Hepatorenal Syndrome This is a particularly aggressive form ofARF that frequently complicates hepatic failure due to advanced cirrhosis or other liver diseases, including malignancy, hepatic resection, and biliary obstruction. Intrarenal vasoconstriction and avid sodium retention are early sequelae of these diseases and may be detected before changes in systemic hemodynamics. Patients with advanced liver disease, portal hypertension, and ascites also have increased plasma volume but reduced "effective" arterial blood volume as a consequence of systemic vasodilatation and pooling of blood in the portal circulation. Renal failure typically develops slowly over weeks or months in parallel with deteriorating hepatic function but may accelerate dramatically following a variety of hemodynamic insults, including hemorrhage, paracentesis, and overzealous use of diuretics, vasodilators, or cyclooxygenase inhibitors. In full-blown hepatorenal syndrome, ARF progresses even after optimization of systemic hemodynamics and systemic arterial blood volume and removal of nephrotoxins, probably as a result of ongoing intrarenal vasoconstriction, hypoperfusion, and ischemia triggered by circulating factors or neural impulses originating in the failing liver. Indeed, it must be remembered that patients with liver disease may develop other forms of ARF (e.g., sepsis, nephrotoxic medications), and a diagnosis of hepatorenal syndrome should be

made only after exclusion of other possible reversible causes.

INTRINSIC RENAL ARF (INTRINSIC RENAL AZOTEMIA)

Intrinsic renal ARF can complicate many diverse diseases of the renal parenchyma. From a clinicopathologic viewpoint, it is useful to divide the causes of intrinsic renal ARF into (1) diseases of large renal vessels, (2) diseases of the renal microcirculation and glomeruli, (3) ischemic and nephrotoxic ARF, and (4) tubulointerstitial diseases (Table 269-1). Most intrinsic renal ARF is triggered by ischemia (ischemic ARF) or nephrotoxins (nephrotoxic ARF), insults that classically induce acute tubular necrosis (ATN). Accordingly, the terms ARF and ATN are usually used interchangeably in these settings. However, as many as 20 to 30% of patients with ischemic or nephrotoxic ARF do not have clinical (granular or tubular cell urinary casts) or morphologic evidence of tubular necrosis, underscoring the role of sublethal injury to tubular epithelium and injury to other renal cells (e.g., endothelial cells) in the pathophysiology of this syndrome.

Etiology and Pathophysiology of IschemicARF Prerenal ARF and ischemic ARF are part of a spectrum of manifestations of renal hypoperfusion. Ischemic ARF differs from prerenal ARF in that the hypoperfusion induces ischemic injury to renal parenchymal cells, particularly tubular epithelium, and recovery typically takes 1 to 2 weeks after normalization of renal perfusion as it requires repair and regeneration of renal cells. In its most extreme form, ischemia leads to bilateral renal cortical necrosis and irreversible renal failure. Ischemic ARF occurs