill patients may fail to develop fever.

Tuberculosis also produces an atypical presentation that is characterized by fever, night sweats, cough, and shortness of breath and sometimes by pleuritic chest pain and blood-streaked sputum. Several weeks usually elapse before the patient seeks medical attention because of the gradual worsening of these symptoms, by which time he or she will have lost considerable weight.

Nosocomial Pneumonia Patients with nosocomial pneumonia often pose a diagnostic challenge. The differential diagnosis of acute respiratory disease in critically ill, hospitalized patients is diverse and includes noninfectious entities, such as congestive heart failure, acute respiratory distress syndrome, preexisting lung disease, atelectasis, and oxygen- or drug-related toxicities, that may be difficult to distinguish clinically or radiologically from pneumonia. The usual criteria for nosocomial pneumonia, which include new or progressive pulmonary infiltrates, purulent tracheobronchial secretions,

fever, and leukocytosis, are frequently unreliable in these patients, who often have preexisting pulmonary disease, endotracheal tubes that irritate the tracheal mucosa and may elicit an inflammatory exudate in respiratory secretions, or multiple other problems likely to produce fever and leukocytosis. Patients with nosocomial pneumonia complicating an underlying illness associated with significant neutropenia often have no purulent respiratory tract secretions or pulmonary infiltrates, and patients with nosocomial pneumonia complicating uremia or cirrhosis often remain afebrile. In addition, the patients at greatest risk for nosocomial pneumonia are most likely to be heavily colonized with potential pulmonary pathogens in the oropharyngeal or tracheobronchial mucosa; thus the presence of these organisms in gram-stained preparations or cultures of respiratory tract secretions does not necessarily confirm the diagnosis of pneumonia.

Aspiration Pneumonia and Anaerobic Lung Abscess Aspiration of a sufficient volume of gastric acid produces a chemical pneumonitis characterized by acute dyspnea and wheezing with hypoxemia and infiltrates on chest radiographs in one or both lower lobes. Clinical findings following aspiration of particulate matter depend on the extent of endobronchial obstruction and range from acute apnea to persistent cough with or without recurrent infection. Although the aspiration of oral anaerobes can initially lead to an infiltrative process, it ultimately results in putrid sputum, tissue necrosis, and pulmonary cavities. In about three-quarters of cases, the clinical course of an abscess of anaerobic polymicrobial etiology is indolent and mimics that of pulmonary tuberculosis, with cough, shortness of breath, chills, fever, night sweats, weight loss, pleuritic chest pain, and blood-streaked sputum lasting for several weeks or more. In other patients the disease may present more acutely. Patients with anaerobic abscesses are usually prone to aspiration of oropharyngeal contents and have periodontal disease. One genus of oral anaerobes, *Actinomyces*, produces a chronic fibrotic necrotizing process that crosses tissue planes and may involve the pleural space, ribs, vertebrae, and subcutaneous tissue, with eventual discharge of sulfur granules (macroscopic bacterial masses) through the skin (empyema necessitatis).

DIAGNOSIS

Radiography Chest radiography is more sensitive than physical examination for detection of pulmonary infiltrates. Indeed, *P. carinii* pneumonia (PCP) is the only relatively common form of pneumonia associated with false-negative chest radiographs; up to 30% of patients with PCP have false-negative results. Chest radiographs can confirm the presence and location of the pulmonary infiltrate; assess the extent of the pulmonary infection; detect pleural involvement, pulmonary cavitation, or hilar lymphadenopathy; and gauge the response to antimicrobial therapy. However, chest radiographs may be normal when the patient is unable to mount an inflammatory response (e.g., in agranulocytosis) or is in the early stage of an infiltrative process (e.g., in hematogenous *S. aureus* pneumonia or PCP associated with AIDS). High-resolution computed tomography of the lungs can improve the accuracy of diagnosis of pneumonia, especially when the process involves lung obscured by the diaphragm, liver, ribs and clavicles, or heart.

The anatomic localization of the inflammatory process, as visualized in chest radiographs, occasionally has diagnostic implications. Most pulmonary pathogens

produce focal lesions. A multicentric distribution suggests hematogenous infection, in which case the remote location of the primary infection (e.g., endocarditis or thrombophlebitis) should be sought. Hematogenous pneumonia, which results from septic embolization in patients with thrombophlebitis or right-sided endocarditis and from bacteremia in patients with left-sided endocarditis, appears on the chest radiograph as multiple areas of pulmonary infiltration that subsequently may cavitate. A diffuse distribution suggests the involvement of *P. carinii*, cytomegalovirus, hantavirus, measles virus, or herpes zoster virus (with pneumonia due to the last two pathogens diagnosed by the characteristic accompanying rash). Pleurisy and hilar nodal enlargement are unusual with PCPand cytomegalovirus pneumonia; their presence suggests another etiology. Diffuse lesions in immunocompromised patients also suggest legionellosis, tuberculosis, histoplasmosis, *Mycoplasma* infection, or disseminated strongyloidiasis.

Oral anaerobes, *S. aureus, S. pneumoniae* serotype III, aerobic gram-negative bacilli, *M. tuberculosis*, and fungi as well as certain noninfectious conditions can produce tissue necrosis and pulmonary cavities (Table 255-3). In contrast, *H. influenzae*, *M. pneumoniae*, viruses, and most other serotypes of *S. pneumoniae* almost never cause cavities. Apical disease, with or without cavities, suggests reactivation tuberculosis. Anaerobic abscesses are located in dependent, poorly ventilated, and poorly draining bronchopulmonary segments and characteristically have air-fluid levels, unlike the well-ventilated, well-drained upper-lobe cavities caused by *M. tuberculosis*, an obligate aerobe. Air-fluid levels may also be present in cavities due to pulmonary necrosis of other infectious etiologies, such as *S. aureus* and aerobic gram-negative bacilli. *Mucor* and *Aspergillus* invade blood vessels and cause pleural-based, wedge-shaped areas of pulmonary infarction; these infarcts may subsequently cavitate.

In the patient with an uncomplicated course, chest radiographs need not be repeated before discharge, since the resolution of infiltrates may take up to 6 weeks after initial presentation. However, patients who do not respond clinically, who have a pleural effusion on admission, who may have postobstructive pneumonia, or who are infected with certain pathogens (e.g., *S. aureus*, aerobic gram-negative bacilli, or oral anaerobes) need more intensive surveillance. At times, computed tomography may be especially helpful in distinguishing different processes -- e.g., pleural effusion versus underlying pulmonary consolidation, hilar adenopathy versus pulmonary mass, and pulmonary abscess versus empyema with an air-fluid level.

Sputum Examination Examination of the sputum remains the mainstay of the evaluation of a patient with acute bacterial pneumonia. Unfortunately, expectorated material is frequently contaminated by potentially pathogenic bacteria that colonize the upper respiratory tract (and sometimes the lower respiratory tract) without actually causing disease. This contamination reduces the diagnostic specificity of any lower respiratory tract specimen. In addition, it has been estimated that the usual laboratory processing methods detect the pulmonary pathogen in fewer than 50% of expectorated sputum samples from patients with bacteremic *S. pneumoniae* pneumonia. This low sensitivity may be due to misidentification of the a-hemolytic colonies of *S. pneumoniae* as nonpathogenic a-hemolytic streptococci ("normal flora"), overgrowth of the cultures by hardier colonizing organisms, or loss of more fastidious organisms due to slow transport or improper processing. In addition, certain common pulmonary pathogens, such as anaerobes, mycoplasmas, chlamydiae, *Pneumocystis*, mycobacteria, fungi, and

legionellae, cannot be cultured by routine methods.

Since expectorated material is routinely contaminated by oral anaerobes, the diagnosis of anaerobic pulmonary infection is frequently inferred. Confirmation of such a diagnosis requires the culture of anaerobes from pulmonary secretions that are uncontaminated by oropharyngeal secretions, which in turn requires the collection of pulmonary secretions by special techniques, such as transtracheal aspiration (TTA), transthoracic lung puncture, and protected brush via bronchoscopy. These procedures are invasive and are usually not used unless the patient fails to respond to empirical therapy.

Gram's staining of sputum specimens, screened initially under low-power magnification (10´ objective and 10´ eyepiece) to determine the degree of contamination with squamous epithelial cells, is of utmost diagnostic importance. In patients with the typical pneumonia syndrome who produce purulent sputum, the sensitivity and specificity of Gram's staining of sputum minimally contaminated by upper respiratory tract secretions (>25 polymorphonuclear leukocytes and<10 epithelial cells per low-power field) in identifying the pathogen as *S. pneumoniae* are 62 and 85%, respectively. Gram's staining in this case is more specific and probably more sensitive than the accompanying sputum culture. The finding of mixed flora on Gram's staining of an uncontaminated sputum specimen suggests an anaerobic infection. Acid-fast staining of sputum should be undertaken when mycobacterial infection is suspected. Examination by an experienced pathologist of Giemsa-stained expectorated respiratory secretions from patients with AIDS has given satisfactory results in the diagnosis ofPCP. The sensitivity of sputum examination is enhanced by the use of monoclonal antibodies to *Pneumocystis* and is diminished by prior prophylactic use of inhaled pentamidine. Blastomycosis can be diagnosed by the examination of wet preparations of sputum. Sputum stained directly with fluorescent antibody can be examined for *Legionella*, but this test yields false-negative results relatively often. Thus sputum should also be cultured for *Legionella* on special media.

Expectorated sputum usually is easily collected from patients with a vigorous cough but may be scant in patients with an atypical syndrome, in the elderly, and in persons with altered mental status. If the patient is not producing sputum and can cooperate, respiratory secretions should be induced with ultrasonic nebulization of 3% saline. An attempt to obtain lower respiratory secretions by passage of a catheter through the nose or mouth rarely achieves the desired results in an alert patient and is discouraged; usually the catheter can be found coiled in the oropharynx.

In some cases that do not require the patient's hospitalization (see "Decision to Hospitalize," below), an accurate microbial diagnosis may not be crucial, and empirical therapy can be started on the basis of clinical and epidemiologic evidence alone. This approach may also be appropriate for hospitalized patients who are not severely ill and who are unable to produce an induced sputum specimen. Use of invasive procedures to establish a microbial diagnosis carries risks that must be weighed against potential benefits. However, the decision to initiate empirical therapy without an evaluation of induced sputum should be undertaken with caution and, in the case of hospitalized patients, should always be accompanied by the culture of several blood samples. The ability to understand the cause of a poor response to empirical antimicrobial therapy (Table 255-4) may be compromised by the lack of initial sputum and blood cultures.

Establishing a specific microbial etiology in the individual patient is important, for it allows institution of specific pathogen-directed antimicrobial therapy and reduces the use of broad-spectrum combination regimens to cover multiple possible pathogens. Use of a single narrow-spectrum antimicrobial agent exposes the patient to fewer potential adverse drug reactions and reduces the pressure for selection of antimicrobial resistance. Emergence of antimicrobial resistance is a type of adverse drug reaction unlike others, because it is "contagious." In addition, establishing a microbial diagnosis can help define local community outbreaks and antimicrobial resistance patterns.

Invasive Procedures The sensitivities and specificities of the invasive procedures described below for obtaining pulmonary material vary with the type of immunocompromised patient, the type of pulmonary lesion, and the degree of prior exposure to therapeutic or prophylactic antimicrobial agents.

Transtracheal Aspiration Popular several decades ago,TTA is rarely performed today. Although the sensitivity of the procedure is high (approaching 90%), the specificity is low. The material obtained by TTA (from a catheter inserted through the cricothyroid cartilage and advanced toward the carina) is not contaminated by upper respiratory tract secretions but can contain organisms that colonize the tracheobronchial tree without necessarily causing pneumonia. Significant morbidity and even death have attended the use of TTA. Contraindicated in patients with a bleeding diathesis, TTA may cause infection at the puncture site and may lead to severe subcutaneous and mediastinal emphysema in patients who are coughing vigorously.

Percutaneous Transthoracic Lung Puncture This procedure employs a skinny (small-gauge) needle that is advanced into the area of pulmonary consolidation with computed tomographic guidance. It requires that the patient cooperate, have good hemostasis, and be able to tolerate a possible associated pulmonary hemorrhage or pneumothorax. Patients on mechanical ventilation cannot undergo lung puncture because of the high incidence of complicating pneumothorax.

Fiberoptic Bronchoscopy Fiberoptic bronchoscopy is safe and relatively well tolerated and has become the standard invasive procedure used to obtain lower respiratory tract secretions from seriously ill or immunocompromised patients with complex or progressive pneumonia. This technique provides a direct view of the lower airways. Specimens obtained by bronchoscopy should be subjected to Gram's, acid-fast, *Legionella*direct fluorescent antibody, and Gomori's methenamine silver staining and should be cultured for routine aerobic and anaerobic bacteria, legionellae, mycobacteria, and fungi. Samples are collected with a protected double-sheathed brush (PSB), by bronchoalveolar lavage (BAL), or by transbronchial biopsy (TBB) at the site of pulmonary consolidation. The PSB sample is usually contaminated by oropharyngeal flora; quantitative cultures of the 1 mL of sterile culture medium into which the brush is placed after withdrawal from the inner catheter must be performed to differentiate contamination (<1000CFU/mL) from infection (³1000 CFU/mL). The results of PSB are highly specific and highly sensitive, especially when the patient has not received antibiotics before culture. BAL is usually performed with 150 to 200 mL of sterile, nonbacteriostatic saline. When used to facilitate endoscopy, local anesthetic agents with antibacterial activity can lower the sensitivity of culture results. Quantitative bacteriologic evaluation of BAL fluid has given results similar to those obtained with the PSB

technique. Gram's staining of the cytocentrifuged BAL fluid specimen can serve as an immediate guide in the selection of antimicrobial therapy to be administered while culture results are awaited.

Open-Lung Biopsy This procedure is most commonly needed when specimens obtained bronchoscopically from an immunocompromised patient with progressive pneumonia have been unrevealing. Limitations on the performance of an open-lung biopsy include hypoxemia and a bleeding diathesis, which may supervene while the physician is deciding whether to undertake this procedure. Results of an open-lung biopsy are considered diagnostic because of the large size of the tissue sample. The diagnostic yield of this procedure is greatest in focal lesions, whereas bronchoscopic evaluation is most useful in diffuse lesions.

Other Diagnostic Tests In the initial evaluation of a patient with pneumonia, at least two blood samples for culture should be obtained from different venipuncture sites; if empyema is a clinical consideration, diagnostic thoracentesis is indicated. Positive blood or pleural fluid culture is generally considered diagnostic of the etiology of pneumonia. However, bacteremia and empyema each occur in fewer than 10 to 30% of patients with pneumonia.

Serologic studies are sometimes helpful in defining the etiology of certain types of pneumonia, although serologic diagnosis -- because it is often delayed by the need to demonstrate at least a fourfold rise in convalescent-phase antibody titer -- is usually retrospective. A single IgM antibody titer of >1:16, a single IgG antibody titer of >1:128, or a fourfold or greater rise in the IgG titer obtained by indirect immunofluorescence is diagnostic of *M. pneumoniae* infection. A single IgM antibody titer of³1:20, a single IgG antibody titer of³1:128, or a fourfold or greater rise in the IgG titer obtained by micro-indirect immunofluorescence is diagnostic of *C. pneumoniae* infection. A single *Legionella* antibody titer of³1:256 or a fourfold rise to a titer of³1:128 suggests acute legionellosis. A highly sensitive and specific urinary antigen test is available to detect *L. pneumophila* serogroup 1 in patients with pneumonia; this organism accounts for ~70% of *L. pneumophila* infections. The diagnosis of hantavirus infection is confirmed by detection of IgM serum antibodies, a rising titer of IgG serum antibodies, hantavirus-specific RNA by polymerase chain reaction in clinical specimens, and hantavirus-specific antigen by immunohistochemistry.

DECISION TO HOSPITALIZE

Approximately 20% of patients with community-acquired pneumonia are hospitalized, some perhaps unnecessarily. Use of inpatient hospital services is costly and at times poses risks to the patient (e.g., the risk of nosocomial infections). Thus hospitalization must be justified by anticipation of a poor outcome if the case is managed in an outpatient setting.

The Pneumonia Patient Outcomes Research Team (PORT) has attempted to quantify the risk of death and other adverse outcomes of community-acquired pneumonia by assignment of points to 19 variables (Fig. 255-1), with stratification of patients into five classes based on cumulative point score. This prediction rule was derived and validated in a large number of patients. On the basis of their observations, the PORT investigators

suggest that outpatient management is appropriate for many patients in classes I and II, in whom the risks of subsequent hospitalization (£8.2%) and of death (<0.6%) are low. They suggest outpatient management after a short hospital stay for patients in class III, whose risk of subsequent hospitalization if initially treated at home is 16.7% but whose risk of admission to the intensive care unit (ICU) is 5.9% -- similar to that for patients in classes I and II. The PORT investigators further suggest that patients in classes IV and V (risk of death, 8.2 and 29.2%, respectively; risk of ICU admission, 11.4 and 17.3%, respectively) should receive traditional inpatient care. An expert panel from the Infectious Diseases Society of America (IDSA) endorses the PORT recommendations.

Other characteristics that favor a decision to hospitalize the patient include the known presence of certain etiologic microorganisms (e.g., *S. aureus*) that are associated with a poor prognosis, multilobe pulmonary involvement, suppurative complications (e.g., empyema or septic arthritis), evidence of poor functional status (e.g., hypotension or hypoxemia on presentation in patients otherwise in classes I, II, and III), evidence of a patient's inability to comply with treatment recommendations, anticipated difficulty in assessing the response to outpatient treatment, and an inadequate home support system that may compromise outpatient care. Discharge from the hospital should be guided by similar considerations.

TREATMENT

Community-Acquired Pneumonia: Outpatient Management Most cases of community-acquired pneumonia in otherwise-healthy adults do not require hospitalization. Although desirable, it is often impractical in the outpatient setting to obtain a chest radiograph and sputum Gram's stain and culture in order to confirm the clinical diagnosis of pneumonia and its microbial etiology before starting antimicrobial therapy. Consequently, the oral antimicrobial treatment administered in the outpatient setting is frequently empirical (Table 255-5). The pathogen in such a situation is likely to be *M. pneumoniae*, *S. pneumoniae*, or *C. pneumoniae*. In older patients with underlying chronic respiratory disease, *L. pneumophila*, *H. influenzae*, or *M. catarrhalis* should also be considered. In patients at risk of aspiration, oral anaerobes may be involved. Few oral antimicrobial drugs have a reliable spectrum encompassing all of these pathogens (Table 255-5). Whatever regimen is chosen, its antimicrobial activity should encompass *S. pneumoniae*, the most common cause of pneumonia. Increasing resistance among pneumococci to all the available oral antimicrobial agents precludes the designation of any one agent as the clear drug of choice.

Strains of *S. pneumoniae* for which the minimal inhibitory concentration (MIC) of penicillin (as determined by the broth dilution method) is 0.1 to 1.0 ug/mL are considered to have intermediate-level resistance, while strains whose MIC is>1.0 ug/mL are considered to have high-level resistance. The current, less time-consuming method to screen for penicillin resistance is the use of a 1-ug oxacillin disk in a disk diffusion assay. Penicillin resistance (i.e., an MIC ³0.1 ug/mL) is indicated by a zone of growth inhibition of£19 mm. Antimicrobial gradient paper strips (the E-test), which yield the exact MIC, are as accurate as the broth dilution technique, can be performed as rapidly as the oxacillin disk diffusion assay, and have replaced the oxacillin disk test in many institutions.

The resistance of *S. pneumoniae* to penicillin varies greatly with the source of the clinical sample tested (e.g., strains isolated from middle-ear fluid are most often resistant), the age of the patient (e.g., resistance is more frequent among children than among adults), the setting (e.g., resistance is more common in day-care centers), the patient's socioeconomic status (the frequency of resistance is highest in samples from suburban and white patients), and the geographic region in which the specimen was collected. Caution must be exercised in the interpretation of surveys of antimicrobial resistance among pneumococci in the United States, which can be strongly affected by these types of sampling bias. In a national survey of clinical isolates from normally sterile body sites that was conducted in 1997 in various surveillance areas throughout the United States by the Centers for Disease Control and Prevention (CDC), 11% (range, 6 to 19%) of 3110 isolates of *S. pneumoniae* exhibited intermediate-level resistance to penicillin, and 14% (range, 8 to 26%) displayed high-level resistance. However, in another national survey of the antimicrobial susceptibility of clinical isolates obtained from respiratory tract sites between February and June 1997 at 27 U.S. medical centers (SENTRY surveillance program), 28% of 845 isolates (with a range of 11 to 52% at the various medical centers) displayed intermediate-level penicillin resistance, and an additional 16% (with a range of 0 to 33%) displayed high-level penicillin resistance.

As a consequence of the production of altered penicillin-binding proteins with decreasedb-lactam affinity, penicillin-resistant *S. pneumoniae* exhibits at least some degree of cross-resistance to allb-lactams, including the extended-spectrum third- and fourth-generation cephalosporins. Since the mechanism of penicillin resistance does not involve b-lactamase production,b-lactam/b-lactamase inhibitor combinations (e.g., amoxicillin/clavulanate) offer no advantage. Indeed, theMICs of penicillin and amoxicillin are nearly identical, but the serum levels after equivalent doses are much higher for amoxicillin than for penicillin, a difference that may reflect a therapeutic advantage of amoxicillin. Among the oral cephalosporins, cefaclor, cefadroxil, and cephalexin have variable activity against penicillin-sensitive strains; cefuroxime and cefpodoxime have activity against penicillin-susceptible strains but variable activity against penicillin-intermediate strains and no activity against highly penicillin-resistant strains.

Resistance to other antimicrobial agents, such as the macrolides (erythromycin, clarithromycin, and azithromycin), clindamycin, tetracycline and doxycycline, and trimethoprim-sulfamethoxazole (TMP-SMZ), is also more common among penicillin-intermediate strains than among penicillin-susceptible strains, and it is most common among highly penicillin-resistant strains. Overall rates of resistance among *S. pneumoniae* strains are ~14% for the macrolides, 4% for clindamycin, up to 10% for tetracyclines, and 20 to 30% for TMP-SMZ. Rates of resistance to the newer fluoroquinolones levofloxacin, gatifloxacin, moxifloxacin, and sparfloxacin are <4%, regardless of penicillin susceptibility. At best, the older fluoroquinolones (e.g., ciprofloxacin) have borderline activity, as judged by serum levels in relation to MICsof these drugs against the pneumococcus.

Optimally, the choice of antimicrobial drugs for empirical therapy should be guided by local resistance patterns, if known. Options for empirical antimicrobial therapy should be modified in light of continually evolving antimicrobial resistance patterns resulting from the introduction of new resistant clones into the community from other regions or the

emergence of resistant mutants under the selective pressure of local patterns of antimicrobial use. TheIDSA has published guidelines for the treatment of community-acquired pneumonia. These guidelines emphasize the need for a chest radiograph when pneumonia is suspected and for the establishment of a microbial diagnosis (e.g., by sputum Gram's stain with or without culture) whenever possible. Doxycycline and the newer fluoroquinolones are recommended alternatives for initial empirical oral therapy, especially when penicillin-resistant pneumococci are suspected. The utility of the macrolides and amoxicillin depends on susceptibility of pneumococci in the local community.

The regimen should be modified for patients with particular epidemiologic factors or comorbidities related to specific pathogens\em\e.g., structural lung disease or suspected aspiration. Aspiration pneumonia can be treated with amoxicillin/clavulanate, clindamycin, or amoxicillin plus metronidazole because these regimens are active against oral anaerobes. Metronidazole alone has inadequate activity against microaerophilic gram-positive cocci and must be supplemented with a b-lactam agent that compensates for this defect in spectrum. If macrolides are used and *H. influenzae* is suspected, azithromycin or clarithromycin is preferred because of erythromycin's poor activity against this organism. Alternative agents for *H. influenzae* include amoxicillin/clavulanate, doxycycline, or a fluoroquinolone. Theb-lactams are not active against pathogens causing atypical pneumonia (e.g., *Mycoplasma*, *C. pneumoniae*, or *Legionella*), in which case doxycycline, a macrolide, or a fluoroquinolone is preferred.

TheIDSAguidelines recommend that pneumococcal pneumonia be treated for 7 to 10 days or until the patient has been afebrile for 72 h. Pneumonia caused by *Legionella, C. pneumoniae*, or *Mycoplasma* should be treated for 2 to 3 weeks unless azithromycin is used, in which case a 5-day course is acceptable because of the drug's prolonged half-life in tissues.

Community-Acquired Pneumonia: Inpatient Management Patients who have community-acquired pneumonia and are ill enough to be hospitalized (Fig. 255-1) must have a chest radiograph to establish the diagnosis of pneumonia, must undergo prompt microbiologic evaluation (including Gram's staining and culture of sputum and culture of two blood samples drawn by separate venipuncture), and must receive empirical antimicrobial therapy based on Gram's staining of sputum and knowledge of the current antimicrobial sensitivities of the pulmonary pathogens in the local geographic area (Tables 255-6 and255-7). Antimicrobial therapy should be initiated promptly (e.g., within 8 h of admission). Parenteral antimicrobial therapy in the hospitalized patient is usually mandatory. A lack of sputum production, an atypical clinical presentation, the presence of diffuse radiographic infiltrates, a rapidly progressive downhill course, and a poor response to prior empirical therapy are among the indications for the use of invasive procedures to detect the pulmonary pathogen, especially in the immunocompromised patient. Although broad-spectrum antibacterial therapy should be started during a full evaluation in severely ill patients with rapidly progressing illness, these empirical regimens cannot encompass all the possible pathogens without producing unnecessary toxicity and expense. Indeed, in immunocompromised patients (including those with neutropenia or HIV infection), the number of microbial and noninfectious causes of pulmonary disease is large and increasing. Since failure to provide specific treatment can prove rapidly fatal, a diagnosis should be sought aggressively so that optimal

therapy can be started promptly.

Penicillin or ampicillin remains the drug of choice for infection due to penicillin-susceptible pneumococci. Studies suggest that high-dose intravenous penicillin G (e.g., 10 to 20 million units daily), ampicillin (2 g every 6 h), ceftriaxone (1 or 2 g every 24 h), or cefotaxime (1 to 2 g every 6 h) constitutes adequate therapy for pneumonia due to strains exhibiting intermediate resistance to penicillin (MIC, 0.1 to 1 ug/mL). The effectiveness of high-dose intravenous penicillin against pneumonia due to highly resistant pneumococcal strains is unknown, but MICs of cefotaxime and ceftriaxone for these strains are usually lower than those of penicillin or ampicillin and most other b-lactam antibiotics. Ceftriaxone or cefotaxime may be effective when the MIC of penicillin is ³1 ug/mL and those of ceftriaxone and cefotaxime are £2 ug/mL. However, highly cephalosporin-resistant strains have become a problem in certain geographic areas. Since all penicillin-resistant strains are sensitive to vancomycin, initial empirical therapy should include this antibiotic (1 g intravenously every 12 h) when the patient with pneumococcal pneumonia is severely ill, has significant comorbidity, and lives in a region where highly penicillin- or cephalosporin-resistant strains have become common.

If the result of Gram's staining of sputum is not interpretable or not available, then theIDSAguidelines recommend empirical therapy for patients hospitalized on a general medical unit with a b-lactam (e.g., ceftriaxone, cefotaxime) or ab-lactam/b-lactamase inhibitor combination, with or without a macrolide, or with one of the fluoroquinolones alone. Seriously ill patients who are hospitalized in theICUshould always receive a macrolide or a newer fluoroquinolone in addition to theb-lactam to cover *Legionella*. The therapeutic regimens should be modified further in the following situations: structural disease of the lung (e.g., bronchiectasis) requires treatment with an anti-*Pseudomonas* b-lactam plus a macrolide or with a newer fluoroquinolone plus an aminoglycoside; penicillin allergy requires treatment with a newer fluoroquinolone, with or without clindamycin; and suspected aspiration requires treatment with a newer fluoroquinolone plus either clindamycin or metronidazole or with ab-lactam/b-lactamase inhibitor combination alone. A recent study of almost 13,000 elderly hospitalized patients with pneumonia, which controlled for severity of illness, baseline differences in patient characteristics, and processes of care, documented 30-day mortality that was 26 to 36% lower among those treated initially with a fluoroquinolone alone or a macrolide combined with a second- or nonpseudomonal third-generation cephalosporin than among those initially given a nonpseudomonal third-generation cephalosporin alone. This result may reflect the importance of pathogens such as *Mycoplasma*, *Legionella*, and *C. pneumoniae* in these patients.

Therapy can be switched from intravenous to oral agents within 3 days to complete a 7- to 10-day course if the patient's clinical condition improves rapidly and if antimicrobial agents that are readily absorbed after oral administration and that reach tissue levels above theMIC are available. The presence of *S. aureus* or aerobic gram-negative bacilli or the development of suppurative complications requires a more prolonged course of therapy. Pneumonia caused by *Legionella*, *C. pneumoniae*, or *Mycoplasma* should be treated for 2 to 3 weeks unless azithromycin is used. Anaerobic lung abscess should be treated with the regimens suggested for aspiration pneumonia until a chest radiograph (with radiography performed at 2-week intervals) is clear or shows only a small stable

scar. Therapy is prolonged for ³6 weeks to prevent relapse, although shorter courses are probably sufficient for many patients. Surgery is rarely required for lung abscess; indications for surgery include massive hemoptysis and suspected neoplasm. Supportive measures include the administration of supplemental oxygen and intravenous fluids, assistance in clearing secretions, fiberoptic bronchoscopy, and (if necessary) ventilatory support. Caution should be exercised in bronchoscopic drainage of large, fluid-filled lung abscesses because of the potential for sudden massive spillage of large collections of pus into the airways.

Patients with risk factors for HIV infection and an atypical pneumonia syndrome should be evaluated forPCPbecause of its frequency as an index diagnosis in HIV infection and its potential severity. Tuberculosis and other causes of atypical pneumonia must be excluded as part of the evaluation of these patients. Empirical therapy can consist of eitherTMP-SMZ(15 to 20 mg of trimethoprim per kg, given daily in four divided doses intravenously or by mouth) or pentamidine (3 to 4 mg/kg daily, given intravenously), and therapy is continued for 3 weeks in confirmed cases of PCP. Although some data suggest that TMP-SMZ is more effective than pentamidine, further studies directly comparing the two agents are needed. The frequency and severity of the adverse effects of the two drugs are generally thought to be equivalent. The addition of glucocorticoids (prednisone, 40 mg twice daily, with subsequent tapering of the dose) early in the course of PCP in patients with an arterial P_{O2} of<70 mmHg decreases the need for mechanical ventilation and improves the patient's chances of survival and functional status. Prophylaxis for recurrent PCP must be started at the end of therapy.

Institutionally Acquired Pneumonia Pneumonia acquired in institutions such as nursing homes or hospitals is frequently caused by enteric aerobic gram-negative bacilli, *P. aeruginosa*, or *S. aureus*, with or without oral anaerobes. Again, the selection of empirical antimicrobial therapy should be guided by Gram's staining of sputum (Tables 255-7 and255-8) and knowledge of the prevalent nosocomial pathogens and their current in vitro antimicrobial sensitivity patterns in the institution involved. An aggressive diagnostic approach is needed in some circumstances, especially for the immunocompromised patient (as outlined above).

S. aureus acquired in some institutions is frequently methicillin resistant. Such strains are resistant to all b-lactam antibiotics and may also be resistant to clindamycin, erythromycin, and the fluoroquinolones. Only vancomycin is predictably active against these organisms, and this drug should be added to the empirical regimen when methicillin-resistant organisms may be involved in pneumonia.

When multiantibiotic resistance is a problem, pneumonia due to gram-negative bacilli in the institutionalized patient can be treated initially with a b-lactam active against *P. aeruginosa* (ceftazidime, cefepime, piperacillin/tazobactam, ticarcillin/clavulanate, aztreonam, or imipenem) or with a parenterally administered fluoroquinolone (ciprofloxacin, ofloxacin, gatifloxacin, or levofloxacin). Among the fluoroquinolones, ciprofloxacin remains the most potent antipseudomonal agent. Ticarcillin/clavulanate and piperacillin/tazobactam are preferred over other penicillins with activity against *P. aeruginosa* (e.g., ticarcillin or piperacillin alone), which are not sufficiently active against *Klebsiella pneumoniae*, a relatively common pathogen. However, for infection suspected to be due to *P. aeruginosa*, the higher dose recommended by the package insert is

required; a lower dose contains less piperacillin or ticarcillin than is needed to be effective against this organism. Ampicillin/sulbactam, the other parenterally administeredb-lactam/b-lactamase inhibitor combination, is not active against many nosocomial pathogens, such as *P. aeruginosa*, *Enterobacter* spp., and *Serratia* spp., and therefore is inappropriate as empirical therapy for nosocomial pneumonia.

In seriously ill patients, especially those infected with organisms in which resistance frequently emerges during therapy (e.g., *P. aeruginosa*), use of ab-lactam/aminoglycoside orb-lactam/fluoroquinolone combination is prudent. Combinations of a b-lactam plus an aminoglycoside are used for bactericidal synergy. Combinations of ab-lactam or an aminoglycoside with a fluoroquinolone are not expected to enhance the already-rapid bactericidal activity of the fluoroquinolone alone. However, such combinations are also used to broaden the spectrum of antibacterial activity, to cover the possibility of infection with resistant pathogens, to treat polymicrobial infection, and to prevent the emergence of antimicrobial resistance.

Pneumonia due to possible coinfection with aerobic gram-negative bacilli and anaerobes, as reflected by a polymicrobial flora on Gram's staining of sputum, can usually be treated with any of the following regimens: (1) cefepime or ceftazidime plus metronidazole or clindamycin, (2) aztreonam or a fluoroquinolone plus clindamycin, or (3) imipenem, piperacillin/tazobactam, or ticarcillin/clavulanate. The regimens should include double coverage for *P. aeruginosa* when this organism is suspected (Table 255-8).

The production of chromosomally encoded, inducibleb-lactamases by some aerobic gram-negative bacilli, including *Serratia marcescens*, *Enterobacter cloacae*, *Citrobacter freundii*, *Morganella morganii*, *P. aeruginosa*, and *Acinetobacter calcoaceticus*, has important implications for the treatment of nosocomial pneumonia in institutions where these organisms are common nosocomial pathogens. Antibiotic resistance in these pathogens has been attributed to two related mechanisms: inducible production of chromosomally encoded b-lactamases and selection of mutants that have lost the genes that control expression ofb-lactamase production. The control genes repressb-lactamase production in the absence of ab-lactam agent and allowb-lactamase production in the presence of ab-lactam agent. This group of organisms has a relatively high mutation rate for loss of these control genes, and their loss results in continuous production of large amounts ofb-lactamase (*stable derepression*). The derepressed mutants are resistant to third-generation cephalosporins, aztreonam, and broad-spectrum penicillins. These chromosomally encoded, inducibleb-lactamases are not inhibited by clavulanic acid, tazobactam, or sulbactam.

Selection by theb-lactam antibiotic of the derepressed mutants present in the dense bacterial populations of infected pulmonary tissue at the initiation of antibiotic therapy apparently accounts for the emergence of resistance during therapy, which is especially problematic in severely compromised patients whose defective host defenses are unable to control the growth of a few resistant mutants. The only b-lactam agents that maintain activity against the derepressed mutants are the fourth-generation cephalosporin cefepime and the carbapenem imipenem. The fluoroquinolones and aminoglycosides may also retain activity against these mutants.TMP-SMZmay remain

active against all of these gram-negative bacilli except *P. aeruginosa*, which is inherently resistant to this agent. Some clinicians have questioned the efficacy of aminoglycosides alone for the treatment of gram-negative bacillary pneumonia. The poor clinical efficacy of aminoglycosides has been attributed to the low drug levels attained in bronchial secretions and to a loss of antimicrobial activity due to the relative acidity of purulent secretions, the anaerobic conditions in infected lung, and (in the case of *P. aeruginosa*) the divalent cations calcium and magnesium. The nephrotoxicity and ototoxicity of aminoglycosides frequently lead to underdosing with these agents. These problems are compounded by unpredictable pharmacokinetics that necessitate measurement of serum levels of aminoglycosides. If multiantibiotic-resistant nosocomial organisms are likely to be the pathogens infecting severely compromised patients, reliable empirical agents may be fluoroquinolones, cefepime, and imipenem -- unless resistance to these drugs is also endemic in the institution. Some strains of *K. pneumoniae* and *Escherichia coli* have acquired a plasmid encoding the production of an extended-spectrumb-lactamase that can be detected as in vitro resistance to ceftazidime or aztreonam. The presence of an extended-spectrumb-lactamase confers resistance to all third-generation cephalosporins and aztreonam. Some of these strains may also be resistant to piperacillin/tazobactam and cefepime, and many are also resistant to the fluoroquinolones. The only reliable agents are the carbapenems, such as imipenem. Up-to-date knowledge of the antimicrobial sensitivities of an institution's nosocomial pathogens and use of various preventive practices are mandatory.

Amantadine (200 mg/d for most adults and 100 mg/d for persons >65 years of age) is effective for the prevention of influenza A virus infection in the unimmunized patient during an influenza A outbreak and for the treatment (for 5 to 7 days) of early influenza A virus infection. Ribavirin is effective for respiratory syncytial virus infection. Intravenous acyclovir (5 to 10 mg/kg every 8 h for 7 to 14 days) is appropriate for varicella pneumonia. Treatment of cytomegalovirus pneumonia has yielded unsatisfactory results, but intravenous immunoglobulin combined with ganciclovir may be effective in some instances. Therapy for hantavirus pulmonary syndrome is supportive, and overall mortality has been 55%.

PREVENTION

The prevention of pneumonia involves either (1) decreasing the likelihood of encountering the pathogen or (2) strengthening the host's response once the pathogen is encountered. The first approach can include measures such as hand washing and glove use by persons who care for patients infected with contact-transmitted pathogens (e.g., aerobic gram-negative bacilli); use of face masks or negative-pressure isolation rooms for patients with pneumonia due to pathogens spread by the aerosol route (e.g., *M. tuberculosis*); prompt institution of effective chemotherapy for patients with contagious illnesses; and correction of conditions that facilitate aspiration. The second approach includes the use of chemoprophylaxis or immunization for patients at risk. Chemoprophylaxis may be administered to patients who have encountered or are likely to encounter the pathogen before they become symptomatic (e.g., amantadine during a community outbreak of influenza A, as mentioned above; isoniazid for tuberculosis; orTMP-SMZfor pneumocystosis) or to patients who are likely to have a recurrence following recovery from a symptomatic episode (e.g., TMP-SMZ for pneumocystosis in patients with HIV infection). The prevention of nosocomial pneumonia requires good

infection control practices, judicious use of broad-spectrum antimicrobial agents, and maintenance of patients' gastric acidity -- a major factor that prevents colonization of the gastrointestinal tract by nosocomial gram-negative bacillary pathogens. To prevent stress ulceration, it is preferable to use sucralfate, which maintains gastric acidity, rather than H_2-blocking agents. To prevent ventilator-associated nosocomial pneumonia, the following strategies have been proposed: use of the semirecumbent position, of endotracheal tubes that allow continuous aspiration of secretions accumulating above the cuff, and of heat and moisture exchangers that reduce the formation of condensate within the tubing circuitry. Vaccines (Chaps. 122,138,149,190, and194) are available for immunization against *S. pneumoniae*, *H. influenzae* type b, influenza viruses A and B, and measles virus. Influenza vaccine is strongly recommended for individuals > 55 years old and pneumococcal vaccine for those > 65 years old; these vaccines should be administered to persons of any age who are at risk of adverse consequences of influenza or pneumonia because of underlying conditions. Pneumococcal, *Haemophilus*, and influenza vaccines are recommended for HIV-infected patients who are still capable of responding to a vaccine challenge. The currently available 23-valent pneumococcal vaccine covers 88% of the serotypes causing systemic disease as well as 8% of related serotypes. The increasing prevalence of multiantibiotic resistance among pneumococci makes pneumococcal immunization of high-risk individuals of utmost importance. Immune serum globulin is available for intravenous replacement therapy in those patients with congenital or acquired hypogammaglobulinemia. Some patients who have selective IgG2 subtype deficiency and recurrent sinopulmonary infections and who are immunologically unresponsive to capsular polysaccharide vaccines may nevertheless have an antibody response to the capsular polysaccharide that is covalently linked to a protein, as it is in the conjugate *H. influenzae* type b vaccine and a similar experimental conjugate pneumococcal vaccine.

256. BRONCHIECTASIS - *Steven E. Weinberger*

DEFINITION

Bronchiectasis is an abnormal and permanent dilatation of bronchi. It may be either focal, involving airways supplying a limited region of pulmonary parenchyma, or diffuse, involving airways in a more widespread distribution. Although this definition is based on pathologic changes in the bronchi, diagnosis is often suggested by the clinical consequences of chronic or recurrent infection in the dilated airways and the associated secretions that pool within these airways.

PATHOLOGY

The bronchial dilatation of bronchiectasis is associated with destructive and inflammatory changes in the walls of medium-sized airways, often at the level of segmental or subsegmental bronchi. The normal structural components of the wall, including cartilage, muscle, and elastic tissue, are destroyed and may be replaced by fibrous tissue. The dilated airways frequently contain pools of thick, purulent material, while more peripheral airways are often occluded by secretions or obliterated and replaced by fibrous tissue. Additional microscopic features include bronchial and peribronchial inflammation and fibrosis, ulceration of the bronchial wall, squamous metaplasia, and mucous gland hyperplasia. The parenchyma normally supplied by the affected airways is abnormal, containing varying combinations of fibrosis, emphysema, bronchopneumonia, and atelectasis. As a result of the inflammation, vascularity of the bronchial wall increases, with associated enlargement of the bronchial arteries and anastomoses between the bronchial and pulmonary arterial circulations.

Three different patterns of bronchiectasis were described by Reid in 1950. In *cylindrical bronchiectasis* the bronchi appear as uniformly dilated tubes that end abruptly at the point that smaller airways are obstructed by secretions. In *varicose bronchiectasis* the affected bronchi have an irregular or beaded pattern of dilatation resembling varicose veins. In *saccular (cystic) bronchiectasis* the bronchi have a ballooned appearance at the periphery, ending in blind sacs without recognizable bronchial structures distal to the sacs.

ETIOLOGY AND PATHOGENESIS

Bronchiectasis is a consequence of inflammation and destruction of the structural components of the bronchial wall. Infection is the usual cause of the inflammation; microorganisms such as *Pseudomonas aeruginosa* and *Haemophilus influenzae* produce pigments, proteases, and other toxins that injure the respiratory epithelium and impair mucociliary clearance. The host inflammatory response induces epithelial injury, largely as a result of mediators released from neutrophils. As protection against infection is compromised, the dilated airways become more susceptible to colonization and growth of bacteria. Thus, a reinforcing cycle can result, with inflammation producing airway damage, impaired clearance of microorganisms, and further infection, which then completes the cycle by inciting more inflammation.

Infectious Causes Adenovirus and influenza virus are the main viruses that cause

bronchiectasis in association with lower respiratory tract involvement. Virulent bacterial infections, especially with potentially necrotizing organisms such as *Staphylococcus aureus*, *Klebsiella*, and anaerobes, remain important causes of bronchiectasis when antibiotic treatment of a pneumonia is not given or is significantly delayed. Bronchiectasis has been reported in patients with HIV infection, perhaps at least partly due to recurrent bacterial infection. Tuberculosis can produce bronchiectasis by a necrotizing effect on pulmonary parenchyma and airways and indirectly as a consequence of airway obstruction from bronchostenosis or extrinsic compression by lymph nodes. Nontuberculous mycobacteria are frequently cultured from patients with bronchiectasis, often as secondary infections or colonizing organisms. However, it has now also been recognized that these organisms, especially those of the *Mycobacterium avium* complex, can serve as primary pathogens associated with the development and/or progression of bronchiectasis. Mycoplasmal and necrotizing fungal infections are rare causes of bronchiectasis.

Impaired host defense mechanisms are often involved in the predisposition to recurrent infections. The major cause of localized impairment of host defenses is endobronchial obstruction. Bacteria and secretions cannot be cleared adequately from the obstructed airway, which develops recurrent or chronic infection. Slowly growing endobronchial neoplasms such as carcinoid tumors may be associated with bronchiectasis. Foreign-body aspiration is another important cause of endobronchial obstruction, particularly in children. Airway obstruction can also result from bronchostenosis, from impacted secretions, or from extrinsic compression by enlarged lymph nodes.

Generalized impairment of pulmonary defense mechanisms occurs with immunoglobulin deficiency, primary ciliary disorders, or cystic fibrosis. Infections and bronchiectasis are therefore often more diffuse. With panhypogammaglobulinemia, the best described of the immunoglobulin disorders associated with recurrent infection and bronchiectasis, patients often also have a history of sinus or skin infections. Selective deficiency of an IgG subclass, especially IgG2, has also been described in a small number of patients with bronchiectasis.

The primary disorders associated with ciliary dysfunction, termed *primary ciliary dyskinesia*, are responsible for 5 to 10% of cases of bronchiectasis. Numerous defects are encompassed under this category, including structural abnormalities of the dynein arms, radial spokes, and microtubules. The cilia become dyskinetic; their coordinated, propulsive action is diminished, and bacterial clearance is impaired. The clinical effects include recurrent upper and lower respiratory tract infections, such as sinusitis, otitis media, and bronchiectasis. Because normal sperm motility also depends on proper ciliary function, males are generally infertile (Chap. 335). Approximately half of patients with primary ciliary dyskinesia fall into the subgroup of *Kartagener's syndrome*, in which situs inversus accompanies bronchiectasis and sinusitis.

In cystic fibrosis (Chap. 257), the tenacious secretions in the bronchi are associated with impaired bacterial clearance, resulting in colonization and recurrent infection with a variety of organisms, particularly mucoid strains of *P. aeruginosa* but also *S. aureus*, *H. influenzae*, *Escherichia coli*, and *Burkholderia cepacia*.

Noninfectious Causes Some cases of bronchiectasis are associated with exposure to

a toxic substance that incites a severe inflammatory response. Examples include inhalation of a toxic gas such as ammonia or aspiration of acidic gastric contents, though the latter problem is often also complicated by aspiration of bacteria. An immune response in the airway may also trigger inflammation, destructive changes, and bronchial dilatation. This mechanism is presumably responsible at least in part for bronchiectasis with allergic bronchopulmonary aspergillosis (ABPA), which is due to an immune response to *Aspergillus* organisms that have colonized the airway (Chap. 253). Bronchiectasis accompanying ABPA often involves proximal airways and is associated with mucoid impaction. Bronchiectasis also occurs rarely in ulcerative colitis, rheumatoid arthritis, and Sjogren's syndrome, but it is not known whether an immune response triggers airway inflammation in these patients.

In α_1-antitrypsin deficiency, the usual respiratory complication is the early development of panacinar emphysema, but affected individuals may occasionally have bronchiectasis. In the *yellow nail syndrome*, which is due to hypoplastic lymphatics, the triad of lymphedema, pleural effusion, and yellow discoloration of the nails is accompanied by bronchiectasis in approximately 40% of patients.

CLINICAL MANIFESTATIONS

Patients typically present with persistent or recurrent cough and purulent sputum production. Hemoptysis occurs in 50 to 70% of cases and can be due to bleeding from friable, inflamed airway mucosa. More significant, even massive bleeding is often a consequence of bleeding from hypertrophied bronchial arteries.

When a specific infectious episode initiates bronchiectasis, patients may describe a severe pneumonia followed by chronic cough and sputum production. Alternatively, patients without a dramatic initiating event often describe the insidious onset of symptoms. In some cases, patients are either asymptomatic or have a nonproductive cough, often associated with "dry" bronchiectasis in an upper lobe. Dyspnea or wheezing generally reflects either widespread bronchiectasis or underlying chronic obstructive pulmonary disease. With exacerbations of infection, the amount of sputum increases, it becomes more purulent and often more bloody, and patients may become febrile. Such episodes may be due solely to exacerbations of the airway infection, but associated parenchymal infiltrates sometimes reflect an adjacent pneumonia.

Physical examination of the chest overlying an area of bronchiectasis is quite variable. Any combination of crackles, rhonchi, and wheezes may be heard, all of which reflect the damaged airways containing significant secretions. As with other types of chronic intrathoracic infection, clubbing may be present. Patients with severe, diffuse disease, particularly those with chronic hypoxemia, may have associated cor pulmonale and right ventricular failure. Amyloidosis can result from chronic infection and inflammation but is now seldom seen.

RADIOGRAPHIC AND LABORATORY FINDINGS

Though the chest radiograph is important in the evaluation of suspected bronchiectasis, the findings are often nonspecific. At one extreme, the radiograph may be normal with mild disease. Alternatively, patients with saccular bronchiectasis may have prominent

cystic spaces, either with or without air-liquid levels, corresponding to the dilated airways. These may be difficult to distinguish from enlarged airspaces due to bullous emphysema or from regions of honeycombing in patients with severe interstitial lung disease. Other findings are due to dilated airways with thickened walls, which result from peribronchial inflammation. Because of decreased aeration and atelectasis of the associated pulmonary parenchyma, these dilated airways are often crowded together in parallel. When seen longitudinally, the airways appear as "tram tracks"; when seen in cross-section, they produce "ring shadows." Because the dilated airways may be filled with secretions, the lumen may appear dense rather than radiolucent, producing an opaque tubular or branched tubular structure.

Bronchography, which involves coating the airways with a radiopaque, iodinated lipid dye instilled through a catheter or bronchoscope, can provide excellent visualization of bronchiectatic airways. However, this technique has now been replaced by computed tomography (CT), which also provides an excellent view of dilated airways as seen in cross-sectional images (Fig. 256-1). With the advent of high-resolution CT scanning, in which the images are 1.0 to 1.5 mm thick, the sensitivity for detecting bronchiectasis has improved even further. Other features on high-resolution CT scanning can suggest a specific etiology of the bronchiectasis. For example, bronchiectasis of relatively proximal airways suggestsABPA, whereas the presence of multiple small pulmonary nodules (nodular bronchiectasis) suggests infection with *M. avium* complex.

Examination of sputum often reveals an abundance of neutrophils and colonization or infection with a variety of possible organisms. Appropriate staining and culturing of sputum often provide a guide to antibiotic therapy.

Additional evaluation is aimed at diagnosing the cause for the bronchiectasis. When bronchiectasis is focal, fiberoptic bronchoscopy may reveal an underlying endobronchial obstruction. In other cases, upper lobe involvement may be suggestive of either tuberculosis orABPA. With more widespread disease, measurement of sweat chloride levels for cystic fibrosis, structural or functional assessment of nasal or bronchial cilia or sperm for primary ciliary dyskinesia, and quantitative assessment of immunoglobulins may explain recurrent airway infection. In an asthmatic person with proximal bronchiectasis or other historical features to suggest ABPA, skin testing, serology, and sputum culture for *Aspergillus* are helpful in confirming the diagnosis.

Pulmonary function tests may demonstrate airflow obstruction as a consequence of diffuse bronchiectasis or associated chronic obstructive lung disease. Bronchial hyperreactivity, e.g., to methacholine challenge, and some reversibility of the airflow obstruction with inhaled bronchodilators are relatively common.

TREATMENT

Therapy has four major goals: (1) elimination of an identifiable underlying problem; (2) improved clearance of tracheobronchial secretions; (3) control of infection, particularly during acute exacerbations; and (4) reversal of airflow obstruction. Appropriate treatment should be instituted when a treatable cause is found, for example, treatment of hypogammaglobulinemia with immunoglobulin replacement, tuberculosis with antituberculous agents, andABPAwith glucocorticoids.

Secretions are typically copious and thick and contribute to the symptoms. Chest physical therapy with vibration, percussion, and postural drainage frequently helps patients with copious secretions. Mucolytic agents to thin secretions and allow better clearance are controversial. Aerosolized recombinant DNase, which decreases viscosity of sputum by breaking down DNA released from neutrophils, has been shown to improve pulmonary function in cystic fibrosis, but similar benefits have not been found with bronchiectasis due to other etiologies.

Antibiotics have an important role in management. For patients with infrequent exacerbations characterized by an increase in quantity and purulence of the sputum, antibiotics are commonly used only during acute episodes. Although choice of an antibiotic may be guided by Gram's stain and culture of sputum, empiric coverage (e.g., with ampicillin, amoxicillin, trimethoprim-sulfamethoxazole, or cefaclor) is often given initially. When *P. aeruginosa* is present, oral therapy with a quinolone or parenteral therapy with an aminoglycoside or third-generation cephalosporin may be appropriate. In patients with chronic purulent sputum despite short courses of antibiotics, more prolonged courses, e.g., with oral amoxicillin or inhaled aminoglycosides, or intermittent but regular courses of single or rotating antibiotics have been used.

Bronchodilators to improve obstruction and aid clearance of secretions are particularly useful in patients with airway hyperreactivity and reversible airflow obstruction. Although surgical therapy was common in the past, more effective antibiotic and supportive therapy has largely replaced surgery. However, when bronchiectasis is localized and the morbidity is substantial despite adequate medical therapy, surgical resection of the involved region of lung should be considered.

When massive hemoptysis, often originating from the hypertrophied bronchial circulation, does not resolve with conservative therapy, including rest and antibiotics, therapeutic options are either surgical resection or bronchial arterial embolization (Chap. 33). Although resection may be successful if disease is localized, embolization is preferable with widespread disease. In patients with extensive disease, chronic hypoxemia and cor pulmonale may indicate the need for long-term supplemental oxygen. For selected patients who are disabled despite maximal therapy, lung transplantation is a therapeutic option.

257. CYSTIC FIBROSIS - *Richard C. Boucher*

Cystic fibrosis (CF) is a monogenetic disorder that presents as a multisystem disease. The first signs and symptoms typically occur in childhood, but about 7% of patients in the United States are diagnosed as adults. Due to improvements in therapy, more than 36% of patients are now adults³18 years of age and 12% are past the age of 30. The median survival is over 32 years for males and 29 years for females with CF. Thus, CF is no longer only a pediatric disease, and internists must be prepared to recognize and treat its many complications. This disease is characterized by chronic airways infection that ultimately leads to bronchiectasis and bronchiolectasis, exocrine pancreatic insufficiency and intestinal dysfunction, abnormal sweat gland function, and urogenital dysfunction.

PATHOGENESIS

GENETIC CONSIDERATIONS

CFis an autosomal recessive disease resulting from mutations in a gene located on chromosome 7. The prevalence of CF varies with the ethnic origin of a population. CF is detected in approximately 1 in 3000 live births in the Caucasian population of North America and northern Europe, 1 in 17,000 live births of African-Americans, and 1 in 90,000 live births of the Asian population of Hawaii. The most common mutation in the CF gene (~70% of CF chromosomes) is a 3-bp deletion that results in an absence of phenylalanine at amino acid position 508 (DF_{508}) of the CF gene protein product, known as the CF transmembrane regulator (CFTR). The large number (>800) of relatively uncommon (<2%) mutations identified in the CF gene makes it difficult to use DNA diagnostic technologies for identifying heterozygotes in populations at large, and no simple physiologic measurements allow heterozygote detection.

CFTRPROTEIN

TheCFTRprotein is a single polypeptide chain containing 1480 amino acids that appears to function both as a cyclic AMP-regulated Cl^- channel and, as its name implies, a regulator of other ion channels. The fully processed form of CFTR is found in the plasma membrane in normal epithelia (Fig. 257-1). Biochemical studies indicate that theDF_{508}mutation leads to improper processing and intracellular degradation of the CFTR protein. Thus, absence of CFTR at appropriate cellular sites is often part of the pathophysiology ofCF. However, other mutations in the CF gene produce CFTR proteins that are fully processed but are nonfunctional or only partially functional at the appropriate cellular sites.

EPITHELIAL DYSFUNCTION

The epithelia affected byCFexhibit different functions in their native state; i.e., some are volume-absorbing (airways and distal intestinal epithelia), some are salt-absorbing but not volume absorbing (sweat duct), and others are volume-secretory (proximal intestine and pancreas). Given this diverse array of native activities, it should not be surprising that CF produces very different effects on patterns of electrolyte and water transport. However, the unifying concept is that all affected tissues express abnormal ion transport

function.

ORGAN-SPECIFIC PATHOPHYSIOLOGY

Lung The diagnostic biophysical hallmark ofCF is the raised transepithelial electric potential difference (PD) detected in airway epithelia. The transepithelial PD reflects components of both the rate of active ion transport and the resistance to ion flow of the superficial epithelium. CF airway epithelia exhibit both raised transport rates (Na^+) and decreased Cl^-permeability (Fig. 257-2). The Cl^- permeability defect reflects at least in part the absence of cyclic AMP-dependent kinase and protein kinase C-regulated Cl^- transport that is mediated by the Cl^-channel functions ofCFTR. An important observation is that there is an alternative Cl^- channel expressed in airway epithelia. This "alternative" Cl^- channel (Cl_{a^-}) is different from CFTR and is regulated by intracellular Ca^{2+}levels. This channel can substitute for CFTR with regard to net Cl^- transport and may be a potential therapeutic target.

Raised Na^+absorption is a routine feature ofCFairway epithelia. Na^+transport abnormalities in CF are not a widespread feature of the CF epithelial phenotype and appear confined to volume-absorbing epithelia. Recent studies demonstrate that the increased Na^+transport reflects the absence ofCFTR's tonic inhibitory regulatory function on Na^+channel activity. It appears that CFTR inhibits Na^+channel activity as a part of its general function to act as a "switch" that coordinates the balance between Na^+absorption and Cl^-secretion.

The central hypothesis ofCFairways pathophysiology has been that an abnormally high rate of Na^+absorption and low rate of Cl^- secretion reduce the salt and water content of mucus and deplete the volume of the perciliary liquid (PCL). Both the thickening of mucins and the depletion of the PCL lead to a failure to clear mucus normally from the airways by either ciliary or airflow-dependent (cough) mechanisms. An alternative hypothesis suggests that the central defect in CF airways is raised salt concentration in secretions that inhibits the function of antimicrobial substances. Direct measurements of salt concentration *in vivo* have, however, provided no evidence that there are differences in salt concentration in CF versus normal airway secretions.

The unique predisposition ofCFairways to chronic infection by *Staphylococcus aureus* and *Pseudomonas aeruginosa* raises the issue that other as yet undefined abnormalities in airway surface liquids also may contribute to the failure of lung defense. However, it may be that *Pseudomonas* is selected by its propensity to grow in biofilm colonies on the surfaces of thickened, retained mucus plaques in CF airways.

Gastrointestinal Tract The gastrointestinal effects ofCF are diverse. In the exocrine pancreas, the absence of theCFTRCl^- channel in the apical membrane of pancreatic ductal epithelia limits the function of an apical membrane Cl^--HCO_3^-exchanger to secrete $HCO_3^-$and Na^+(by a passive process) into the duct. The failure to secrete Na^+-$HCO_3^-$and water leads to retention of enzymes in the pancreas and ultimately destruction of virtually all pancreatic tissue. The CF intestinal epithelium, because of the lack of Cl^- and water secretion, fails to flush the secreted mucins and other macromolecules from intestinal crypts. The diminished CFTR-mediated secretion of liquid may be exacerbated by excessive absorption of liquid in the distal intestine,

reflecting abnormalities of CFTR-mediated regulation of Na^+absorption (both mediated by Na^+channels and possibly other Na^+transporters, e.g., Na^+-H^+exchangers). Both dysfunctions lead to dessicated intraluminal contents and obstruction of both the small and large intestines. In the hepatobiliary system, defective hepatic ductal Cl^- and water secretion causes retention of biliary secretions and focal biliary cirrhosis and bile duct proliferation in approximately 25 to 30% of patients with CF. The inability of the CF gallbladder epithelium to secrete salt and water can lead to both chronic cholecystitis and cholelithiasis.

Sweat Gland Patients with CFsecrete nearly normal volumes of sweat in the sweat acinus. However, they are not able to absorb NaCl from sweat as it moves through the sweat duct due to the inability to absorb Cl^- across the ductal epithelial cells.

CLINICAL FEATURES

Most patients withCFpresent with signs and symptoms of the disease in childhood. Approximately 15% of patients present within the first 24 h of life with gastrointestinal obstruction, termed *meconium ileus*. Other common presentations within the first year or two of life include respiratory tract symptoms, most prominently cough and/or recurrent pulmonary infiltrates, and failure to thrive. A significant proportion of patients (~7%), however, are diagnosed after age 18.

RESPIRATORY TRACT

Upper respiratory tract disease is almost universal in patients withCF. Chronic sinusitis is common in childhood and leads to nasal obstruction and rhinorrhea. The occurrence of nasal polyps approaches 25% and often requires surgery.

In the lower respiratory tract, the first symptom ofCF is cough. With time, the cough becomes persistent and produces viscous, purulent, often greenish colored sputum. Inevitably, periods of clinical stability are interrupted by "exacerbations," defined by increased cough, weight loss, increased sputum volume, and decrements in pulmonary function. These exacerbations require aggressive therapy, including frequent postural drainage and oral antibiotics, and often intravenous antibiotics (see below), with the goal being recovery of lung function. Over the course of years, the exacerbations become more frequent and the recovery of lost lung function incomplete, leading to respiratory failure.

Patients withCFexhibit a characteristic sputum microbiology. *Haemophilus influenzae* and *S. aureus* are often the first organisms recovered from samples of lung secretions in newly diagnosed patients with CF. *P. aeruginosa* is typically cultured from lower respiratory tract secretions thereafter. After repetitive antibiotic exposure, *P. aeruginosa*, often in a mucoid form, is usually the predominant organism recovered from sputum and may be present as several strains with different antibiotic sensitivities. *Burkholderia* (formerly *Pseudomonas*) *cepacia* has been recovered from CF sputum and is pathogenic. Patient-to-patient spread of certain strains of this organism indicates that infection control in the hospital should be practiced. Other gram-negative rods recovered from CF sputum include *Xanthomonas zylosoxida* and *P. gladioli*, and occasionally, mucoid forms of *Proteus*, *Escherichia coli*, and *Klebsiella*. Up to 50% of

patients with CF have *Aspergillus fumigatus* in their sputum, and up to 10% of these patients exhibit the syndrome of allergic bronchopulmonary aspergillosis. *Mycobacterium tuberculosis* is rare in patients with CF. However, 10 to 20% of adult patients with CF have sputum cultures positive for nontuberculous mycobacteria, and in some patients these microorganisms are associated with disease.

The first lung function abnormalities observed in children withCF, increased ratios of residual volume to total lung capacity, suggest that small airways disease is the first functional lung abnormality in CF. As the disease progresses, both reversible and irreversible changes in forced vital capacity and forced expiratory volume in 1 s are noted. The reversible component reflects the accumulation of intraluminal secretions and/or airway reactivity, which occurs in 40 to 60% of patients with CF. The irreversible component reflects chronic destruction of the airway wall and bronchiolitis.

The earliest chest x-ray change in CFlungs is hyperinflation, reflecting small airways obstruction. Later, signs of luminal mucus impaction, bronchial cuffing, and finally, bronchiectasis, e.g., ring shadows, are noted. For reasons that are still unknown, the right upper lobe displays the earliest and most severe changes. Neither CT nor MRI scanning is routinely performed on patients with CF.

CFpulmonary disease is associated with many intermittent complications. Pneumothorax is common (>10% of patients). The production of small amounts of blood in sputum is common in CF patients with advanced pulmonary disease and appears to be associated with lung infection. Massive hemoptysis is life-threatening and difficult to localize bronchoscopically. With advanced lung disease, digital clubbing becomes evident in virtually all patients with CF. As late events, respiratory failure and cor pulmonale are prominent features of CF.

GASTROINTESTINAL TRACT

The syndrome of meconium ileus in infants presents with abdominal distention, failure to pass stool, and emesis. The abdominal flat plate can be diagnostic with small intestinal air fluid levels, a granular appearance representing meconium, and a small colon. In children and young adults, a syndrome termed *meconium ileus equivalent* or distal intestinal obstruction occurs. The syndrome presents with right lower quadrant pain, loss of appetite, occasional emesis, and often a palpable mass. The syndrome can be confused with appendicitis, which occurs frequently in patients withCF. The characteristic intestinal abnormalities are complicated by exocrine pancreatic insufficiency in more than 90% of patients with CF. Insufficient pancreatic enzyme release yields the typical pattern of protein and fat malabsorption, with frequent, bulky, foul-smelling stools. Signs and symptoms of malabsorption of fat-soluble vitamins, including vitamins E and K, are also noted. Pancreatic beta cells are typically spared, but function decreases with age, causing hyperglycemia and increasing requirements for insulin in older patients with CF.

GENITOURINARY SYSTEM

Late onset of puberty is common in both males and females withCF. The delayed maturational pattern is likely secondary to the effects of chronic lung disease and

inadequate nutrition on reproductive endocrine function. More than 95% of male patients with CF are azoospermic, reflecting obliteration of the vas deferens that probably reflects defective liquid secretion. Twenty percent of women with CF are infertile due to effects of chronic lung disease on the menstrual cycle; thick, tenacious cervical mucus that blocks sperm migration; and possibly fallopian tube/uterine wall abnormalities in liquid transport. More than 90% of completed pregnancies produce viable infants, and women with CF are generally able to breast-feed infants normally.

DIAGNOSIS

Because of the large number ofCFmutations, DNA analysis is not used for primary diagnosis. The primary diagnosis of CF rests on a combination of clinical criteria and analyses of sweat Cl^- values. The values for the Na^+ and Cl^- concentration in sweat vary with age, but typically in adults a Cl^- concentration of>70 mEq/L discriminates between patients with CF and patients with other lung diseases.

DNA analyses are being performed increasingly in patients withCF. Comprehensive genotype-phenotype relationships have not yet been established sufficiently for prognosis. A relationship betweenDF_{508}homozygosity and pancreatic insufficiency has been established, but no predictive relationship holds forDF_{508}homozygosity and lung disease.

Between 1 and 2% of patients with the clinical syndrome ofCF have normal sweat Cl^-values. In most of these patients, the nasal transepithelialPD is raised into the diagnostic range for CF, and sweat acini do not secrete in response to injected beta-adrenergic agonists. A single mutation of theCFTRgene, 3849 + 10 kb C ® T, is associated with approximately 50% of CF patients with normal sweat Cl^-values.

TREATMENT

The major objectives of therapy forCF are to promote clearance of secretions and control infection in the lung, provide adequate nutrition, and prevent intestinal obstruction. Ultimately, gene therapy may become the treatment of choice.

Lung Disease The principal techniques for clearing pulmonary secretions are breathing exercises, flutter valves, and chest percussion. Regular use of these maneuvers is effective in preserving lung function. There is increasing interest in the use of hypertonic saline (3 to 7%) aerosols to augment the clearance of secretions.

More than 95% of patients withCF die of complications resulting from lung infection. Antibiotics are the principal agents available for treating lung infection, and their use should be guided by sputum culture results. Early intervention with antibiotics is useful, and long courses of treatment are the rule. Because of increased total-body clearance and volume of distribution of antibiotics in patients with CF, the required doses are higher for patients with CF than for patients with similar chest infections who do not have CF.

Increased cough and mucus production are treated with antibiotics given orally. Typical oral agents used to treat *Staphylococcus* include a semisynthetic penicillin or a

cephalosporin. Oral ciprofloxacin may reduce pseudomonal bacterial counts and control symptoms. However, its clinical usefulness may be limited by rapid emergence of resistant organisms, and accordingly, courses should be intermittent (2 to 3 weeks) and not chronic. More severe exacerbations, or exacerbations associated with bacteria resistant to oral antibiotics, require intravenous antibiotics. Traditionally, intravenous therapy has been given in the hospital, but outpatient intravenous antibiotic administration has gained widespread acceptance. Usually, two drugs, often one of them an aminoglycoside, are used to treat *P. aeruginosa* to hinder emergence of resistant organisms. Drug dosage should be monitored so that levels for gentamicin or tobramycin peak at ranges of ~10 ug/mL and exhibit troughs of<2 ug/mL. Usually, a cephalosporin, e.g., ceftazadime, and/or a penicillin derivative is used as the second drug. Antibiotics directed at *Staphylococcus* and/or *H. influenzae* are added depending on the results of the culture. Aerosolization of antibiotics also may have an important role in treatingCF lung infection. Large doses of aminoglycosides, e.g., 600 mg tobramycin twice daily, via aerosol may be effective at delaying exacerbations. Aerosol administration also permits the use of other drugs, e.g., colistin, that are relatively ineffective by the intravenous route.

A number of pharmacologic agents for promoting mucus clearance are in use. *N*-acetyl-cysteine, which solubilizes mucus glycoproteins, has not been shown to have clinically significant effects on mucus clearance and/or lung function. Recombinant human DNAse, however, degrades the concentrated DNA inCFsputum, decreases sputum viscosity, and increases airflow during short-term administration. Long-term (6 months) DNAse treatment increases the time between pulmonary exacerbations. Most patients receive a therapeutic trial of DNAse to test for efficacy, and a sizeable minority appear to demonstrate persistent objective benefits. Clinical trials of experimental drugs aimed at restoring salt and water content of secretions are underway. The most promising may be long-acting nucleotide (UTP)-based compounds that appear active in inducing liquid secretion in CF airways.

Inhaledb-adrenergic agonists can be useful to control airways constriction. They achieve a short-term increase in airflow, but long-term benefit has not been shown. Inhaled anticholinergics provide an alternative. Oral steroids are not first-line agents for controlling airways constriction and are of no use in improving the nonreversible component of lung function. Steroids may be useful for treating allergic bronchopulmonary aspergillosis.

The chronic damage to airway walls reflects to some extent the destructive activities of inflammatory enzymes generated in part by inflammatory cells. To date, specific therapies with antiproteases have not been successfully developed. However, a subset of adolescents withCFappears to benefit from long-term, high-dose non-steroidal (ibuprofen) therapy.

A number of pulmonary complications require acute interventions. Atelectasis is best treated with chest physiotherapy and antibiotic therapy. Pneumothoraces involving 10% or less of the lung can be observed without intervention. The use of chest tubes to expand collapsed, diseased lung often requires long periods of time, and sclerosing agents should be used with caution because of possible limitations for subsequent lung transplantation. Small-volume hemoptysis requires no specific therapy other than

treatment of lung infection and assessment of coagulation and vitamin K status. If massive hemoptysis occurs, bronchial artery embolization can be successful. The most ominous complications ofCF are respiratory failure and cor pulmonale. The most effective conventional therapy for these conditions is vigorous medical management of the lung disease and O_2supplementation. Noninvasive positive pressure ventilation through a face mask may be an effective adjunctive therapy. Ultimately, the only effective treatment for respiratory failure in CF is lung transplantation (Chap. 267). The 2-year survival for lung transplantation exceeds 60%, and deaths in transplant patients result principally from graft rejection, often involving obliterative bronchiolitis. The transplanted lungs do not develop a CF-specific phenotype.

Gastrointestinal Disease Maintenance of adequate nutrition is critical for the health of the patient withCF. Most (>90%) of patients with CF benefit from pancreatic enzyme replacement. Capsules generally contain between 4000 and 29,000 units of lipase. The dose of enzymes (typically no more than 20,000 units/kg per meal) should be adjusted on the basis of weight gain, abdominal symptomatology, and character of stools. Replacement of fat-soluble vitamins, particularly vitamins E and K, is usually required. Hyperglycemia most often becomes manifest in the adult and typically requires insulin treatment.

For treatment of acute obstruction due to meconium ileus equivalent, megalodiatrizoate or other hypertonic radiocontrast materials delivered by enema to the terminal ileum are utilized. For control of symptoms, adjustment of pancreatic enzymes and the supplementation of intake by salt solutions containing osmotically active agents, e.g., propyleneglycol or lactulose, are utilized. Persistent symptoms may indicate a diagnosis of gastrointestinal malignancy, which is increased in incidence in patients withCF. Hepatic and gallbladder complications are treated as for patients without CF. End-stage liver disease can be treated by transplantation, which has a 2-year survival rate exceeding 50%.

Psychosocial Factors CFimposes a tremendous burden on patients. Health insurance, career options, family planning, and life expectancy become major issues. Thus, assisting patients with the psychosocial adjustments required by CF is critical.

258. CHRONIC BRONCHITIS, EMPHYSEMA, AND AIRWAYS OBSTRUCTION - *Eric G. Honig*, *Roland H. Ingram, Jr.*

DEFINITION

Chronic obstructive pulmonary disease (COPD) is the name of a group of chronic and slowly progressive respiratory disorders characterized by reduced maximal expiratory flow during forced exhalation. Most of the airflow obstruction is fixed, but a variable degree of reversibility and bronchial hyperreactivity may be seen. COPD may coexist with asthma and, when abnormal airway reactivity is present, differentiation between these disorders can be challenging. COPD comprises emphysema and chronic bronchitis, two distinct processes, although most often present in combination. The definition excludes other causes of chronic airflow obstruction such as cystic fibrosis (Chap. 257), bronchiolitis obliterans (Chap. 259), and bronchiectasis (Chap. 256).

Emphysema is defined anatomically as a permanent and destructive enlargement of airspaces distal to the terminal bronchioles without obvious fibrosis and with loss of normal architecture. *Chronic bronchitis* is defined clinically as the presence of a cough productive of sputum not attributable to other causes on most days for at least 3 months over 2 consecutive years. Chronic bronchitis may be present in the absence of airflow limitation, butCOPDalways involves clinically significant airflow limitation.

EPIDEMIOLOGY

COPDis a common medical problem affecting an estimated 16 million Americans. Males are more frequently affected than females, and Caucasians more frequently than African Americans. There is a higher prevalence of COPD among persons with a lower socioeconomic status and in those with a history of low birth weight. COPD is the fourth leading cause of death in the United States and is the only one of the 10 leading causes of death for which mortality rates are still rising. Prevalence peaks in the seventh and eighth decades, then levels off, largely due to mortality.

DISEASE MECHANISMS

PATHOGENESIS

COPDevolves from an inflammatory process involving the airways and distal airspaces. Increased activity of oxidants combined with decreased activity of antioxidants, termed *oxidative stress*, have been implicated in the development of inflammation and COPD. Cigarette smoke produces high concentrations of oxygen free radicals including superoxide, hydrogen peroxide, and hypochlorous acid. Cigarette smoke is an independent source of Fe^{2+}, releases $Fe^{2+}$from ferritin, and catalyzes the formation of the highly active hydroxyl radical from $O_2^-$and $H_2O_2$by eosinophils, neutrophils, and alveolar macrophages. Cigarette tar contains nitric oxide and induces nitric oxide synthase. In the presence of oxidants, NO is metabolized to cytotoxic peroxynitrates. In order for elastase to degrade elastin,$a_1$antitrypsin (a_1AT) must be inactivated. Cigarette smoke, oxidants, activated neutrophils, and type II alveolar pneumocytes are all capable of inactivating a_1AT as well as matrix metalloproteinase inhibitors. Oxidant stress is also capable of inducing mucus hypersecretion. Cigarette smoke also acts as a

chemoattractant and upregulates adhesion molecules. Smoke increases neutrophil transit time through the pulmonary circulation, increases adhesion, and decreases deformability. Smoke and elastase both increase the expression of the proinflammatory nuclear transcription factor kB (NfkB) as well as interleukin 8, a chemokine found to be elevated in COPD patients, that recruits neutrophils, basophils, eosinophils, and T lymphocytes.

The submucosa of the small airway in patients withCOPD has increased numbers of CD8 lymphocytes and eosinophils, macrophages, and mast cells. Neutrophils are increased in smokers, but their numbers do not correlate with the presence of airflow obstruction. Patients with chronic airflow obstruction show higher levels of myeloperoxidase and eosinophilic cationic protein than do patients with normal airflow. Macrophages and mast cells produce transforming growth factor b(TGF-b), a peptide related to fibrogenesis. Patients with chronic airflow obstruction show a twofold elevation of TGF-b in lavage liquid; the amount of TGF-b shows a significant negative correlation with FEV_1(the forced expiratory volume in 1 s). Smoke also leads to lipid peroxidation and to DNA damage. Widespread point mutations of the p53 gene locus have been identified in patients with lung cancer and precancerous dysplasia. These may predispose to the development of lung cancer.

RISK FACTORS

COPDis characterized by a reducedFEV$_1$and an accelerated rate of decline of FEV_1. The reduction in FEV_1 can occur by any of three pathways: (1) impaired childhood growth and development, with a lower peak in early adulthood and a normal rate of decline with aging (e.g., early childhood infection and passive smoke exposure); (2) normal growth and development with a premature peak but normal subsequent decline (e.g., asthma and passive smoking); and (3) normal growth and development and peak with accelerated decline (e.g., active smoking and, to a lesser degree, environmental exposures).

Smoking Cigarette smoking is the most commonly identified correlate with both chronic bronchitis during life and extent of emphysema at postmortem. The prevalence ofCOPDshows a dose-response relationship with the number of pack-years of tobacco consumed. Some 90% of all COPD patients are current or former tobacco smokers. Experimental studies have shown that prolonged cigarette smoking impairs respiratory epithelial ciliary movement, inhibits function of alveolar macrophages, and leads to hypertrophy and hyperplasia of mucus-secreting glands; massive exposure in dogs can produce emphysematous changes. Cigarette smoke also inhibits antiproteases and causes polymorphonuclear leukocytes to release proteolytic enzymes acutely. Cigarette smoke can produce an acute increase in airways resistance due to vagally mediated smooth-muscle constriction by stimulating submucosal irritant receptors. Increased airways responsiveness is associated with more rapid progression in patients with chronic airways obstruction. Obstruction of small airways is the earliest demonstrable mechanical defect in young cigarette smokers and may disappear completely after cessation of smoking.

Although smoking cessation does not result in complete reversal of more pronounced obstruction, there is a significant slowing of the decline in lung function in all smokers

who give up cigarettes. Passive exposure to tobacco smoke correlates with respiratory symptoms such as cough, wheeze, and sputum production. Not only is cigarette smoking the most common single factor leading to chronic airways obstruction, it also adds to the effects of every other contributory factor to be discussed below.

Air Pollution The incidence and mortality rates of both chronic bronchitis and emphysema may be higher in heavily industrialized urban areas. Exacerbations of bronchitis are clearly related to periods of heavy pollution with sulfur dioxide (SO_2) and particulate matter. While nitrogen dioxide (NO_2) can produce small-airways obstruction (bronchiolitis) in experimental animals exposed to high concentrations, there are no data convincingly implicating NO_2, at even the highest pollutant levels, in the pathogenesis or worsening of airways obstruction in humans (Chap. 254).

Occupation Chronic bronchitis is more prevalent in workers who engage in occupations exposing them to either inorganic or organic dusts or to noxious gases. Epidemiologic surveys have succeeded in demonstrating an accelerated decline in lung function in many such workers -- e.g., workers in plastics plants exposed to toluene diisocyanate, and carding room workers in cotton mills (Chap. 254) -- suggesting that their occupational exposure contributes to their future disability.

Infection Morbidity, mortality, and frequency of acute respiratory illnesses are higher in patients with chronic bronchitis. Many attempts have been made to relate these illnesses to infection with viruses, mycoplasmas, and bacteria. However, only the rhinovirus is found more often during exacerbations; that is to say, pathogenic bacteria, mycoplasmas, and viruses other than rhinovirus are found just as often between as during exacerbations. Epidemiologic studies, however, implicate acute respiratory illness as one of the major factors associated with the etiology as well as the progression of chronic airways obstruction. Cigarette smokers may either transitorily develop or worsen small-airways obstruction in association with even mild viral respiratory infections. There is also some evidence that severe viral pneumonia early in life may lead to chronic obstruction, predominantly in small airways.

GENETIC CONSIDERATIONS

Despite the strong etiologic association between smoking and COPD, only 15 to 20% of smokers lose FEV_1 at a rate fast enough to manifest COPD. Epidemiologic evidence of familial clustering of COPD cases is strong and repeated, suggesting that susceptibility to the effects of tobacco smoke has genetic determinants. Twin studies show that even after controlling for active and passive smoking, FEV_1 correlated more closely in monozygotic than dizygotic twins and more than in other family members with a lesser percentage of shared genotype. In first-degree relatives of a cohort of COPD patients with normal α_1AT levels, FEV_1 was reduced compared to controls but only among current or ex-smokers. Smoking and nonsmoking relatives of control subjects both had normal FEV_1. These data suggest genetic risk factors that are expressed in response to smoking.

α_1Antitrypsin Deficiency Thus far, deficiency of α_1AT is the only genetic abnormality that has been specifically linked to COPD. α_1AT is a 394-amino acid serine proteinase inhibitor whose synthesis is governed by a 12.2-kB 7-exon gene located at

14q32.1.a_1AT synthesis is expressed primarily in the liver and to a lesser degree in neutrophils and monocytes. Hepatica_1AT escapes into the general circulation, where it counteracts neutrophil elastase. Normal levels ofa_1AT are 20 to 48 umol/L; levels above 11 umol/L (35% of normal) are considered protective. There are 75 known alleles ofa_1AT, which are inherited in an autosomal codominant manner and are generally classified as normal (MM), deficient, null, or dysfunctional. The most common deficient allele, termed ZZ (or Pi_{ZZ}phenotype), results from a single amino acid substitution$_{342}$Glu® Lys, which causes spontaneous polymerization of the polypeptide, markedly impeding its release into the circulation from the liver. What does escape is vulnerable to oxidation and spontaneous polymerization, further impeding its function. The retained material is associated with hepatic cirrhosis (Chap. 299), while diminished circulating levels (2.5 to 7 umol/L, averaging 16% of normal) lead to antiprotease deficiency. Pi_{ZZ}, the most common disease-relateda_1AT abnormality, occurs in 1:2000 to 1:7000 persons of European descent and is rare in those of Oriental and African lineage. Pi_{SS}phenotypes are associated witha_1AT levels of 15 to 33 umol (mean 52% of normal). Pi_{null}have no detectable antiprotease levels. Heterozygotes have intermediate levels of antiprotease.

Clinically significant deficiency ofa_1AT, with levels below 11 umol/L, has been associated with homozygous Pi_{ZZ}, $Pi_{nullnull}$, or $Pi_{nullZ}$and the premature development of severe emphysema, chronic bronchitis, or bronchiectasis.a_1AT deficiency accounts for 2% of observed cases of emphysema. Rare below age 25, the disease usually presents as dyspnea and cough in patients in their fourth decade. Although not a true population-based study, a large national registry of 1129 severea_1AT-deficiency cases indicated that the typical patient was in the mid-forties, with an$FEV_1$and a pulmonary diffusing capacity at or below 50% of the predicted levels. Most had exertional dyspnea and wheezing, but fewer than half reported a chronic cough. Nearly 80% had a positive family history of lung disease, and 25% reported a positive family history for liver disease. The average rate of decline of FEV_1 is reported to be 100 to 130 mL per year for smokers and 50 to 80 mL per year for ex-smokers or lifetime nonsmokers witha_1AT deficiency.

Pathologically, panacinar emphysema predominates, and radiographically, changes are more marked in the lower lobes. It is becoming increasingly apparent that tobacco smoking is an extremely important cofactor for the development of disease ina_1AT-deficient individuals. Only a few lifetime nonsmokers with Pi_{ZZ}develop emphysema. Most never have symptoms, have a normal rate of decline ofFEV_1, and live a normal life span. Many cases are discovered only as a consequence of family screening of emphysema patients. Because the total number of Pi_{ZZ}individuals is unknown, the risk of disease for smokers is difficult to ascertain accurately. The risk of disease is lower still for heterozygotes with one M or S allele. Smoking is again an important cofactor.

PATHOLOGY

The pathologic changes ofCOPDinvolve large and small airways and the terminal respiratory unit. Airway narrowing is seen in large and small airways and is caused by changes in their normal constituents in response to persistent inflammation.

The airway epithelium is characterized by squamous metaplasia, atrophy of ciliated cells, and hypertrophy of mucus glands. The remodeled epithelium actively produces cytokines that amplify and sustain the inflammatory process. The small airways are the major site of airflow limitation. Small airways show a variety of lesions narrowing their lumina, including goblet cell hyperplasia, mucosal and submucosal inflammatory cells, edema, peribronchial fibrosis, intraluminal mucus plugs, and increased smooth muscle. CD8+ T lymphocytes and B lymphocytes characterize the inflammatory infiltrate. The marked thickening of the subepithelial lamina reticularis, characteristic of asthma, is absent inCOPD.

In the central airways, subepithelial inflammation is present with increased numbers of eosinophils and CD8+ T lymphocytes. Unlike asthma, the eosinophils are not activated and do not degranulate. Neutrophils are present in the epithelium but not in the subepithelial layers. In larger cartilaginous airways, chronic bronchitis is associated with hypertrophy of submucosal mucus-producing glands. Quantitation of this anatomic change, known as the *Reid index*, is based on the ratio of the thickness of the submucosal glands to that of the bronchial wall. In persons without a history of chronic bronchitis, the mean ratio is 0.44 ± 0.09, whereas in those with such a history, the mean ratio is 0.52 ± 0.08. Although a low index is rarely associated with symptoms and a high index is commonly associated with symptoms during life, there is a great deal of overlap. Therefore, many persons will have morphologic changes in large airways without having had chronic bronchitis.

Emphysema begins as an increase in the number and size of alveolar fenestrae and results in the eventual destruction of alveolar septae and their attachments to terminal and respiratory bronchioles. Emphysema is classified according to the pattern of involvement of the gas-exchanging units (acini) of the lung distal to the terminal bronchiole. With *centriacinar emphysema*, the distention and destruction are mainly limited to the respiratory bronchioles with relatively less change peripherally in the acinus. Because of the large functional reserve in the lung, many units must be involved in order for overall dysfunction to be detectable. The centrally destroyed regions of the acinus have a high ventilation/perfusion ratio because the capillaries are missing, yet ventilation continues. This results in a deficit of perfusion relative to ventilation, while the peripheral portions of the acinus have crowded and small alveoli with intact, perfused capillaries giving a low ventilation/perfusion ratio. This results in a deficit of ventilation relative to blood flow, giving a high alveolar-arterial P_{O_2}difference (PA_{O_2}-Pa_{O_2}) (Chap. 250).

During normal aging, airspaces enlarge and alveolar ducts increase in diameter. These changes are extremely common in lungs from persons over age 50 and may be misidentified as emphysema.

Panacinar emphysema involves both the central and peripheral portions of the acinus, which results, if the process is extensive, in a reduction of the alveolar-capillary gas exchange surface and loss of elastic recoil properties. When emphysema is severe, it may be difficult to distinguish between the two types, which most often coexist in the same lung.

PATHOPHYSIOLOGY

Airflow Limitation Although both chronic bronchitis and emphysema can exist without evidence of obstruction, by the time a patient begins to experience dyspnea as a result of these processes, obstruction is always demonstrable. Airflow limitation and increased airways resistance may be caused by loss of elastic recoil driving passive exhalation due to emphysema, by increased collapsibility of small airways through loss of radial traction on airways, or to increased resistance due to intrinsic narrowing of small airways.

In addition to providing radial support to airways during quiet breathing, the elastic recoil properties of the lung serve as a major determinant of maximal expiratory flow rates. The static recoil pressure of the lung is the difference between alveolar and intrapleural pressure. During forced exhalations, when alveolar and intrapleural pressures are high, there are points in the airway at which bronchial pressure equals pleural pressure. Flow does not increase with higher pleural pressure after these points become fixed, so that the effective driving pressure between alveoli and such points is the elastic recoil pressure of the lung (Fig. 258-1). Hence maximal expiratory flow rates represent a complex and dynamic interplay among airways caliber, elastic recoil pressures, and collapsibility of airways. Correlative studies of structure and function suggest that small-airway narrowing is the most important correlate of airflow obstruction, followed by loss of elastic recoil. Collapsibility is probably a less important factor. As a direct consequence of the altered pressure-airflow relationships, the work of breathing is increased in bronchitis and emphysema. Since flow-resistive work is flow rate-dependent, there is a disproportionate increase in the work of breathing when ventilation must be increased, as in exercise.

Hyperinflation The designated subdivisions of the lung volume outlined inChap. 250 are abnormal to varying degrees in both bronchitis and emphysema. The residual volume and functional residual capacity (FRC) are almost always higher than normal. Since the normal FRC is the volume at which the inward recoil of the lung is balanced by the outward recoil of the chest wall, loss of elastic recoil of the lung results in a higher FRC. In addition, prolongation of expiration in association with obstruction would lead to a dynamic increase in FRC (dynamic hyperinflation) if inspiration is initiated before the respiratory system reaches its static balance point. Dynamic hyperinflation contributes additionally to the discomfort associated with airflow obstruction by flattening the diaphragm and placing it at a mechanical disadvantage due to shortened diaphragmatic fiber length and a perpendicular insertion with the lower ribs. The exertional increase in end-expiratory lung volume and consequent decrease in inspiratory capacity have been strongly associated with the degree of dyspnea. Elevations of total lung capacity (TLC) are frequent. The exact cause is uncertain, but increases in total lung capacity are often found in association with decreases in the elastic recoil of the lung. Although the vital capacity is frequently reduced, significant airways obstruction can be present with a normal to near-normal vital capacity.

Impaired Gas Exchange Maldistribution of inspired gas and blood flow is always present to some extent. When the mismatching is severe, impairment of gas exchange is reflected in abnormalities of arterial blood gases. Small-airway narrowing causes a decrease in ventilation of their distal alveolar acini. When alveolar capillaries remain intact, this results in mismatching of ventilation and blood flow, reduced

ventilation-perfusion ratios, and mild to moderate hypoxemia. With emphysema, destruction of alveolar walls may decrease alveolar capillary perfusion as well, better preserving ventilation-perfusion matching, and Pa_{O_2}. Shunt hypoxemia is unusual. There are regions of the lung with a deficit of perfusion in relation to ventilation that increase the wasted ventilation ratio (i.e., V_d/V_t; Chap. 250). At a normal resting CO_2 production, the net effective alveolar ventilation, as reflected by the arterial P_{CO_2}, may be excessive, normal, or insufficient, depending on the relationship of the overall minute volume to the wasted ventilation ratio.

The severity of gas exchange disturbances and, in large part, the clinical manifestations depend on the ventilatory response to the disordered lung function. Some patients, at the cost of extremely high effort of breathing and chronic dyspnea, maintain a strikingly increased minute volume, which results both in a normal to low arterial P_{CO_2}, despite the high V_d/V_t, and a relatively high arterial P_{O_2}, despite the high difference, PA_{O_2}-Pa_{O_2}. Other patients with only modest increases in effort of breathing and less dyspnea maintain a normal to only moderately elevated minute volume at the cost of accepting a high arterial P_{CO_2} and a severely depressed arterial P_{O_2}.

Factors that account for clear differences in ventilatory responses among patients have been studied and debated for years. The bulk of available evidence suggests that those patients who maintain relatively normal or low arterial P_{CO_2} levels are those with an increased ventilatory drive relative to their blood gas values, and those who chronically maintain high arterial P_{CO_2} and lower P_{O_2} levels have a diminished ventilatory drive in relation to their more severely deranged blood gas values. It is not at all certain whether individual differences are accounted for by variations in peripheral or central chemoreceptor sensitivity or through other afferent pathways.

Pulmonary Circulation The pulmonary circulation malfunctions not only in terms of regional distribution of blood flow but also in terms of abnormal overall pressure-flow relationships. In advanced disease, there is often mild to severe pulmonary hypertension at rest, with further increases disproportionate to cardiac output elevations during exercise. A reduction in the total cross-sectional area of the pulmonary vascular bed can be attributed to thickening of medium and large muscular pulmonary arteries, to enhanced contraction of vascular smooth muscle in pulmonary arteries and arterioles, as well as to destruction of alveolar septa with loss of capillaries. Rarely does loss of capillaries alone lead to severe pulmonary hypertension with cor pulmonale, except as a near-terminal event (Chap. 237). Of more importance is the constriction of pulmonary vessels in response to alveolar hypoxia. The pulmonary arteries of patients with severe hypoxemia COPD have been shown to exhibit increased contractility and impaired relaxation in response to pharmacologic stimuli in vitro. These differences between the pulmonary arteries of COPD patients and normal individuals are abolished by inhibition of NO synthase, suggesting that patients develop an endothelial defect in NO synthesis. The constriction is somewhat reversible by an increase in alveolar P_{O_2} with therapy.

There is a synergism between hypoxia and acidosis that assumes importance during episodes of acute or chronic respiratory insufficiency. Chronic hypoxia, especially in concert with carboxyhemoglobinemia, often seen with heavy cigarette smoking, leads not only to pulmonary vascular constriction but also to secondary erythrocytosis. The latter, although not proved to be a significant contributor to pulmonary hypertension,

could add to pulmonary vascular resistance. As discussed inChap. 237, chronic afterload on the right ventricle leads to hypertrophy and, in association with disordered blood gases, ultimately to failure. Hypoventilation may occur during rapid eye movement sleep and lead to desaturation, which may be severe. Repeated desaturation may cause pulmonary hypertension.

Renal and Hormonal Dysfunction Chronic hypoxemia and hypercapnia have been shown to cause increased circulating levels of norepinephrine, renin, and aldosterone and decreased levels of antidiuretic hormone. Renal arterial endothelium inCOPDpatients exhibits defects similar to those seen in the pulmonary arteries, shifting renal blood flow from the cortex to the medulla and impairing renal functional reserve. The combination of hemodynamic and hormonal disturbances leads to defective excretion of salt and water loads and, together with right ventricular dysfunction, to the plethoric and cyanotic manifestations of some patients with COPD.

Cachexia Weight loss sometimes occurs in patients with advancedCOPD. A body-mass index (BMI) < 25 kg/m_2 is associated with increased frequency of exacerbations and with significantly reduced survival. Cachexia has been attributed to caloric intake failing to keep pace with energy expenditures associated with increased work of breathing, but more recent evidence suggests that a biochemical basis is more likely. Hypoxemia leads to increased circulating levels of tumor necrosis factora (TNF-a), and weight loss has now been correlated with levels of the latter.

Peripheral Muscle Dysfunction Protein and muscle are lost as part of wasting in advancedCOPD. Skeletal muscle bulk is lost with proportional reductions in strength. Proximal limb girdle muscles of the upper and lower extremities are particularly affected, contributing to dyspnea with activities of daily living. Fiber composition in skeletal muscle changes, favoring endurance over strength. These changes occur in parallel with$FEV_1$and independently of glucocorticoid use, which can also cause myopathy and muscle weakness.

Osteoporosis Loss of bone density is common in advanced disease. Over half ofCOPDpatients lose more than 1 SD of bony density, and more than one-third have values more than 2 SDs below normal. Vertebral fractures are especially common. These changes are even more severe in patients receiving chronic glucocorticoid therapy.

NATURAL HISTORY

COPDis identified by the presence of an abnormalFEV_1in middle age, usually early in the fifth decade, and is characterized by an accelerated decline of $FEV_1$with aging. In normal individuals, FEV_1normally reaches a lifetime peak at age 25 and undergoes a linear decline of about 35 mL per year thereafter. Annual loss of FEV_1among susceptible individuals who develop COPD is between 50 and 100 mL per year. Greater rates of decline have been associated with mucus hypersecretion, especially in men, and with bronchial hyperreactivity. Acute exacerbations do not alter the rate of decline. Dyspnea and impairment of physical work capacity are characteristic only of moderately severe to severe airways obstruction. There is considerable variation among individual patients. The majority of patients usually experience exertional dyspnea when FEV_1falls

below 40% of predicted and have dyspnea at rest when the FEV_1<25% of predicted. In addition to dyspnea at rest, CO_2retention and cor pulmonale frequently occur when the FEV_1falls to 25% of predicted. With a respiratory infection, small changes in the degree of obstruction can make a large difference in symptoms and gas exchange. Thus small therapeutic gains may have rewarding results.

Exacerbation The clinical course ofCOPD can be characterized as one of slow progression and relative stability punctuated by episodic exacerbations occurring, on average, a little more than once per year. Exacerbations are generally described as a worsening of previously stable disease characterized by increased dyspnea, wheeze, and cough and sputum volume, tenacity, and purulence, with variable degrees of water retention and with worsening gas exchange and ventilation-perfusion relationships. Hyperinflation and work of breathing are increased. To the extent that diaphragmatic function and neuromuscular drive can compensate for the increased work, Pa_{CO_2}will not rise, but when work demands exceed respiratory pump capacity, hypercapnia and respiratory acidemia ensue. Cardiac output often does not increase sufficiently to compensate for the increased oxygen consumption from respiratory muscles, thereby compounding the hypoxemia due to / mismatching and hypercapnia.

MostCOPDexacerbations are thought to be a consequence of acute tracheobronchitis, usually infectious. Most infections are primarily bacterial or the consequence of bacterial superinfection of a primary viral process. Exacerbations may also be triggered by, and must be distinguished from, left ventricular failure, cardiac arrhythmias, pneumothorax, pneumonia, and pulmonary thromboembolism. Upper airway obstruction, aspiration, rhinitis or sinusitis, asthma, or gastroesophageal reflux should be excluded. Although COPD exacerbations are individually serious and potentially life-threatening, they do not cause accelerated declines ofFEV_1over time.

CLINICAL MANIFESTATIONS

HISTORY

Patients withCOPD are most often tobacco smokers with a history of at least one pack per day for at least 20 years. The disease is only rarely seen in nonsmokers. Onset is typically in the fifth decade and often comes to attention as a productive cough or acute chest illness. Exertional dyspnea is usually not encountered until the sixth or seventh decade. The patient's perception of dyspnea correlates poorly with physiologic measurements, especially among older patients. A morning "smoker's cough" is frequent, usually mucoid in character but becoming purulent during exacerbations, which in early disease are intermittent and infrequent. Volume is generally small. Production of more than 60 mL/d should prompt investigation for bronchiectasis. The frequency and severity of cough generally do not correlate with the degree of functional impairment. Wheezing may be present but does not indicate severity of illness. As COPD progresses, exacerbations become more severe and more frequent. Gas exchange disturbances, worsen and dyspnea becomes progressive. Exercise tolerance becomes progressively limited. With worsening hypoxemia, erythrocytosis and cyanosis may occur. The development of morning headache may indicate the onset of significant CO_2retention. In advanced disease, weight loss is frequent and correlates with an adverse prognosis. When blood gas derangements are severe, cor pulmonale may

manifest itself by peripheral edema and water retention. Anxiety, depression, and sleep disturbances are not infrequent.

PHYSICAL FINDINGS

The physical examination has poor sensitivity and variable reproducibility inCOPD. Findings may be minimal or even normal in mild disease, requiring objective laboratory data for confirmation. In early disease, the only abnormal findings may be wheezes on forced expiration and a forced expiratory time prolonged beyond 6 s. With progressive disease, findings of hyperinflation become more apparent. These include an increased anteroposterior diameter of the chest, inspiratory retraction of the lower rib margins (Hoover's sign), decreased cardiac dullness, and distant heart and breath sounds. Coarse inspiratory crackles and rhonchi may be heard, especially at the bases. To gain better mechanical advantage for their compromised respiratory muscles, patients with severe airflow obstruction may adopt a characteristic tripod sitting posture with the neck angled forward and the upper torso supported on the elbows and arms. Breathing through pursed lips prolongs expiratory time and may help reduce dynamic hyperinflation.

Cor pulmonale and right heart failure may be evidenced by dependent edema and an enlarged, tender liver (Chap. 237). With pulmonary hypertension, a loud pulmonic component of the second heart sound may be audible, along with a right ventricular heave and a murmur of tricuspid regurgitation; these findings may be obscured by hyperinflation. If right-sided pressures are sufficiently high, neck veins may elevate instead of collapse with inspiration (Kussmaul's sign). Cyanosis is a somewhat unreliable manifestation of severe hypoxemia and is seen when severe hypoxemia and erythrocytosis are present.

Radiographic Findings A posteroanterior and lateral chest film should be obtained primarily to exclude competing diagnoses. They may be entirely normal in mild disease. AsCOPDprogresses, abnormalities reflect emphysema, hyperinflation, and pulmonary hypertension. Emphysema is manifested by an increased lucency of the lungs. In smokers, these changes are more prominent in the upper lobes, while ina_1ATdeficiency, they are more likely in basal zones. Local radiolucencies>1 cm in diameter and surrounded by hairline arcuate shadows indicate the presence of bullae and are highly specific for emphysema. With hyperinflation, the chest becomes vertically elongated with low flattened diaphragms. The heart shadow is also vertical and narrow. The retrosternal airspace is increased on the lateral view, and the sternal-diaphragmatic angle exceeds 90°. In the presence of pulmonary hypertension, the pulmonary arteries become enlarged and taper rapidly. The right heart border may become prominent and impinge on the retrosternal airspace. The presence of "dirty lung fields" may reflect the presence of bronchiolitis.

Computed tomography has greater sensitivity and specificity for emphysema than the plain film but is rarely necessary except for the diagnosis of bronchiectasis and evaluation of bullous disease. Nonhomogeneous distribution of emphysema is thought by some to be an indicator of suitability for lung volume reduction surgery (LVRS).

PULMONARY FUNCTION TESTING (See alsoChap. 250)

Because of the imprecision of clinical findings, objective evaluation of the presence, severity, and reversibility of airflow obstruction is essential in the diagnostic evaluation ofCOPD. A normalFEV$_1$essentially excludes the diagnosis. The spirogram in COPD shows decreased volume changes with time and a failure to reach a plateau after 3 to 5 s. Continued airflow may be evident for 10 s or more on forced exhalation. The flow-volume curve shows diminished expiratory flow at all lung volumes. Expiratory flow is concave to the volume axis. When flow is plotted against absolute lung volume, the entire curve is shifted to higher volumes, reflecting hyperinflation. Serial spirometry is important in assessing the rate of decline of FEV$_1$.

Reversibility is assessed by spirometry before and after administration of an inhaled bronchodilator, most often a short-actingb$_2$-adrenergic agonist. Testing should be performed when the patient is clinically stable. Short-acting bronchodilators should be withheld for 6 h, long-acting dilators for 12 h, and theophylline for 24 h prior to testing. A significant response is an increase of at least 12% and 200 mL in eitherFEV$_1$or forced vital capacity (FVC). Postbronchodilator FEV$_1$ is useful for prognostication. Although only one-third ofCOPDpatients show a significant response to an inhaled bronchodilator in the pulmonary function laboratory on any one day, two-thirds will show a significant response when tested with different bronchodilators on several different occasions. The degree of bronchodilator response at any one testing session does not predict the degree of clinical benefit to the patient. Therefore, bronchodilators are given irrespective of the acute response obtained in the pulmonary function laboratory. The American Thoracic Society recommends staging COPD by FEV$_1$. Stage I, mild disease, is defined as FEV$_1$[3] 50% predicted; stage II, moderate disease, 35 to 49% predicted; and stage III, severe disease,<35% predicted.

Lung volumes are useful for the assessment of hyperinflation. Transfer factor for carbon monoxide (DL$_{CO}$) correlates negatively with the degree of emphysema but is not specific and may miss mild disease. Neither test is indicated routinely, but DL$_{CO}$ may help distinguish chronic asthma from emphysema.

Measurements for arterial blood gas are not needed for mild disease, but they should be assessed routinely for stage II or stage IIICOPD. Patients with pulmonary hypertension or cor pulmonale with normal daytime blood gases should be evaluated for nocturnal desaturation by overnight oximetry. Polysomnography to exclude concurrent sleep apnea should be obtained for patients who also complain of excessive daytime somnolence or who have a history of snoring.

a$_1$ATlevels are not needed routinely but should be obtained for chronic airflow obstruction or chronic bronchitis in nonsmokers, as well as inCOPDpatients with bronchiectasis, cirrhosis without apparent risks, premature emphysema, or basilar emphysema; in patients under age 50 with unremitting asthma; and in individuals with a family history ofa$_1$AT deficiency.

TREATMENT

Treatment of COPDis based on the principles of prevention of further evolution of disease, preservation of airflow, preservation and enhancement of functional capacity,

management of physiologic complications, and avoidance of exacerbations.

Smoking Cessation (See also Chap. 390) The Lung Health Study has demonstrated that elimination of tobacco smoking confers significant survival benefit to patients with COPD. Prolonged survival is associated with reduced rates of malignancy and cardiovascular disease as well as with a significant increment in FEV_1 in the first year after smoking cessation. The rate of decline of FEV_1 reverts back to that of a nonsmoker. Although bronchodilator therapy produces similar first-year gains in FEV_1, pharmacotherapy alone does not modify the decline of airflow over time. Even unsuccessful quitters show significant benefits when compared to continuing smokers.

Despite the demonstrated benefits of smoking cessation, sustained quitting is difficult to achieve. Overall, only 6% of smokers succeed in quitting long term, and 70 to 80% of short-term quitters start smoking again. Successful quitting requires concerted active and continuing intervention by the physician. The physician should address the issue in regular patient visits, assess the patient's readiness to quit, advise the patient as to the best methods for smoking cessation, provide emotional and pharmacologic support, and arrange close follow-up of the patient's efforts. The concept of "lung age" may be helpful in promoting smoking cessation by determining the age at which the observed FEV_1 would be a normal finding. Lungs of 50- to 60-year-old smokers may be "normal" for a 70- to 80-year-old individual. Nicotine patches and nicotine polacrilex gum improve quit rates, especially among nicotine-dependent smokers. The addition of oral bupropion at 150 mg twice daily produces significant additional benefit, with a 1-year sustained abstinence rate of 22.5% compared to 6% for placebo. Smoking cessation is typically associated with weight gain of 3 to 4 kg. To minimize weight gain, reluctance to quit, and relapse, prospective quitters should be counseled to reduce caloric intake and to increase physical activity.

Bronchodilators These drugs improve dyspnea and exercise tolerance by improving airflow and by reducing end-expiratory lung volume and air-trapping. Although airflow limitation is relatively fixed, some degree of response to bronchodilator medication is usually present. Bronchodilator medication is available in metered-dose inhaler (and some dry-powder inhalers) and in nebulizable and oral forms. Inhalers deliver medications directly to the airways and have limited systemic absorption and side effects. Proper use requires timing and coordination of inspiration and inhaler actuation and presents frequent difficulties for chronic lung patients. These problems can usually be overcome with education and with the use of holding chambers. Aerosol nebulizers have no pharmacologic advantage over metered-dose inhalers. Their use should be limited to patients who remain unable to master metered dose inhalers adequately. Oral medication is associated with higher rates of adherence than inhalers but shows higher rates of systemic side effects without superior bronchodilation.

Three major classes of bronchodilators are commonly employed in the treatment of patients with COPD: short- and long-acting β_2-adrenergic agonists, anticholinergics, and theophylline derivatives. Short-acting β_2-agonists (albuterol, pirbuterol, terbutaline, metaproterenol) are relatively bronchoselective with minimal effects on heart rate and blood pressure. They produce significant bronchodilation at 5 to 15 min and remain effective for 4 to 6 h. Long-acting β_2-agonists (oral sustained-release albuterol and inhaled salmeterol) have an onset of action of 15 to 30 min and a 12-h duration of

action. Anticholinergic agents (ipratropium bromide) have a 30- to 60-min onset of action and a 4- to 6-h duration. Theophyllines are generally administered orally in 12- or 24-h preparations. Recommended bronchodilator regimens are shown in Table 258-1.

Regular use of ipratropium may lead to improvements in baseline FEV_1 when compared with short-acting β_2-agonists. When used together, ipratropium and short-acting β_2-agents show greater clinical efficacy than either agent alone, without an increase in side effects. Salmeterol as a single agent produces longer lasting bronchodilation than ipratropium, improves baseline FEV_1 over time, and is not associated with loss of efficacy over a period of several months. Salmeterol, however, has not yet been evaluated as a component of combination therapy.

Theophylline is a weak bronchodilator with a narrow therapeutic window. Much of its clinical benefit derives from effects other than bronchodilation; therapeutic doses of theophylline increase ventilatory drive, enhance diaphragmatic contractility, and increase cardiac output. About 20% of COPD patients respond to theophylline with improved airflow, exercise tolerance, and quality of life. Theophylline produces additional benefits in exercise capacity and quality of life when used in combination with short-acting β_2-adrenergic agonists. The therapeutic range for theophylline is commonly given as 10 to 20 ug/mL, with greater efficacy but greater toxicity seen at higher serum levels. The risk of toxicity is greater in older patients and in those with heart and kidney disease. Optimal dosing must balance the competing considerations of risk and benefit for each individual patient.

Glucocorticoids Because COPD, like asthma, is a disease associated with airway inflammation, glucocorticoids are an intuitively attractive therapeutic modality. Nevertheless, results of clinical trials of glucocorticoid therapy in COPD patients have shown less impressive benefits when compared to patients with asthma. The degree of response to glucocorticoids appears to correlate with the presence of asthmatic features, but data supporting their use is limited. Only 10% more patients show subjective benefit and increase their FEV_1 or forced vital capacity by at least 20% when compared to those on placebo. Responders cannot be reliably identified on clinical grounds, although response to an inhaled β_2-agonist is commonly used as a predictor. The benefits of a 10- to 14-day trial of 30 to 40 mg/d of prednisone for patients with stage III disease who have not responded adequately to mixed bronchodilator therapy remain to be proven. Long-term systemic glucocorticoid use is associated with multiple side effects. In particular, they have been associated with worsened osteoporosis and increased risk of vertebral fracture. If systemic steroids are used, the lowest effective dose should be employed and alternate-day dosing used whenever possible. The use of inhaled glucocorticoids ameliorates systemic side effects. Three large clinical trials have shown that inhaled glucocorticoids do not alter the rate of decline of FEV_1. While an inhaled glucocorticoid does not decrease the number or frequency of COPD exacerbations, it may decrease their severity and reduce the need for hospitalization. Symptoms and exercise tolerance improve on inhaled glucocorticoids.

Management of α_1AT Deficiency Given the central role of smoking in the pathogenesis of disease, smoking cessation is an important cornerstone in the management of α_1AT deficiency. Exogenous α_1AT derived from pooled human plasma administered intravenously in a weekly dose of 60 mg/kg has been shown to induce protective levels

ofa1AT in deficient individuals. Because of the expense and inconvenience of the treatment, replacement ofa1AT is used only for patients over age 18 witha1AT levels below 11 umol/L who have stopped smoking and who have airflow obstruction. A recently published large nonrandomized trial showed that augmentation therapy significantly decreased 5-year mortality (RR 0.64) for patients receiving replacement. The rate of decline ofFEV1also decreased with augmentation therapy. In both instances, benefit was largely restricted to those patients with FEV1 35 to 49% of predicted. These findings require confirmation in randomized controlled trials.

Oxygen Severe and progressive hypoxemia is often seen in advancedCOPD and may result in cellular hypoxia with deleterious physiologic consequences. The establishment of adequate systemic oxygen transport is essential to the prevention of tissue hypoxia and requires attention to cardiac output and hemoglobin concentration as well as to arterial O2saturation (SaO2). Long-term O2therapy has been shown to reverse secondary polycythemia; improve body weight; ameliorate cor pulmonale; and enhance neuropsychiatric function, exercise tolerance, and activities of daily living. Two major studies, one in the United States and one in the United Kingdom, established a survival benefit for long-term O2therapy that increased with the number of hours per day that O2 was used. The mechanism for this benefit has not been conclusively elucidated, but it appears to be related to the stabilization of pulmonary hemodynamics.

The need for long-term O2therapy should be documented with measurement of arterial blood gases obtained at rest and confirmed by a separate determination of resting arterial blood gases during a period of medical stability after 30 to 90 days of optimum medical therapy. Once the need for O2 has been demonstrated in a stable patient, the requirement is generally for the duration of the patient's life. Patients with a PaO2£ 55 mmHg or SaO2£ 88% should be provided with oxygen titrated to raise SaO2 to³90%. Oxygen is likewise indicated for patients who have a PaO2 of 56 to 59 mmHg with SaO2³ 89% when hematocrit is >55% or when cor pulmonale or other objective evidence of pulmonary hypertension is present. Oxygen may be appropriate for patients whose resting awake PaO2³60 mmHg with SaO2³ 90% if they become hypoxic during exercise or sleep. Once oxygen is prescribed, the dose should be titrated to maintain SaO2³ 90% during sleep and normal walking, as well as at rest, and it should be used for a minimum of 15 h a day to realize a survival benefit.

Oxygen is most frequently delivered through a nasal cannula at rates of 2 to 5 L/min. Oxygen-sparing cannulae are available. Transtracheal administration provides further O2-sparing benefits but requires scrupulous attention to catheter maintenance and hygiene and is not suitable for all patients. Oxygen is packaged as compressed gas or compressed liquid or can be delivered from an O2concentrator, a molecular sieve that enriches O2 by removing nitrogen from ambient air. O2should be prescribed from sources that are appropriate to the individual patient's life-style and needs. It is customary to provide a stationary O2source, either an O2concentrator, which is dependent on a reliable source of electricity, or 100-kg (200-lb) H cylinders of compressed O2. Flow resistance imposes a 15-m (50-ft) practical limit to the length of tubing connecting the O2source to the patient's cannula. For patients whose activities of daily living require ambulation beyond this limit, ambulatory or portable systems should be provided. Ambulatory O2 needs may be met with rolling 10-kg (22-lb) E cylinders of compressed O2, or with portable 2-kg (4.5-lb) aluminum cylinders or 3-kg (6.6-lb) liquid

oxygen packs. The duration of O_2availability from an O_2concentrator is unlimited. For compressed gas and liquid sources, the amount of available oxygen is determined by the size of the system and the patient's liter flow needs. Portable systems generally provide 4 to 5 h of O_2flow.

Oxygen therapy is generally safe. Cylinders should be secured to prevent tipping over or potentially explosive disconnection of the regulator valve. Oxygen should be stored away from open flames or other source of heat, and patients and family members should be educated to be especially scrupulous about avoiding smoking in the presence of flowing O_2.

Prophylaxis No evidence supports the prophylactic use of antibiotics in stableCOPD. Yearly influenza vaccination is recommended for all patients with chronic cardiopulmonary disease, although objective benefit has not been conclusively demonstrated. Pneumococcal vaccination with 23-valent polysaccharide is also recommended. Amantadine should be used for unvaccinated patients who are placed at risk by an outbreak of influenza A.

Rehabilitation Airflow limitation, dyspnea, and muscle loss and deconditioning all compromise cardiopulmonary fitness and contribute to a progressively constrained daily life and unsatisfactory quality of life. Pulmonary rehabilitation is a multidisciplinary program of care for patients with chronic respiratory impairments that is individually tailored and designed to optimize physical and social performance. A pulmonary rehabilitation program consists of exercise training, patient education, psychosocial and behavioral intervention, and regular assessment of outcomes and is designed to minimize the disability and handicap imposed by the physiologic impairments consequent toCOPD. Rehabilitation in COPD should be considered for patients with persistent symptoms and disability despite optimal medical management. Spirometric criteria should not be the primary basis for referral into rehabilitation programs. Exercise consists of 20 to 30 min of upper and lower extremity exercise at 60 to 75% maximumO_2 or heart rate two to five times a week. Both strength and endurance exercises are provided. Education covers pursed lip and other breathing strategies to minimize dyspnea, energy-conservation skills, principles of medications and proper use of metered-dose inhalers, nutrition, and end-of-life decision-making. Behavioral interventions focus on dyspnea, depression, and self-sufficiency and on issues of control, coping, and role function. Dyspnea, exercise tolerance, activity level, and quality of life are followed at regular intervals. Pulmonary rehabilitation programs have been shown to improve endurance time for submaximal exercise by 38 to 80% and 6-min walking distance by 80 to 113 m. Clinically meaningful reduction in dyspnea and improvement of quality of life have been reported. No clinical trials have been adequately designed to address the issue of survival benefit. Reductions in costs of care and resource consumption have not reached statistical significance.

Despite maximal medical therapy, whenCOPDprogresses to stage III and is complicated by hypercapnia or pulmonary hypertension, surgical approaches to treatment may be considered.

Transplantation (See alsoChap. 267) Owing to its frequency in the general population, emphysema is the most common indication for lung transplantation. Transplantation

should be actively considered for end-stage COPD patients when the prognosis from the disease is worse than the survival statistics for the surgery. Lung transplantation should be considered for COPD patients who, despite maximal medical therapy, have an FEV_1 < 25% predicted and with pulmonary hypertension or cor pulmonale. Precedence is given to those patients with a Pa_{CO2} of 55 mmHg and progressive deterioration. Asthma and other reversible airflow limitation must be excluded. Rehabilitation and long-term O_2 therapy, where appropriate, should be provided prior to transplant evaluation.

Lung Volume Reduction Surgery LVRS, or pneumectomy, is designed to relieve dyspnea and improve exercise function in severely disabled patients with stage III emphysema. At operation, severely emphysematous lung tissue is resected, leading to improvement in elastic recoil in the remaining pulmonary parenchyma. This decreases hyperinflation and enhances diaphragmatic function, with consequent 25 to 50% improvement of airflow and exercise capacity. In early uncontrolled studies, hospital mortality for LVRS ranged from 5 to 18% and hospital stays averaged 9 to 18 days, with frequent significant air leaks. Cost of LVRS was $33,000 to $70,000 per case. Because of the large number of potential candidates, the high cost involved, and unanswered questions about the benefits of the operation, use of LVRS in the United States has been restricted to a multicenter randomized controlled trial, the National Emphysema Treatment Trial (NETT), comparing LVRS with best medical therapy. Stage III emphysema patients accepted for evaluation into NETT are under age 75, are severely hyperinflated, and have severe dyspnea despite optimal medical therapy. Contraindications to LVRS are similar to those for lung transplantation, including active smoking, marked obesity or cachexia, and inability to undertake pulmonary rehabilitation successfully. There has been little consensus regarding features identifying ideal and suboptimal candidates for the surgery. Radiographic heterogeneity of disease and the absence of significant intrinsic airway disease have been suggested characteristics of patients likely to benefit. Results from the NETT suggest that physiologic benefits from LVRS may begin to be lost as early as 1 year after surgery. Accelerated declines of FEV_1 have been reported, averaging 100 mL per year and particularly marked in those patients with the greatest postoperative gains in airflow. Improvements in dyspnea and exercise tolerance may be sustained for as long as 3 years but may decline thereafter. Until these issues are satisfactorily resolved, LVRS will remain an experimental procedure.

Treatment of Exacerbations

Triage The initial decision in the management of an exacerbation of COPD is whether hospitalization is necessary. Rapidity of evolution of symptoms and response to initial therapy, level of consciousness, presence or absence of respiratory distress, severity of gas exchange disturbance, and arterial blood gas deviation from the patient's stable baseline should influence the decision to hospitalize. The patient's ability to manage at home and the resources available for home care should weigh heavily in the decision-making process.

Home Therapy For patients with mild exacerbations for whom outpatient therapy is appropriate, a combination of anticholinergic and short-acting b_2-adrenergic agonist bronchodilators should be prescribed. Although b_2-agonists may be given as frequently as once an hour, there is no advantage to administering anticholinergic bronchodilators

more frequently than every 4 to 6 h. Metered-dose inhalers should be used with spacers. There is no evidence that the use of nebulizers provides any improvement in outcome.

The presence of increased sputum volume or purulence suggest an infectious cause of an exacerbation. With either of these features is present in conjunction with increased breathlessness or when both are present, antibiotics should be prescribed. The organisms most frequently associated with mildCOPDexacerbations include *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. Trimethoprim/sulfamethoxazole, doxycycline, or amoxicillin is an appropriate management option, although choices may be modified by local antibiotic sensitivity data.

There is a need for well-controlled studies on the utility of glucocorticoids in the outpatient management ofCOPDexacerbations. Oral glucocorticoids may be continued in patients already receiving such treatment or given to patients who do not show a satisfactory response to bronchodilator therapy. The usual dose is 20 to 40 mg daily for 7 to 10 days. Short-term glucocorticoid therapy lasting less than 3 weeks may be discontinued without the use of a tapering dose.

Hospital Management For patients with exacerbations of sufficient severity to warrant hospitalization, improvement of airflow, gas exchange, and acid-base status are of central importance. Hospitalized patients should receive bronchodilators, antibiotics, oral glucocorticoids, and sufficient O_2 to keep the Sa_{O2}³ 90%.b_2-agonists and anticholinergic agents should be given together every 4 to 6 h. The frequency of sympathomimetic bronchodilator administration may be increased as needed to as often as every 20 min. Because high doses ofb_2-agonists may cause hypokalemia, serum potassium levels and heart rate should be monitored closely for patients receiving frequent doses of these agents. Data are contradictory regarding the addition of theophylline to the bronchodilator regiment of patients showing an inadequate initial response, yet the current American and British Thoracic Societies' guidelines recommend consideration of its use to produce plasma theophylline levels between 10 and 20 ug/mL. Oral glucocorticoids have been shown to produce modest improvements in$FEV_1$and in the duration of hospitalization forCOPDexacerbations. Recent data indicate that more severe COPD exacerbations are associated with the recovery of enterobacteriaciae in respiratory secretions. For this reason, a second- or third-generation cephalosporin, a fluoroquinolone, a second-generation macrolide, or an extended-spectrum penicillin is now recommended as initial therapy. Attempts to obtain diagnostically adequate sputum should be made, and, when available, sputum results should be used to individualize therapy in the light of local microbial sensitivity spectra. Oxygen therapy is an important component of the management of a severe exacerbation of COPD. It is important to maintain the Sa_{O2}> 90% and Pa_{O2}between 60 and 65 mmHg for most patients. In many cases, administration of O_2 will result in worsening hypercapnia, although rarely to a clinically significant degree if the O_2 is used only in amounts to achieve the minimal goals. The elevation of Pa_{CO2} is multifactorial, resulting from increased dead space due to reduced tidal volume as well as from the Haldane effect, i.e., a right wave shift of the CO_2dissociation curve in the presence of increased saturated hemoglobin. The lower the initial Pa_{O2} and the greater the increase, the larger the increase in Pa_{CO2}observed. Patients whose pH on presentation is below

7.25 and with Pa_{O_2}< 50 mmHg are at particular risk and should be observed closely.

For patients at increased risk of hypercapnia, administration of controlled concentrations of O_2through a Venturi mask is reasonable. Inspired O_2concentrations (FI_{O_2}) of 0.24 to 0.28 are usually sufficient to keep Sa_{O_2}³90%.

*MECHANICAL VENTILATION (See also*Chap. 266*)* Patients with impaired consciousness, respiratory distress evidenced by tachypnea with a respiratory rate greater than 35 breaths per minute and/or abdominal paradox, severe hypoxemia, or significant respiratory acidosis with pH< 7.25 and who deteriorate despite treatment are candidates for immediate ventilatory support using either noninvasive (mask) or invasive (intubation) approaches. The goals are to buy time for medical treatments to take effect, to rest the respiratory muscles, and to improve gas exchange abnormalities while avoiding the major complications of mechanical ventilatory support.

Noninvasive positive-pressure ventilation (NIPPV) delivered by nasal mask should be considered in units that have experience with the technique for patients who remain alert and cooperative, who are not heavily sedated, who are hemodynamically stable, and who are able to clear their airways by coughing up secretions. In these circumstances, NIPPV has been shown to be successful in avoiding the need for endotracheal intubation in up to 70% of cases. Success, as evidenced by improved $Pa_{CO_2}$and pH, should be evident within the first 60 min. Part-time NIPPV for 6 to 8 h per day may afford sufficient respiratory muscle rest to avert the need for invasive conventional ventilation. Failed attempts at NIPPV can be followed by intubation and conventional ventilation and do not appear to carry a worse prognosis. Successful application of NIPPV has been associated with a decrease in intensive care and hospital stays, incidence of nosocomial pneumonia, and costs.

Before committing to endotracheal intubation and conventional ventilatory support, the patient's wishes for such support, the patient's quality of life, and the benefits and costs of care should be thoroughly reviewed. Where the patient's wishes cannot be clearly ascertained or there is uncertainty about the appropriateness of the intervention, intubation and ventilation should proceed. If mechanical ventilatory support is subsequently determined to be inappropriate, support may then be withdrawn.

Once intubation is accomplished, the patient can be ventilated in the controlled ventilation, assist-control, intermittent mandatory ventilation, or pressure support modes. FI_{O_2}should be sufficient to obtain Sa_{O_2}³ 90% and Pa_{O_2} of 60 to 65 mmHg. An FI_{O_2} of 0.24 to 0.40 is usually adequate for the purpose. Minute volume should be adequate to keep pH ³ 7.25, but one should not strive to achieve a "normal" Pa_{CO_2}. It is important to try to avoid overventilation and hyperinflation in ventilatedCOPDpatients. Because the time constant for exhalation is abnormally prolonged, it is essential to allow adequate expiratory time to permit as complete emptying of each breath as possible, preferably at least 3 to 4 s. This is best accomplished by minimizing tidal volume and respiratory rate. Lesser gains in expiratory (E) time can be obtained by high inspiratory (I) flow rates and I:E ratios of 1:2 or higher. Inadequate expiratory time leads to dynamic hyperinflation and in turn to the development of intrinsic positive end-expiratory pressure (PEEPi). PEEPi is just as capable of producing hypotension as extrinsically applied PEEP. When a mechanically ventilated patient with obstructive lung disease abruptly develops

hypotension, PEEPi should be excluded, either by direct measurement or by disconnecting the patient from the ventilator for 30 to 60 s. PEEPi and dynamic hyperinflation increase the work of breathing, place the diaphragm at mechanical disadvantage, and contribute significantly to difficulties in weaning from ventilatory support. Over a period of days, as the underlying precipitants of the exacerbation are controlled, airway obstruction gradually remits and gas exchange improves and it becomes appropriate to consider removal from mechanical ventilatory support.

The principles of weaning from mechanical ventilation are discussed in detail in Chap. 266.

Prognosis after Exacerbation The hospital mortality rate for an episode of respiratory failure in COPD ranges from 11 to 25% and depends on the severity of the episode, the patient's chronic health and nutritional status, and the presence of cor pulmonale or congestive heart failure. Data regarding subsequent course may be helpful in educating COPD patients and in guiding their subsequent management decisions. Among survivors of mechanical ventilation, the 6-month mortality rate is approximately 40%. Two-thirds of survivors have frequent recurrences of exacerbations, and functional status thereafter is often poor.

259. INTERSTITIAL LUNG DISEASES - *Talmadge E. King, Jr.*

The interstitial lung diseases (ILDs) represent a large number of conditions that involve the parenchyma of the lung -- the alveoli, the alveolar epithelium, the capillary endothelium, and the spaces between these structures, as well as the perivascular and lymphatic tissues. This heterogeneous group of disorders is classified together because of similar clinical, roentgenographic, physiologic, or pathologic manifestations. These disorders are often associated with considerable morbidity and mortality, and there is little consensus regarding the best management of most of them.

ILDshave been difficult to classify because more than 200 known individual diseases are characterized by diffuse parenchymal lung involvement, either as the primary condition or as a significant part of a multiorgan process, as may occur in the connective tissue diseases (CTDs). One useful approach to classification is to separate the ILDs into two groups, those of known and those of unknown causes (Table 259-1). Each of these groups can be subdivided into subgroups according to the presence or absence of histologic evidence of granulomas in interstitial or vascular areas. For each ILD there may be an acute phase, and there is usually a chronic one as well. Rarely, some are recurrent, with intervals of subclinical disease.

Sarcoidosis (Chap. 318), idiopathic pulmonary fibrosis (IPF), and pulmonary fibrosis associated withCTDs(Chaps. 311 to 317) are the most commonILDs of unknown etiology. Among the ILDs of known cause, the largest group comprises occupational and environmental exposures, especially the inhalation of inorganic dusts, organic dusts, and various fumes or gases (Chaps. 253 and254). A clinical diagnosis is possible for many forms of ILD, especially if an occupational and environmental history is aggressively pursued. For other forms, tissue examination, usually obtained by thoracoscopic or open lung biopsy is critical to confirmation of the diagnosis. High-resolution computed tomography (HRCT) scanning promises to improve diagnostic accuracy further as histologic-image correlation is perfected.

PATHOGENESIS

TheILDs are nonmalignant disorders and are not caused by identified infectious agents. The precise pathway(s) leading from injury to fibrosis is not known. Although there are multiple initiating agent(s) of injury, the immunopathogenic responses of lung tissue are limited, and the mechanisms of repair have common features. Two major histopathologic patterns are found in patients with ILD: a granulomatous pattern (Fig. 259-1) and a pattern in which inflammation and fibrosis predominate.

GRANULOMATOUS LUNG DISEASE

This process is characterized by an accumulation of T lymphocytes, macrophages, and epithelioid cells organized into discrete structures (granulomas) in the lung parenchyma. The granulomatous lesions can progress to fibrosis. Many patients with granulomatous lung disease remain free of severe impairment of lung function, or, when symptomatic, they improve after treatment. The main differential diagnosis is between sarcoidosis (Chap. 318) and hypersensitivity pneumonitis (Chap. 253).

INFLAMMATION AND FIBROSIS

The initial insult is an injury to the epithelial surface causing inflammation in the air spaces and alveolar walls. If the disease becomes chronic, inflammation spreads to adjacent portions of the interstitium and vasculature and eventually causes interstitial fibrosis. Other important histopathologic patterns inILDsinclude diffuse alveolar damage (acute or organizing), desquamative interstitial pneumonia, respiratory bronchiolitis, lymphocytic interstitial pneumonia, and an organizing pneumonia [bronchiolitis obliterans with organizing pneumonia (BOOP) pattern]. The development of irreversible scarring (fibrosis) of alveolar walls, airways, or vasculature is the most feared outcome in all of these conditions because it is often progressive and leads to significant derangement of ventilatory function and gas exchange.

INITIAL EVALUATION

Patients withILDscome to medical attention mainly because of the onset of progressive exertional dyspnea or a persistent, nonproductive cough. Hemoptysis, wheezing, and chest pain may be present. Often, the identification of interstitial opacities on chest x-ray focuses the diagnostic approach toward one of the ILDs.

HISTORY

Duration of Illness *Acute presentation* (days to weeks), while unusual, occurs with allergy (drugs, fungi, helminths), acute idiopathic interstitial pneumonia, eosinophilic pneumonia, and hypersensitivity pneumonitis. These conditions may be confused with atypical pneumonias because of diffuse alveolar opacities on chest x-ray. *Subacute presentation* (weeks to months) may occur in all ILDs but is seen especially in sarcoidosis, drug-induced ILDs, the alveolar hemorrhage syndromes, cryptogenic organizing pneumonia (COP), and the acute immunologic pneumonia that complicates systemic lupus erythematosus (SLE) or polymyositis. In most ILDs the symptoms and signs are *chronic* (months to years). Examples includeIPF, sarcoidosis, pulmonary Langerhans cell histiocytosis (PLCH) (also known as Langerhans cell granulomatosis, eosinophilic granuloma, and histiocytosis X), pneumoconioses, andCTDs. *Episodic presentations* are unusual and include eosinophilic pneumonia, hypersensitivity pneumonitis, cryptogenic organizing pneumonia, vasculitides, pulmonary hemorrhage, and Churg-Strauss syndrome.

Age Most patients with sarcoidosis,ILDassociated withCTD, lymphangioleiomyomatosis (LAM),PLCH, inherited forms of ILD (familialIPF, Gaucher's disease, Hermansky-Pudlak syndrome) present between the ages of 20 and 40 years. Most patients with IPF are older than 50 years.

Gender LAM and pulmonary involvement in tuberous sclerosis occur exclusively in premenopausal women. Also,ILD in Hermansky-Pudlak syndrome and in theCTDs is more common in women; an exception is ILD in rheumatoid arthritis, which is more common in men. Because of occupational exposures, pneumoconioses also occur more frequently in men.

Family History Family history is occasionally helpful because familial associations (with

an autosomal dominant pattern) have been identified in tuberous sclerosis and neurofibromatosis. An autosomal recessive pattern of inheritance occurs in Niemann-Pick disease, Gaucher's disease, and the Hermansky-Pudlak syndrome. Familial clustering has been increasingly identified in sarcoidosis and familial pulmonary fibrosis, a process similar toIPF.

Smoking History Patients withPLCH, desquamative interstitial pneumonia (DIP), Goodpasture's syndrome, and respiratory bronchiolitis are almost always current or former smokers. Two-thirds to 75% of patients withIPF have a history of smoking.

Occupation and Environmental History A strict chronological listing of the patient's lifelong employment must be sought, including specific duties and known exposures. In hypersensitivity pneumonitis (Fig. 259-1), respiratory symptoms, fever, chills, and an abnormal chest roentgenogram are often temporally related to a hobby (pigeon breeder's disease) or to the workplace (Farmer's lung) (Chap. 253). Symptoms may diminish or disappear after the patient leaves the site of exposure for several days; similarly, symptoms may reappear on returning to the exposure site.

Other Important Past History Parasitic infections may cause pulmonary eosinophilia, and therefore a travel history should be taken in patients with known or suspectedILD. History of risk factors for HIV infection should be elicited from all patients with ILD because several processes may occur at the time of initial presentation or during the clinical course, e.g., HIV infection,BOOP, acute interstitial pneumonia, lymphocytic interstitial pneumonitis, or diffuse alveolar hemorrhage.

RESPIRATORY SYMPTOMS AND SIGNS

Dyspnea is a common and prominent complaint in patients withILD, especially the idiopathic interstitial pneumonias, hypersensitivity pneumonitis,COP, sarcoidosis, eosinophilic pneumonias, andPLCH. Some patients, especially patients with sarcoidosis, silicosis, PLCH, hypersensitivity pneumonitis, lipoid pneumonia, or lymphangitis carcinomatosis may have extensive parenchymal lung disease on chest x-ray without significant dyspnea, especially early in the course of the illness. Wheezing is an uncommon manifestation of ILD but has been described in patients with chronic eosinophilic pneumonia, Churg-Strauss syndrome, respiratory bronchiolitis, and sarcoidosis. Clinically significant chest pain is uncommon in most ILDs. However, substernal discomfort is common in sarcoidosis. Sudden worsening of dyspnea, especially if associated with acute chest pain, may indicate a spontaneous pneumothorax, which occurs in PLCH, tuberous sclerosis,LAM, and neurofibromatosis. Frank hemoptysis and blood-streaked sputum are rarely presenting manifestations of ILD but can be seen in the diffuse alveolar hemorrhage syndromes (DAHs), LAM, tuberous sclerosis, and the granulomatous vasculitides. Fatigue and weight loss are common in all ILDs.

PHYSICAL EXAMINATION

The findings are usually not specific. Most commonly, physical examination reveals tachypnea, and bibasilar end-inspiratory dry crackles, which are common in most forms ofILDassociated with inflammation but are less likely to be heard in the granulomatous

lung diseases. Crackles may be present in the absence of radiographic abnormalities on the chest radiograph. Scattered late inspiratory high-pitched rhonchi -- so-called inspiratory squeaks -- are heard in patients with bronchiolitis. The cardiac examination is usually normal except in the mid or late stages of the disease when findings of pulmonary hypertension and cor pulmonale may become evident (Chap. 237). Cyanosis and clubbing of the digits occurs in some patients with advanced disease.

LABORATORY

Antinuclear antibodies, anti-immunoglobulin antibodies (rheumatoid factors), and circulating immune complexes are identified in some patients, even in the absence of a definedCTD. A raised LDH is a nonspecific finding common to ILDs. Elevation of the serum angiotensin-converting enzyme level is common in sarcoidosis. Serum precipitins confirm exposure when hypersensitivity pneumonitis is suspected, although they are not diagnostic of the process. Antineutrophil cytoplasmic or anti-basement membrane antibodies are useful if vasculitis is suspected. The electrocardiogram is usually normal unless pulmonary hypertension is present; then it demonstrates right-axis deviation or right ventricular hypertrophy. Echocardiography also reveals right ventricular dilatation and/or hypertrophy in the presence of pulmonary hypertension.

CHEST IMAGING STUDIES

Chest X-ray ILD may be first suspected on the basis of an abnormal chest radiograph, which most commonly reveals a bibasilar reticular pattern. A nodular or mixed pattern of alveolar filling and increased reticular markings may also be present (seeFig. 249-1). A subgroup of ILDs exhibit nodular opacities with a predilection for the upper lung zones [sarcoidosis,PLCH, chronic hypersensitivity pneumonitis, silicosis, berylliosis, rheumatoid arthritis (necrobiotic nodular form), ankylosing spondylitis]. The chest x-ray correlates poorly with the clinical or histopathologic stage of the disease. The radiographic finding of honeycombing correlates with pathologic findings of small cystic spaces and progressive fibrosis; when present, it portends a poor prognosis. In most cases, the chest radiograph is nonspecific and usually does not allow a specific diagnosis.

Computed Tomography HRCT is superior to the plain chest x-ray for early detection and confirmation of suspectedILD. Also, HRCT allows better assessment of the extent and distribution of disease, and it is especially useful in the investigation of patients with a normal chest radiograph. Coexisting disease is often best recognized on HRCT scanning, e.g., mediastinal adenopathy, carcinoma, or emphysema. In the appropriate clinical setting HRCT may be sufficiently characteristic to preclude the need for lung biopsy inIPF, sarcoidosis, hypersensitivity pneumonitis, asbestosis, lymphangitic carcinoma, andPLCH. When a lung biopsy is required, HRCT scanning is useful for determining the most appropriate area from which biopsy samples should be taken.

Radionuclide Scanning Gallium-67 lung scanning is of limited value in evaluating the inflammatory component ofILD. An accelerated clearance from the lung of soluble aerosolized hydrophilic radionuclides such as^{99m}Tc-diethylenetriamene pentaacetate (DTPA) is an index of pulmonary epithelial permeability that results from inflammation. This test may provide a means of assessing the activity of ILD. Normal^{99m}Tc-DTPA

clearance inIPFpredicts stable disease, while rapid clearance identifies patients at risk for deterioration.

PULMONARY FUNCTION TESTING

Spirometry and Lung Volumes Measurement of lung function is important in assessing the extent of pulmonary involvement in patients withILD. Most forms of ILD produce a restrictive defect with reduced total lung capacity (TLC), functional residual capacity, and residual volume (Chap. 250). Forced expiratory volume in one second (FEV_1) and forced vital capacity (FVC) are reduced, but these changes are related to the decreased TLC. The FEV_1/FVC ratio is usually normal or increased. Reductions in lung volumes increase as lung stiffness worsens with disease progression. A few disorders (uncommon in sarcoidosis and hypersensitivity pneumonitis, while common in tuberous sclerosis and LAM) produce interstitial opacities on chest x-ray and obstructive airflow limitation on lung function testing.

Diffusing Capacity A reduction in the diffusing capacity of the lung for carbon monoxide D_{LCO} is a common but nonspecific finding in mostILDs. This decrease is due, in part, to effacement of the alveolar capillary units but, more importantly, to mismatching of ventilation and perfusion (/). Lung regions with reduced compliance due to either fibrosis or cellular infiltration may be poorly ventilated but may still maintain adequate blood flow and / in these regions act like true venous admixture. The severity of the reduction in D_{LCO}does not correlate with disease stage.

Arterial Blood Gas The resting arterial blood gas may be normal or reveal hypoxemia (secondary to a mismatching of ventilation to perfusion) and respiratory alkalosis. A normal arterial O_2tension (or saturation by oximetry) at rest does not rule out significant hypoxemia during exercise or sleep. CO_2retention is rare and is usually a manifestation of end-stage disease.

Cardiopulmonary Exercise Testing Because hypoxemia at rest is not always present and because severe exercise-induced hypoxemia may go undetected, it is useful to perform exercise testing with measurement of arterial blood gases to detect abnormalities of gas exchange. Arterial oxygen desaturation, a failure to decrease dead space appropriately with exercise [i.e., a high V_D/V_Tratio (Chap. 250)], and an excessive increase in respiratory rate with a lower-than-expected recruitment of tidal volume provide useful information about physiologic abnormalities and extent of disease. Serial assessment of resting and exercise gas exchange is an excellent method for following disease activity and responsiveness to treatment, especially in patients withIPF.

FIBEROPTIC BRONCHOSCOPY AND BRONCHOALVEOLAR LAVAGE (BAL)

In selected diseases (e.g., sarcoidosis, hypersensitivity pneumonitis,DAHs, cancer, pulmonary alveolar proteinosis), cellular analysis of BAL fluid may be useful in narrowing the differential diagnostic possibilities among various types ofILD. The role for BAL in defining the stage of disease and assessment of disease progression or response to therapy remains poorly understood, and the usefulness of BAL in the clinical assessment and management remains to be established.

TISSUE AND CELLULAR EXAMINATION

Lung biopsy is the most effective method for confirming the diagnosis and assessing disease activity. The findings may identify a more treatable process than originally suspected, particularly chronic hypersensitivity pneumonitis,COP, respiratory bronchiolitis-associatedILD, or sarcoidosis. Biopsy should be obtained before initiation of treatment. A definitive diagnosis avoids confusion and anxiety later in the clinical course if the patient does not respond to therapy or suffers serious side effects from it.

Fiberoptic bronchoscopy with multiple transbronchial lung biopsies (4 to 8 biopsy samples) is often the initial procedure of choice, especially when sarcoidosis, lymphangitic carcinomatosis, eosinophilic pneumonia, Goodpasture's syndrome, or infection are suspected. If a specific diagnosis is not made by transbronchial biopsy, then surgical lung biopsy by video-assisted thoracic surgery or open thoracotomy is indicated. Adequate-sized biopsies from multiple sites, usually from two lobes, should be obtained. Relative contraindications to lung biopsy include serious cardiovascular disease, "honeycombing" and other roentgenographic evidence of diffuse end-stage disease, severe pulmonary dysfunction, or other major operative risks, especially in the elderly.

TREATMENT

Although the course ofILD is variable, progression is common and often insidious. All treatable possibilities should be carefully considered. Since therapy does not reverse fibrosis, the major goals of treatment are permanent removal of the offending agent when known and early identification and aggressive suppression of the acute and chronic inflammatory process, thereby reducing further lung damage.

Hypoxemia (PaO_2<55 mmHg) at rest and/or with exercise should be managed by supplemental oxygen. If cor pulmonale develops, diuretic therapy and phlebotomy may occasionally be required (Chap. 237).

Drug Therapy Glucocorticoids are the mainstay of therapy for suppression of the alveolitis present inILD, but the success rate is low. There have been no placebo-controlled trials of glucocorticoids in ILD, so there is no direct evidence that steroids improve survival in many of the diseases for which they are commonly used. Glucocorticoid therapy is recommended for symptomatic ILD patients with idiopathic interstitial pneumonias, eosinophilic pneumonias,COP,CTD, sarcoidosis, acute inorganic dust exposures, acute radiation pneumonitis,DAH, and drug-induced ILD. In organic dust disease, glucocorticoids are recommended for both the acute and chronic stages.

The optimal dose and proper length of therapy with glucocorticoids in the treatment of mostILDs is not known. A common starting dose is prednisone, 0.5 to 1 mg/kg in a once-daily oral dose (based on the patient's lean body weight). This dose is continued for 4 to 12 weeks, at which time the patient is reevaluated. If the patient is stable or improved, the dose is tapered to 0.25 to 0.5 mg/kg and is maintained at this level for an additional 4 to 12 weeks depending on the course. Rapid tapering or a shortened course of glucocorticoid treatment can result in recurrence. If the patient's condition

continues to decline while on glucocorticoids, a second agent (see below) is often added and the prednisone dose is lowered to or maintained at 0.25 mg/kg per day.

Cyclophosphamide and azathioprine (1 to 2 mg/kg lean body weight per day) with or without glucocorticoids, have been tried with variable success inIPF, vasculitis, and otherILDs. An objective response usually requires at least 8 to 12 weeks to occur. In situations in which these drugs have failed or could not be tolerated, other agents, including methotrexate, colchicine, penicillamine, and cyclosporine, have been tried. However, their role in the treatment of ILDs remains to be determined.

Many cases ofILD are chronic and irreversible despite the therapy discussed above, and lung transplantation may then be considered (Chap. 267).

INDIVIDUAL FORMS OF ILD

IDIOPATHIC PULMONARY FIBROSIS

Several risk factors appear to be associated with the development ofIPF, a commonILD of unknown etiology. These include cigarette smoking; exposure to antidepressants; a history of chronic aspiration secondary to gastroesophageal reflux; and exposures to metal dust, wood dust, and solvents. Numerous viruses have been implicated in the pathogenesis of IPF, but no clear evidence for a viral etiology has been confirmed. The most compelling evidence for participation of genetic factors is the description fo familial cases of pulmonary fibrosis, which is transmitted as an autosomal dominant trait with variable penetrance. An association has been reported between IPF and a, antitrypsin inhibition (Pi) alleles on chromosome 14.

Clinical Manifestations Exertional dyspnea, a nonproductive cough, and inspiratory crackles with or without digital clubbing may be present on physical examination. The chest roentgenogram andHRCTtypically show patchy, predominantly peripheral, subpleural, reticular opacities in the lower lung zones. There may also be a ground-glass opacity usually associated with traction bronchiectasis and bronchiolectasis or subpleural honeycombing. Pulmonary function tests often reveal a restrictive pattern, a reduced D_{LCO}, and arterial hypoxemia that is exaggerated or elicited by exercise.

Histologic Findings Confirmation of the presence of the usual interstitial pneumonia (UIP) pattern on histologic examination is essential to confirm this diagnosis (Fig. 259-2). Transbronchial biopsies are not helpful in making the diagnosis of UIP, and surgical biopsy is usually required. The histologic hallmark and chief diagnostic criterion of UIP is a heterogeneous appearance at low magnification with alternating areas of normal lung, interstitial inflammation, fibrosis, and honeycomb changes. The latter are composed of cystic fibrotic air spaces that are frequently lined by bronchiolar epithelium and filled with mucin. Smooth muscle hyperplasia is commonly present in areas of fibrosis and honeycomb change. Biopsies taken from patients during an accelerated phase of their illness may show a combination of UIP and diffuse alveolar damage. These histologic abnormalities affect the peripheral, subpleural parenchyma most severely. The interstitial inflammation is usually patchy and consists of a lymphoplasmacytic infiltrate in the alveolar septa, associated with hyperplasia of type 2

pneumocytes. The fibrotic zones are composed mainly of dense collagen, although scattered foci of proliferating fibroblasts are a consistent finding. The extent of fibroblastic proliferation is predictive of disease progression. A UIP-like pattern can also be seen withCTDs, pneumoconioses (e.g., asbestosis), radiation injury, certain drug-induced lung diseases (e.g., nitrofurantoin), and chronic aspiration. Also, a fibrotic pattern may be found in the chronic stage of several specific disorders such as sarcoidosis, chronic hypersensitivity pneumonitis, organized chronic eosinophilic pneumonia, andPLCH. Since other histopathologic features are frequently present in these syndromes, the term UIP is used for those patients in whom the lesion is idiopathic and not associated with another condition.

TREATMENT

The clinical course is variable with a 5-year survival rate of 30 to 50% after diagnosis. Treatment options include glucocorticoids, cytotoxic agents (e.g., azathioprine, cyclophosphamide), and antifibrotic agents (e.g., colchicine, perfenidone, or interferon gamma-1b), alone or in combination with glucocorticoids. However, there is no firm evidence that any of these treatment approaches improves survival or the quality of life. Because of the poor prognosis in untreated patients, a therapeutic trial may be tried. If therapy is recommended, it should be started at the first identification of clinical or physiologic evidence of impairment of lung function. Lung transplantation should be considered for those patients who experience progressive deterioration despite optimal medical management and who meet the established criteria (Chap. 267).

DESQUAMATIVE INTERSTITIAL PNEUMONIA

DIPis a rare but distinct clinical and pathologic entity found exclusively in cigarette smokers. The histologic hallmark is the extensive accumulation of macrophages in intraalveolar spaces with minimal interstitial fibrosis. The peak incidence is in the fourth and fifth decades. Most patients present with dyspnea. Lung function testing shows a restrictive pattern with reduced DL_{CO} and arterial hypoxemia. The chest x-ray usually shows diffuse hazy opacities. Clinical recognition of DIP is important because the process is associated with a better prognosis (10-year survival rate is ~70%) and a better response to smoking cessation and systemic glucocorticoids than the more commonIPF. Respiratory bronchiolitis-associatedILD is considered to be a subset of DIP and is characterized by the accumulation of macrophages in peribronchical alveoli.

ACUTE INTERSTITIAL PNEUMONIA (AIP) (HAMMAN-RICH SYNDROME)

This is a rare, fulminant form of lung injury characterized by diffuse alveolar damage on lung biopsy. Most patients are older than 40 years. AIP is similar in presentation to the acute respiratory distress syndrome (ARDS) (Chap. 265) and probably corresponds to the subset of cases of idiopathic ARDS. The onset is usually abrupt in a previously healthy individual. A prodromal illness, usually lasting 7 to 14 days before presentation, is common. Fever, cough, and dyspnea are frequent manifestations at presentation. Diffuse, bilateral, air-space opacification is present on chest radiograph. HRCT scans show bilateral, patchy, symmetric areas of ground-glass attenuation. Bilateral areas of air-space consolidation may also be present. A predominantly subpleural distribution may be seen. The diagnosis of AIP requires the presence of a clinical syndrome of

idiopathic ARDS and pathologic confirmation of organizing diffuse alveolar damage. Therefore, lung biopsy is required to confirm the diagnosis. Most patients have moderate to severe hypoxemia and develop respiratory failure. Mechanical ventilation is often required. The mortality rate is high (>60%), with most patients dying within 6 months of presentation. Recurrences have been reported. However, those who recover often have substantial improvement in lung function. The main treatment is supportive. It is not clear that glucocorticoid therapy is effective.

NONSPECIFIC INTERSTITIAL PNEUMONIA (NSIP)

This condition defines a subgroup of the idiopathic interstitial pneumonias that can be distinguished clinically and pathologically fromUIP,DIP,AIP, and idiopathicBOOP. Lung biopsy shows varying proportions of chronic interstitial inflammation and fibrosis. NSIP is a subacute restrictive process that usually occurs at a younger age than UIP. It is often associated with a febrile illness, relative lack of clubbing, andHRCTfindings that show ground-glass opacities and areas of consolidation. Unlike patients withIPF, most patients with NSIP have a good prognosis, and most show improvement after treatment with glucocorticoids.

ILDASSOCIATED WITH CONNECTIVE TISSUE DISORDERS

Clinical findings suggestive of aCTD(musculoskeletal pain, weakness, fatigue, fever, joint pains or swelling, photosensitivity, Raynaud's phenomenon, pleuritis, dry eyes, dry mouth) should be sought in any patient withILD. The CTDs may be difficult to rule out since the pulmonary manifestations occasionally precede the more typical systemic manifestations by months or years. The most common form of pulmonary involvement is a chronic interstitial pattern similar to that in patients withIPF. However, determining the precise nature of lung involvement in most of the CTDs is difficult due to the high incidence of lung involvement caused by disease-associated complications of esophageal dysfunction (predisposing to aspiration and secondary infections), respiratory muscle weakness (atelectasis and secondary infections), complications of therapy (opportunistic infections), and associated malignancies.

Progressive Systemic Sclerosis (PSS) (See alsoChap. 313) Clinical evidence ofILD is present in about one-half of patients with progressive systemic sclerosis, and pathologic evidence in three-quarters. Pulmonary function tests show a restrictive pattern and impaired diffusing capacity, often before any clinical or radiographic evidence of lung disease appears. Pulmonary vascular disease alone or in association with pulmonary fibrosis, pleuritis, or recurrent aspiration pneumonitis is strikingly resistant to current modes of therapy.

Rheumatoid Arthritis (RA) (See alsoChap. 312) ILDassociated with rheumatoid arthritis is more common in men. Pulmonary manifestations of rheumatoid arthritis include pleurisy with or without effusion, ILD in up to 20% of cases, necrobiotic nodules (nonpneumoconiotic intrapulmonary rheumatoid nodules) with or without cavities, Caplan's syndrome (rheumatoid pneumoconiosis), pulmonary hypertension secondary to rheumatoid pulmonary vasculitis,BOOP, and upper airway obstruction due to arytenoid arthritis.

Systemic Lupus Erythematosus (See also Chap. 311) Lung disease is a common complication inSLE. Pleuritis with or without effusion is the most common pulmonary manifestation. Other lung manifestations include the following: atelectasis, diaphragmatic dysfunction with loss of lung volumes, pulmonary vascular disease, pulmonary hemorrhage, uremic pulmonary edema, infectious pneumonia, andBOOP. Acute lupus pneumonitis characterized by pulmonary capillaritis leading to alveolar hemorrhage is common. Chronic, progressiveILD is uncommon. It is important to exclude pulmonary infection. Although pleuropulmonary involvement may not be evident clinically, pulmonary function testing, particularly D_{LCO}reveals abnormalities in many patients with SLE.

Polymyositis and Dermatomyositis (PM/DM) (See also Chap. 382) ILDoccurs in ~10% of patients with polymyositis and dermatomyositis, and the clinical features are similar to those ofIPF. Diffuse reticular or nodular opacities with or without an alveolar component occur radiographically, with a predilection for the lung bases. ILD occurs more commonly in the subgroup of patients with an anti-Jo-1 antibody that is directed to histidyl tRNA synthetase. Weakness of respiratory muscles contributing to aspiration pneumonia may be present. A rapidly progressive illness characterized by diffuse alveolar damage may cause respiratory failure.

Sjogren's Syndrome (See alsoChap. 314) General dryness and lack of airways secretion cause the major problems of hoarseness, cough, and bronchitis. Lymphocytic interstitial pneumonitis, lymphoma, pseudolymphoma, bronchiolitis, and bronchiolitis obliterans are associated with this condition. Lung biopsy is frequently required to establish a precise pulmonary diagnosis. Glucocorticoids have been used in the management ofILDassociated with Sjogren's syndrome with some degree of clinical success.

DRUG-INDUCED ILD (See alsoChap. 71)

Many classes of drugs have the potential to induce diffuseILD, which is manifest most commonly as exertional dyspnea and nonproductive cough. A detailed history of the medications taken by the patient is needed to identify drug-induced disease, including over-the-counter medications, oily nose drops, or petroleum products (mineral oil). In most cases, the pathogenesis is unknown, although a combination of direct toxic effects of the drug (or its metabolite) and indirect inflammatory and immunologic events is likely. The onset of the illness may be abrupt and fulminant, or it may be insidious, extending over weeks to months. The drug may have been taken for several years before a reaction develops (e.g., amiodarone), or the lung disease may occur weeks to years after the drug has been discontinued (e.g., carmustine). The extent and severity of disease are usually dose related. Treatment consists of discontinuation of any possible offending drug and supportive care.

CRYPTOGENIC ORGANIZING PNEUMONIA (COP)

Also known as idiopathicBOOP,COP is a clinicopathologic syndrome of unknown etiology. The onset is usually in the fifth and sixth decades. The presentation may be of a flu-like illness with cough, fever, malaise, fatigue, and weight loss. Inspiratory crackles are frequently present on examination. Pulmonary function is usually impaired, with a

restrictive defect and arterial hypoxemia being most common. The roentgenographic manifestations are distinctive, revealing bilateral, patchy, or diffuse alveolar opacities in the presence of normal lung volume. Recurrent and migratory pulmonary opacities are common.HRCTshows areas of air-space consolidation, ground-glass opacities, small nodular opacities and bronchial wall thickening and dilation. These changes occur more frequently in the periphery of the lung and in the lower lung zone. Lung biopsy shows granulation tissue within small airways, alveolar ducts, and airspaces, with chronic inflammation in the surrounding alveoli. Glucocorticoid therapy induces clinical recovery in two-thirds of patients. A few patients have rapidly progressive courses with fatal outcomes despite glucocorticoids.

Foci of organizing pneumonia (i.e., a "BOOPpattern") is a nonspecific reaction to lung injury found adjacent to other pathologic processes or as a component of other primary pulmonary disorders (e.g., cryptococcosis, Wegener's granulomatosis, lymphoma, hypersensitivity pneumonitis, and eosinophilic pneumonia). Consequently, the clinician must carefully reevaluate any patient found to have this histopathologic lesion to rule out these possibilities.

EOSINOPHILIC PNEUMONIA See Chap. 253

PULMONARY ALVEOLAR PROTEINOSIS

Although not strictly anILD, pulmonary alveolar proteinosis (PAP) resembles and is therefore considered with these conditions. It has been proposed that a defect in macrophage function, more specifically an impaired ability to process surfactant, may play a role in the pathogenesis of PAP. This diffuse disease is characterized by the accumulation of an amorphous, periodic acid-Schiff-positive lipoproteinaceous material in the distal air spaces. There is little or no lung inflammation, and the underlying lung architecture is preserved. Mutant mice lacking the gene for granulocyte-macrophage colony stimulating factor (GM-CSF) have a similar accumulation of surfactant and surfactant apoprotein in the alveolar spaces. Moreover, reconstitution of the respiratory epithelium of GM-CSF knockout mice with the GM-CSF gene completely corrects the alveolar proteinosis. Data from BAL studies in patients suggest that PAP is an autoimmune disease with neutralizing antibody of immunoglobulin G isotype against GM-CSF. These findings suggest that neutralization of GM-CSF bioactivity by the antibody causes dysfunction of alveolar macrophages, which results in reduced surfactant clearance.

The typical age of presentation is 30 to 50 years, and males predominate. The clinical presentation is usually insidious and manifested by progressive exertional dyspnea, fatigue, weight loss, and low-grade fever. A nonproductive cough is common, but occasionally expectoration of "chunky" gelatinous material may occur. Polycythemia, hypergammaglobulinemia, and increased LDH levels are frequent. Markedly elevated serum levels of lung surfactant proteins A and D have been found in PAP. Radiographically, bilateral symmetrical alveolar opacities located centrally in mid and lower lung zones result in a "bat-wing" distribution.HRCTshows a ground-glass opacification and thickened intralobular structures and interlobular septa. Whole lung lavage(s) through a double-lumen endotracheal tube provides relief to many patients with dyspnea or progressive hypoxemia and also may provide long-term benefit.

PULMONARY LYMPHANGIOLEIOMYOMATOSIS

PulmonaryLAM is a rare condition that afflicts premenopausal women and should be suspected in young women with emphysema, recurrent pneumothorax, or chylous pleural effusion. It is often misdiagnosed as asthma or chronic obstructive pulmonary disease. Pathologically, LAM is characterized by the proliferation of atypical pulmonary interstitial smooth muscle and cyst formation. The immature-appearing smooth-muscle cells react with monoclonal antibody HMB45, which recognizes a 100-kDa glycoprotein (gp100) originally found in human melanoma cells. Caucasians are affected much more commonly than members of other racial groups. The disease accelerates during pregnancy and abates after oopherectomy. Common complaints at presentation are dyspnea, cough, and chest pain. Hemoptysis may be life threatening. Spontaneous pneumothorax occurs in 50% of patients; it may be bilateral and necessitate pleurodesis. Chylothorax, chyloperitonium (chylous ascites), chyluria, and chylopericardium are other complications. Pulmonary function testing usually reveals an obstructive or mixed obstructive-restrictive pattern, and gas exchange is often abnormal.HRCTshows thin-walled cysts surrounded by normal lung without zonal predominance. Progression is common, with a median survival of 8 to 10 years from diagnosis. Oophorectomy, progesterone (10 mg/d), and, more recently, tamoxifen and luteinizing hormone-releasing hormone analogs have been used. Lung transplantation offers the only hope for cure despite reports of recurrent disease in the transplanted lung.

SYNDROMES OF ILD WITH DIFFUSE ALVEOLAR HEMORRHAGE

Injury to arterioles, venules, and the alveolar septal (alveolar wall or interstitial) capillaries can result in hemoptysis secondary to disruption of the alveolar-capillary basement membrane. This results in bleeding into the alveolar spaces, which characterizesDAH. Pulmonary capillaritis, characterized by a neutrophilic infiltration of the alveolar septae, may lead to necrosis of these structures, loss of capillary structural integrity, and the pouring of red blood cells into the alveolar space. Fibrinoid necrosis of the interstitium and red blood cells within the interstitial space are sometimes seen. Bland pulmonary hemorrhage (i.e., DAH without inflammation of the alveolar structures) may also occur.

The clinical onset is often abrupt, with cough, fever, and dyspnea. Severe respiratory distress requiring ventilatory support may be evident at initial presentation. Although hemoptysis is expected, it can be absent at the time of presentation in one-third of the cases. For patients without hemoptysis, new alveolar opacities, a falling hemoglobin level, and hemorrhagicBALfluid point to the diagnosis. The chest radiograph is nonspecific and most commonly shows new patchy or diffuse alveolar opacities. Recurrent episodes ofDAH may lead to pulmonary fibrosis, resulting in interstitial opacities on the chest radiograph. An elevated white blood cell count and falling hematocrit are frequent. Evidence for impaired renal function caused by focal segmental necrotizing glomerulonephritis, usually with crescent formation, may also be present.

Varying degrees of hypoxemia may occur and often are severe enough to require ventilatory support. TheD_{LCO}may be increased, resulting from the increased hemoglobin

within the alveoli compartment. Evaluation of either lung or renal tissue by immunofluorescent techniques indicates an absence of immune complexes (pauci-immune) in Wegener's granulomatosis, microscopic polyangiitis pauci-immune glomerulonephritis, and isolated pulmonary capillaritis. A granular pattern is found in theCTDs, particularlySLE, and a characteristic linear deposition is found in Goodpasture's syndrome. Granular deposition of IgA-containing immune complexes are present in Henoch-Schonlein purpura.

The mainstay of therapy for theDAHassociated with systemic vasculitis,CTD, Goodpasture's syndrome, and isolated pulmonary capillaritis is intravenous methylprenisolone, 0.5 to 2.0 g daily in divided doses for up to 5 days, followed by a gradual tapering, and then maintenance on an oral preparation. Prompt initiation of therapy is important, particularly in the face of renal insufficiency, since early initiation of therapy has the best chance of preserving renal function. The decision to start other immunosuppressive therapy (cyclophosphamide or azathioprine) acutely depends on the severity of illness.

Goodpasture's Syndrome Pulmonary hemorrhage and glomerulonephritis are features in most patients with this disease (Chap. 275). Autoantibodies to renal glomerular and lung alveolar basement membranes are present. This syndrome can present and recur asDAHwithout an associated glomerulonephritis. In such case, circulating anti-basement membrane antibody is often absent, and the only way to establish the diagnosis is by demonstrating linear immunofluorescence in lung tissue. The underlying histology may be bland hemorrhage or DAH associated with capillaritis. Plasmapheresis has been recommended as adjunctive treatment.

Idiopathic Pulmonary Hemosiderosis This condition is a diagnosis of exclusion. Only 20% of reported cases occur in adults. In children, the condition is associated with celiac disease, and elevated IgA levels are found in 50% of patients. These associations are lacking in most adults. A lung biopsy is usually necessary to document the lack of inflammatory injury in the lung tissues and to exclude other diseases with confidence.

INHERITED DISORDERS ASSOCIATED WITH ILD

Pulmonary opacities and respiratory symptoms typical ofILD can develop in related family members and in several inherited diseases. These include the phakomatoses, tuberous sclerosis and neurofibromatosis (Chap. 370), and the lysosomal storage diseases, Niemann-Pick disease and Gaucher's disease (Chap. 349). The Hermansky-Pudlak syndrome (Chap. 116) is an autosomal recessive disorder in which granulomatous colitis and ILD may occur. It is characterized by oculocutaneous albinism, bleeding diathesis secondary to platelet dysfunction, and the accumulation of a chromolipid, lipofuscin material in cells of the reticuloendothelial system. The pulmonary fibrosis is similar toIPF, but the alveolar macrophages may contain cytoplasmic ceroid-like inclusions.

ILD WITH A GRANULOMATOUS RESPONSE IN LUNG TISSUE OR VASCULAR STRUCTURES

Inhalation of organic dusts, which cause hypersensitivity pneumonitis, or of inorganic

dust, such as silica, which elicits a granulomatous inflammatory reaction leading toILD, produces diseases of known etiology (Table 259-1) that are discussed inChaps. 253 and254. Sarcoidosis (Chap. 318) is prominent among granulomatous diseases of unknown cause in which ILD is an important feature.

Pulmonary Langerhans Cell Histiocytosis (PLCH, Pulmonary Histiocytosis X, Langerhans Cell Granulomatosis, or Eosinophilic Granuloma PLCH is a rare, smoking-related, diffuse lung disease that primarily affects men between the ages of 20 and 40 years. The clinical presentation varies from an asymptomatic state to a rapidly progressive condition. The most common clinical manifestations at presentation are cough, dyspnea, chest pain, weight loss, and fever. Pneumothorax occurs in about 25% of patients. Hemoptysis and diabetes insipidus are rare manifestations. The radiographic features vary with the stage of the disease. The combination of ill-defined or stellate nodules (2 to 10 mm in diameter), reticular or nodular opacities, bizarre-shaped upper zone cysts, preservation of lung volume, and sparing of the costophrenic angles are characteristics of PLCH.HRCTthat reveals a combination of nodules and thin-walled cysts is virtually diagnostic of PLCH. The most frequent pulmonary function abnormality is a markedly reducedD_{LCO}, although varying degrees of restrictive disease, airflow limitation, and diminished exercise capacity may occur. Discontinuance of smoking is the key treatment, resulting in clinical improvement in one-third of patients. Most patients with PLCH suffer persistent or progressive disease. Death due to respiratory failure occurs in ~10% of patients.

Granulomatous Vasculitides (See also Chap. 317) The granulomatous vasculitides are characterized by pulmonary angiitis (i.e., inflammation and necrosis of blood vessels) with associated granuloma formation (i.e., infiltrates of lymphocytes, plasma cells, epithelioid cells, or histiocytes, with or without the presence of multinucleated giant cells, sometimes with tissue necrosis). The lungs are almost always involved, although any organ system may be affected. Wegener's granulomatosis and allergic angiitis and granulomatosis (Churg-Strauss syndrome) primarily affect the lung but are associated with a systemic vasculitis as well. The granulomatous vasculitides generally limited to the lung include necrotizing sarcoid granulomatosis and benign lymphocytic angiitis and granulomatosis. Granulomatous infection and pulmonary angiitis due to irritating embolic material (e.g., talc) are important known causes of pulmonary vasculitis.

LYMPHOCYTIC INFILTRATIVE DISORDERS

This group of disorders features lymphocyte and plasma cell infiltration of the lung parenchyma. The disorders either are benign or can behave as low-grade lymphomas. Included are angioimmunoblastic lymphadenopathy with dysproteinemia, a rare lymphoproliferative disorder characterized by diffuse lymphadenopathy, fever, hepatosplenomegaly, and hemolytic anemia, withILD in some cases.

Lymphocytic Interstitial Pneumonitis This rare form ofILDoccurs in adults, some of whom have an autoimmune disease or dysproteinemia. It has been reported in patients with Sjogren's syndrome and HIV infection.

Lymphomatoid Granulomatosis This multisystem disorder of unknown etiology is an angiocentric malignant (T cell) lymphoma characterized by a polymorphic lymphoid

infiltrate, an angiitis, and granulomatosis. Although it may affect virtually any organ, it is most frequently characterized by pulmonary, skin, and central nervous system involvement.

BRONCHOCENTRIC GRANULOMATOSIS

Rather than a specific clinical entity, bronchocentric granulomatosis (BG) is a descriptive histologic term that describes an uncommon and nonspecific pathologic response to a variety of airway injuries. There is evidence that BG is caused by a hypersensitivity reaction to *Aspergillus* or other fungi in patients with asthma. About half of the patients described have chronic asthma with severe wheezing and peripheral blood eosinophilia. In patients with asthma, BG probably represents one pathologic manifestation of allergic bronchopulmonary aspergillosis, or another allergic mycosis. In patients without asthma, BG has been associated with rheumatoid arthritis and a variety of infections, including tuberculosis, echinococcosis, histoplasmosis, coccidiodomycosis, and nocardiosis. The chest roentgenogram reveals irregularly shaped nodular or mass lesions with ill-defined margins, which are usually unilateral and solitary, with an upper-lobe predominance. Glucocorticoids are the treatment of choice, often with excellent outcome, although recurrences may occur as therapy is tapered or stopped.

(Bibliography omitted in Palm version)

260. PRIMARY PULMONARY HYPERTENSION - *Stuart Rich*

Primary pulmonary hypertension is an uncommon disease characterized by increased pulmonary artery pressure and pulmonary vascular resistance. The incidence has been estimated at approximately 2 cases per million. There is a female-to-male preponderance (1.7:1), with patients most commonly presenting in the third and fourth decades, although the age range is from infancy to greater than 60 years. Because the predominant symptom of primary pulmonary hypertension is dyspnea, which can have an insidious onset in an otherwise healthy person, the disease is typically diagnosed late in its course. By that time, the clinical and laboratory findings of severe pulmonary hypertension are usually present.

PATHOLOGY

The histopathology of primary pulmonary hypertension is not pathognomonic for the disease but represents a pulmonary arteriopathy that is observed in pulmonary hypertension from a variety of causes. A wide spectrum of vascular abnormalities involving the endothelium, smooth muscle cells, and extracellular matrix is present. Heterogeneity with respect to these abnormalities is often seen from patient to patient, and within patients. The most common features noted are medial hypertrophy, concentric and eccentric intimal fibrosis, recanalized thrombi appearing as fibrous webs, and plexiform lesions. In most patients, varying degrees of these abnormalities can be found. Rare variant forms of primary pulmonary hypertension also exist.

Pulmonary venoocclusive disease is a rare and distinct pathologic entity, found in fewer than 10% of patients with primary pulmonary hypertension. Histologically, it is manifest by widespread intimal proliferation and fibrosis of the intrapulmonary veins and venules, occasionally extending to the arteriolar bed. The pulmonary venous obstruction explains the increased pulmonary capillary wedge pressure observed in patients with advanced disease. These patients may develop orthopnea that can mimic left ventricular failure.

Pulmonary capillary hemangiomatosis is also a very rare form of primary pulmonary hypertension. Histologically, it is characterized by infiltrating thin-walled blood vessels that are widespread throughout the pulmonary interstitium and walls of the pulmonary arteries and veins. These patients often have hemoptysis as a clinical feature.

ETIOLOGY

It is likely that there are several pathobiologic processes that result in pulmonary hypertension as a final common pathway. These include inhibition of the voltage-regulated (Kv) potassium channel producing vasoconstriction secondary to contraction of the pulmonary artery smooth muscle cells, an imbalance in vasocontricting and vasodilating mediators that are involved in the control of pulmonary vascular tone (including prostacyclin and thromboxane), reduced expression of nitric oxide synthase in the endothelium of the pulmonary arterial bed, inflammation, thrombosis in situ of the pulmonary vascular bed from a procoagulant state, and persistent matrix protein synthesis in the pulmonary arteries. The types of abnormalities that occur are likely influenced by the patient's genotype and exposure to risk factors that serve to trigger these processes. Risk factors that have been linked to the

development of pulmonary hypertension include anorexigens, collagen vascular diseases, congenital systemic to pulmonary shunts, portal hypertension, and HIV infection.

Recently, a marked increase in the incidence of primary pulmonary hypertension occurred in Europe and the United States as a result of the widespread use of the fenfluramine appetite suppressants. The clinical and pathologic features of these cases were identical to patients with primary pulmonary hypertension who were unexposed. Atlhough very limited exposure to the fenfluramines can cause primary pulmonary hypertension, the risk increased dramatically with prolonged use. Like the experience with aminorex, an anorexigen that produced a similar epidemic in the 1960s, the incidence of primary pulmonary hypertension fell when the drugs were withdrawn from the market. The mechanism by which these agents produce pulmonary hypertension is unknown.

GENETIC CONSIDERATIONS

The locus of a gene linked to familial primary pulmonary hypertension has been identified on chromosome 2q31-32. Familial primary pulmonary hypertension occurs in approximately 6 to 12% of cases and is characterized by autosomal dominant inheritance, variable age of onset, and incomplete penetrance. The clinical and pathologic features of familial and sporadic primary pulmonary hypertension are virtually identical. Genetic anticipation, which relates to offspring of subsequent generations manifesting the disease at younger ages or with greater severity, is also a feature. Trinucleotide repeat expansion, originally described in several neurologic disorders, remains the only biologic explanation for genetic anticipation and raises the possibility that the pathogenesis of familial primary pulmonary hypertension may have a neurologic basis. Patients who present with sporadic disease probably possess a genetic predisposition that becomes expressed following exposure to an external trigger or risk factor.

PATHOPHYSIOLOGY

The underlying hemodynamic derangement in primary pulmonary hypertension is an increased resistance to pulmonary blood flow. Early in the disease there is a marked elevation in pulmonary artery pressure with relatively normal cardiac function. Over time the cardiac output becomes progressively reduced rather than the pulmonary artery pressure becoming progressively increased. Initially, the pulmonary arteries may respond to vasodilators, but as the disease progresses, the elevated pulmonary vascular resistance becomes fixed. The pulmonary capillary wedge pressure remains normal until the late stages, when it tends to rise in response to impaired diastolic filling of the left ventricle due to the altered configuration of the intraventricular septum. Eventually, as the right ventricle fails, the right atrial and right ventricular end-diastolic pressures rise in an attempt to compensate for the myocardial depression that has developed in response to chronic severe right ventricular pressure overload.

Pulmonary function is usually normal in primary pulmonary hypertension, although a mild restrictive pattern (Chap. 250) is sometimes seen. Hypoxemia is common and is believed to be due to a mismatch between pulmonary ventilation and perfusion,

magnified by a low cardiac output. Occasional patients with a patent foramen ovale may develop right-to-left shunting, which can also contribute to systemic arterial desaturation.

DIAGNOSIS

Primary pulmonary hypertension refers to pulmonary arterial hypertension wihtout an identifiable risk factor. Clinically, primary pulmonary arterial hypertension should be distinguished from pulmonary venous hypertension, pulmonary hypertension associated with disorders of the respiratory system and/or hypoxema, and pulmonary hypertension due to chronic thrombotic and/or embolic disease (Chap. 261).

A thorough diagnostic evaluation to look for all potential causes should be undertaken (Fig. 260-1). The history usually reveals the gradual onset of shortness of breath with effort, progressing until the patient is dyspneic with minimal activity. The average duration from symptom onset until diagnosis is 2.5 years. Other common symptoms are fatigue, angina pectoris that likely represents right ventricular ischemia, syncope, near syncope, and peripheral edema.

The physical examination is characteristic. Increased jugular venous pressure, a reduced carotid pulse, and an easily palpable right ventricular lift are typical. Most patients have an increased pulmonic component of the second heart sound and right-sided third and fourth heart sounds. Tricuspid regurgitation is a clinical feature of right ventricular failure. Peripheral cyanosis and/or edema tend to occur in later stages of the disease. Clubbing is not a feature.

The chest x-ray generally shows enlarged central pulmonary arteries and clear lung fields. The electrocardiogram usually reveals right axis deviation and right ventricular hypertrophy. The echocardiogram demonstrates right ventricular enlargement, a reduction in left ventricular cavity size, and abnormal septal configuration consistent with right ventricular pressure overload. Doppler studies have revealed a marked dependence on atrial systole for ventricular filling. Hypoxemia, hypocapnia, and an abnormal diffusing capacity for carbon monoxide are almost invariable findings. A mild restrictive pattern on pulmonary function is sometimes observed, but evidence of airways obstruction suggests a secondary etiology for the pulmonary hypertension. The presence of significant restrictive changes on pulmonary function testing (Chap. 250) should prompt a high-resolution computed tomographic scan to look for interstitial lung disease, which may otherwise not be obvious. A perfusion lung scan may be normal or abnormal with multiple diffuse patchy filling defects of a nonsegmental nature and not suggestive of pulmonary thromboembolism. If the lung scan reveals perfusion defects of a segmental or subsegmental nature, a pulmonary angiogram must be done. Severe pulmonary hypertension in a patient with a high-probability lung scan should suggest a chronic process and *not* acute pulmonary embolism, since the nonconditioned right ventricle is unable to generate high systolic pressures acutely in the face of pulmonary thromboembolism. Chronic thromboembolic obstruction of the large pulmonary arteries (Chap. 261) can mimic primary pulmonary hypertension but can be amenable to treatment with surgical thromboendarterectomy.

There is risk in performing pulmonary angiography in patients with primary pulmonary

hypertension, and it is recommended that selective or subselective injections with small amounts of low-osmolar, nonionic contrast material be made following the pretreatment with 1 mg atropine to prevent vagally mediated bradycardia.

Cardiac catheterization is mandatory to characterize the disease and exclude an underlying cardiac shunt as the cause. The use of balloon-flotation catheters, especially those with removable guidewires, can facilitate right heart catheterization. A right-to-left shunt might be attributable to a patent foramen ovale, but any left-to-right shunting implies the presence of a congenital defect. Although it may be difficult to obtain, the pulmonary capillary wedge pressure is normal. If it is increased, left heart catheterization should also be performed to exclude mitral stenosis or increased left ventricular end-diastolic pressures as the cause of the pulmonary hypertension. Although the diagnostic evaluation of these patients can be hazardous, experience from a national multicenter study revealed no mortality or serious morbidity in more than 300 patients whose evaluation included pulmonary angiography and cardiac catheterization. It is not necessary to perform an open lung biopsy in these patients to make an accurate diagnosis. Laboratory tests should also be performed, including antinuclear antibody and HIV testing.

On occasion, a patient may have marked elevations in pulmonary artery pressure in association with mild obstructive or interstitial lung disease, essential hypertension, ischemic heart disease, or valvular heart disease. Although it may appear that the pulmonary hypertension is out of proportion to the underlying associated condition, it likely represents a pulmonary vasoconstrictive response to the associated condition, which is serving as a trigger of pulmonary arterial hypertension. Thus severe pulmonary hypertension can coexist with mild chronic obstructive pulmonary disease, small intracardiac shunts, mild mitral stenosis, and even ischemic heart disease. The distinction is important because the treatment of pulmonary hypertension should always include treating the underlying associated cause.

NATURAL HISTORY

The natural history of primary pulmonary hypertension is unknown because initially the disease is largely asymptomatic. Several older series have reported a mean survival of 2 to 3 years for patients from the time of diagnosis. Functional class is a strong predictor of survival, since patients who are New York Heart Association functional classes II and III have a mean survival of 3.5 years compared with those who are functional class IV, in whom the mean survival is 6 months. The cause of death is usually right ventricular failure or sudden death; sudden death appears to be a late feature of the disease. Increased right atrial pressure above 15 mmHg and reduced cardiac index below 2 (L/min)/$m^2$are hemodynamic predictors of a poor prognosis.

TREATMENT

Because the pulmonary vascular resistance increases dramatically with exercise, patients should be cautioned against participating in activities that demand increased physical stress. Digoxin may increase cardiac output and lower circulating levels of norepinephrine. Diuretic therapy relieves dyspnea and peripheral edema and may be useful in reducing right ventricular volume overload in the presence of tricuspid

regurgitation.

It is recommended that all patients in whom primary pulmonary hypertension is confirmed undergo acute drug testing with short-acting pulmonary vasodilators to determine the extent of pulmonary vasodilator reserve or reactivity (Fig. 260-2). Intravenous adenosine, inhaled nitric oxide, and intravenous prostacyclin all appear to have similar effects in reducing pulmonary vascular resistance acutely with little effect on the systemic vascular bed. Adenosine is given as a constant infusion in doses of 50 (ug/kg)/min and increased every 2 min until side effects develop. Similarly, prostacyclin is given in doses of 2 (ng/kg)/min and increased every 30 min until side effects develop. Maximal physiologic effectiveness of the therapy is determined at the highest tolerated dose. Nitric oxide is generally administered via inhalation in 5 to 10 parts per million and increased every few minutes until no further effectiveness is obtained.

Calcium Channel Antagonists Patients who have substantial reductions in pulmonary vascular resistance from the short-acting vasodilators may be candidates to receive oral calcium channel blockers. These drugs should be administered under direct hemodynamic guidance in order to determine effectiveness and safety. Typically, patients will require high doses (e.g., nifedipine, 120 to 240 mg/d, or diltiazem, 540 to 900 mg/d).*

*These agents have not been approved for the treatment of primary pulmonary hypertension by the U.S. Food and Drug Administration.

Patients who manifest significant reductions in mean pulmonary artery pressure and pulmonary vascular resistance should demonstrate improved symptoms, regression of right ventricular hypertrophy, and improved survival with chronic therapy. However, fewer than half the patients who are responsive to the short-acting vasodilators will respond to this regimen. It is unknown whether the response to calcium blockers depends on the histologic subtype, but the therapy appears to be more successful in patients who are diagnosed early and have less advanced disease.

Prostacyclin This agent has been approved as a treatment of primary pulmonary hypertension for patients who are functional class III or IV and unresponsive to conventional therapy. Clinical trials have demonstrated that patients realize an improvement in symptoms and exercise tolerance and reduction in mortality, even if no acute hemodynamic response to drug challenge occurs. The drug can only be administered intravenously and requires placement of a permanent central venous catheter and continuous dose titration, as tolerance develops in all patients over a short period of time. The optimal dose has not been determined. Patients may deteriorate clinically from too much or too little drug. The side effects of prostacyclin, which include flushing, jaw pain, and diarrhea, are generally tolerated by most patients. The major problems with this therapy have been infections related to the venous catheter, which requires close monitoring and diligence on behalf of the patient. Recent data suggest that prostacyclin, in addition to its vasodilator and antithrombotic properties, may lead to reversal of the vascular remodeling that occurs in primary pulmonary hypertension. Long-term use of prostacyclin has been associated with adverse effects such as severe thrombocytopenia and severe foot pain, which can be disabling. The basis for these conditions is unknown. Because of the complexity involved in managing patients on

prostacyclin, it has been recommended that they be referred to centers with expertise in managing primary pulmonary hypertension for initiation of therapy.

Adverse Effects The administration of vasodilators can have serious acute and chronic adverse effects. The most common response is a reduction in pulmonary vascular resistance, manifest by an increased cardiac output, without a reduction in the mean pulmonary artery pressure. This results in increased stroke work of the right ventricle, which can result in worsening of ventricular function and precipitate right ventricular failure over time. In addition, maintenance of adequate systemic blood pressure is crucial, since right ventricular coronary blood flow is already compromised due to the loss of the normal gradient for myocardial perfusion between the aorta and right ventricle. Vasodilator drugs can provoke acute right ventricular ischemia, and deaths have been reported. For these reasons, the pharmacologic evaluation of primary pulmonary hypertension should always be undertaken with direct monitoring of systemic and pulmonary arterial pressures and cardiac output.

Anticoagulant therapy has also been advocated based on the evidence that thrombosis in situ is common. One retrospective study and one prospective study have demonstrated that the anticoagulant warfarin increases the survival of patients with primary pulmonary hypertension, and thus consideration for its use should be given to all patients. The dose of warfarin is generally titrated to achieve an increase in INR of 2.0 to 2.5 of control. Anticoagulants should not be expected to cause regression of the disease and result in any substantial change in symptoms.

Transplantation Because of the dramatic effects that prostacyclin has had in stabilizing the clinical course of patients with advanced disease, transplantation should be considered for patients on prostacyclin who develop or continue to manifest right heart failure. Acceptable results have been achieved with heart-lung, bilateral lung, and single lung transplant (Chap. 267). The availability of donor organs often influences the choice of procedure. The operation is best reserved for patients who are in the advanced stages of the disease in spite of medical therapy, or in whom medical therapy is not tolerated. Recurrence of disease has not been reported in any patient with primary pulmonary hypertension who has undergone single lung or heart-lung transplantation.

261. PULMONARY THROMBOEMBOLISM - *Samuel Z. Goldhaber*

GENETIC CONSIDERATIONS

Rudolf Virchow postulated more than a century ago that three potentially overlapping factors predisposed to venous thrombosis: (1) local trauma to the vessel wall; (2) hypercoagulability; and (3) stasis. We now believe that many patients who suffer pulmonary thromboembolism (PTE) have an underlying inherited predisposition that remains clinically silent until an acquired stressor occurs such as surgery, obesity, or pregnancy (Table 261-1). When PTE is identified, a detailed family history for venous thromboembolism should be obtained.

Factor V Leiden The most frequent inherited predisposition to hypercoagulability is resistance to the endogenous anticoagulant protein, activated protein C. The phenotype of activated protein C resistance is associated with a single point mutation, designated *factor V Leiden*, in the factor V gene. This missense mutation -- a single nucleotide substitution of adenine for guanine 1691 -- causes an amino acid substitution of glutamine for arginine at position 506.

The prevalence of the heterozygous state was about 6% in healthy American male physicians participating in the Physicians' Health Study and was three times higher among those physicians who subsequently developed venous thrombosis. Furthermore, after anticoagulation (for at least 3 months) was completed and discontinued, those participants with factor V Leiden had a much higher rate of recurrent venous thrombosis than those without. A single-point mutation in the 3¢untranslated region of the prothrombin gene (G-to-A transition at nucleotide position 20210) appears to be associated with increased levels of prothrombin (factor II), the precursor of thrombin. In the Physicians' Health Study, the prevalence of the prothrombin gene mutation among control subjects was 3.9%. The G20210A mutation conferred an approximate doubling of the risk of venous thrombosis. Nevertheless, factor V Leiden is more common than all other (identified) inherited hypercoagulable states, including the prothrombin gene mutation, deficiencies in protein C, protein S, antithrombin III, and disorders of plasminogen (Chap. 117).

PATHOPHYSIOLOGY

EMBOLIZATION

When venous thrombi become dislodged from their site of formation, they embolize to the pulmonary arterial circulation or, paradoxically, to the arterial circulation through a patent foramen ovale or atrial septal defect. About half of patients with pelvic vein thrombosis or proximal leg deep venous thrombosis (DVT) havePTE, which is usually asymptomatic. Isolated calf vein or upper extremity venous thromboses also pose a risk (albeit lower) of PTE. Isolated calf vein thrombi are the most common source of paradoxical embolism.

PHYSIOLOGY

Pulmonary embolism can have the following effects:

1. *Increased pulmonary vascular resistance* due to vascular obstruction or neurohumoral agents including serotonin

2. *Impaired gas exchange* due to increased alveolar dead space from vascular obstruction and hypoxemia from alveolar hypoventilation in the nonobstructed lung, right-to-left shunting, and impaired carbon monoxide transfer due to loss of gas exchange surface

3. *Alveolar hyperventilation* due to reflex stimulation of irritant receptors

4. *Increased airway resistance* due to bronchoconstriction

5. *Decreased pulmonary compliance* due to lung edema, lung hemorrhage, or loss of surfactant

Right Ventricular Dysfunction Progressive right heart failure is the usual cause of death fromPTE. In the International Cooperative Pulmonary Embolism Registry (ICOPER), the presence of right ventricular dysfunction on baseline echocardiography of PTE patients was associated with a doubling of the 3-month mortality rate. As pulmonary vascular resistance increases, right ventricular wall tension rises and perpetuates further right ventricular dilatation and dysfunction. Consequently, the interventricular septum bulges into and compresses an intrinsically normal left ventricle. Increased right ventricular wall tension also compresses the right coronary artery and may precipitate myocardial ischemia and right ventricular infarction. Underfilling of the left ventricle may lead to a fall in left ventricular output and systemic arterial pressure, thereby provoking myocardial ischemia due to compromised coronary artery perfusion. Eventually, circulatory collapse and death may ensue.

DIAGNOSIS

The clinical setting can be immensely helpful in suggesting the diagnosis ofPTE. Patients with prior venous thromboembolism are at increased risk of recurrence (Table 261-1).

CLINICAL SYNDROMES

Patients with *massivePTE*present with systemic arterial hypotension and usually have anatomically widespread thromboembolism. Primary therapy with thrombolysis or embolectomy offers the greatest chance of survival. Those with *moderate to large PTE* have right ventricular hypokinesis on echocardiography but normal systemic arterial pressure. Optimal management is controversial; such patients may benefit from primary therapy to prevent recurrent embolism. Patients with *small to moderate PTE* have both normal right heart function and normal systemic arterial pressure. They have a good prognosis with either adequate anticoagulation or an inferior vena caval filter. The presence of *pulmonary infarction* usually indicates a small PTE, but one that is exquisitely painful, because it lodges near the innervation of pleural nerves.

Nonthrombotic pulmonary embolism may be easily overlooked. Possible etiologies

include fat embolism after blunt trauma and long bone fractures, tumor embolism, or air embolism. Intravenous drug users may inject themselves with a wide array of substances, such as hair, talc, or cotton. *Amniotic fluid embolism* occurs when fetal membranes leak or tear at the placental margin. The pulmonary edema seen in this syndrome is probably due primarily to alveolar capillary leakage.

SYMPTOMS AND SIGNS

Dyspnea is the most frequent symptom of PTE, and tachypnea is its most frequent sign. Whereas dyspnea, syncope, hypotension, or cyanosis indicate a massive PTE, pleuritic pain, cough, or hemoptysis often suggest a small embolism located distally near the pleura. On *physical examination*, young and previously healthy individuals may simply appear anxious but otherwise seem deceptively well, even with an anatomically large PTE. They need not have "classic" signs such as tachycardia, low-grade fever, neck vein distention, or an accentuated pulmonic component of the second heart sound. Sometimes, a paradoxical bradycardia occurs.

In older patients who complain of vague chest discomfort, the diagnosis ofPTE may not be apparent unless signs of right heart failure are present. Unfortunately, because acute coronary ischemic syndromes are so common, one may overlook the possibility of life-threatening PTE and may inadvertently discharge these patients from the hospital after the exclusion of myocardial infarction with serial cardiac enzyme measurements and electrocardiograms.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis ofPTE is broad (Table 261-2). Although PTE is known as "the great masquerader," quite often another illness simulates PTE. For example, when the proposed diagnosis of PTE is supposedly confirmed with a combination of dyspnea, chest pain, and an abnormal lung scan, the correct diagnosis of pneumonia might become apparent 12 h later when an infiltrate blossoms on chest x-ray, purulent sputum is first produced, and high fever and shaking chills develop.

Some patients havePTE and a coexisting illness such as pneumonia or heart failure. In such circumstances, clinical improvement will often fail to occur despite standard medical treatment of the concomitant illness. This situation can serve as a clinical clue to the possible coexistence of PTE.

NONIMAGING DIAGNOSTIC MODALITIES

These are generally safer, less expensive, but also less specific than diagnostic modalities that employ imaging.

Blood Tests The quantitative *plasma D*-dimer *enzyme-linked immunosorbent assay (ELISA)* level is elevated (>500 ng/mL) in more than 90% of patients withPTE, reflecting plasmin's breakdown of fibrin and indicating endogenous (though clinically ineffective) thrombolysis. A qualitative latex agglutination D-dimer assay, which is more readily available and less expensive than an ELISA, can be obtained initially; if elevated, the ELISA will also be elevated. However, if the latex agglutination is normal, a D-dimer

ELISA should be obtained, because the ELISA is much more sensitive than the latex agglutination D-dimer assay, which cannot be used to exclude PTE. The plasma D-dimer ELISA has a high negative predictive value and can be used to help exclude PTE. However, neither D-dimer assay is specific. Levels increase in patients with myocardial infarction, sepsis, or almost any systemic illness.

Data from the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) indicate that, contrary to classic teaching, *arterial blood gases* lack diagnostic utility forPTE. Among patients suspected of PTE, neither the room air arterial P_{O2} nor calculation of the alveolar-arterial oxygen gradient can reliably differentiate or triage patients who actually have PTE at angiography.

Electrocardiogram Classic abnormalities include sinus tachycardia; new-onset atrial fibrillation or flutter; and an S wave in lead I, a Q wave in lead III, and an inverted T wave in lead III (Chap. 226). Often, the QRS axis is greater than 90°. T-wave inversion in leads V_1 to V_4reflects right ventricular strain.

NONINVASIVE IMAGING MODALITIES

Chest Roentgenography A normal or near-normal chest x-ray in a dyspneic patient suggestsPTE. Well-established abnormalities include focal oligemia (Westermark's sign), a peripheral wedged-shaped density above the diaphragm (Hampton's hump), or an enlarged right descending pulmonary artery (Palla's sign).

Venous Ultrasonography ConfirmedDVT is usually an adequate surrogate forPTE. Ultrasonography of the deep venous system relies upon loss of vein compressibility as the primary criterion for DVT. About one-third of patients with PTE have no imaging evidence of DVT. In these situations, the clot may have already embolized to the lung or is in the pelvic veins, where ultrasonography is usually inadequate. Therefore, the workup for PTE should continue if there is high clinical suspicion, despite a normal ultrasound examination.

Lung Scanning (See alsoChap. 251) Lung scanning is the principal imaging test for the diagnosis ofPTE. Small particulate aggregates of albumin labeled with a gamma-emitting radionuclide are injected intravenously and are trapped in the pulmonary capillary bed. A perfusion scan defect indicates absent or decreased blood flow, possibly due to PTE. Ventilation scans, obtained with radiolabeled inhaled gases such as xenon or krypton, improve the specificity of the perfusion scan. Abnormal ventilation scans indicate abnormal nonventilated lung, thereby providing possible explanations for perfusion defects other than acute PTE. A high probability scan for PTE is defined as having two or more segmental perfusion defects in the presence of normal ventilation (Fig. 261-1).

Lung scanning is particularly useful if the results are normal or near-normal, or if there is a high probability forPTE. The diagnosis of PTE is very unlikely in patients with normal and near-normal scans but, in contrast, is about 90% certain in patients with high-probability scans. Unfortunately, fewer than half of patients with angiographically confirmed PTE have a high-probability scan. Importantly, as many as 40% of patients with high clinical suspicion for PTE and "low-probability" scans do, in fact, have PTE at

angiography.

Chest CT Computed tomography (CT) of the chest with intravenous contrast effectively diagnoses large, centralPTE but may fail to detect more peripherally located thrombi that are clinically important. In a comparison with standard contrast pulmonary angiography at Massachusetts General Hospital, the sensitivity of chest CT for PTE was only 60%.

Echocardiography This technique is useful for rapid triage of acutely ill patients who may havePTE. Bedside echocardiography can usually reliably differentiate among illnesses that have radically different treatment, including acute myocardial infarction, pericardial tamponade, dissection of the aorta, and PTE complicated by right heart failure. Detection of right ventricular dysfunction due to PTE helps to stratify the risk, delineate the prognosis, and plan optimal management.

INVASIVE DIAGNOSTIC MODALITIES

Pulmonary Angiography Selective pulmonary angiography is the most specific examination available for establishing the definitive diagnosis ofPTE and can detect emboli as small as 1 to 2 mm. A definitive diagnosis of PTE depends upon visualization of an intraluminal filling defect in more than one projection. Secondary signs of PTE include abrupt occlusion ("cut-off") of vessels; segmental oligemia or avascularity; a prolonged arterial phase with slow filling; or tortuous, tapering peripheral vessels.

Pulmonary angiography can be carried out safely among properly selected patients at hospitals that perform at least several studies per month. InPIOPED, the procedure resulted in death in five patients (0.5%), two of whom had severe heart failure prior to the procedure. Angiography is most useful when the clinical likelihood ofPTEdiffers substantially from the lung scan result or when the lung scan is of intermediate probability for PTE.

Contrast Phlebography This technique has been mostly replaced by ultrasonography. Venography is costly, uncomfortable, and occasionally results in contrast allergy or contrast-induced phlebitis. Contrast phlebography is worthwhile when there is a discrepancy between the clinical suspicion and the ultrasound result. Phlebography is also useful for diagnosing isolated calf vein thrombosis or recurrentDVT. A recently approved nuclear medicine test utilizing a synthetic peptide that binds preferentially to the glycoprotein IIb/IIIa receptors on activated platelets may eventually replace contrast phlebography in clinical practice. This radiopharmaceutical permits scintigraphic imaging of acute DVT and may be especially useful for differentiating acute from chronic DVT.

INTEGRATED DIAGNOSTIC APPROACH

We advocate an integrated diagnostic approach to streamline the workup ofPTE(Fig. 261-2). This strategy combines the clinical likelihood of PTE with the results of noninvasive testing especially D-dimerELISA, venous ultrasonography, and lung scanning to determine whether pulmonary angiography is warranted.

TREATMENT

ConsensusGuidelinesfrom the American College of Chest Physicians are summarized as follows.

Primary versus Secondary Therapy Primary therapy consists of clot dissolution with thrombolysis or removal ofPTE by embolectomy. Anticoagulation with heparin and warfarin or placement of an inferior vena caval filter constitutes secondary prevention of recurrent PTE rather than primary therapy.

Primary therapy should be reserved for patients at high risk of an adverse clinical outcome. When right ventricular function remains normal, patients typically have good clinical outcomes with anticoagulation alone (Fig. 261-3).

Adjunctive Therapy Important adjunctive measures include pain relief (especially with nonsteroidal anti-inflammatory agents), supplemental oxygenation, and psychological support. Dobutamine -- ab-adrenergic agonist with positive inotropic and pulmonary vasolidating effects -- may successfully treat right heart failure and cardiogenic shock. Volume loading should be undertaken cautiously because increased right ventricular dilatation can lead to even further reductions in left ventricular forward output.

Heparin Heparin binds to and accelerates the activity of antithrombin III, an enzyme that inhibits the coagulation factors thrombin (factor IIa), Xa, IXa, XIa, and XIIa. Heparin thus prevents additional thrombus formation and permits endogenous fibrinolytic mechanisms to lyse clot that has already formed. After 5 to 7 days of heparin, residual thrombus begins to stabilize in the endothelium of the vein or pulmonary artery. However, heparin does *not* directly dissolve thrombus that already exists.

Low-Molecular-Weight Heparins These fragments of unfractionated heparin exhibit less binding to plasma proteins and endothelial cells and consequently have greater bioavailability, a more predictable dose response, and a longer half-life than unfractionated heparin. No laboratory monitoring or dose adjustment is needed unless the patient is markedly obese or has renal insufficiency. Therefore, low-molecular-weight heparins are far more convenient to use than unfractionated heparin.

A meta-analysis of more than 3,500 acuteDVTpatients showed that those treated with low-molecular-weight heparin had an overall 29% reduction in mortality and major bleeding compared with the unfractionated heparin group. *Enoxaparin*, originally approved for prophylaxis, has recently received Food and Drug Administration approval for treatment ofPTE in the presence of DVT with a once-daily dose of 1.5 mg/kg subcutaneously. However, it is almost always administered as 1 mg/kg twice daily. *Dalteparin* is approved for prophylaxis but not for treatment of venous thromboembolism.

Dosing For unfractionated heparin, a typical bolus is 5000 to 10,000 units followed by a continuous infusion of 1000 to 1500 units/h. An activated partial thromboplastin time that is at least twice the control value should provide a therapeutic level of heparin. Nomograms based upon a patient's weight may assist in adjusting the infusion rate of heparin.

Complications The most important adverse effect of heparin is hemorrhage. For life-threatening or intracranial hemorrhage, protamine sulfate can be administered. Heparin-associated thrombocytopenia and osteopenia are far less common with low-molecular-weight heparins than with unfractionated heparin. Heparin-associated elevations in transaminase levels occur commonly but are rarely associated with clinical toxicity.

Warfarin This vitamin K antagonist prevents g carboxylation activation of coagulation factors II, VII, IX, and X. The full effect of warfarin often requires 5 days, even if the prothrombin time, used for monitoring, becomes elevated more rapidly. When warfarin is initiated during an active thrombotic state, the levels of protein C and S decline, thus creating a thrombogenic potential. By overlapping heparin and warfarin for 5 days, the procoagulant effect of unopposed warfarin can be counteracted. Thus, heparin acts as a "bridge" until the full anticoagulant effect of warfarin is obtained.

Dosing In an average-sized adult, warfarin is usually initiated in a dose of 5 mg. Doses of 7.5 or 10 mg can be used in obese or large framed young patients who are otherwise healthy. Patients who are malnourished or who have received prolonged courses of antibiotics are probably deficient in vitamin K and should receive smaller initial doses of warfarin, such as 2.5 mg. The prothrombin time is standardized by using the International Normalized Ratio (INR) to assess the anticoagulant effect of warfarin (Chap. 118). The target INR should be approximately 2.5-3.0.

Complications As with heparin, bleeding is the most important and common complication associated with warfarin administration. Life-threatening bleeding can be treated with cryoprecipitate or fresh frozen plasma (usually 2 units) to achieve immediate hemostasis. For less serious bleeding, or an excessively highINR in the absence of bleeding, vitamin K may be administered. An initial dose of 5 to 10 mg subcutaneously will help lower the INR toward the upper portion of the therapeutic range within about 6 h. Reversing excessive INRs with oral rather than subcutaneous vitamin K will facilitate re-establishing a stable dose of warfarin.

Warfarin-induced skin necrosis is a rare complication that may be related to warfarin-induced reduction of protein C. It is usually associated with administration of a high initial dose of warfarin during an acute thrombotic state in which heparin is withheld. During pregnancy, warfarin should be avoided if possible because of warfarin embryopathy, which is most common with exposure during the sixth through twelfth weeks of gestation. However, women can take warfarin postpartum and breast feed safely.

Duration of Anticoagulation After discontinuation of anticoagulation, the risk of recurrentPTE is surprisingly high. Nevertheless, the optimal duration of anticoagulation remains unknown. Schulman and colleagues found that after a 6-month course of anticoagulation, 14% of PTE patients suffered a recurrent venous thromboembolism within the ensuing 2 years. The recurrence rate was twice as high among patients who received only 6 weeks of anticoagulation. It is reasonable to anticoagulate the first episode of PTE for at least 6 months.

Inferior Vena Caval Filters When anticoagulation cannot be undertaken because of active bleeding, insertion of an inferior vena caval filter is usually necessary. Other indications include recurrent venous thrombosis despite adequate anticoagulation, prevention of recurrentPTE in patients with right heart failure who are not candidates for thrombolysis, or prophylaxis of extremely high risk patients. The Bird's Nest filter infrarenally or, if necessary, a Greenfield filter suprarenally are recommended.

Thrombolysis Thrombolytic therapy may rapidly reverse right heart failure and thus lead to a lower rate of death and recurrentPTE. Thrombolysis usually achieves the following: (1) dissolves much of the anatomically obstructing pulmonary arterial thrombus; (2) prevents the continued release of serotonin and other neurohumoral factors that might otherwise exacerbate pulmonary hypertension; and (3) dissolves much of the source of the thrombus in the pelvic or deep leg veins, thereby decreasing the likelihood of recurrent PTE.

The preferred thrombolytic regimen is 100 mg of recombinant tissue plasminogen activator administered as a continuous peripheral intravenous infusion over 2 h. Patients appear to respond to thrombolysis for up to 14 days after thePTEoccurred.

Contraindications to thrombolysis include intracranial disease, recent surgery, or trauma. There is about a 1% risk of intracranial hemorrhage. Careful screening of patients for contraindications to thrombolysis is the best way to minimize bleeding risk.

Pulmonary Thromboendarterectomy Patients who develop chronic pulmonary hypertension due to priorPTE may become severely dyspneic at rest or with minimal exertion. They should be considered for pulmonary thromboendarterectomy which, if successful, can markedly reduce and at times even cure pulmonary hypertension.

Prevention Prevention ofPTE is of paramount importance because it is both difficult to recognize and expensive to treat. Fortunately, effective mechanical and pharmacologic prophylaxis modalities are widely available and usually effective (Table 261-3).

262. DISORDERS OF THE PLEURA, MEDIASTINUM, AND DIAPHRAGM - *Richard W. Light*

DISORDERS OF THE PLEURA

PLEURAL EFFUSION

The pleural space lies between the lung and chest wall and normally contains a very thin layer of fluid, which serves as a coupling system. A pleural effusion is present when there is an excess quantity of fluid in the pleural space.

Etiology Pleural fluid accumulates when pleural fluid formation exceeds pleural fluid absorption. Normally, fluid enters the pleural space from the capillaries in the parietal pleura and is removed via the lymphatics situated in the parietal pleura. Fluid also can enter the pleural space from the interstitial spaces of the lung via the visceral pleura or from the peritoneal cavity via small holes in the diaphragm. The lymphatics have the capacity to absorb 20 times more fluid than is normally formed. Accordingly, a pleural effusion may develop when there is excess pleural fluid formation (from the parietal pleura, the interstitial spaces of the lung, or the peritoneal cavity) or when there is decreased fluid removal by the lymphatics.

Diagnostic Approach When a patient is found to have a pleural effusion, an effort should be made to determine the cause (Fig. 262-1). The first step is to determine whether the effusion is a transudate or an exudate. A *transudative* pleural effusion occurs when *systemic factors* that influence the formation and absorption of pleural fluid are altered. The leading causes of transudative pleural effusions in the United States are left ventricular failure, pulmonary embolism, and cirrhosis. An *exudative* pleural effusion occurs when *local factors* that influence the formation and absorption of pleural fluid are altered. The leading causes of exudative pleural effusions are bacterial pneumonia, malignancy, viral infection, and pulmonary embolism. The primary reason to make this differentiation is that additional diagnostic procedures are indicated with exudative effusions to define the cause of the local disease.

Transudative and exudative pleural effusions are distinguished by measuring the lactate dehydrogenase (LDH) and protein levels in the pleural fluid. Exudative pleural effusions meet at least one of the following criteria, whereas transudative pleural effusions meet none:

1. pleural fluid protein/serum protein>0.5

2. pleural fluid LDH/serum LDH>0.6

3. pleural fluid LDH more than two-thirds normal upper limit for serum

If a patient has an exudative pleural effusion, the following tests on the pleural fluid should be obtained: description of the fluid, glucose level, amylase level, differential cell count, microbiologic studies, and cytology.

Effusion due to Heart Failure The most common cause of pleural effusion is left

ventricular failure. The effusion occurs because the increased amounts of fluid in the lung interstitial spaces exit in part across the visceral pleura. This overwhelms the capacity of the lymphatics in the parietal pleura to remove fluid. A diagnostic thoracentesis should be performed if the effusions are not bilateral and comparable in size, if the patient is febrile, or if the patient has pleuritic chest pain to verify that the patient has a transudative effusion. Otherwise the patient is best treated with diuretics. If the effusion persists despite diuretic therapy, a diagnostic thoracentesis should be performed. Diuretic therapy for a few days does not significantly change the biochemical characteristics of the pleural fluid.

Hepatic Hydrothorax Pleural effusions occur in approximately 5% of patients with cirrhosis and ascites. The predominant mechanism is the direct movement of peritoneal fluid through small holes in the diaphragm into the pleural space. The effusion is usually right-sided and frequently is large enough to produce severe dyspnea. If medical management does not control the ascites and the effusion, the best treatment is a liver transplant. If the patient is not a candidate for this, the best alternative is insertion of a transjugular intrahepatic portal systemic shunt.

Parapneumonic Effusion Parapneumonic effusions are associated with bacterial pneumonia, lung abscess, or bronchiectasis and are probably the most common exudative pleural effusion in the United States. A *complicated parapneumonic effusion* requires tube thoracostomy for its resolution. *Empyema* refers to a grossly purulent effusion.

Patients with aerobic bacterial pneumonia and pleural effusion present with an acute febrile illness consisting of chest pain, sputum production, and leukocytosis. Patients with anaerobic infections present with a subacute illness with weight loss, a brisk leukocytosis, mild anemia, and a history of some factor that predisposes them to aspiration.

The possibility of a parapneumonic effusion should be considered whenever a patient with a bacterial pneumonia is initially evaluated. The presence of free pleural fluid can be demonstrated with a lateral decubitus radiograph. If the free fluid separates the lung from the chest wall by more than 10 mm on the decubitus radiograph, a therapeutic thoracentesis should be performed. Factors indicating the likely need for a procedure more invasive than a thoracentesis (in increasing order of importance) include:

1. loculated pleural fluid

2. pleural fluid pH below 7.20

3. pleural fluid glucose less than 60 mg/dL

4. positive Gram stain or culture of the pleural fluid

5. the presence of gross pus in the pleural space

If the fluid recurs after the initial therapeutic thoracentesis, a repeat thoracentesis should be performed if any of the above characteristics are present. If the fluid recurs a second

time, tube thoracostomy should be performed if any of the poor prognostic factors are present. If the fluid cannot be completely removed with the therapeutic thoracentesis, consideration should be given to inserting a chest tube and instilling a thrombolytic (streptokinase, 250,000 units or urokinase, 100,000 units) or performing thoracoscopy with the breakdown of adhesions. Decortication should be considered when the above are ineffective.

Effusion Secondary to Malignancy Malignant pleural effusions secondary to metastatic disease are the second most common type of exudative pleural effusion. The three tumors that cause approximately 75% of all malignant pleural effusions are lung carcinoma, breast carcinoma, and lymphoma. Most patients complain of dyspnea, which is frequently out of proportion to the size of the effusion. The pleural fluid is an exudate, and its glucose level may be reduced if the tumor burden in the pleural space is high.

The diagnosis is usually made via cytology of the pleural fluid. If the initial cytologic examination is negative, then thoracoscopy is the best next procedure if malignancy is strongly suspected. At the time of thoracoscopy, talc or some similar agent should be instilled into the pleural space to effect a pleurodesis. If thoracoscopy is unavailable, then needle biopsy of the pleura should be performed.

Patients with a malignant pleural effusion are treated symptomatically for the most part, since the presence of the effusion indicates disseminated disease and most malignancies associated with pleural effusion are not curable with chemotherapy. The only symptom that can be attributed to the effusion itself is dyspnea. If the patient's lifestyle is compromised by dyspnea, and if the dyspnea is relieved with a therapeutic thoracentesis, then one of the following procedures should be performed: (1) tube thoracostomy with the instillation of a sclerosing agent such as talc, 5 g in a slurry, or doxycycline, 500 mg; (2) outpatient insertion of a small indwelling catheter; or (3) thoracoscopy with pleural abrasion or the insufflation of talc.

Mesothelioma Malignant mesotheliomas are primary tumors that arise from the mesothelial cells that line the pleural cavities. Most are related to asbestos exposure. Patients with mesothelioma present with chest pain and shortness of breath. The chest radiograph reveals a pleural effusion, generalized pleural thickening, and a shrunken hemithorax. Thoracoscopy or open pleural biopsy is usually necessary to establish the diagnosis. Various treatment modalities, including radical surgery, chemotherapy, and radiation therapy, have been tried, but none has been proven to be more effective than symptomatic therapy. It is recommended that chest pain be treated with opiates and that shortness of breath be treated with oxygen and/or opiates.

Effusion Secondary to Pulmonary Embolization The diagnosis most commonly overlooked in the differential diagnosis of a patient with an undiagnosed pleural effusion is pulmonary embolism. Dyspnea is the most common symptom. The pleural fluid can be either transudative or exudative. The diagnosis is suggested by spiral CT scans, perfusion lung scanning and/or pulmonary arteriography (Chap. 261). Treatment of the patient with a pleural effusion secondary to pulmonary embolism is the same as for any patient with pulmonary emboli. If the pleural effusion increases in size after anticoagulation, the patient probably has recurrent emboli or another complication such as a hemothorax or a pleural infection.

Tuberculous Pleuritis (See also Chap. 169) In many parts of the world, the most common cause of an exudative pleural effusion is tuberculosis, but this is relatively uncommon in the United States. Tuberculous pleural effusions are thought to be due primarily to a hypersensitivity reaction to tuberculous protein in the pleural space. Patients with tuberculous pleuritis present with fever, weight loss, dyspnea, and/or pleuritic chest pain. The pleural fluid is an exudate with predominantly small lymphocytes. The diagnosis is established by demonstrating high levels of TB markers in the pleural fluid (adenosine deaminase > 45 IU/L, gamma interferon> 140 pg/mL, or positive PCR for tuberculous DNA). Alternatively, the diagnosis can be established by culture of the pleural fluid, needle biopsy of the pleura, or thoracoscopy. The recommended treatment of pleural and pulmonary tuberculosis is identical (Chap. 169).

Effusion Secondary to Viral Infection Viral infections are probably responsible for a sizable percentage of undiagnosed exudative pleural effusions. In many series, no diagnosis is established for approximately 20% of exudative effusions, and these effusions resolve spontaneously with no long-term residua. The importance of these effusions is that one should not be too aggressive in trying to establish a diagnosis for the undiagnosed effusion, particularly if the patient is improving clinically.

AIDS Pleural effusions are uncommon in such patients. The most common cause is Kaposi's sarcoma, followed by parapneumonic effusion. Other common causes are tuberculosis, cryptococcosis, and lymphoma. Pleural effusions are very uncommon with *Pneumocystis carinii* infection.

Chylothorax A chylothorax occurs when the thoracic duct is disrupted and chyle accumulates in the pleural space. The most common cause of chylothorax is trauma, but it also may result from tumors in the mediastinum. Patients with chylothorax present with dyspnea, and a large pleural effusion is present on the chest radiograph. Thoracentesis reveals milky fluid, and biochemical analysis reveals a triglyceride level that exceeds 110 mg/dL. Patients with chylothorax and no obvious trauma should have a lymphangiogram and a mediastinal computed tomographic (CT) scan to assess the mediastinum for lymph nodes. The treatment of choice for most chylothoraces is implantation of a pleuroperitoneal shunt. Patients with chylothoraces should not undergo prolonged tube thoracostomy with chest tube drainage because this will lead to malnutrition and immunologic incompetence.

Hemothorax When a diagnostic thoracentesis reveals bloody pleural fluid, a hematocrit should be obtained on the pleural fluid. If the hematocrit is>50% that of the peripheral blood, the patient has a hemothorax. Most hemothoraces are the result of trauma; other causes include rupture of a blood vessel or tumor. Most patients with hemothorax should be treated with tube thoracostomy, which allows continuous quantification of bleeding. If the bleeding emanates from a laceration of the pleura, apposition of the two pleural surfaces is likely to stop the bleeding. If the pleural hemorrhage exceeds 200 mL/h, consideration should be given to thoracotomy.

Miscellaneous Causes of Pleural Effusion There are many other causes of pleural effusion (Table 262-1). Key features of some of these conditions are as follows: If the pleural fluid amylase level is elevated, the diagnosis of esophageal rupture or pancreatic

disease is likely. If the patient is febrile, has predominantly polymorphonuclear cells in the pleural fluid, and has no pulmonary parenchymal abnormalities, an intraabdominal abscess should be considered. The diagnosis of an asbestos pleural effusion is one of exclusion. Benign ovarian tumors can produce ascites and a pleural effusion (Meigs' syndrome), as can the ovarian hyperstimulation syndrome. Several drugs can cause pleural effusion; the associated fluid is usually eosinophilic. Pleural effusions commonly occur following coronary artery bypass surgery. Effusions occurring within the first weeks are typically left-sided and bloody, with large numbers of eosinophils, and respond to one or two therapeutic thoracenteses. Effusions occurring after the first few weeks are typically left-sided and clear yellow, with predominantly small lymphocytes, and tend to recur. Other medical manipulations that induce pleural effusions include abdominal surgery, endoscopic variceal sclerotherapy, radiation therapy, liver or lung transplantation, or the intravascular insertion of central lines.

PNEUMOTHORAX

Pneumothorax is the presence of gas in the pleural space. A *spontaneous pneumothorax* is one that occurs without antecedent trauma to the thorax. A *primary spontaneous pneumothorax* occurs in the absence of underlying lung disease, while a *secondary spontaneous pneumothorax* occurs in its presence. A *traumatic pneumothorax* results from penetrating or nonpenetrating chest injuries. A *tension pneumothorax* is a pneumothorax in which the pressure in the pleural space is positive throughout the respiratory cycle.

Primary Spontaneous Pneumothorax Primary spontaneous pneumothoraces are usually due to rupture of apical pleural blebs, small cystic spaces that lie within or immediately under the visceral pleura. Primary spontaneous pneumothoraces occur almost exclusively in smokers, which suggests that these patients have subclinical lung disease. Approximately one-half of patients with an initial primary spontaneous pneumothorax will have a recurrence. The initial recommended treatment for primary spontaneous pneumothorax is simple aspiration. If the lung does not expand with aspiration, or if the patient has a recurrent pneumothorax, thoracoscopy with stapling of blebs and pleural abrasion is indicated. Thoracoscopy or thoracotomy with pleural abrasion is almost 100% successful in preventing recurrences.

Secondary Spontaneous Pneumothorax Most secondary spontaneous pneumothoraces are due to chronic obstructive pulmonary disease, but pneumothoraces have been reported with virtually every lung disease. Pneumothorax in patients with lung disease is more life-threatening than it is in normal individuals because of the lack of pulmonary reserve in these patients. Nearly all patients with secondary spontaneous pneumothorax should be treated with tube thoracostomy and the instillation of a sclerosing agent such as doxycycline or talc. Patients with secondary spontaneous pneumothoraces who have a persistent air leak, an unexpanded lung after 3 days of tube thoracostomy, or a recurrent pneumothorax should be subjected to thoracoscopy with bleb resection and pleural abrasion.

Traumatic Pneumothorax Traumatic pneumothoraces can result from both penetrating and nonpenetrating chest trauma. Traumatic pneumothoraces should be treated with tube thoracostomy unless they are very small. If a hemopneumothorax is present, one

chest tube should be placed in the superior part of the hemithorax to evacuate the air, and another should be placed in the inferior part of the hemithorax to remove the blood. Iatrogenic pneumothorax is a type of traumatic pneumothorax which is becoming more common. The leading causes are transthoracic needle aspiration, thoracentesis, and the insertion of central intravenous catheters. The treatment differs according to the degree of distress and can be observation, supplemental oxygen, aspiration, or tube thoracostomy.

Tension Pneumothorax This condition usually occurs during mechanical ventilation or resuscitative efforts. The positive pleural pressure is life-threatening both because ventilation is severely compromised and because the positive pressure is transmitted to the mediastinum, which results in decreased venous return to the heart and reduced cardiac output.

Difficulty in ventilation during resuscitation or high peak inspiratory pressures during mechanical ventilation strongly suggest the diagnosis. The diagnosis is made by the finding of an enlarged hemithorax with no breath sounds and shift of the mediastinum to the contralateral side. Tension pneumothorax must be treated as a medical emergency. If the tension in the pleural space is not relieved, the patient is likely to die from inadequate cardiac output or marked hypoxemia. A large-bore needle should be inserted into the pleural space through the second anterior intercostal space. If large amounts of gas escape from the needle after insertion, the diagnosis is confirmed. The needle should be left in place until a thoracostomy tube can be inserted.

DISORDERS OF THE MEDIASTINUM

The mediastinum is the region between the pleural sacs. It is separated into three compartments. The *anterior mediastinum* extends from the sternum anteriorly to the pericardium and brachiocephalic vessels posteriorly. It contains the thymus gland; the anterior mediastinal lymph nodes; and the internal mammary arteries and veins. The *middle mediastinum* lies between the anterior and posterior mediastina and contains the heart; the ascending and transverse arches of the aorta; the venae cavae; the brachiocephalic arteries and veins; the phrenic nerves; the trachea, main bronchi, and their contiguous lymph nodes; and the pulmonary arteries and veins. The *posterior mediastinum* is bounded by the pericardium and trachea anteriorly and the vertebral column posteriorly. It contains the descending thoracic aorta; esophagus; thoracic duct; azygos and hemiazygos veins; and the posterior group of mediastinal lymph nodes.

MEDIASTINAL MASSES

The first step in evaluating a mediastinal mass lesion is to place it in one of the three mediastinal compartments, since each has different characteristic lesions. The most common lesions in the anterior mediastinum are thymomas, lymphomas, teratomatous neoplasms, and thyroid masses. The most common masses in the middle mediastinum are vascular masses, lymph node enlargement from metastases or granulomatous disease, and pleuropericardial and bronchogenic cysts. In the posterior mediastinum, neurogenic tumors, meningoceles, meningomyeloceles, gastroenteric cysts, and esophageal diverticula are commonly found.

CTscanning is the most valuable imaging technique for evaluating mediastinal masses and is the only imaging technique that should be done in most instances. Barium studies of the gastrointestinal tract are indicated in many patients with posterior mediastinal lesions, since hernias, diverticula, and achalasia are readily diagnosed in this manner. An ^{131}I nuclear medicine scan can efficiently establish the diagnosis of intrathoracic goiter.

A definite diagnosis can be obtained with mediastinoscopy or anterior mediastinotomy in many patients with masses in the anterior or middle mediastinal compartments. A diagnosis can be established without thoracotomy via percutaneous fine-needle aspiration biopsy of mediastinal masses in any of the mediastinal compartments. In many cases the diagnosis can be established and the mediastinal mass removed with video-assisted thoracoscopy.

ACUTE MEDIASTINITIS

Most cases of acute mediastinitis are either due to esophageal perforation or occur after median sternotomy for cardiac surgery. Patients with esophageal rupture are acutely ill with chest pain and dyspnea due to the mediastinal infection. The esophageal rupture can occur spontaneously or as a complication of esophagoscopy or the insertion of a Blakemore tube. Appropriate treatment is exploration of the mediastinum with primary repair of the esophageal tear and drainage of the pleural space and the mediastinum.

The incidence of mediastinitis following median sternotomy is 0.4 to 5.0%. Patients most commonly present with wound drainage. Other presentations include sepsis or a widened mediastinum. The diagnosis is usually established with mediastinal needle aspiration. Treatment includes immediate drainage, debridement, and parenteral antibiotic therapy, but the mortality still exceeds 20%.

CHRONIC MEDIASTINITIS

The spectrum of chronic mediastinitis ranges from granulomatous inflammation of the lymph nodes in the mediastinum to fibrosing mediastinitis. Most cases are due to tuberculosis or histoplasmosis, but sarcoidosis, silicosis, and other fungal diseases are at times causative. Patients with granulomatous mediastinitis are usually asymptomatic. Those with fibrosing mediastinitis usually have signs of compression of some mediastinal structure such as the superior vena cava or large airways, phrenic or recurrent laryngeal nerve paralysis, or obstruction of the pulmonary artery or proximal pulmonary veins. Other than antituberculous therapy for tuberculous mediastinitis, no medical or surgical therapy has been demonstrated to be effective for mediastinal fibrosis.

PNEUMOMEDIASTINUM

In this condition, there is gas in the interstices of the mediastinum. The three main causes are: (1) alveolar rupture with dissection of air into the mediastinum; (2) perforation or rupture of the esophagus, trachea, or main bronchi; and (3) dissection of air from the neck or the abdomen into the mediastinum. Typically, there is severe substernal chest pain with or without radiation into the neck and arms. The physical

examination usually reveals subcutaneous emphysema in the suprasternal notch and *Hamman's sign*, which is a crunching or clicking noise synchronous with the heartbeat and best heard in the left lateral decubitus position. The diagnosis is confirmed with the chest radiograph. Usually no treatment is required, but the mediastinal air will be absorbed faster if the patient inspires high concentrations of oxygen. If mediastinal structures are compressed, the compression can be relieved with needle aspiration.

DISORDERS OF THE DIAPHRAGM

DIAPHRAGMATIC PARALYSIS

The presence of bilateral diaphragmatic paralysis almost always causes severe morbidity in adults. The most common causes include high spinal cord injury, thoracic trauma (including cardiac surgery), multiple sclerosis, anterior horn disease, and muscular dystrophy. Most patients with severe diaphragmatic weakness present with hypercapnic respiratory failure, frequently complicated by cor pulmonale and right ventricular failure, atelectasis, and pneumonia.

The degree of diaphragmatic weakness is best quantitated by measuring transdiaphragmatic pressures. The treatment of choice is assisted ventilation for all or part of each day. This is best accomplished without tracheostomy using nasal intermittent positive airway pressure. If the nerve to the diaphragm is intact, diaphragmatic pacing may be a viable alternative. If the paralysis occurs during open heart surgery, recovery frequently occurs, but it may take 6 months or more.

Unilateral paralysis of the diaphragm is much more common than is bilateral paralysis. The most common cause is nerve invasion from malignancy, usually a bronchogenic carcinoma. If the patient does not have malignancy, then usually no cause for the paralysis is found. The diagnosis is suggested by finding an elevated hemidiaphragm on the chest roentgenogram. Confirmation is best established with the "sniff test." When a patient is observed with fluoroscopy while sniffing, the paralyzed diaphragm will move paradoxically upward due to the negative intrathoracic pressure. Patients with a unilateral paralyzed diaphragm are usually asymptomatic. Their vital capacity and total lung capacity are each reduced about 25%. If a patient has a mediastinal mass in conjunction with the diaphragmatic paralysis, further workup should be done. However, if the patient is asymptomatic with a normal chest radiograph, no invasive procedures are warranted.

263. DISORDERS OF VENTILATION - *Eliot A. Phillipson*

HYPOVENTILATION

DEFINITION AND ETIOLOGY

Alveolar hypoventilation exists by definition when arterial P_{CO_2}(Pa_{CO_2}) increases above the normal range of 37 to 43 mmHg, but in clinically important hypoventilation syndromes Pa_{CO_2} is generally in the range of 50 to 80 mmHg. Hypoventilation disorders can be acute or chronic. The acute disorders, which represent life-threatening emergencies, are discussed in Chap. 265; this **chapter** deals with chronic hypoventilation syndromes.

Chronic hypoventilation can result from numerous disease entities (Table 263-1), but in all cases the underlying mechanism involves a defect in either the metabolic respiratory control system, the respiratory neuromuscular system, or the ventilatory apparatus. Disorders associated with impaired respiratory drive, defects in the respiratory neuromuscular system, some chest wall disorders such as obesity, and upper airway obstruction produce an increase in Pa_{CO_2}, despite normal lungs, because of a reduction in overall minute volume of ventilation and hence in alveolar ventilation. In contrast, most disorders of the chest wall and disorders of the lower airways and lungs may produce an increase in Pa_{CO_2}, despite a normal or even increased minute volume of ventilation, because of severe ventilation-perfusion mismatching that results in net alveolar hypoventilation.

Several hypoventilation syndromes involve combined disturbances in two elements of the respiratory system. For example, patients with chronic obstructive pulmonary disease may hypoventilate not simply because of impaired ventilatory mechanics but also because of a reduced central respiratory drive, which can be inherent or secondary to a coexisting metabolic alkalosis (related to diuretic and steroid therapy).

PHYSIOLOGIC AND CLINICAL FEATURES

Regardless of cause, the hallmark of all alveolar hypoventilation syndromes is an increase in alveolar P_{CO_2}(PA_{CO_2}) and therefore in Pa_{CO_2}(Fig. 263-1). The resulting respiratory acidosis eventually leads to a compensatory increase in plasma HCO_3^- concentration and a decrease in Cl^- concentration. The increase in PA_{CO_2} produces an obligatory decrease in PA_{O_2}, resulting in hypoxemia. If severe, the hypoxemia manifests clinically as cyanosis and can stimulate erythropoiesis and induce secondary polycythemia. The combination of chronic hypoxemia and hypercapnia may also induce pulmonary vasoconstriction, leading eventually to pulmonary hypertension, right ventricular hypertrophy, and congestive heart failure. The disturbances in arterial blood gases are typically magnified during sleep because of a further reduction in central respiratory drive. The resulting increased nocturnal hypercapnia may cause cerebral vasodilation leading to morning headache; sleep quality may also be severely impaired, resulting in morning fatigue, daytime somnolence, mental confusion, and intellectual impairment. Other clinical features associated with hypoventilation syndromes are related to the specific underlying disease (Table 263-1).

DIAGNOSIS

Investigation of the patient with chronic hypoventilation involves several laboratory tests that will usually localize the disorder to either the metabolic respiratory control system, the neuromuscular system, or the ventilatory apparatus (Fig. 263-2). Defects in the control system impair responses to chemical stimuli, including ventilatory, occlusion pressure, and diaphragmatic electromyographic (EMG) responses. During sleep, hypoventilation is usually more marked, and central apneas and hypopneas are common. However, because the behavioral respiratory control system (which is anatomically distinct from the metabolic control system), the neuromuscular system, and the ventilatory apparatus are intact, such patients can usually hyperventilate voluntarily, generate normal inspiratory and expiratory muscle pressures (PI_{max}, PE_{max}, respectively) against an occluded airway, generate normal lung volumes and flow rates on routine spirometry, and have normal respiratory system resistance and compliance and a normal alveolar-arterial P_{O2}[$(A\text{-}a)P_{O2}$] difference. Patients with defects in the respiratory neuromuscular system also have impaired responses to chemical stimuli but in addition are unable to hyperventilate voluntarily or to generate normal static respiratory muscle pressures, lung volumes, and flow rates. However, at least in the early stages of the disease, the resistance and compliance of the respiratory system and the alveolar-arterial oxygen difference are normal.

In contrast to patients with disorders of the respiratory control or neuromuscular systems, patients with disorders of the chest wall, lungs, and airways typically demonstrate abnormalities of respiratory system resistance and compliance and have a widened $(A\text{-}a)P_{O2}$. Because of the impaired mechanics of breathing, routine spirometric tests are abnormal, as is the ventilatory response to chemical stimuli. However, because the neuromuscular system is intact, tests that are independent of resistance and compliance are usually normal, including tests of respiratory muscle strength and of respiratory control that do not involve airflow.

TREATMENT

The management of chronic hypoventilation must be individualized to the patient's particular disorder, circumstances, and needs and should include measures directed toward the underlying disease. Coexistent metabolic alkalosis should be corrected, including elevations of HCO_3^- that are inappropriately high for the degree of chronic hypercapnia. Administration of supplemental oxygen is effective in attenuating hypoxemia, polycythemia, and pulmonary hypertension, but can aggravate CO_2 retention and the associated neurologic symptoms. For this reason, supplemental oxygen must be prescribed judiciously and the results monitored carefully. Pharmacologic agents that stimulate respiration (particularly progesterone) are of benefit in some patients, but generally, results are disappointing.

Most patients with chronic hypoventilation related to impairment of respiratory drive or neuromuscular disease eventually require mechanical ventilatory assistance for effective management. When hypoventilation is severe, treatment may be required on a 24-h basis, but in most patients ventilatory assistance only during sleep produces dramatic clinical improvement and lowering of daytime Pa_{CO2}. In patients with reduced respiratory drive but intact respiratory lower motor neurons, phrenic nerves, and

respiratory muscles, diaphragmatic pacing through an implanted phrenic electrode can be very effective. However, for patients with defects in the respiratory nerves and muscles, electrophrenic pacing is contraindicated. Such patients can usually be managed effectively with either intermittent negative-pressure ventilation in a cuirass or intermittent positive-pressure ventilation delivered through a tracheostomy or nose mask. For patients who require ventilatory assistance only during sleep, positive-pressure ventilation through a nose mask is the preferred method because it obviates a tracheostomy and avoids the problem of upper airway occlusion that can arise in a negative-pressure ventilator. Hypoventilation related to restrictive disorders of the chest wall (Table 263-1) can also be managed effectively with nocturnal intermittent positive-pressure ventilation through a nose mask or tracheostomy.

HYPOVENTILATION SYNDROMES

PRIMARY ALVEOLAR HYPOVENTILATION

Primary alveolar hypoventilation (PAH) is a disorder of unknown cause characterized by chronic hypercapnia and hypoxemia in the absence of identifiable neuromuscular disease or mechanical ventilatory impairment. The disorder is thought to arise from a defect in the metabolic respiratory control system, but few neuropathologic studies have been reported in such patients. Recent studies in animals suggest an important role for genetic factors in the pathogenesis of hypoventilation. Isolated PAH is relatively rare, and although it occurs in all age groups, the majority of reported cases have been in males aged 20 to 50 years. The disorder typically develops insidiously and often first comes to attention when severe respiratory depression follows administration of standard doses of sedatives or anesthetics. As the degree of hypoventilation increases, patients typically develop lethargy, fatigue, daytime somnolence, disturbed sleep, and morning headaches; eventually cyanosis, polycythemia, pulmonary hypertension, and congestive heart failure occur (Fig. 263-1). Despite severe arterial blood gas derangements, dyspnea is uncommon, presumably because of impaired chemoreception and ventilatory drive. If left untreated, PAH is usually progressive over a period of months to years and ultimately fatal.

The key diagnostic finding inPAH is a chronic respiratory acidosis in the absence of respiratory muscle weakness or impaired ventilatory mechanics (Fig. 263-2). Because patients can hyperventilate voluntarily and reduce Pa_{CO_2} to normal or even hypocapnic levels, hypercapnia may not be demonstrable in a single arterial blood sample, but the presence of an elevated plasma HCO_3-level should draw attention to the underlying chronic disturbance. Despite normal ventilatory mechanics and respiratory muscle strength, ventilatory responses to chemical stimuli are reduced or absent (Fig. 263-2), and breath-holding time may be markedly prolonged without any sensation of dyspnea.

Patients withPAHmaintain rhythmic respiration when awake, although the level of ventilation is below normal. However, during sleep, when breathing is critically dependent on the metabolic control system, there is typically a further deterioration in ventilation with frequent episodes of central hypopnea or apnea.

PAHmust be distinguished from other central hypoventilationsyndromes that are secondary to underlying neurologic disease of the brainstem or chemoreceptors (Table

263-1). This distinction requires a careful neurologic investigation for evidence of brainstem or autonomic disturbances. Unrecognized respiratory neuromuscular disorders, particularly those that produce diaphragmatic weakness, are often misdiagnosed as PAH. However, such disorders can usually be suspected on clinical grounds (see below) and can be confirmed by the finding of reduced voluntary hyperventilation, as well as PI_{max} and PE_{max}.

Some patients with PAH respond favorably to respiratory stimulant medications and to supplemental oxygen. However, the majority eventually require mechanical ventilatory assistance. Excellent long-term benefits can be achieved with diaphragmatic pacing by electrophrenic stimulation or with negative- or positive-pressure mechanical ventilation. The administration of such treatment only during sleep is sufficient in most patients.

RESPIRATORY NEUROMUSCULAR DISORDERS

Several primary disorders of the spinal cord, peripheral respiratory nerves, and respiratory muscles produce a chronic hypoventilation syndrome (Table 263-1). Hypoventilation usually develops gradually over a period of months to years and often first comes to attention when a relatively trivial increase in mechanical ventilatory load (such as mild airways obstruction) produces severe respiratory failure. In some of the disorders (such as motor neuron disease, myasthenia gravis, and muscular dystrophy), involvement of the respiratory nerves or muscles is usually a later feature of a more widespread disease. In other disorders, respiratory involvement can be an early or even isolated feature, and hence the underlying problem is often not suspected. Included in this category are the postpolio syndrome (a form of chronic respiratory insufficiency that develops 20 to 30 years following recovery from poliomyelitis), the myopathy associated with adult acid maltase deficiency, and idiopathic diaphragmatic paralysis.

Generally, respiratory neuromuscular disorders do not result in chronic hypoventilation unless there is significant weakness of the diaphragm. Distinguishing features of bilateral diaphragmatic weakness include orthopnea, paradoxical movement of the abdomen in the supine posture, and paradoxical diaphragmatic movement under fluoroscopy. However, the absence of these features does not exclude diaphragmatic weakness. Important laboratory features are a rapid deterioration of ventilation during a maximum voluntary ventilation maneuver and reduced PI_{max} and PE_{max} (Fig. 263-2). More sophisticated investigations reveal reduced or absent transdiaphragmatic pressures, calculated from simultaneous measurement of esophageal and gastric pressures; reduced diaphragmatic EMG responses (recorded from an esophageal electrode) to transcutaneous phrenic nerve stimulation; and marked hypopnea and arterial oxygen desaturation during rapid eye movement sleep, when there is normally a physiologic inhibition of all nondiaphragmatic respiratory muscles and breathing becomes critically dependent on diaphragmatic activity.

The management of chronic alveolar hypoventilation due to respiratory neuromuscular disease involves treatment of the underlying disorder, where feasible, and mechanical ventilatory assistance as described for the primary alveolar hypoventilation syndrome. However, electrophrenic diaphragmatic pacing is contraindicated in these disorders, except for high cervical spinal cord lesions in which the phrenic lower motor neurons and nerves are intact.

OBESITY-HYPOVENTILATION SYNDROME

Massive obesity represents a mechanical load to the respiratory system because the added weight on the rib cage and abdomen serves to reduce the compliance of the chest wall. As a result, the functional residual capacity (i.e., end-expiratory lung volume) is reduced, particularly in the recumbent posture. An important consequence of breathing at a low lung volume is that some airways, particularly those in the lung bases, may be closed throughout part or even all of each tidal breath, resulting in underventilation of the lung bases and widening of the (A-a)P_{O2}. Nevertheless, in the majority of obese individuals, central respiratory drive is increased sufficiently to maintain a normal Pa_{CO2}. However, a small proportion of obese patients develop chronic hypercapnia, hypoxemia, and eventually polycythemia, pulmonary hypertension, and right-sided heart failure. Recent studies in mice demonstrate that genetically obese mice lacking circulating leptin also develop chronic hypoventilation that can be reversed by leptin infusions. Those patients who also develop daytime somnolence have been designated as having the *Pickwickian syndrome* (Chap. 27). In many such patients, obstructive sleep apnea is a prominent feature, and even in those patients without sleep apnea, sleep-induced hypoventilation is an important element of the disorder and contributes to its progression. Most patients demonstrate a decrease in central respiratory drive, which may be inherent or acquired, and many have mild to moderate degrees of airflow obstruction, usually related to smoking. Based on these considerations, several therapeutic measures can be of considerable benefit, including weight loss, cessation of smoking, elimination of obstructive sleep apnea, and enhancement of respiratory drive by medications such as progesterone.

HYPERVENTILATION AND ITS SYNDROMES

DEFINITION AND ETIOLOGY

Alveolar hyperventilation exists when Pa_{CO2}decreases below the normal range of 37 to 43 mmHg. *Hyperventilation* is not synonymous with *hyperpnea*, which refers to an increased minute volume of ventilation without reference to Pa_{CO2}. Although hyperventilation is frequently associated with dyspnea, patients who are hyperventilating do not necessarily complain of shortness of breath; and conversely, patients with dyspnea need not be hyperventilating.

Numerous disease entities can be associated with alveolar hyperventilation (Table 263-2), but in all cases the underlying mechanism involves an increase in respiratory drive that is mediated through either the behavioral or the metabolic respiratory control systems (Fig. 263-3). Thus hypoxemia drives ventilation by stimulating the peripheral chemoreceptors, and several pulmonary disorders and congestive heart failure drive ventilation by stimulating afferent vagal receptors in the lungs and airways. Low cardiac output and hypotension stimulate the peripheral chemoreceptors and inhibit the baroreceptors, both of which increase ventilation. Metabolic acidosis, a potent respiratory stimulant, excites both the peripheral and central chemoreceptors and increases the sensitivity of the peripheral chemoreceptors to coexistent hypoxemia. Hepatic failure can also produce hyperventilation, presumably as a result of metabolic stimuli acting on the peripheral and central chemoreceptors.

Several neurologic and psychological disorders are thought to drive ventilation through the behavioral respiratory control system. Included in this category are psychogenic or anxiety hyperventilation and severe cerebrovascular insufficiency, which may interfere with the inhibitory influence normally exerted by cortical structures on the brainstem respiratory neurons. Rarely, disorders of the midbrain and hypothalamus induce hyperventilation, and it is conceivable that fever and sepsis also cause hyperventilation through effects on these structures. Several drugs cause hyperventilation by stimulating the central or peripheral chemoreceptors or by direct action on the brainstem respiratory neurons. Chronic hyperventilation is a normal feature of pregnancy and results from the effects of progesterone and other hormones acting on the respiratory neurons.

PHYSIOLOGIC AND CLINICAL FEATURES

Because hyperventilation is associated with increased respiratory drive, muscle effort, and minute volume of ventilation, the most frequent symptom associated with hyperventilation is dyspnea. However, there is considerable discrepancy between the degree of hyperventilation, as measured by P_{aCO_2}, and the degree of associated dyspnea. From a physiologic standpoint, hyperventilation is beneficial in patients who are hypoxemic, because the alveolar hypocapnia is associated with an increase in alveolar and arterial P_{O_2}. Conversely, hyperventilation can also be detrimental. In particular, the alkalemia associated with hypocapnia may produce neurologic symptoms, including dizziness, visual impairment, syncope, and seizure activity (secondary to cerebral vasoconstriction); parasthesia, carpopedal spasm, and tetany (secondary to decreased free serum calcium); and muscle weakness (secondary to hypophosphatemia). Severe alkalemia can also induce cardiac arrhythmias and evidence of myocardial ischemia. Patients with a primary respiratory alkalosis are also prone to periodic breathing and central sleep apnea (Chap. 264).

DIAGNOSIS

In most patients with a hyperventilation syndrome, the cause is readily apparent on the basis of history, physical examination, and knowledge of coexisting medical disorders (Table 263-2). In patients in whom the cause is not clinically apparent, investigation begins with arterial blood gas analysis, which establishes the presence of alveolar hyperventilation (decreased P_{aCO_2}) and its severity. Equally important is the arterial pH, which generally allows the disorder to be classified as either a primary respiratory alkalosis (elevated pH) or a primary metabolic acidosis (decreased pH). Also of importance is the P_{aO_2} and calculation of the $(A-a)P_{O_2}$, since a widened alveolar-arterial oxygen difference suggests a pulmonary disorder as the underlying cause. The finding of a reduced plasma HCO_3^- level establishes the chronic nature of the disorder and points toward an organic cause. Measurements of ventilation and arterial or transcutaneous P_{CO_2} during sleep are very useful in suspected psychogenic hyperventilation, since such patients do not maintain the hyperventilation during sleep.

The disorders that most frequently give rise to unexplained hyperventilation are pulmonary vascular disease (particularly chronic or recurrent thromboembolism) and psychogenic or anxiety hyperventilation. Hyperventilation due to pulmonary vascular disease is associated with exertional dyspnea, a widened $(A-a)P_{O_2}$ and maintenance of

hyperventilation during exercise. In contrast, patients with psychogenic hyperventilation typically complain of dyspnea at rest and not during mild exercise and of the need to sigh frequently. They are also more likely to complain of dizziness, sweating, palpitations, and paresthesia. During mild to moderate exercise, their hyperventilation tends to disappear and (A-a)P_{O2} is normal, but heart rate and cardiac output may be increased relative to metabolic rate.

TREATMENT

Alveolar hyperventilation is usually of relatively minor clinical consequence and therefore is generally managed by appropriate treatment of the underlying cause. In the few patients in whom alkalemia is thought to be inducing significant cerebral vasoconstriction, paresthesia, tetany, or cardiac disturbances, inhalation of a low concentration of CO_2 can be very beneficial. For patients with disabling psychogenic hyperventilation, careful explanation of the basis of their symptoms can be reassuring and is often sufficient. Others have benefited fromb-adrenergic antagonists or an exercise program. Specific treatment for anxiety may also be indicated.

264. SLEEP APNEA - *Eliot A. Phillipson*

DEFINITION AND CLASSIFICATION

Sleep apnea is defined as an intermittent cessation of airflow at the nose and mouth during sleep. By convention, apneas of at least 10 s duration have been considered important, but in most patients the apneas are 20 to 30 s in duration and may be as long as 2 to 3 min. *Sleep apnea syndrome* refers to a clinical disorder that arises from recurrent apneas during sleep. The clinical importance of sleep apnea arises from the fact that it is one of the leading causes of excessive daytime sleepiness. Indeed, epidemiologic studies have established a prevalence of clinically important sleep apnea of at least 2% in middle-aged women and 4% in middle-aged men.

Sleep apneas can be central or obstructive in type. In central sleep apnea (CSA) the neural drive to all the respiratory muscles is transiently abolished. In contrast, in obstructive sleep apnea (OSA) airflow ceases despite continuing respiratory drive because of occlusion of the oropharyngeal airway.

OBSTRUCTIVE SLEEP APNEA

Pathogenesis The definitive event inOSA is occlusion of the upper airway usually at the level of the oropharynx. The resulting apnea leads to progressive asphyxia until there is a brief arousal from sleep, whereupon airway patency is restored and airflow resumes. The patient then returns to sleep, and the sequence of events is repeated, often up to 400 to 500 times per night, resulting in marked fragmentation of sleep.

The immediate factor leading to collapse of the upper airway inOSA is the generation of a critical subatmospheric pressure during inspiration that exceeds the ability of the airway dilator and abductor muscles to maintain airway stability. During wakefulness, upper airway muscle activity is greater than normal in patients with OSA, presumably to compensate for airway narrowing (see below) and a high upper airway resistance. Sleep plays a permissive but crucial role by reducing the activity of the muscles and their protective reflex response to subatmospheric airway pressures. Alcohol is frequently an important cofactor because of its selective depressant influence on the upper airway muscles and on the arousal response that terminates each apnea. In most patients the patency of the airway is also compromised structurally and therefore predisposed to occlusion. In a minority of patients the structural compromise is due to obvious anatomic disturbances, such as adenotonsillar hypertrophy, retrognathia, and macroglossia. However, in the majority of patients the structural defect is simply a subtle reduction in airway size that can often be appreciated clinically as "pharyngeal crowding" and that can usually be demonstrated by imaging and acoustic reflection techniques. Obesity frequently contributes to the reduction in size of the upper airways, either by increasing fat deposition in the soft tissues of the pharynx or by compressing the pharynx by superficial fat masses in the neck. More sophisticated studies also demonstrate a high airway compliance -- i.e., the airway is "floppy" and therefore prone to collapse.

Pathophysiologic and Clinical Features The narrowing of the upper airways during sleep, which predisposes to OSA, inevitably results in snoring. In most patients, snoring

antedates the development of obstructive events by many years. However, the majority of snoring individuals do not have an OSA disorder, nor is there definitive evidence that snoring per se is associated with long-term health risks. Hence, in the absence of other symptoms, snoring alone does not warrant an investigation for OSA but does call for preventive counselling, particularly with regard to weight gain and alcohol consumption.

The recurrent episodes of nocturnal asphyxia and of arousal from sleep that characterizeOSA lead to a series of secondary physiologic events, which in turn give rise in some patients to the clinical complications of the syndrome (Fig. 264-1). The most common manifestations are neuropsychiatric and behavioral disturbances that are thought to arise from the fragmentation of sleep and loss of slow-wave sleep induced by the recurrent arousal responses. Nocturnal cerebral hypoxia may also play an important role. The most pervasive manifestation is excessive daytime sleepiness. Initially, daytime sleepiness manifests under passive conditions, such as reading or watching television; but as the disorder progresses, sleepiness encroaches into all daily activities and can become disabling and dangerous. Several studies have demonstrated two to seven times more motor vehicle accidents in patients with OSA compared with other drivers. Other related symptoms include intellectual impairment, memory loss, and personality disturbances.

The other major manifestations ofOSA are cardiorespiratory in nature and are thought to arise from the recurrent episodes of nocturnal asphyxia and of negative intrathoracic pressure, which increases left ventricular afterload (Fig. 264-1). Many patients demonstrate a cyclical slowing of the heart during the apneas to 30 to 50 beats per minute, followed by a tachycardia of 90 to 120 beats per minute during the ventilatory phase. A small number of patients develop severe bradycardia or dangerous tachyarrhythmias, leading to the notion that OSA may result in sudden death during sleep, but firm corroborative data are lacking. Unlike in healthy subjects, in patients with OSA systemic blood pressure fails to decrease during sleep. In fact, blood pressure typically rises abruptly at the termination of each obstructive event as a result of sympathetic nervous activation and reflex vasoconstriction. Furthermore, over 50% of patients with OSA have systemic hypertension. Several epidemiologic studies have implicated OSA as a risk factor for the development of systemic hypertension, and recent studies in an animal model demonstrate directly that OSA can cause sustained increases in daytime blood pressure. Emerging data also suggest that OSA can precipitate myocardial ischemia in patients with coronary artery disease and can adversely affect left ventricular function, both acutely and chronically, in patients with congestive heart failure. This complication is probably due to the combined effects of increased left ventricular afterload during each obstructive event, secondary to increased negative intrathoracic pressure (Fig. 264-1), recurrent nocturnal hypoxemia, and chronically elevated sympathoadrenal activity. Treatment of OSA in such patients often results in dramatic improvement in left ventricular function and in clinical cardiac status. Finally, up to 20% of patients with OSA develop mild pulmonary hypertension (in the absence of intrinsic lung disease), and a small proportion (<10%) develop pulmonary hypertension, right ventricular failure, polycythemia, and chronic hypercapnia and hypoxemia. All such patients have evidence of sustained daytime hypoxemia in addition to the nocturnal ventilatory disturbance, usually as a result of reduced ventilatory drive and/or diffuse airways obstruction.

Diagnosis AlthoughOSAoccurs at any age, and is more prevalent in women than was previously thought, the typical patient is a male aged 30 to 60 years who presents with a history of snoring, excessive daytime sleepiness, nocturnal choking or gasping, witnessed apneas during sleep, moderate obesity, and often mild to moderate hypertension. The definitive investigation for suspected OSA is polysomnography, a detailed overnight sleep study that includes recording of (1) electrographic variables (electroencephalogram, electrooculogram, and submental electromyogram) that permit the identification of sleep and its various stages, (2) ventilatory variables that permit the identification of apneas and their classification as central or obstructive, (3) arterial O_2saturation by ear or finger oximetry, and (4) heart rate. Continuous measurement of transcutaneous P_{CO2}(which reflects arterial P_{CO2}) can also be very useful, particularly in patients withCSA. The key diagnostic finding in OSA is episodes of airflow cessation at the nose and mouth despite evidence of continuing respiratory effort. By the time most patients come to clinical attention they have at least 10 to 15 obstructive events per hour of sleep. However, recent data suggest that a high upper airway resistance during sleep (manifested by snoring) that is accompanied by recurrent arousals from sleep, even in the absence of apneas and hypopneas, can result in a clinically important sleep-related syndrome. Therefore, the absence of outright apneas and hypopneas in a symptomatic patient may not definitely exclude a sleep-related respiratory disorder.

Because polysomnography is a time-consuming and expensive test, there is considerable interest in the role of simplified, unattended, ambulatory sleep monitoring for the investigation ofOSA that would allow the patient to be studied at home, rather than in the sleep laboratory. The most useful test in this context is the recording of arterial O_2saturation by oximetry. However, the reliability of overnight oximetry in the diagnosis of OSA is dependent on the pretest probability of the disorder. In patients with a high pretest probability (based on a history of daytime sleepiness, habitual snoring, nocturnal choking or gasping, and witnessed apneas during sleep), overnight oximetry can be used to *confirm* the diagnosis by demonstrating recurrent episodes of arterial O_2desaturation (at a rate of at least 10 to 15 events per hour). Such findings obviate the need for full polysomnography and allow initiation of treatment with nasal continuous positive airway pressure (CPAP) during sleep (see "Treatment"). However, negative results in a patient with a high clinical probability of OSA do not exclude the diagnosis but mandate that the patient proceed to polysomnography to investigate the cause of the daytime sleepiness. In contrast, when the pretest probability of OSA is low (such as the patient with only occasional snoring, few witnessed apneas, and no daytime sleepiness), the absence of arterial O_2desaturation can be used to *exclude* the diagnosis and thereby obviate the need for full polysomnography.

Studies suggest that overnight oximetry can obviate the need for polysomnography in about one-third of clinic patients referred for consideration ofOSA, either by *confirming* the diagnosis in patients with a *high* pretest probability of the disorder, or by *excluding* the diagnosis in patients with a *low* pretest probability. In the remaining two-thirds of patients with an intermediate pretest probability of OSA, overnight oximetry alone will not be definitive; hence such patients will require polysomnography.

TREATMENT

(Table 264-1) Several approaches to treatment ofOSA have been advocated, based on

an understanding of the mechanisms underlying the disorder. Mild to moderate OSA can often be managed effectively by modest weight reduction, avoidance of alcohol, improvement of nasal patency, and avoidance of sleeping in the supine posture. Intraoral appliances, designed to keep the mandible and tongue forward, are also effective in 55 to 80% of patients. The most widely used treatments in severe OSA are uvulopalatopharyngoplasty and nasalCPAPduring sleep. Uvulopalatopharyngoplasty is a surgical procedure designed to increase the pharyngeal lumen by resecting redundant soft tissue. When applied to unselected patients with OSA, it produces long-term cure in fewer than 50% but more discriminating selection of patients yields a higher rate of success. Other surgical approaches, including mandibular advancement and hyoid osteotomy have a more limited application but higher rate of success in selected patients. Nasal CPAP, which prevents upper airway occlusion by splinting the pharyngeal airway with a positive pressure delivered through a nose mask, is currently the most successful long-term approach to treatment, being well tolerated and effective in over 80% of patients, provided that they have received proper training. Patients who are unable to tolerate conventional nasal CPAP may respond to newer generation devices that provide more flexibility in adjusting the timing and levels of inspiratory and expiratory pressure cycles. For patients with ischemic heart disease or congestive heart failure who also have OSA, nasal CPAP is the only treatment that has been specifically tested and is considered the treatment of choice. Finally, for the few patients with severe OSA in whom all other treatment approaches have failed, tracheostomy can provide immediate relief, but in most centers is performed only very rarely.

CENTRAL SLEEP APNEA

Pathogenesis The definitive event inCSA is transient abolition of central drive to the ventilatory muscles. The resulting apnea leads to a primary sequence of events similar to those ofOSA(Fig. 264-1). Several underlying mechanisms can result in cessation of respiratory drive during sleep (Table 264-2). First are defects in the metabolic respiratory control system and respiratory neuromuscular apparatus. Such defects usually produce a chronic alveolar hypoventilation syndrome (in addition to CSA) that becomes more severe during sleep when the stimulatory effect of wakefulness on breathing is abolished. In contrast are CSA disorders that arise from transient instabilities in an otherwise intact respiratory control system. Common to all these disorders is a P_{CO_2}level during sleep that falls transiently below the critical P_{CO_2}required for respiratory rhythm generation. The most frequent instability of this type occurs at sleep onset, because the P_{CO_2}level of wakefulness is often lower than that required for rhythm generation in sleep; hence with loss of the stimulatory effect of wakefulness on breathing (referred to as the *waking neural drive*), an apnea develops at sleep onset until P_{CO_2}rises to the critical level (Fig. 264-2). However, if the central nervous system state fluctuates at sleep onset between "asleep" and "awake," a pattern of periodic breathing develops as respiration follows the changes in state. During each cycle, the waning phase of ventilation includes an hypopnea or outright central apnea (Cheyne-Stokes respiration). In most patients with CSA, the tendency to develop periodic breathing and central apneas during sleep is enhanced by some degree of chronic hyperventilation during wakefulness that drives the P_{CO_2}level below the threshold required for rhythm generation during sleep. Such hyperventilation is frequently idiopathic in nature. Hypoxia, whether due to high altitude or to underlying cardiorespiratory disease, also enhances the tendency to periodic breathing and CSA

for the same reasons. Periodic breathing and CSA are also common in patients with congestive heart failure. In such patients the decreases in P_{aCO_2} that trigger transient abolition of central respiratory drive are associated with higher left ventricular end-diastolic volume and filling pressure than in congestive heart failure patients without CSA. The hyperventilation probably results, therefore, from pulmonary congestion and stimulation of pulmonary vagal receptors.

Pathophysiologic and Clinical Features Many healthy individuals demonstrate a small number of central apneas during sleep, particularly at sleep onset and in rapid eye movement sleep. These apneas are not associated with any physiologic or clinical disturbances. In patients with clinically important CSA, the primary sequence of events that characterizes the disorder leads to prominent physiologic and clinical consequences (Fig. 264-1). In those patients whose CSA is a component of an alveolar hypoventilation syndrome, daytime hypercapnia and hypoxemia are usually evident, and the clinical picture is dominated by a history of recurrent respiratory failure, polycythemia, pulmonary hypertension, and right-sided heart failure. Complaints of sleeping poorly, morning headache, and daytime fatigue and sleepiness are also prominent. In contrast, in patients whose CSA results from an instability in respiratory drive, the clinical picture is dominated by features related to sleep disturbance, including recurrent nocturnal awakenings, morning fatigue, and daytime sleepiness. In patients with congestive heart failure, CSA can be an important (and frequently overlooked) cause of daytime sleepiness and fatigue. Recent studies also indicate that CSA can trigger sympathetic nervous activation in patients with heart failure and thereby exert a secondary deleterious effect on the underlying cardiac disorder.

Diagnosis Initially, many patients with CSA are suspected clinically of having OSA because of a history of snoring, sleep disturbance, and daytime sleepiness. However, obesity and hypertension are less prominent in CSA than in OSA. Definitive diagnosis of CSA requires a polysomnographic study, with the *key observation being recurrent apneas that are not accompanied by respiratory effort*. Measurements of transcutaneous P_{CO_2} are particularly useful in CSA. Those patients with a defect in respiratory control or neuromuscular function typically demonstrate an elevated P_{CO_2} that tends to increase progressively during the night, particularly during rapid eye movement sleep. In contrast, patients with instabilities in the respiratory control system typically demonstrate a mild degree of hypocapnia, which is an integral pathogenetic feature of their disorder (see above).

TREATMENT

The management of patients whose CSA is a component of an alveolar hypoventilation syndrome is essentially the same as management of the underlying hypoventilation disorder (Chap. 263). Management of patients whose CSA arises from an instability of respiratory drive is more problematic. Patients with hypoxemia usually respond favorably to nocturnal supplemental oxygen. Others have responded to acidification with acetazolamide, and recent reports indicate a good response to nasal CPAP (as for OSA). The mechanism by which CPAP abolishes central apneas probably involves a small increase in P_{aCO_2} as a result of the added expiratory mechanical load. In patients whose CSA is secondary to congestive heart failure, CPAP is particularly effective in improving sleep quality and daytime cardiac function. In fact, recent randomized trials have

demonstrated that CPAP has a beneficial effect on several surrogate markers of mortality in patients with congestive heart failure, including left ventricular ejection fraction, functional mitral regurgitation, and norepinephrine concentrations.

265. ACUTE RESPIRATORY DISTRESS SYNDROME - *Marc Moss*, *Roland H. Ingram, Jr.*

Lung injury in acute respiratory distress syndrome (ARDS) is characterized by increased permeability of the alveolar-capillary membrane, diffuse alveolar damage, and the accumulation of proteinaceous pulmonary edema. This clinical syndrome was first described in the archival literature by military physicians when respiratory failure occurred in battlefield casualties during World Wars I and II. However, it was not until the 1960s, when mechanical ventilation was used for patients with acute respiratory failure, that ARDS was first officially named. Initially the "A" in ARDS stood for "adult" to differentiate this syndrome from the infantile respiratory distress syndrome. With the more recent recognition that ARDS occurs in all age groups, the "A" now stands for "acute."

The diagnostic criteria used to defineARDShave evolved over the past three decades. Originally, most definitions required three general criteria: severe hypoxemia, decreased pulmonary compliance, and diffuse pulmonary infiltrates on chest radiograph. With the increasing utilization of pulmonary arterial catheters in the intensive care unit, ARDS was noted to be a "noncardiogenic" form of pulmonary edema (Chap. 32). Subsequently, some proposed definitions of ARDS required documentation of a normal pulmonary arterial occlusion pressure. However, due to the lack of an established definition and the recognition that ARDS is the severe form of a wide spectrum of lung injury, an American-European Consensus Conference proposed a new definition of ARDS that is now uniformly accepted (Table 265-1). Acute lung injury, which is a mild form of ARDS, was also defined and differs from ARDS based on less severe hypoxemia (Table 265-1).

CLINICAL CHARACTERISTICS

Many predisposing factors are associated with the development ofARDS, including conditions that injure the lung directly and those that produce damage through indirect mechanisms via the hematogenous delivery of inflammatory mediators (Table 265-2). The most common of these at-risk conditions are severe sepsis, major trauma, and aspiration of gastric contents. In general, 30 to 40% of individuals with at least one of these diagnoses will eventually develop ARDS. This incidence increases in patients with more than one at-risk condition. A history of chronic alcohol abuse is also associated with an increased risk of developing ARDS in critically ill patients with an at-risk diagnosis.

ARDSoccurs within 5 days of the initial at-risk diagnosis in the majority of patients, and over 50% will develop ARDS in the first 24 h. The earliest clinical sign is often an increase in the respiratory frequency, followed by dyspnea. There are no characteristic laboratory abnormalities for ARDS patients except those related to a specific underlying condition, such as leukocytosis in sepsis or an elevated serum amylase level in pancreatitis. Radiographically, the lung fields may be clear initially; diffuse bilateral interstitial or alveolar infiltrates occur as ARDS develops (Fig. 265-1). Though these radiographic changes appear homogeneous on chest radiograph, computed tomography demonstrates a heterogeneous pattern with a predominance of infiltrates in the dependent regions of the lung (Fig. 265-2).

PATHOPHYSIOLOGY

ARDSmay be the pulmonary manifestation of a systemic process and is the consequence of an overexpression of the normal inflammatory response. This inflammatory cascade has been divided into three overlapping phases -- initiation, amplification, and injury. During *initiation*, a precipitating event, such as sepsis, causes both immune and nonimmune cells to produce and release a variety of mediators and cytokines, such as tumor necrosis factor a and interleukin 1. Subsequently, during *amplification*, effector cells, such as neutrophils, are activated, recruited, and retained in specific target organs including the lung. Interleukin 8, which is produced by monocytes and other cell types, appears to play an important role in neutrophil activation. Once the effector cells have been sequestered in the lung, they then release reactive oxygen metabolites and proteases, causing cellular damage during the *injury phase*. This inflammatory cascade can occur systemically and therefore may alter the function of many organ systems -- a clinical entity called *multiple organ dysfunction syndrome*.

The pathophysiologic hallmark ofARDS is increased vascular permeability to proteins, so that even mild elevations of pulmonary capillary pressures (due to increased intravenous liquid administration and/or myocardial depression, which may occur in sepsis) greatly increase interstitial and alveolar edema. Alveolar damage is further exaggerated by the quantitative reduction is surfactant synthesis due to injury to type II pneumocytes as well as to further qualitative abnormalities in the size, composition, and metabolism of the remaining surfactant pool, leading to alveolar collapse. Although these atelectatic and liquid-filled regions of the lung contribute to a reduction in the compliance of the lung as a whole, significant regions of nondependent lung have relatively normal mechanical and gas-exchanging properties. However, the decreased overall pulmonary compliance requires large inspiratory pressures to be generated by the respiratory muscles, resulting in an increase in the work of breathing.

ThoughARDS is not routinely considered a disease of the airways, airway resistance may be increased due to bronchial wall edema and cytokine-mediated bronchospasm. Pulmonary vascular resistance and pulmonary arterial pressures may also be elevated as a result of increased pulmonary vascular smooth-muscle tone, perivascular edema, microvascular thrombosis, and the production of humoral factors such as leukotrienes and thromboxane A_2, which can directly cause vasoconstriction.

PATHOLOGY

During the initial exudative phase, covering the first few days after lung injury, the following occur: (1) epithelial cell injury represented by extensive necrosis of type I pneumocytes and a denuded basement membrane, (2) swelling of endothelial cells with the widening of intercellular junctions, (3) the formation of hyaline membranes composed of fibrin and other matrix proteins in alveolar ducts and airspaces, and (4) a neutrophilic inflammation. Fibrin thrombi may be seen in the alveolar capillaries and smaller pulmonary arteries. The second pathologic phase ofARDS is characterized by proliferation of a variety of cells and resolution of the neutrophilic inflammation. Cuboidal type II cells and squamous epithelium cover denuded alveolar basement membranes. Over the ensuing days to weeks, architectural restoration of lung tissue is usually

observed in survivors of ARDS. However, interstitial fibrosis and extensive restructuring of the lung parenchyma may occur with cystic and honeycomb changes in some ARDS patients, resulting in chronic pulmonary dysfunction or death.

TREATMENT

Currently there are no specific therapies that correct the underlying abnormalities in the permeability of the alveolar-capillary membrane or control the activated inflammatory response in patients withARDS. However, the use of physiologically targeted strategies of mechanical ventilation and intensive care unit management have led to a more favorable outcome for these critically ill patients.

Mechanical Ventilatory Support In the presence ofARDS, adequate oxygenation is not usually maintained when oxygen is supplied through noninvasive measures. Therefore, most ARDS patients require mechanical ventilation during their hospitalization. The primary goal of the ventilatory management in ARDS is to achieve ventilation and oxygenation that are adequate to support organ function. The major complications of mechanical ventilation are oxygen toxicity and barotrauma, which include not only pneumothorax, pneumomedistinum, and subcutaneous emphysema but also primary alveolar damage. As demonstrated on computed tomography images of the lungs in ARDS patients (Fig. 265-2), a large portion of the alveoli are atelectatic or liquid-filled. However, some nondependent regions of the lung remain radiographically unaffected, and due to their greater compliance they receive a greater proportion of the tidal volume. When large tidal volumes (10 to 12 mL/kg of ideal body weight) are forced into these smaller areas, damage may occur in epithelial and endothelial cells. The sequelae of this injury include alterations in lung liquid balance, increases in permeability, and severe alveolar damage. The deleterious effects of these large tidal volumes and subsequent high alveolar pressures has been termed *volutrauma*.

The currently recommended ventilatory strategies forARDSpatients focus on the limitation of airway pressures to a maximum inflation pressure that should not exceed 30 to 35 cmH_2O, rather than on strategies that attempt to achieve a normal Pa_{CO_2}. Because of the decreased overall lung compliance in ARDS patients, the use of low tidal volumes (~ 6 mL/kg of ideal body weight) is usually required. The subsequent decrease in minute ventilation may result in hypercapnia and respiratory acidosis. This ventilatory strategy, which emphasizes the limitation of transpulmonary pressures at the expense of hypercapnia, has been termed *permissive hypercapnia*.

After intubation, the inspired oxygen fraction (FI_{O_2}) is initially set at 1.0 and then decreased in steps to the lowest FI_{O_2}that will maintain an arterial oxygen tension (Pa_{O_2}) of approximately 60 mmHg. If Pa_{O_2}cannot be maintained at 60 mmHg by an FI_{O_2}£ 0.6, positive end-expiratory pressure (PEEP) may be added (Chap. 266). PEEP improves oxygenation by elevating mean alveolar pressure, thereby recruiting atelectatic alveoli and preventing end-expiratory airway and alveolar closure. In addition, PEEP may prevent alveolar damage by reducing the repetitive and cyclical reopening of closed alveoli during the respiratory cycle. Because PEEP may also overdistend uninvolved alveoli, it should be added cautiously, starting at 5 cmH_2O and increasing in increments of 3 to 5 cmH_2O to a maximum of 20 to 24 cmH_2O. Because airway pressure is transmitted to the pleural space, cardiac output may be adversely affected by the

addition of PEEP. In general, the optimal level of PEEP is the amount that achieves an acceptable arterial O_2saturation (³90%) with nontoxic FI_{O2}levels (£0.6) but without significantly compromising cardiac output. The comprehensive ventilatory strategy that combines low tidal volumes with adequate levels of PEEP has been termed a *lung-protective strategy*. ARDS patients ventilated with this technique have improved 28-day survival and require less time on mechanical ventilation when compared with ARDS patients treated with conventional ventilation using large tidal volumes achieving normal Pa_{CO2}levels.

Several other ventilatory strategies have been examined with the goal of improving oxygenation. However, none of these techniques has definitively been proven to be beneficial forARDSpatients. When turned from a supine to prone position, ARDS patients develop a more uniform distribution of pleural pressures, with an improvement in ventilation/perfusion matching and better postural drainage of secretions. Prone positioning may improve oxygenation in >75% of ARDS patients. However, the turning of these critically ill patients from the supine to the prone position is not without potential complications, such as unplanned extubation and removal of central venous catheters. The term *inverse ratio ventilation* is defined when the inspiratory (I) time exceeds the expiratory (E) time (i.e., > one-half of the respiratory cycle; I:E ratio > 1:1). This mode of ventilation is able to maintain a higher mean airway pressure, a major determinant of oxygenation, with lower peak airway pressures than conventional ventilation. However, due to the decrease in expiratory time, inverse ratio ventilation is potentially associated with dynamic hyperinflation and increases in end-expiratory pressure. Finally, partial liquid ventilation with perfluorocarbon, a radiopaque, inert, colorless liquid that carries a large quantity of O_2, and CO_2, has been studied in patients with severe ARDS. When perfluorocarbon is administered into the trachea of intubated patients, patients can be safely and adequately oxygenated and ventilated with routine mechanical ventilation.

Intravascular Volume Management Although pulmonary edema inARDSpatients is a consequence of increased permeability of the alveolar-capillary membrane, elevations in the intravascular hydrostatic pressure may also contribute to the accumulation of alveolar liquid and result in worsening oxygenation. Therefore, the optimal fluid management for patients with ARDS requires a balancing between liquid restriction, which may cause hypotension and decreased perfusion to vital organs, and liquid administration, which may increase oxygen requirements. Small decrements in the intravascular volume with diuretic use produce significant decreases in extravascular lung water. Caution must be exercised in reducing intravascular volume, since vigorous diuresis, especially in the setting ofPEEP, may reduce cardiac output and perfusion of critical organs. Ideally, the lowest intravascular hydrostatic pressure that also achieves an adequate cardiac output should be maintained. The placement of a pulmonary arterial catheter may be helpful in monitoring cardiac output and pulmonary arterial occlusion pressure (a measure of intravascular volume) in order to optimize the fluid management of patients with ARDS. However, the placement of a pulmonary arterial catheter and the clinical decisions based upon information derived from the catheter do not appear to improve and may actually worsen the outcome of general intensive care unit patients. Therefore the role of the pulmonary arterial catheter for ARDS patients is presently unclear.

Pharmacologic Therapies Due to their anti-inflammatory properties, glucocorticoids

have been used in patients withARDS, but when administered in high doses (30 mg/kg intravenously every 6 h for a total of four doses), they are not beneficial in the early course of the disease. In contrast, one small randomized study reported an improvement in mortality when glucocorticoids were given after 7 days of unresolving ARDS. In this study, active surveillance for infection was required before enrollment, and glucocorticoids were administered for up to 32 days. Future recommendations regarding the use of these drugs for ARDS patients will be based upon the results of an ongoing multicenter study.

Patients withARDShave both quantitative and qualitative abnormalities in surfactant, rendering surfactant-replacement therapy an attractive therapeutic modality. In one large randomized study of sepsis-induced ARDS, the administration of synthetic surfactant in an aerosolized form had no significant effect on outcome. Due to concerns with the efficacy of the delivery technique and the lack of essential surfactant-associated proteins in this particular replacement therapy, further studies of different surfactant preparations and modes of administration are presently ongoing.

When inhaled, nitric oxide vasodilates the pulmonary vasculature adjacent to well-ventilated alveoli, thereby improving ventilation-perfusion mismatching. Because of its subsequent inactivation by hemoglobin, nitric oxide produces a selective pulmonary vasodilation without systemic hemodynamic effects. Though inhaled nitric oxide appears to improve oxygenation initially, it is presently unknown whether this therapy will reduce mortality rates inARDSpatients.

PROGNOSIS

Since the initial descriptions ofARDS, mortality rates have ranged from 50 to 70%, although they may now be declining with optimal therapy. Mortality rates are higher in patients over 65 years of age, in those with an at-risk diagnosis of sepsis, and when associated with dysfunction of other organ systems. The cause of death for patients with ARDS has been traditionally divided into early causes (within 72 h) and late causes (after 3 days). Most early deaths are attributed to the original presenting illness or injury. Secondary infection and sepsis, persistent respiratory failure, and multiple-organ dysfunction are the most common causes of death in those ARDS patients who live at least 3 days.

In survivors ofARDS, abnormalities in pulmonary function normally improve considerably by 3 months and reach maximum levels of correction by 6 months after extubation. Although pulmonary function markedly recovers in many survivors, over 50% of these patients will continue to have abnormalities, including restrictive impairment or decreased diffusing capacity. Patients with severe ARDS, characterized by extreme hypoxemia and a longer duration of illness, usually have more pulmonary dysfunction than individuals with mild ARDS. Survivors of ARDS also have significant reductions in their quality of life, specifically in regard to physical functioning when compared to other previously critically ill patients.

266. MECHANICAL VENTILATORY SUPPORT - *Edward P. Ingenito*, *Jeffrey M. Drazen*

Ventilators are specially designed pumps that can support the ventilatory function of the respiratory system and improve oxygenation through application of high oxygen content gas and positive pressure. They are a mainstay of physiologic supportive care and are used to stabilize patients with respiratory failure as the underlying disease process is definitively treated.

INDICATIONS FOR MECHANICAL VENTILATION

Respiratory failure is the primary indication for initiation of mechanical ventilation. There are two basic types of respiratory failure.

Hypoxemic respiratory failure most commonly results from pulmonary conditions such as severe pneumonia, pulmonary edema, pulmonary hemorrhage, and respiratory distress syndrome causing ventilation-perfusion (/) mismatch and shunt. Hypoxemic respiratory failure is present when arterial O_2saturation (Sa_{O2})< 90% is observed despite an inspired O_2fraction (FI_{O2})> 0.6. The goal of ventilator treatment in this setting is to provide adequate Sa_{O2}through a combination of supplemental O_2 and specific patterns of ventilation that enhance oxygenation.

Hypercarbic respiratory failure results from disease states causing either a decrease in minute ventilation or an increase in physiologic dead space such that, despite adequate total minute ventilation, alveolar ventilation is inadequate to meet metabolic demands. Common clinical conditions associated with hypercarbic respiratory failure include neuromuscular diseases, such as myasthenia gravis, ascending polyradiculopathy, and myopathies, as well as diseases that cause respiratory muscle fatigue due to increased workload, such as asthma, chronic obstructive pulmonary disease, and restrictive lung disease. *Acute* hypercarbic respiratory failure is characterized by arterial P_{CO2}values of greater than 50 mmHg and an arterial pH above 7.30.

Mechanical ventilation generally should be instituted in acute hypercarbic respiratory failure. In contrast, the decision to institute mechanical ventilation when components of both acute and chronic hypercarbic respiratory failure are present depends on blood gas parameters and clinical evaluation. In particular, if a patient is not in respiratory distress and is not mentally impaired by CO_2accumulation, it is not mandatory to initiate mechanical ventilation while other forms of treatment are being administered. The goal of ventilator treatment in hypercarbic respiratory failure is to normalize arterial pH through changes in CO_2tensions. In patients with severe obstructive or restrictive lung disease, elevation in airway pressures may limit tidal volumes to the extent that normalization of pH is not possible, a situation known as *permissive hypercapnia*. Hypoxemic and hypercarbic respiratory failure may coexist in a given individual; in such cases, the indications for and goals of mechanical ventilation are similar to those in these two individual entities.

Accepted therapeutic applications of mechanical ventilation include controlled hyperventilation to reduce cerebral blood flow in patients with increased intracranial pressure or to improve pulmonary hemodynamics in patients with postoperative

pulmonary hypertension. Mechanical ventilation also has been used to reduce the work of breathing in patients with congestive heart failure, especially in the presence of myocardial ischemia. Ventilator support is also frequently used in conjunction with endotracheal intubation to prevent aspiration of gastric contents in otherwise unstable patients during gastric lavage for suspected drug overdose or during upper gastrointestinal endoscopy. In the critically ill patient, intubation and mechanical ventilation are indicated before essential diagnostic or therapeutic studies if it appears that respiratory failure may occur during these maneuvers.

PHYSIOLOGIC ASPECTS OF MECHANICAL VENTILATION

Most modern mechanical ventilators function by providing warmed and humidified gas to the airway opening in conformance with various specific volume, pressure, and time patterns. The ventilator serves as the energy source for inspiration, replacing the muscles of the diaphragm and chest wall. Expiration is passive, driven by the recoil of the lungs and chest wall; at the completion of inspiration, internal ventilator circuitry vents the airway to atmospheric pressure or a specified level of positive end-expiratory pressure (PEEP).

PEEPhelps maintain alveolar patency in the presence of destabilizing factors and therefore reverses hypoxemia and atelectasis by improving/)">/matching of ventilation and perfusion. PEEP levels between 0 and 10 cmH_2O are generally safe and effective; higher levels are recommended only in the management of significant refractory hypoxemia unresponsive to increments in FI_{O2} up to 0.6.

ESTABLISHING AND MAINTAINING AN AIRWAY

A cuffed endotracheal tube must be inserted to allow positive-pressure ventilators to deliver conditioned gas, at pressures above atmospheric pressure, to the lungs in a controlled fashion. If neuromuscular paralysis is to be induced during intubation, the use of agents whose mechanism of action includes depolarization at the neuromuscular junction, such as succinylcholine chloride, should be avoided in patients with renal failure, tumor lysis syndrome, crush injuries, medical conditions associated with elevated serum potassium levels, and muscular dystrophy syndromes. Opiates and benzodiazepines can have a deleterious effect on hemodynamics in patients with depressed cardiac function or low systemic vascular resistance and should be used cautiously in this setting. Morphine can promote histamine release from tissue mast cells and may worsen bronchospasm in patients with asthma; fentanyl, sufentanil, and alfentanil are acceptable alternatives to morphine. Ketamine may increase systemic arterial pressure as well as intracranial pressure and has been associated with dramatic hallucinatory responses; it should be used with caution in patients with hypertensive crisis, increased intracranial pressures, or a history of psychiatric disorders.

Patients who require ventilator support for extended periods of time may be candidates for tracheostomy. Although definitive guidelines for performing a tracheostomy in the ventilated patient have not been established, in current clinical practice patients who are anticipated to require ventilator therapy for more than 3 weeks should be considered for this procedure. While it does not clearly reduce the incidence of laryngeal injury or tracheal stenosis, tracheostomy has been associated with improved patient comfort and

enhanced ability to partake in rehabilitation-oriented activities.

VENTILATOR MODES

This setting specifies the manner in which ventilator breaths are triggered, cycled, and limited; commonly used modes of mechanical ventilation are given inTable 266-1. The *trigger*, either an inspiratory effort or a time-based signal, defines what the ventilator senses to initiate an assisted cycle. *Cycle* refers to the factors that determine the end of inspiration. For example, in volume-cycled ventilation, inspiration ends when a specific tidal volume is delivered to the patient. Other types of cycling include pressure cycling, time cycling, and flow cycling. *Limiting factors* are operator-specified values, such as airway pressure, that are monitored by transducers internal to the ventilator circuit throughout the respiratory cycle; if the specified values are exceeded, inspiratory flow is immediately stopped, and the ventilator circuit is vented to atmospheric pressure or the specifiedPEEP.

Assist Control Mode Ventilation (ACMV) An inspiratory cycle is initiated either by the patient's inspiratory effort or, if no patient effort is detected within a specified time window, by a timer signal within the ventilator. Every breath delivered consists of the operator-specified tidal volume. Ventilatory rate is determined either by the patient or by the operator-specified backup rate, whichever is of higher frequency (Fig. 266-1*A*). ACMV is the recommended mode for initiation of mechanical ventilation because it ensures a backup minute ventilation in the absence of an intact respiratory drive and allows for synchronization of the ventilator cycle with the patient's inspiratory effort.

Problems can arise whenACMV is used in patients with tachypnea due to nonrespiratory or nonmetabolic factors such as anxiety, pain, or airway irritation. Respiratory alkalemia may develop and trigger myoclonus or seizures. Dynamic hyperinflation (so-called auto-PEEP) may occur if the patient's respiratory mechanics are such that inadequate time is available for complete exhalation between inspiratory cycles. Auto-PEEP can limit venous return, decrease cardiac output, and increase airway pressures, predisposing to barotrauma. ACMV is not effective for weaning patients from mechanical ventilation because it provides full ventilator assistance on each patient-initiated breath.

Synchronized Intermittent Mandatory Ventilation (SIMV) The major difference between SIMV and ACMVis that in the former the patient is allowed to breathe spontaneously, i.e., without ventilator assist, between delivered ventilator breaths. However, mandatory breaths are delivered in synchrony with the patient's inspiratory efforts at a frequency determined by the operator. If the patient fails to initiate a breath, the ventilator delivers a fixed-tidal-volume breath and resets the internal timer for the next inspiratory cycle (Fig. 266-1*B*). SIMV differs from ACMV in that only the preset number of breaths is ventilator-assisted.

SIMVallows patients with an intact respiratory drive to exercise inspiratory muscles between assisted breaths. This characteristic makes SIMV a useful mode of ventilation for both supporting and weaning intubated patients. SIMV may be difficult to use in patients with tachypnea because they may attempt to exhale during the ventilator-programmed inspiratory cycle. When this occurs, the airway pressure may

exceed the inspiratory pressure limit, the ventilator-assisted breath will be aborted, and minute volume may drop below that programmed by the operator. In this setting, if the tachypnea is in response to respiratory or metabolic acidosis, a change toACMVwill increase minute ventilation and help normalize the pH while the underlying process is further evaluated.

Continuous Positive Airway Pressure (CPAP) This is not a true support-mode of ventilation, inasmuch as all ventilation occurs through the patient's spontaneous efforts. The ventilator provides fresh gas to the breathing circuit with each inspiration and charges the circuit to a constant, operator-specified pressure that can range from 0 to 20 cmH_2O (Fig. 266-1*C*). CPAP is used to assess extubation potential in patients who have been effectively weaned and are requiring little ventilator support and in patients with intact respiratory system function who require an endotracheal tube for airway protection.

Pressure-Control Ventilation (PCV) This form of ventilation is time triggered, time cycled, and pressure limited. During the inspiratory phase, a given pressure is imposed at the airway opening, and the pressure remains at this user-specified level throughout inspiration (Fig. 266-2*A*). Since inspiratory airway pressure is specified by the operator, tidal volume and inspiratory flow rate are *dependent* rather than *independent* variables and are not user specified. PCV is the preferred mode of ventilation for patients with documented barotrauma, because airway pressures can be limited, and for postoperative thoracic surgical patients, in whom the shear forces across a fresh suture line should be limited. When PCV is used, minute ventilation and tidal volume must be monitored; minute ventilation is altered through changes in rate or in the pressure-control value.

The major practical limitation ofPCV is patient-ventilator asynchrony related to its time-cycled and time-triggered characteristics. Because PCV requires that the patient passively accept ventilator breaths, most patients require heavy sedation to be maintained on this ventilatory mode, which may be hazardous in the hemodynamically unstable patient.

PCVwith the use of a prolonged inspiratory time is frequently applied to patients with severe hypoxemic respiratory failure. This approach, called inverse inspiratory-to-expiratory ratio ventilation (IRV), increases mean distending pressures without increasing peak airway pressures. It is thought to work in conjunction withPEEP to open collapsed alveoli and improve oxygenation. IRV may be associated with fewer deleterious effects than conventional volume-cycled ventilation, which requires higher peak airway pressures to achieve an equivalent reduction in shunt fraction.

Pressure-Support Ventilation (PSV) This form of ventilation is patient triggered, flow cycled, and pressure limited; it is specifically designed for use in the weaning process. During PSV, the inspiratory phase is terminated when inspiratory airflow falls below a certain level; in most ventilators this flow rate cannot be adjusted by the operator. When PSV is used, patients receive ventilator assist only when the ventilator detects an inspiratory effort (Fig. 266-2*B*). PSV also can be used in combination withSIMV to ensure volume-cycled backup for patients whose respiratory drive is depressed either spontaneously or as a result of various therapeutic maneuvers.

PSVis well tolerated by most patients who are being weaned; PSV parameters can be set to provide fully or nearly fully ventilatory support and can be withdrawn slowly over a period of days in a systematic fashion to gradually load the respiratory muscles.

Open Lung Ventilation (OLV) OLV is not a distinct mode of ventilation, but rather a strategy for applying either volume-cycled or pressure-control ventilation to patients with severe respiratory failure. In OLV, the primary objectives of ventilator support are maintenance of adequate oxygenation and avoidance of cyclic opening and closing of alveolar units by selecting a level ofPEEPthat allows the majority of units to remain inflated during tidal ventilation. Achievement of eucapnia and normal blood pH through adjustments in ventilator tidal volume and breathing frequency are of lower priority. Clinical and experimental observations indicate that high airway pressures and repeated opening and closing of alveoli can cause microstructural lung damage, propagation of lung injury through generation of inflammatory cytokines, and direct barotrauma. Current data suggest that a small tidal volume (i.e., 6 mL/kg) provides adequate ventilatory support with a lower incidence of adverse effects than more conventional tidal volumes of 10-15 mL/kg. These potential complications can have dire consequences in patients with respiratory failure. Alternatively, hypercapnia and consequent respiratory acidosis tend to be well tolerated physiologically, except in patients with significant hemodynamic compromise, ventricular dysfunction, cardiac dysrrhythmias, or increased intracranial pressure. OLV has been used most extensively in the management of patients with hypoxemic respiratory failure due to acute lung injury. Although few randomized clinical trials of OLV have been performed, available data suggest that OLV reduces the morality rate and improves gas exhange in patients with acute lung injury.

Prone Positioning during Mechanical Ventilation Patients with acute respiratory distress syndrome (ARDS) experience hypoxemia as a result of intrapulmonary shunt due to regional atelectasis. Recent studies in patients with ARDS have demonstrated that collapse occurs most extensively in the dependent regions of the lung. Increasing airway pressures to counterbalance the compressive effects of the surrounding lung in these collapsed regions improves gas exchange but may result in potentially dangerous peak airway pressures. Prone positioning, in both experimental and clinical studies, reduces shunt and improves oxygenation by causing regional improvements in transpulmonary distending pressures wtihout overexpanding already patent alveoli. In clinical practice, prone positioning has been used in conjunction with both volume-cycled and pressure-control ventilation with equivalent clinical effectiveness and appears to be a useful adjunct to conventional ventilator support in patients with severe hypoxemic respiratory failure.

Noninvasive Ventilation (NIV) Noninvasive ventilator support through a tight-fitting facemask or nasal mask, traditionally used for treatment of sleep apnea, has recently been used as primary ventilator support in patients with impending respiratory failure. Facemask and nasal devices for administering NIV therapy are most frequently combined withPSV or bi-level positive airway pressure ventilation, inasmuch as both of these modes are well tolerated by the conscious patient and optimize patient-ventilator synchrony. NIV has met with varying degrees of success when applied to patients with acute or chronic respiratory failure. The major limitation to its widespread application has been patient intolerance, because the tight-fitting mask required for NIV can cause

both physical and emotional discomfort in patients with dyspnea. In general, centers with experience using NIV have reported clinical success with minimal associated morbidity, whereas centers with less experience have reported more limited success. Aggressive medical therapy directed at the cause of impending respiratory failure, together with an experienced respiratory therapy and physician team, appear to be the keys to successful use of NIV in intensive care units.

Extracorporeal Membrane Oxygenation (ECMO) This nonconventional mode of ventilator support employs a large surface area membrane system connected in series with the patient's circulation to exchange CO_2 and O_2. The lung functions primarily as a passive conduit with gas exchange occurring by diffusion across the membrane. ECMO was first examined in 1970 as an alternative to positive-pressure ventilation in the management of patients withARDS. Initial studies failed to demonstrate an improvement in survival rates among patients treated with ECMO. Although several uncontrolled trials have since suggested that ECMO does improve outcome among patients with ARDS, a 1993 study comparing survival rates of patients with ARDS treated with ECMO and those treated with conventional ventilator therapy showed no difference in mortality rates, but the morbidity rates and hospital costs were increased among ECMO-treated patients. Presently, the use of ECMO in patients with ARDS is not recommended.

GUIDELINES FOR MANAGING THE VENTILATED PATIENT

Most patients who are started on ventilator support receiveACMV orSIMV, because these modes ensure user-specified backup minute ventilation in the event that the patient fails to initiate respiratory efforts. Once the intubated patient has been stabilized with respect to oxygenation, definitive therapy for the underlying process responsible for respiratory failure is formulated and initiated. Subsequent modifications in ventilator therapy must be provided in parallel with changes in the patient's clinical status. As improvement in respiratory function is noted, the first priorities are to reducePEEP and supplemental O_2. Once a patient can achieve adequate arterial saturation with an FIO_2£ 0.5 and 5 cmH_2O PEEP, attempts should be made to reduce the level of mechanical ventilatory support. Patients previously on full ventilator support should be switched to a ventilator mode that allows for weaning, such as SIMV,PSV, or SIMV combined with PSV. Ventilator therapy can then be gradually removed, as outlined in the section on weaning. Patients whose condition continues to deteriorate after ventilator support is initiated may require increased O_2, PEEP, and alternative modes of ventilation such asIRV.

GENERAL SUPPORT IN THE VENTILATED PATIENT

Patients who are started on mechanical ventilation usually require some form of sedation and analgesia to maintain an acceptable level of comfort. Often, this regimen consists of a combination of a benzodiazepine and opiate administered intravenously. Medications commonly used for this purpose include lorazepam, midazolam, diazepam, morphine, and fentanyl.

Immobilized patients in the intensive care unit on mechanical ventilator support are at increased risk for deep venous thrombosis; accepted practice consists of administering prophylaxis in the form of subcutaneous heparin and/or pneumatic compression boots.

Fractionated low molecular weight heparin has also been used for this purpose; it appears to be equally effective and is associated with a decreased incidence of heparin-associated thrombocytopenia.

Prophylaxis against diffuse gastrointestinal mucosal injury is indicated for patients who have suffered a neurologic insult or those with severe respiratory failure in association withARDS. Histamine receptor antagonists (H_2-receptor antagonists), antacids, and cytoprotective agents such as carafate have all been used for this purpose and appear to be effective. Recent data suggest that carafate use is associated with a reduction in the incidence of nosocomial pneumonias, since it does not cause changes in stomach pH and is less likely to permit colonization of the gastrointestinal tract by nosocomial organisms at pH levels near neutral.

Nutrition support by enteral feeding through either a nasogastric or an orogastric tube should be maintained in all intubated patients whenever possible. In those patients with a normal baseline nutritional state, support should be initiated within 7 days. In malnourished patients, nutrition support should be initiated within 72 h. Delayed gastric emptying is common in critically ill patients on sedative medications but often responds to promotility agents such as cisapride or metoclopramide. Parenteral nutrition is an alternative to enteral nutrition in patients with severe gastrointestinal pathology.

COMPLICATIONS OF MECHANICAL VENTILATION

Endotracheal intubation and positive-pressure mechanical ventilation have direct and indirect effects on several organ systems, including the lung and upper airways, the cardiovascular system, and the gastrointestinal system. Pulmonary complications include barotrauma, nosocomial pneumonia, oxygen toxicity, tracheal stenosis, and deconditioning of respiratory muscles. *Barotrauma*, which occurs when high pressures (i.e., > 50 cmH_2O) disrupt lung tissue, is clinically manifest by interstitial emphysema, pneumomediastinum, subcutaneous emphysema, or pneumothorax. Although the first three conditions may resolve simply through the reduction of airway pressures, clinically significant pneumothorax, as indicated by hypoxemia, decreased lung compliance, and hemodynamic compromise, requires tube thoracostomy.

Patients intubated for longer than 72 h are at high risk for *nosocomial pneumonia* as a result of aspiration from the upper airways through small leaks around the endotracheal tube cuff; the most common organisms responsible for this condition are enteric gram-negative rods, *Staphylococcus aureus*, and anaerobic bacteria. Because the endotracheal tube and upper airways of patients on mechanical ventilation are commonly colonized with bacteria, the diagnosis of nosocomial pneumonia requires "protected brush" bronchoscopic sampling of airway secretions coupled with quantitative microbiologic techniques to differentiate colonization from infection.

Oxygen toxicity is a potential complication when an FI_{O_2}[3] 0.6 is required for more than 72 h. The condition can be prevented in some cases through the use ofPEEP to allow for FI_{O_2}values to go below 0.6 while primary therapy for the underlying condition is instituted. Although O_2toxicity is thought to result from the effects of oxygen free radical on the lung interstitium, the therapeutic use of antioxidants such as superoxide dismutase, catalase, selenium, and vitamin E remains experimental.

Hypotension resulting from elevated intrathoracic pressures with decreased venous return is almost always responsive to intravascular volume repletion. In patients judged to have hypotension or respiratory failure on the basis of alveolar edema, hemodynamic monitoring with a pulmonary arterial catheter may be of value in optimizing O_2delivery via manipulation of intravascular volume and FI_{O2} andPEEPlevels.

Gastrointestinal effects of positive-pressure ventilation include *stress ulceration* and *mild to moderate cholestasis*. It is common practice to provide prophylaxis with H_2-receptor antagonists or sucralfate for stress-related ulcers. Mild cholestasis (i.e., total bilirubin values £4.0) attributable to the effects of increased intrathoracic pressures on portal vein pressures is common and generally self-limited. Cholestasis of a more severe degree should not be attributed to a positive-pressure ventilation response and is more likely due to a primary hepatic process.

WEANING FROM MECHANICAL VENTILATION

Removal of mechanical ventilator support requires that a number of criteria be met. Upper airway function must be intact for a patient to remain extubated but is difficult to assess in the intubated patient. Therefore, if a patient can breathe on his or her own through an endotracheal tube but develops stridor or recurrent aspiration once the tube is removed, upper airway dysfunction or an abnormal swallowing mechanism should be suspected and plans for achieving a stable airway developed. An intact cough during suctioning is a good indicator of a patient's ability to mobilize secretions. Respiratory drive and chest wall function are assessed by observation of respiratory rate, tidal volume, inspiratory pressure, and vital capacity. The weaning index, defined as the ratio of breathing frequency to tidal volume (breaths per minute per liter), is both sensitive and specific for predicting the likelihood of successful extubation. When this ratio is less than 105 with the patient breathing without mechanical assistance through an endotracheal tube, successful extubation is likely. An inspiratory pressure of more than -30 cmH_2O and a vital capacity of greater than 10 mL/kg are considered indicators of acceptable chest wall and diaphragm function. Alveolar ventilation is generally adequate when elimination of CO_2 is sufficient to maintain arterial pH in the range of 7.35 to 7.40, and anSa_{O2}> 90% can be achieved with an FI_{O2}< 0.5 and a$PEEP$£ 5 cmH_2O. Although many patients may not meet all criteria for weaning, the likelihood that a patient will tolerate extubation without difficulty increases as more criteria are met.

Many approaches to weaning patients from ventilator support have been advocated. T-piece andCPAPweaning are best tolerated by patients who have undergone mechanical ventilation for brief periods and require little respiratory muscle reconditioning, whereasSIMV andPSV are best for patients who have been intubated for extended periods and require gradual respiratory-muscle reconditioning.

T-piece weaning involves brief spontaneous breathing trials with supplemental O_2. These trials are usually initiated for 5 min/h followed by a 1-h interval of rest. T-piece trials are increased in 5- to 10-min increments until the patient can remain ventilator independent for periods of several hours. Extubation can then be attempted.CPAPweaning is similar to T-piece weaning except that trials of spontaneous breathing are conducted on the ventilator in CPAP mode.

Weaning by means ofSIMVinvolves gradually tapering the mandatory backup rate in increments of 2 to 4 breaths per minute while monitoring blood gas parameters and respiratory rates. Rates of greater than 25 breaths per minute on withdrawal of mandatory ventilator breaths generally indicate respiratory muscle fatigue and the need to combine periods of exercise with periods of rest. Exercise periods are gradually increased until a patient remains stable on SIMV at 4 breaths per minute or less without needing rest at higher SIMV rates. ACPAP or T-piece trial can then be attempted before planned extubation.

PSV, as described in detail above, is used primarily for weaning from mechanical ventilation. PSV is usually initiated at a level adequate for full ventilator support (PSV_{max}); i.e., PSV is set slightly below the peak inspiratory pressures required by the patient during volume-cycled ventilation. The level of pressure support is then gradually withdrawn in increments of 5 cmH_2O until a level is reached at which the respiratory rate increases to 25 breaths per minute. At this point, intermittent periods of higher-pressure support are alternated with periods of lower-pressure support to provide muscle reconditioning without causing diaphragmatic fatigue. Gradual withdrawal of PSV continues until the level of support is just adequate to overcome the resistance of the endotracheal tube (approximately 5 to 10 cmH_2O). Support can be discontinued and the patient extubated.

267. LUNG TRANSPLANTATION - *Janet R. Maurer*

Lung transplantation for end-stage lung disease has been a therapeutic option since the 1980s. Several transplant options are available for carefully selected patients: unilateral lung transplant, bilateral lung transplant, heart-lung transplant (Chap. 233), and living lobar transplant. The first successful type of lung transplant was heart-lung, which was performed for a variety of indications and in increasing numbers until 1989. Beginning in 1989, the numbers of both unilateral and bilateral lung transplants performed increased dramatically and, along with the increasing demand for heart donors, greatly reduced the number of donor organs available for heart-lung procedures. By the mid-1990s, unilateral and bilateral lung transplant numbers also had plateaued because of donor shortages and have remained relatively stable at approximately 1250 operations worldwide per year. Of these, 60% are unilateral lung transplants and 40% are bilateral. Heart-lung transplants have leveled off at between 100 and 150 per year. In its 1999 report, the Registry of the International Society for Heart and Lung Transplantation, in conjunction with the United Network for Organ Sharing, had recorded a cumulative total of 8997 isolated lung transplants and 2350 heart-lung transplants.

INDICATIONS

Emphysema, either smoking-induced or secondary to α_1-antitrypsin deficiency, has been the single largest indication for lung transplantation. This diagnosis accounts for about 55% of unilateral lung transplants, 29% of bilateral, and 6% of heart-lung transplants. Other major indications for unilateral lung transplants include idiopathic pulmonary fibrosis (21%) and primary pulmonary hypertension (5%). Patients with cystic fibrosis comprise the largest group of bilateral lung recipients, approximately 34% of the total, followed by patients with emphysema, patients with primary pulmonary hypertension (10%), and those with idiopathic pulmonary fibrosis (7.5%). The major diagnoses among heart-lung recipients are primary and secondary pulmonary hypertension (54%) and cystic fibrosis (16%). With the widespread use of unilateral and bilateral lung transplants, the indications for heart-lung transplant have become very circumscribed, so that now most candidates for this type of transplant have either concomitant left ventricular disease and end-stage lung disease or irreparable congenital heart disease with Eisenmenger's syndrome. Patients receiving living lobar donations have been either children or young adults, and most have suffered from cystic fibrosis. In most of these operations, a lower lobe is donated from each of two adults, who are often, but not always, related to the recipient. Living donation is performed in a limited number of lung transplant programs, and the donor morbidity rate has been acceptable.

RECIPIENT SELECTION

Because donor lungs are the scarcest of the common solid organs transplanted, patients with end-stage lung disease undergo extensive evaluation to select the best potential candidates. In 1998, this process was further standardized with the publication of the International Guidelines for the Selection of Lung Transplant Candidates. Approximate age limits of 65 years for unilateral lung, 60 years for bilateral lung, and 55 years for heart-lung transplants were set. Chronic medical conditions that can be adequately controlled and have not resulted in end-organ damage, e.g., systemic hypertension, are acceptable in lung transplant candidates. However, in a case where a

chronic illness is often associated with nonpulmonary organ damage, e.g., diabetes mellitus, a careful assessment of target organ function is necessary.

Absolute contraindications to lung transplantation include dysfunction of major organs (other than lung), infection with HIV, active malignancy within 2 years with the exception of basal cell and squamous cell skin cancer, hepatitis B antigen positivity, and hepatitis C with biopsy-proven histologic evidence of liver disease. Conditions that represent relative contraindications include symptomatic osteoporosis; severe musculoskeletal disease affecting the thorax; high-dose corticosteroid use; weight less than 70% or greater than 130% of ideal body weight; alcohol, cigarette, or narcotic abuse/addiction within 6 months before evaluation; psychosocial problems, including noncompliance, that cannot be adequately resolved through pharmacologic treatment or counseling; requirement for invasive ventilation; and colonization with fungi or atypical mycobacteria. Colonization is of particular concern when a unilateral lung transplant is being considered. Disease-specific guidelines (Table 267-1) are chosen to identify candidates who are within the transplant "window" -- that is, patients who are ill enough to fit within the category of "end-stage" and have progressive disease, yet are able to survive the pre-transplant waiting and perioperative time periods. In the past few years, increasing experience with large numbers of patients with end-stage disease has made it much easier to estimate life expectancies; however, patients with diagnoses of emphysema and Eisenmenger's type pulmonary hypertension remain problematic in this regard because posttransplant statistical analysis does not show a clear survival benefit for recipients within the first 2 years. In these types of patient, selection usually includes consideration of quality-of-life issues as well as survival rates.

SELECTION OF TRANSPLANT PROCEDURE

The only diseases that currently mandate a specific procedure are (1) irreparable congenital cardiac defects with Eisenmenger's syndrome (heart-lung transplant); (2) advanced lung disease with concomitant left ventricular dysfunction (heart-lung transplant); and (3) bronchiectatic lung disease, e.g., cystic fibrosis (bilateral lung transplant or bilobar living donor lung transplant). In essentially all other circumstances unilateral lung transplantation can be performed with acceptable early and midterm results. Bilateral lung transplantation, however, is often preferred if difficulty is anticipated in postoperative management, especially in patients with pulmonary hypertension; if significant bullous disease in present in emphysema; if a patient is very young; or if there are specific individual recipient considerations. As noted below, the long-term survival rates of bilateral lung recipients may be superior; nevertheless, transplant centers have generally chosen to maximize the donor organ resource by performing unilateral lung transplants whenever possible, rather than opting for potentially slightly increased survival periods.

PROGNOSIS

The 1- and 2-year survival rates for unilateral and bilateral lung transplant recipients are 67 and 62%, respectively. Longer term data show a divergence in survival rates by 5 years, with the half-life of bilateral transplant recipients (4.9 years) significantly longer than that of unilateral transplant recipients (3.6 years). Among unilateral graft recipients, patients with emphysema appear to have the best early survival rate (nearly 80% at one

year), and patients with idiopathic pulmonary fibrosis and those with pulmonary hypertension have the worst (60 to 65%). Living lobar recipients have early survival rates that are between the rates of these groups, but long-term data are not available for this population.

FUNCTIONAL OUTCOMES

Arterial blood gas levels improve markedly in unilateral and bilateral lung transplant recipients by 3 months posttransplant. In both groups, Pa_{CO_2} normalizes; in bilateral lung transplant recipients, Pa_{O_2} also normalizes. Unilateral lung recipients may continue to have mild hypoxemia but rarely require supplemental oxygen. Pulmonary function studies usually reach their maximum values for both groups between 3 and 12 months postoperatively. Unilateral graft recipients who had a preoperative diagnosis of parenchymal lung disease attain 60 to 65% of their predicted FVC and FEV_1 values. The values for bilateral lung recipients often approach normal predicted values, but these patients can have mild restrictive physiology. Diffusing capacities are usually slightly decreased in all groups. Airway hyperresponsiveness without clinically relevant asthma can be demonstrated in the majority of lung transplant recipients.

Exercise capacity has been the most interesting functional outcome observed in lung transplant recipients. With respect to nongraded exercise capacity, usually measured by 6- or 12-min walk studies, unilateral and bilateral graft recipients demonstrate marked and similar improvement in distances covered after transplantation. Typically, transplant recipients can walk 100 to 120 m/min within 6 months of transplant and are generally able to sustain this rate over time. On graded exercise studies, however, both groups achieve only 40 to 60% of predicted maximum values, with bilateral lung recipients usually performing slightly better than unilateral lung recipients. This exercise limitation has been extensively studied particularly in bilateral lung recipients. The limitation appears not to be cardiac or ventilatory but rather related to muscle deconditioning and abnormalities in skeletal muscle oxidative capacity. Rarely is the exercise limitation in these patients enough to impact on their normal daily activities or their quality of life.

POSTTRANSPLANT MANAGEMENT ISSUES

Airway Complications Technical improvements and surgical experience have greatly reduced significant anastomotic complications in lung transplant recipients. It is not uncommon to see small dehiscences of the airway in the first weeks posttransplant, but these generally heal without significant stricture. Probably fewer than 10% of patients will have stenosis severe enough to require balloon dilatation, laser resection, or a stent. When required, wire stents are most often used and are well tolerated. Late-occurring bronchomalacia, often at the anastomotic site, has also been treated with stents.

Acute Rejection A three-pronged immunosuppressive approach, which is used in most lung transplant programs, includes either cyclosporine or tacrolimus, either azathioprine or mycophenolate mofetil, and prednisone. Cytolytic induction is rarely used in these patients because of the risk of infection. Most lung transplant recipients experience at least one episode of acute rejection, usually within the first 3 months, although episodes have been reported to occur up to several years after transplantation. From 10 to 15% of patients have recurrent acute or persistent acute rejection, which predisposes them to

chronic rejection. Symptoms include a general feeling of malaise, dyspnea, and sometimes cough. Findings may include low grade fever, rales, mild hypoxemia, decreasing FVC and FEV_1values, increased white blood cell count, and ill-defined infiltrates with or without pleural effusion on chest x-ray. If a patient presents early in an episode of acute rejection, as most do, the findings are minimal and the chest radiogram is clear. Histologic diagnosis, which is the "gold standard," is routinely made by transbronchial biopsy, with a sensitivity of about 80% and a specificity approaching 100%. Bronchoscopy is also helpful in this setting to rule out infections that may have similar presentations.

Acute rejection episodes occurring early after transplantation respond in at least 80% of patients to bolus methylprednisolone. Late episodes and recurrent or persistent episodes often require both intensification of immunosuppression and changes in immunosuppressive drugs. Up to 20% of asymptomatic patients have at least one episode of acute rejection detected by surveillance transbronchial biopsy in the first 2 years posttransplant. It is not clear whether asymptomatic rejection requires therapy, as the impact on outcome is unknown. Thus, the use of surveillance bronchoscopy and the treatment of asymptomatic rejection vary considerably from institution to institution, and there are at present no clear guidelines in this area.

Bronchiolitis Obliterans Bronchiolitis obliterans is both the primary manifestation of chronic rejection and the most feared complication in lung transplant recipients. It occurs to some degree in at least 50% of survivors by 5 years posttransplant and is a factor in more than one-third of late deaths. Although it can occur as early as 2 months posttransplant, the onset is more often at least 6 months and the mean onset is from 1 to 2 years after surgery. The precipitating factors and initiating events in bronchiolitis obliterans are topics of intensive research both in transplant recipients and in several animal models. Those factors most consistently associated with the process include the numbers and severity of acute rejection episodes and episodes of cytomegalovirus (CMV) pneumonia, but not clearly CMV infection alone. Other factors with weaker associations include HLA mismatches, other viral infections, and the development of anti-HLA antibodies. Clinically, the onset of this process is often subacute, with a very gradual onset of dyspnea and fatigue or malaise, often accompanied by viral-type symptoms or dry cough. It can also be asymptomatic and detected by routine pulmonary function studies that show, initially, a decrease in the FEF_{25-75}, often followed one to several months later by decreasing FEV_1. This insidious development of small airway obstruction is often well established before it is clinically recognized, and for that reason frequent pulmonary function testing is recommended for lung transplant recipients. Chest radiograms are usually normal, but even early in the disease expiratory computed tomography (CT) scans show a mottled appearance with peripheral hyperlucency. Transbronchial biopsy is very specific but not sensitive in diagnosis, but patients usually undergo at least one bronchoscopy at the onset of disease to attempt histologic documentation and to rule out possible infections. Because of the difficulty in histologic diagnosis, a typical clinical picture in the absence of other etiology is considered sufficient to establish a diagnosis of *bronchiolitis obliterans syndrome*. The progression of this complication can be very rapid, with early death; but more often it is one of a gradually decreasing FEV_1over months to years, which in the later stages is frequently accompanied by bronchomalacia, proximal bronchiectasis, and recurrent pseudomonal or other infections.

Effective treatment remains evasive. A few immunosuppressive protocols tried in small numbers of patients have been found to "stabilize" pulmonary function, but improved function is unusual. Likely, by the time the process is recognized in most patients, fibrotic obliteration of the airway is already present; the key to treatment may lie in identifying markers of incipient disease and much earlier intervention.

Infections Infections rank second only to rejection as a cause of morbidity in lung transplant recipients and are the most common cause of mortality, accounting for one-third of all deaths in both the early and the late posttransplant periods. The transplanted lung may be uniquely vulnerable to infection because of impaired mucociliary clearance, loss of cough reflex, and other poorly defined local factors. In addition, the donor lungs are often colonized with organisms that are transmitted directly to the immunosuppressed recipient. Early series reported that at least 60% of lung recipients early in their course develop infections requiring treatment. Now the extensive use of broad antibacterial, antifungal, anti-*pneumocystis*, and antiviral prophylaxis, often maintained for at least 3 months postoperatively, seems to have reduced the early infective morbidity and mortality.

Infections with paramyxoviral organisms, adenovirus, and influenza A have now been well documented and have an overall death rate of about 20%. The role of antiviral therapy is unclear. The most lethal infections are those with invasive fungal organisms, particularly those caused by *Aspergillus* species, which have been reported to colonize in 20 to 50% of recipients. Invasive disease caused by these organisms can vary from ulcerative bronchitis to localized parenchymal infiltrates to empyema to disseminated disease. *Aspergillus* is particularly likely to be problematic when patients require increased immunosuppression or have other complications; one study has reported an increased rate of invasive disease in the native lung of unilateral lung transplant recipients.

The highest risk periods for infection are in the first few months posttransplant and late after transplant if bronchiolitis obliterans or other vital organ dysfunction, e.g., renal failure, develops. Since it may be very difficult to distinguish infection from rejection in the early posttransplant period, bronchoscopy with appropriate biopsies and cultures is often necessary to establish a diagnosis.

Immunosuppressive and Medical Complications Medical complications related to immunosuppression, to the underlying diagnosis, or to aging are major causes of morbidity in long-term survivors of lung transplantation and account for up to 10% of late deaths. Current immunosuppressive regimens with cyclosporine or tacrolimus cause some nephrotoxicity in virtually all patients. Although few progress to renal failure, hypertension and hyperlipidemia are common. Neurotoxicity, including delirium, headaches, seizures, and, occasionally, strokes, has been reported in up to 20% of patients. Osteoporosis occurs in more than half the patients, and vertebral compression fractures are common. Other problems include thromboembolic disease, gastric complications (especially gastroparesis), hyperglycemia, and increased rates of malignancy.

Posttransplant lymphoproliferative disorders associated with Epstein-Barr virus occur in

5 to 10% of lung transplant recipients. Nearly all occur within the first year after transplant. Recent data suggest a much higher incidence of this disease in patients who are Epstein-Barr naive and who receive an Epstein-Barr positive graft. Treatment for this disorder, reported to have an approximate 50% survival rate, is usually reduced immunosuppression and antiviral and anti-B lymphocyte drugs. Survivors often develop bronchiolitis obliterans.

Recurrence of Underlying Disease Several different underlying diseases may recur in lung transplant recipients. These diseases include sarcoidosis, lymphangioleiomyomatosis, giant cell interstitial pneumonia, panbronchiolitis, eosinophilic granuloma, bronchoalveolar cell carcinoma, and desquamative interstitial pneumonia.

PART TEN -DISORDERS OF THE KIDNEY AND URINARY TRACT

268. DISTURBANCES OF RENAL FUNCTION - *Robert M. Brenner*, *Barry M. Brenner*

Near constancy of the composition of the internal environment, including the volume, tonicity, and compartmental distribution of the body fluids, is essential to survival. With normal day-to-day variations in the intake of food and water, preservation of the internal environment requires the excretion of these substances in amounts that balance the quantities ingested. Although losses from intestines, lungs, and skin contribute to this excretory capacity, the greatest responsibility for solute and water excretion is borne by the kidneys.

The kidneys regulate the composition and volume of the plasma water. This, in turn, determines the composition and volume of the entire *extracellular* fluid compartment. Through the continuous exchange of water and solutes across all cell membranes, the kidneys influence the *intracellular* fluid compartment as well. These functions are served by a variety of physiologic mechanisms that enable individuals to excrete excesses of water and nonmetabolized solutes contained in the diet, as well as the nonvolatile end products of nitrogen metabolism, such as urea and creatinine. Conversely, when faced with deficits of water or solute, excretion of water or specific solute(s) is curtailed via appropriate mechanisms for renal conservation, reducing the likelihood of volume or solute depletion. The purpose of this**chapter**is to review the excretory functions of the kidney and to examine how these functions are affected by chronic renal disease.

EFFECTS OF NEPHRON LOSS ON RENAL EXCRETORY MECHANISMS

The volume of urine excreted (averaging 1.5 L/d or roughly 1 mL/min) represents the sum of two large, directionally opposite processes -- namely, *ultrafiltration* of 180 L/d or more of plasma water (or 125 mL/min) and *reabsorption* of more than 99% of this filtrate by transport processes in the renal tubules. While renal blood flow accounts for about 20% of resting cardiac output, the kidneys comprise only about 1% of total body weight. This disproportionate allocation of cardiac output, greatly exceeding blood flow per gram of brain, heart or liver, is required for the process of ultrafiltration.

GLOMERULAR ULTRAFILTRATION

Urine production begins at the glomerulus where an ultrafiltrate of plasma is formed. The rate of glomerular ultrafiltration (glomerular filtration rate, GFR) is governed chiefly by forces favoring filtration on the one hand (hydraulic pressure in the glomerular capillaries) and forces opposing filtration on the other (the sum of hydraulic pressure in Bowman's space and colloid osmotic pressure in the glomerular capillaries). The rate of glomerular plasma flow and the total surface area of the glomerular capillaries are also determinants of GFR. Decreased GFR can therefore be expected when (1) glomerular hydraulic pressure is reduced (as in circulatory shock); (2) tubule (hence Bowman's space) hydraulic pressure is elevated, as in urinary tract obstruction; (3) plasma colloid osmotic pressure rises to high levels (hemoconcentration due to severe volume depletion, myeloma, or other dysproteinemias); (4) renal, and hence glomerular, blood flow is reduced (severe hypovolemia, cardiac failure); (5) permeability is reduced

(diffuse glomerular disease); or (6) filtration surface area is diminished, through focal or diffuse nephron loss in progressive renal failure.

The glomerular capillary wall is specially adapted to allow passage of extremely large volumes of water while retaining all but the smallest solute molecules. Molecules the size of inulin (approximately 5200 mol wt) pass freely across the glomerular filtration barrier, appearing at approximately the same concentration in Bowman's space as in plasma. The passage of solutes across the glomerular barrier decreases progressively with increasing molecular size such that, as the molecular weight of albumin is approached, most of the solute is retained in the plasma. Albumin, a polyanionic molecule in plasma, is further retarded at the glomerular filtration barrier by *electrostatic forces* imparted by negatively charged cell-surface molecules on the epithelial foot processes that form the *filtration slits* and the *slit diaphragms*. With disruption of these structural and electrostatic barriers, as in many forms of glomerular injury (Chaps. 273 to 275), large quantities of plasma proteins gain access to the glomerular filtrate.

Glomerular Adaptations to Nephron Loss With loss of nephron mass, the remaining functional (or least injured) nephrons tend to hypertrophy and take on an increased workload so that the overall loss of function is minimized. For example, a patient with a unilateral nephrectomy loses one-half of the nephron mass, resulting in a 50% reduction inGFR at the time of surgery. However, the GFR in the remaining kidney begins to increase after 1 or 2 weeks, and within several months GFR may rise to 80% of the preoperative value. This indicates that the GFR of the individual remaining nephrons has increased above normal, a state known as *hyperfiltration*. Increases in single-nephron GFR may be achieved by renal hemodynamic adjustments (increased glomerular plasma flow and increased glomerular capillary hydraulic pressure), which augment the forces driving ultrafiltration, and by glomerular hypertrophy, which increases the maximum surface area available for filtration. These structural adaptations are evident from the enlargement of glomeruli (and tubules) seen on histologic sections from people with single kidneys. Similar structural changes are observed in kidneys damaged by chronic disease processes; foci of hypertrophied glomeruli and tubules are interspersed with areas of atrophic or scarred parenchyma. Although direct measurements of single-nephron GFR cannot be made in humans, it is reasonable to conclude that focal nephron enlargement as occurs in chronically diseased kidneys generally signifies focally increased single-nephron GFR, and that these dynamic adaptations represent compensatory adjustments for the effects of nephron loss through disease.

Glomerulotubular Balance The close integration of glomerular and tubular functions (*glomerulotubular balance*) seen in chronic renal failure (CRF) supports the notion that progressive nephron obliteration is the usual mode ofGFRreduction in CRF. Preservation of glomerulotubular balance until the terminal stages of CRF is fundamental to the *intact-nephron hypothesis*, which states that as CRF advances, kidney function is supported by a diminishing pool of functioning (or hyperfunctioning) nephrons, rather than relatively constant numbers of nephrons, each with diminishing function. This concept has important implications for the mechanisms of disease progression in CRF. A considerable amount of evidence suggests that nephrons subjected to increased excretory burdens for prolonged periods actually sustain injury as a result of these adaptations: thus the cost of these compensatory adaptations to

nephron loss may ultimately be relentless destruction of the remaining nephron pool.

The magnitude of the single-nephron hyperfiltration induced by loss of 50% of the total nephron mass usually has no serious adverse clinical consequences, even when sustained over two to three decades. When more than 50% of the total nephron mass is lost, however, as in renal-sparing surgery for bilateral trauma or neoplasm or from a renal disease whose activity has abated, the remaining nephrons are forced to the limits of their compensatory capacity. While these adaptations achieve remarkable short-term success at offsetting the tendency forGFR to fall, over time, proteinuria and focal and segmental glomerulosclerosis develop, the more so where greater amounts of nephrons are lost or removed. As a result, a progressive decline in GFR ensues. Experimental study of the processes that advance glomerular injury show that the adverse long-term consequences of severe nephron deficits are invariably preceded by increases in glomerular capillary hydraulic pressure (glomerular capillary hypertension), glomerular hyperperfusion, and hypertrophy. Interventions directed against these compensatory and maladaptive responses can greatly ameliorate the subsequent development of renal failure. In particular, drugs (e.g., angiotensin-converting enzyme inhibitors and angiotensin II receptor blockers) and other interventions (such as dietary protein restriction) that lower glomerular pressure can slow the rate of progression of experimental and human renal disease. In the absence of such interventions, more and more glomeruli cease to function through advancing glomerulosclerosis and disruption of tubule structure and function, leading eventually to total loss of GFR (i.e., end-stage renal disease). This *final common pathway* for chronic renal injury helps to explain the observed progressive nature of chronic renal failure resulting from many different kidney diseases.

Biologic Consequences of Sustained Reductions in GFR Although nephron loss can proceed, to some extent, without equivalent loss ofGFR due to the compensatory mechanisms described above, determination of the total GFR of both kidneys remains the most reliable clinical index of overall excretory function. The effects of impaired GFR are to reduce the total rate of delivery of solute into the glomerular filtrate. When accompanied by comparably reduced rates of urinary excretion, *retention* and *accumulation* of the unexcreted solute occurs, resulting in increased concentrations of the substance in the plasma and other body fluids.

Figure 268-1 depicts the major types of response to impairedGFR. The degree of reduction in total GFR is plotted on the abscissa, expressed as a percentage of normal (100%). The renal handling of most solutes normally present in glomerular filtrate conforms to one of three patterns. Curve *A* describes the pattern with substances such as creatinine and urea that normally depend largely on glomerular filtration for urinary excretion; i.e., secretion contributes little to overall excretion. Therefore, as illustrated, gradual reductions in GFR are accompanied by progressive increases in plasma levels of creatinine, urea, and other substances normally excreted primarily by filtration.

The clinical course ofCRFusually also approximates the pattern described by curve *A*. Patients with CRF usually pass from a long asymptomatic period of "compensation" to a more accelerated and clinically overt terminal phase. In other words, despite chronic injury leading to destruction of more than 50% of nephrons, plasma elevations of creatinine and urea may still lie within the normal limits for these substances. With

further nephron loss and reduction inGFR, however, the limits of renal reserve are exceeded and continued accumulations of curve *A*-type solutes lead to abnormally elevated plasma concentrations (Fig. 268-1). Because some of these retained solutes are thought to exert "toxic" effects on all organ systems, clinical manifestations of CRF may now become apparent. Consequently, in patients with substantial reductions in nephron mass but near-normal plasma creatinine, overt uremia may be precipitated by a modest additional decline in GFR.

The accumulation of curve *A*-type solutes with chronic loss of renal function proceeds until external balance is restored, i.e., intake and/or production rates exactly match excretion rates. In the case of creatinine, for example, assuming a constant rate of creatinine production, a 50% reduction inGFRresults in an approximate doubling of the plasma creatinine concentration. The latter restores the filtered load of creatinine (i.e., the product of GFR and plasma creatinine concentration) to normal, and the urinary excretion rate once again is equivalent to creatinine production. Since creatinine secretion contributes only slightly, elimination of the retained creatinine is not possible and the plasma concentration remains twice normal. With further loss of GFR, elevations in plasma creatinine are compounded by loss of nephron excretory function and creatinine retained as the result of earlier nephron destruction (Fig. 268-1). *In practice, so long as the net rates of acquisition and production (i.e., liver function and muscle mass) remain reasonably constant, the inverse relationship between plasma concentrations of solutes such as creatinine and urea and GFR is sufficiently reliable to serve as clinical indices of GFR.* However, where muscle mass is low, as with severe weight loss, unremarkable plasma levels of creatinine may belie substantial reductions in GFR.

In contrast to solutes of the curve *A* type, plasma levels of phosphate (PO_4^{3-}), urate, and potassium (K^+) and hydrogen (H^+) ions usually do not rise until theGFRfalls to a small percentage of normal. With progressive renal failure this pattern of response (curve *B* inFig. 268-1) reflects the participation of tubule transport mechanisms in the excretion of these substances. In other words, *as GFR declines, the tubules facilitate greater elimination of these substances, by enhancing secretion and/or by diminishing reabsorption, so that a greater fraction of the filtered load is excreted.* Plasma levels of curve *B*-type solutes, therefore, rise less than those of curve *A* because, with progressive reductions in GFR, *excretion rate per nephron* and therefore *fractional excretion* both increase. Eventually, however, with further loss of GFR, enhanced fractional excretion can no longer mitigate the reduction in net filtered load of these solutes and plasma levels rise (Fig. 268-1). For urate, PO_4^{3-}, and K^+, at least, increased fractional excretion serves to maintain normal plasma levels until GFR falls to less than one-fourth of normal.

Finally, for certain solutes, such as sodium chloride (NaCl), plasma concentrations remain normal throughout the course ofCRF, despite unrestricted intake of these substances (curve *C* inFig. 268-1). The compensatory mechanism required to achieve this represents a fundamental adaptation to chronic renal injury. To illustrate the magnitude of this adaptation, it is useful to compare the excretion of sodium (Na^+) in a normal individual (GFR of 125 mL/min) with that of a patient with advanced renal failure (GFR of 2 mL/min). Both individuals consume a conventional diet containing 7 g/d of salt (120 mmol Na^+). With a normal serum Na^+concentration of 140 mmol/L, external

Na^+balance is achieved by excreting approximately 0.5% of the filtered load. By contrast, for external balance to be maintained in the patient with CRF, fractional excretion of Na^+ must rise to 30%. In other words, *to maintain external* Na^+balance, the same amount of Na^+ must be excreted into the urine each day in the patient with CRF as in the normal individual. Given the drastic reduction in GFR in CRF, external balance can only be maintained by marked adaptations in the reabsorptive processes in surviving tubules. In this manner, a progressively larger fraction of the filtered load escapes reabsorption and appears in the final urine. In short, *the rate of excretion of* Na^+per surviving nephron increases in inverse proportion to the composite GFR in surviving nephrons.

ADAPTATIONS IN TUBULE TRANSPORT MECHANISMS IN RESPONSE TO NEPHRON LOSS

Despite progressive nephron loss, many mechanisms that regulate renal solute and water balance differ only quantitatively, and not qualitatively, from those that operate normally. Thus, glomerulotubular balance is maintained. The most important of these mechanisms are considered below.

TUBULAR TRANSPORT OF SODIUM CHLORIDE AND WATER

Most of the filtered water and sodium salts are reabsorbed by the tubules, leaving small and variable amounts, equivalent on average to the quantities ingested, to reach the final urine. About two-thirds of the glomerular ultrafiltrate is reabsorbed in the *proximal tubule* with little change in the osmolality or Na^+concentration of the unreabsorbed fraction (Fig. 268-2). In other words, fluid reabsorption in the proximal tubule is nearly *isosmotic* and is coupled to the active transport of Na^+. Since chloride (Cl^-) and bicarbonate (HCO_3^-) are the primary anions in the extracellular fluid, they constitute the main solutes that accompany Na^+reabsorption in the renal tubules. In the earliest portion of the proximal tubule, bicarbonate is the principal anion that accompanies the reabsorption of Na^+. This process occurs via a Na^+/H^+exchanger at the luminal brush border and is dependent on the activity of carbonic anhydrase. Glucose, amino acids, and other organic solutes (e.g., lactate) are also extensively reabsorbed in the proximal tubule by cotransport mechanisms that link the cellular entry of these organic molecules with Na^+. The coupling of water absorption (i.e., volume) with solute absorption appears to be dependent upon three processes. First, given the remarkably high water permeability of this segment, very small transepithelial osmolality differences, i.e., *luminal hypotonicity* of the order of 2 to 3 mosmol/L produced by solute absorption, could drive water absorption. Second, due to preferential absorption of $HCO_3^-$and organic solutes in the early portions of the proximal tubule, the concentrations of these substances decrease along the proximal tubule while that of chloride increases. Volume reabsorption would then occur if the diffusion of Na^+ and Cl^- down their respective electrochemical gradients across the proximal tubule epithelium occurred more easily than the back-diffusion of sodium bicarbonate into the lumen, creating an *effective osmotic pressure gradient*. Finally, *lateral interstitial space hypertonicity* produced by differences in the rates at which solutes are transported into the spaces or exit them by diffusion may also contribute to the coupling of water and solute reabsorption.

Reabsorption of Fluid from Proximal Convoluted Tubules This is sensitive to

Starling forces, i.e., the hydraulic and colloid osmotic (or oncotic) pressures acting across the walls of the peritubular capillaries. Because the plasma proteins in glomerular capillaries are concentrated by ultrafiltration, oncotic pressure rises along the glomerular capillary network. This step-up in oncotic pressure is transmitted largely unchanged to the first branches of the peritubular capillaries via the efferent arterioles. These resistance vessels cause a substantial drop in hydraulic pressure, however, so that when the plasma reaches the peritubular capillaries, oncotic pressure greatly exceeds hydraulic pressure. The Starling forces are therefore oriented in an *uptake* mode, in contrast to their configuration at the glomerulus where hydraulic pressure exceeds oncotic pressure, favoring *filtration.* The extent to which oncotic pressure exceeds hydraulic pressure in the peritubular capillary network modulates the overall rate of fluid absorption by the peritubular capillaries. Therefore, when peritubular capillary oncotic pressure falls, or hydraulic pressure rises, uptake of fluid by these capillaries is reduced. As a result, fluid is retained in the interstitial space, tending to increase hydraulic pressure, ultimately retarding the egress of fluid from the lateral intercellular channels. Without an adequate route of drainage, fluid in the intercellular channels leaks back into the tubule lumen, thereby *diminishing net fluid reabsorption* from this tubule segment. The opposite occurs in states where peritubular oncotic pressure is increased (increased filtration fraction) or hydraulic pressure is decreased (enhanced efferent arteriolar tone). Under these circumstances, peritubular capillary uptake of reabsorbate is augmented, leading ultimately to *enhanced net fluid reabsorption* by the proximal tubule. Although physical factors appear to be the major determinants of fluid reabsorption in the proximal tubule, hormones (e.g., angiotensin II) may also modulate fluid reabsorption directly, by enhancing luminal Na^+ entry into proximal tubule cells via an apical Na^+/H^+ exchanger.

The Limbs of Henle's Loop In contrast to the proximal tubule, active outward transport of Na has not been established for the *thin ascending limb of Henle's loop*. However, passive outward salt transport does occur, as indicated in Fig. 268-2. In the next nephron segment, the *medullary thick ascending limb of Henle*, the concentration of NaCl is reduced as fluid traverses this segment. Here Cl^- absorption occurs by an active process involving a $Na^+:K^+:2Cl^-$ cotransport mechanism in the luminal membrane, with one-half of Na^+ absorption proceeding passively, driven by the lumen positive transepithelial voltage difference. This cotransporter is the site of action of the powerful loop diuretics and mutations give rise to Bartter's syndrome. Since the ascending limb of Henle is impermeable to water, net NaCl reabsorption generates a hypotonic tubule fluid and gives rise to the high NaCl concentration of the outer medullary interstitium (Fig. 268-2). In certain animals, arginine vasopressin (AVP; also called ADH) enhances NaCl absorption in the medullary portion of the thick ascending limb, but whether this occurs in humans is uncertain.

Distal Tubule The fluid leaving the thick ascending limb of Henle is normally of low NaCl concentration, a characteristic independent of the organism's hydration or dietary status. In the *distal tubule*, water reabsorption is variable, depending on the state of hydration or, specifically, on the presence or absence of AVP in plasma. In the absence of AVP, this and more distal nephron segments are impermeable to water, so that hypotonic fluid entering this segment is excreted as *dilute urine.* Indeed, continued salt reabsorption along the distal convoluted tubule (DCT) and connecting tubule segments, a process that can be inhibited by the thiazide classes of diuretics, results in further

dilution of the urine. In the presence of AVP, the permeability of these nephron segments to water increases. This is made possible by the insertion of proteins known as *aquaporins* into the luminal cell membrane of DCT cells. These proteins facilitate water movement from the low osmolality environment of the DCT lumen into the higher osmolality of the medullary interstitium, thereby contributing to the creation of a concentrated final urine. NaCl continues to be reabsorbed from the tubule lumen against moderately steep chemical and electrical gradients. The reabsorption of NaCl at the collecting tubule is enhanced by *aldosterone.*

Collecting Tubules and Ducts The *cortical collecting tubule* possesses a low permeability to water in the absence ofAVP, whereas permeability increases in the presence of this hormone. The sensitivity of this segment to AVP appears to be more pronounced than that of the DCT. As with the DCT, the cortical collecting tubule is capable of active reabsorption of NaCl and its stimulation by aldosterone.

The terminal segment of the distal nephron is the highly branched *papillary collecting duct*. Continued electrolyte transport in this segment results in the large ion concentration differences that normally exist between urine and plasma. As in the cortical collecting tubule, Na^+transport appears to be active, since reabsorption proceeds against sizeable electrochemical gradients. The rate of Na^+transport in this segment depends on the load of Na^+delivered from more proximal segments and is also affected by aldosterone. The permeability to water is also increased markedly in the presence ofAVP.

Effects of Nephron Loss on Sodium Chloride Transport in Surviving Nephrons With progressive nephron loss, *maintenance of external balance for NaCl requires that fractional salt excretion increases in concert with the decline inGFR*. Several mechanisms contribute to this adaptive increase in fractional Na^+excretion. With loss of functioning nephron units, peritubular capillary Starling forces are presumably altered in directions that serve to reduce proximal tubule reabsorption of NaCl and water. For example, a rise in peritubular capillary hydraulic pressure, which tends to inhibit net proximal fluid reabsorption, might be anticipated with systemic hypertension, a common feature of chronic renal failure. Similarly, reductions in peritubular capillary oncotic pressures may be anticipated due to reductions in both filtration fraction and hypoalbuminemia.

Aldosterone, which normally exerts a potent influence on tubule transport, probably does not figure prominently in reducing fractional Na^+excretion, since aldosterone levels are seldom reduced inCRF. Furthermore, external Na^+balance is preserved in bilaterally adrenalectomized dogs on fixed replacement doses of mineralocorticoid. Yet another factor contributing to the suppression of fractional NaCl reabsorption in CRF may relate to the retention of various organic solutes asGFRdeclines.

Several factors that regulate NaCl transport across tubules under resting conditions are also likely to contribute to the enhanced fractional excretion of salt in renal insufficiency. Atrial natriuretic peptides are released from the heart in response to elevated cardiac (atrial) filling pressures as seen with increased plasma volume or atrial tachyarrhythmias. These peptides affect natriuresis by reducing net Na^+reabsorption through complementary actions on Na^+transport in the collecting duct and by altering

Starling forces in the adjacent vasa recta. The vascular actions of natriuretic peptides may also extend to glomerular hemodynamics, with afferent arteriolar vasodilatation contributing to increased single-nephronGFR and hence an increase in the amount of Na^+filtered. Other modulators of tubule transport processes may also contribute to increased single-nephron natriuresis in the setting of reduced renal mass or nephron loss. Vasodilator prostaglandins are present at increased plasma levels in CRF, as are other inhibitors of transport, including inhibitor(s) of the Na^+,K^+-ATPase. This latter factor has not yet been fully characterized; whether its presence represents a homeostatic adaptation for maintenance of fluid balance or an unregulated accumulation of a toxin remains uncertain.

Serum and urine from patients with uremia contain factors capable of experimentally inhibiting NaCl transport across frog skin, toad bladder, and rat renal tubule. Accumulation of natriuretic factors in uremia may not be without cost; the "trade-off" for maintenance of external Na^+balance is the possibility of generalized abnormalities occurring in Na^+transport across cell membranes, which often occur in advanced renal failure (Chap. 270).

The obligatory high rate of solute excretion per surviving nephron (so-called osmotic diuresis due to urea and other retained solutes) also contributes to enhancing fractional NaCl excretion, much as occurs in normal individuals after the administration of mannitol or other nonreabsorbable solutes. Finally, certain forms ofCRF are associated with unusually large losses of salt in the urine. These *salt-wasting nephropathies* include chronic pyelonephritis and other tubulointerstitial diseases (Chap. 277) as well as polycystic and medullary cystic diseases. These disorders have in common greater destruction of medullary and tubulointerstitial, rather than cortical and glomerular, portions of the renal parenchyma. Preferential impairment of tubule reabsorptive function, rather than a primary reduction in glomerular filtration, may, therefore, underlie the salt-losing tendency in these disorders. Clinical derangements that alter renal handling of NaCl in CRF (including hypo- and hypervolemia, hypertension, etc.) are considered in Chap. 270.

EFFECTS OF NEPHRON LOSS ON WATER REABSORPTION IN SURVIVING NEPHRONS

As with NaCl, there is a progressive increase in the fractional excretion of water with advancing renal insufficiency, so that external water balance can be maintained even with a totalGFR of 5 mL/min or less. The adaptations of water handling by the diseased kidney are of importance in the defects in urinary concentration and dilution and hence the polyuria, nocturia, and tendency to develop water overload encountered inCRF(Chap. 47). To appreciate the mechanisms involved, the responses of a normal and a uremic individual maintaining external water balance need to be considered. Assuming both individuals have the same dietary and fluid intakes, total solute and volume excretion in both should be identical as well. If the *obligatory solute load* to be excreted by each is 600 mmol/d (600 mosmol/d) and the urine osmolality is 300 mmol/kg water (300 mosmol/kg), a urine volume of 2 L/d will be required to excrete the total solute. If the GFR in normal and uremic individuals totals 180 and 4 L/d, respectively, urinary volume excretion of 2 L/d represents excretion of slightly more than 1% of the total glomerular filtrate in the normal subject compared with 50% in the uremic

patient. Since the range of urine osmolalities that the diseased kidney can achieve [250 to 350 mmol/kg (250 to 350 mosmol/kg)] is narrower than in the normal kidney [40 to 1200 mmol/kg (40 to 1200 mosmol/kg)], the individual with normal function is able to excrete the obligatory daily solute load of 600 mmol (600 mosmol) in as little as 500 mL urine per day or as much as 15 L/d, compared with the narrower range in renal insufficiency, from about 1.7 to 2.4 L/d.

InCRF, the limited capacity to concentrate the urine often correlates with other measures of impaired renal function. Isosthenuria (urine of similar osmolality to plasma) is therefore an almost universal finding when theGFRfalls below 25 mL/min. At this level of GFR and below, urine osmolality does not rise even when supraphysiologic doses ofAVP are administered, suggesting that the concentrating defect relates to impaired concentrating capacity in surviving nephrons. The associated increased fractional excretion per nephron of a variety of solutes produces an obligatory water loss (solute diuresis) at roughly isotonic proportions. Consequently, formation of a concentrated urine is prevented. Disease-induced abnormalities of the architecture of the renal medulla (loops of Henle, vasa recta), aberrations in medullary blood flow, and defective transport of NaCl in the ascending limb of Henle also contribute to this defect in urine concentration.

Since patients withCRF are unable to excrete concentrated or dilute urine, they must have access to adequate, and to some extent, relatively constant amounts of water per day to ensure that they have adequate water to eliminate total daily solute loads. For this reason, restriction of fluid intake may be hazardous in patients with CRF. Likewise, impairment of diluting capacity may prevent many patients from excreting excess ingested fluid. The consequences of the abnormal patterns of water excretion, and the attendant susceptibilities to develop hypo- and hypernatremia, are considered inChaps. 49 and270.

TUBULE TRANSPORT OF PHOSPHATE WITH NORMAL AND REDUCED NEPHRON MASS

Under normal physiologic conditions, about 80 to 90% of phosphate is reabsorbed, mainly in the proximal tubule. *Parathyroid hormone* (PTH), by augmenting phosphate excretion via inhibition of this proximal reabsorptive process (Chap. 340), plays a central role in phosphate homeostasis. When dietary phosphate intake increases, a *transient* rise in plasma phosphate concentration is usually observed. This results in a similarly transient reduction in the plasma ionized calcium level (due largely to deposition of calcium phosphate in bone), which is sensed by a specific receptor on parathyroid cells, stimulating PTH secretion. By enhancing fractional phosphate excretion, PTH restores external phosphate balance and normophosphatemia. This enables plasma ionized calcium levels to return to normal, thereby removing the stimulus to PTH release and restoring the phosphate control system to the original steady state.

With advancing renal failure and constant dietary intake of phosphate, external phosphate balance is achieved by progressive reduction in fractional phosphate reabsorption. EnhancedPTHsecretion is an important determinant of this phosphaturic response. With succeeding decrements in totalGFR, the amount of phosphate filtered by surviving glomeruli is reduced, leading to transient phosphate retention and,

therefore, a rise (albeit small) in plasma phosphate concentration. This leads to a small, reciprocal decline in plasma levels of ionized calcium and a corresponding increase in PTH secretion. Although the phosphaturic response of surviving tubules to this elevation in circulating PTH restores plasma phosphate and calcium to normal levels (at least in the "compensated" stage ofCRFdescribed by curve *B* in Fig. 268-1), the new steady-state conditions are only achieved at the cost of *persistently elevated plasma PTH levels*. With progressive reductions in GFR, the process is repeated, resulting in substantially elevated PTH levels.

Alterations in Vitamin D Metabolism These alterations also contribute to elevatedPTHlevels inCRF. The kidney is normally the major site of *conversion of vitamin D to its active metabolites*. As discussed in Chap. 340, vitamin D, synthesized in skin or acquired in the diet, undergoes initial hydroxylation in the liver to form 25-hydroxyvitamin D [25(OH)D]. The kidney is the site of a second important conversion to 1,25-hydroxyvitamin D [1,25(OH_2)D]. This active form of vitamin D acts directly on the parathyroid gland to suppress PTH secretion as well as to enhance intestinal absorption of calcium and phosphate resorption and promote resorption of these ions from bone. In addition, 1,25(OH)D_2probably opposes the phosphaturic actions of PTH in the renal tubule by augmenting, rather than diminishing, phosphate reabsorption. With advancing renal disease, nephron loss reduces the renal capacity for vitamin D hydroxylation; phosphate retention also impairs this reaction. Not only are the circulating levels of 1,25(OH)D_2diminished in uremia, but the receptors that mediate its action at the parathyroid gland are also diminished. These two effects remove inhibitory influences on PTH secretion, leading again to increased plasma PTH levels. Reduction in circulating 1,25(OH)D_2levels, by suppressing intestinal calcium absorption, contributes to the development of the hypocalcemia and hyperparathyroidism of CRF (Chap. 270).

Hyperparathyroidism in Chronic Renal Failure At least two additional processes are thought to contribute to hyperparathyroidism inCRF. One relates to resistance of bone to the calcemic effect ofPTH in uremia. This resistance necessitates a higher level of PTH to demineralize bone and maintain the plasma calcium concentration. The other derives from the finding that reductions in renal mass impair the kidneys' capacity to degrade circulating PTH. Ultimately, however, phosphate conforms more to a curve *B*-rather than a curve *C*-type pattern inFig. 268-1, and phosphate retention occurs when theGFRfalls below about 25 mL/min, signifying that these latter forms of adaptation play limited roles.

SincePTHexerts major effects on bone as well as renal tubules, the external balance of phosphate inCRF is achieved at the expense of elevated PTH levels, which, in turn, account for many of the bone changes of renal osteodystrophy (i.e., *secondary hyperparathyroidism*; Fig. 270-1). In support of this *trade-off hypothesis*, when dietary phosphate intake is reduced in proportion to the reduction inGFR in animals with CRF, external balance of phosphate no longer requires augmentation of fractional phosphate excretion in surviving nephrons. Accordingly, circulating levels of PTH no longer rise, and the bone changes of secondary hyperparathyroidism are diminished, if not prevented.

HYDROGEN AND BICARBONATE TRANSPORT WITH NORMAL AND REDUCED RENAL MASS

As discussed in Chap. 50, the pH of extracellular fluid is normally maintained within a narrow range (7.36 to 7.44) despite day-to-day fluctuations in the quantity of acids added to the extracellular fluid from dietary and metabolic sources (approximately 1 mmol H^+ per kilogram of body weight per day). These acids consume buffers from both extracellular and intracellular fluid, of which HCO_3^- is the most important in the intracellular compartment. Such buffering minimizes changes in pH. Long-term effectiveness of the HCO_3^- buffer system, however, requires mechanisms for replenishment, otherwise unrelenting acquisition of nonvolatile acids from dietary and metabolic sources would ultimately exhaust buffering capacity, culminating in fatal acidosis. The kidneys normally function to prevent this eventuality by *regenerating* bicarbonate, thereby maintaining plasma concentrations of HCO_3^-. In addition, the kidneys also *reclaim* HCO_3^- in the glomerular ultrafiltrate. Reclamation of filtered HCO_3^- takes place largely in the proximal tubule and, under normal circumstances, is virtually complete below a critical plasma HCO_3^- concentration -- the threshold concentration -- which in humans is normally about 26 mmol/L, identical to the concentration of HCO_3^- in plasma. As a consequence, HCO_3^- wastage is prevented. Alternatively, when plasma HCO_3^- rises above this threshold, reabsorption becomes less complete, allowing escape of excess HCO_3^- into the final urine, which restores the plasma HCO_3^- towards normal levels. Despite complete reabsorption of HCO_3^-, metabolic acidosis would still ensue if HCO_3^- consumed in buffering nonvolatile acids were not constantly regenerated.

The *reabsorption* of filtered HCO_3^- occurs by the following mechanism. Filtered bicarbonate combines with H^+ secreted from proximal tubule cells via the Na^+/H^+ exchange, to form carbonic acid (H_2CO_3). Dehydration of carbonic acid under the influence of *luminal* carbonic anhydrase yields H_2O and CO_2, which is free to diffuse from lumen to peritubular blood. In the proximal tubule cell, the OH^- left behind by the H^+ secretion reacts with CO_2, under the influence of *intracellular* carbonic anhydrase, forming HCO_3^-. This ion is transported across the contraluminal proximal tubule cell membrane, via an electrogenic Na/HCO_3^- cotransporter, to reenter the extracellular HCO_3^- pool. The net result is *reclamation of a filtered bicarbonate ion*. Secreted H^+ is also free to react with nonbicarbonate buffers [e.g., phosphate or ammonia (NH_4^+)] in the tubule lumen, and hydrogen ions are excreted in these forms in the final urine. Again, the OH^- left behind in the proximal tubule cell from H^+ secretion reacts with CO_2, forming bicarbonate -- also representing *regeneration of an HCO_3^- ion*.

Hydrogen ions in the urine are bound to filtered buffers (e.g., phosphate) in amounts equivalent to the amounts of alkali required to titrate the pH of the urine up to the pH of the blood (the so-called titratable acid). It is not usually possible to excrete all the daily acid load in the form of titratable acid due to limits of urinary pH. Metabolism of glutamine by proximal tubule cells to yield ammonium (ammoniagenesis) serves as an additional mechanism for H^+ elimination and bicarbonate regeneration. Glutamine metabolism forms not only NH_4^+ (i.e., NH_3 plus H^+) but also HCO_3^-, which is transported across the proximal tubule (HCO_3^- regeneration). The NH_4^+ must be excreted in the urine for this process to be effective in bicarbonate regeneration. The excretion of ammonium involves secretion by proximal tubule cells (possibly by the Na^+/H^+ exchanger as Na^+/NH_4^+), generation of high medullary interstitial NH_4^+ concentration by an elaborate countercurrent multiplication/exchange system, and finally, secretion of the interstitial

NH_4^+ by the collecting duct by a combination of H^+ secretion and passive NH_3 diffusion. *Ammoniagenesis* is responsive to the acid-base needs of the individual. When faced with an acute acid burden and an increased need for HCO_3^- regeneration, the rate of renal ammonia synthesis increases sharply.

The quantity of hydrogen ions excreted as titratable acid and NH_4^+ is equal to the quantity of HCO_3^- regenerated in tubule cells and added to plasma. Under steady-state conditions, the net quantity of acid excreted into the urine (the sum of titratable acid and NH_4^+ less HCO_3^-) must equal the quantity of acid gained by the extracellular fluid from all sources. Metabolic acidosis and alkalosis result when this delicate balance is perturbed, the former the result of insufficient net acid excretion, and the latter due to excessive acid excretion.

Progressive loss of renal function usually causes little or no change in arterial pH, plasma bicarbonate concentration, or arterial carbon dioxide tension (P_{CO_2}) until GFR falls below 25% of normal. Thereafter, all three tend to decline as *metabolic acidosis* ensues. In general, the metabolic acidosis of CRF is not due to overproduction of acids but is rather a reflection of nephron loss, which limits the amount of NH_3 (and therefore also HCO_3^-) that can be generated. Although surviving nephrons appear to be capable of generating supranormal amounts of NH_3 *per nephron*, the diminished nephron population causes overall production to be reduced to an extent that is insufficient to permit adequate buffering of H^+ in urine. As a result, although patients with CRF may be able to acidify their urine normally (i.e., urine pH as low as 4.5), the defect in NH_3 production limits daily net acid excretion to 30 to 40 mmol, or one-half to two-thirds the quantity of nonvolatile acid added to the extracellular fluid in the same time period. Metabolic acidosis resulting from this daily positive balance of H^+ is seldom florid in CRF of mild to moderate severity. Relative stability of plasma bicarbonate (albeit at reduced levels of 14 to 18 mmol/L) is maintained at the expense of buffering by bone. Because it contains large reserves of alkaline salts (calcium phosphate and calcium bicarbonate), bone constitutes a major reserve of buffering capacity. Dissolution of these buffers contributes to the osteodystrophy of CRF (Fig. 270-1).

Although the acidosis of CRF is due to loss of tubule mass, it nevertheless depends to a large part on the level of GFR. When GFR is reduced to only a moderate extent (i.e., to about 50% of normal), retention of anions, principally sulfates and phosphates, is not pronounced. Therefore, as the plasma HCO_3^- falls owing to dysfunction or loss of tubules, retention of Cl^- by the kidneys leads to a *hyperchloremic acidosis*. At this stage *the anion gap is normal*. With further reductions in GFR and progressive azotemia, however, the retention of phosphates, sulfates, and other *unmeasured* anions ensues and plasma Cl^- falls to normal levels despite the reduction in plasma HCO_3^- concentration. *An elevated anion gap therefore develops.*

TUBULE POTASSIUM TRANSPORT WITH NORMAL AND REDUCED NEPHRON MASS

As with H^+, the concentration of K^+ in extracellular fluid is normally maintained within a relatively narrow range, 4 to 5 mmol/L. At least 95% of total-body K^+ is in the intracellular compartment, where the intracellular concentration is approximately 160 mmol/L. Normal individuals maintain external K^+ balance by excreting amounts into the

urine that equal the intake, less the relatively small losses in stool and sweat. K^+ is freely filtered at the glomerulus, although the amount excreted usually represents no more than about 20% of the quantity filtered. The great bulk of the K^+filtered is reabsorbed in the early portions of the nephron, about two-thirds in the proximal tubule, and an additional 20 to 25% in the loop of Henle. A *K^+secretory process* operates in the distal tubule and terminal nephron segments. This process is largely dependent on Na^+reabsorption and the accompanying lumen-negative voltage creating an electrical gradient across the tubule wall, favoring K^+secretion into the lumen of the distal tubule and collecting duct.

The ability to maintain external K^+balance and normal plasma K^+concentration until relatively late in the course ofCRF is a consequence primarily of a progressive increase in fractional excretion of K^+. Greatly enhanced rates of K^+secretion occur in distal portions of surviving tubules. The augmented secretion rate of aldosterone contributes to enhanced tubule secretion of K^+. In addition, both the increased distal tubule flow rates in surviving nephrons, due to the osmotic diuresis, and enhanced luminal electronegativity, created by the increased presence of highly impermeable anions such as phosphate and sulfate, enhance K^+secretion. Aldosterone also stimulates net entry of K^+ into the lumen of the colon, a mechanism known to be enhanced in CRF.**More detailed discussions of abnormal K^+homeostasis in acute and chronic forms of renal failure are given in Chaps. 269 and 270.*

269. ACUTE RENAL FAILURE - *Hugh R. Brady*, *Barry M. Brenner*

Acute renal failure (ARF) is a syndrome characterized by rapid decline in glomerular filtration rate (hours to days), retention of nitrogenous waste products, and perturbation of extracellular fluid volume and electrolyte and acid-base homeostasis. ARF complicates approximately 5% of hospital admissions and up to 30% of admissions to intensive care units. Oliguria (urine output< 500 mL/d) is a frequent but not invariable clinical feature (~50%). ARF is usually asymptomatic and is diagnosed when biochemical screening of hospitalized patients reveals a recent increase in plasma urea and creatinine concentrations. It may complicate a wide range of diseases, which for purposes of diagnosis and management are conveniently divided into three categories: (1) diseases that cause renal hypoperfusion without compromising the integrity of renal parenchyma (*prerenal ARF*, prerenal azotemia) (~55%); (2) diseases that directly involve renal parenchyma (*intrinsic renal ARF*, renal azotemia) (~40%); and (3) diseases associated with urinary tract obstruction (*postrenal ARF*, postrenal azotemia) (~5%). Most ARF is reversible, the kidney being relatively unique among major organs in its ability to recover from almost complete loss of function. Nevertheless, ARF is associated with major in-hospital morbidity and mortality, in large part due to the serious nature of the illnesses that precipitate the ARF.

ETIOLOGY AND PATHOPHYSIOLOGY

PRERENALARF(PRERENAL AZOTEMIA)

PrerenalARF is the most common form of ARF and represents a physiologic response to mild to moderate renal hypoperfusion. Prerenal ARF is rapidly reversible upon restoration of renal blood flow and glomerular ultrafiltration pressure. Renal parenchymal tissue is not damaged; indeed, kidneys from individuals with prerenal ARF function well when transplanted into recipients with normal cardiovascular function. More severe hypoperfusion may lead to ischemic injury of renal parenchyma and intrinsic renal ARF. Thus, prerenal ARF and intrinsic renal ARF due to ischemia are part of a spectrum of manifestations of renal hypoperfusion. As shown in Table 269-1, prerenal ARF can complicate any disease that induces hypovolemia, low cardiac output, systemic vasodilatation, or selective renal vasoconstriction.

Hypovolemia leads to a fall in mean systemic arterial pressure, which is detected as reduced stretch by arterial (e.g., carotid sinus) and cardiac baroreceptors. Activated baroreceptors trigger a coordinated series of neural and humoral responses designed to restore blood volume and arterial pressure. These include activation of the sympathetic nervous system and renin-angiotensin-aldosterone system and release of arginine vasopressin (AVP; formerly called antidiuretic hormone). Norepinephrine, angiotensin II, and AVP act in concert in an attempt to preserve cardiac and cerebral perfusion by stimulating vasoconstriction in relatively "nonessential" vascular beds, such as the musculocutaneous and splanchnic circulations, by inhibiting salt loss through sweat glands, by stimulating thirst and salt appetite, and by promoting renal salt and water retention. Glomerular perfusion, ultrafiltration pressure, and filtration rate are preserved during mild hypoperfusion through several compensatory mechanisms. Stretch receptors in afferent arterioles, in response to a reduction in perfusion pressure, trigger afferent arteriolar vasodilatation through a local myogenic reflex (autoregulation).

Biosynthesis of vasodilator prostaglandins (e.g., prostaglandin F_2 and prostacyclin) is also enhanced, and these compounds preferentially dilate afferent arterioles. In addition, angiotensin II induces preferential constriction of efferent arterioles. As a result, intraglomerular pressure is maintained, the fraction of plasma flowing through glomerular capillaries that is filtered is increased (filtration fraction), and glomerular filtration rate (GFR) is preserved. During states of more severe hypoperfusion, these compensatory responses are overwhelmed and GFR falls, leading to prerenalARF.

Autoregulatory dilatation of afferent arterioles is maximal at mean systemic arterial blood pressures of ~80 mmHg, and hypotension below this level is associated with a precipitous decline inGFR. Lesser degrees of hypotension may provoke prerenalARF in the elderly and in patients with diseases affecting the integrity of afferent arterioles (e.g., hypertensive nephrosclerosis, diabetic vasculopathy). In addition, drugs that interfere with adaptive responses in the renal microcirculation may convert compensated renal hypoperfusion into overt prerenal ARF or trigger progression of prerenal ARF to ischemic intrinsic renal ARF (see below). Pharmacologic inhibitors of either renal prostaglandin biosynthesis [*cyclooxygenase inhibitors*; nonsteroidal anti-inflammatory drugs (NSAIDs)] or angiotensin-converting enzyme (ACE) activity (ACE inhibitors) are the major culprits and should be used judiciously in the setting of suspected renal hypoperfusion. NSAIDs do not compromise GFR in healthy individuals but may precipitate prerenal ARF in patients with volume depletion or in those with chronic renal insufficiency in whom GFR is maintained, in part, through prostaglandin-mediated hyperfiltration through the remaining functional nephrons. ACE inhibitors can also compromise GFR in individuals with renal hypoperfusion and should be used with special care in patients with bilateral renal artery stenosis or unilateral stenosis in a solitary functioning kidney. Glomerular perfusion and filtration may be exquisitely dependent on the actions of angiotensin II under the latter circumstances. Angiotensin II preserves glomerular filtration pressure distal to stenoses by elevating systemic arterial pressure and by triggering selective constriction of efferent arterioles. ACE inhibitors blunt these responses and precipitate ARF, usually reversible, in ~30% of these patients.
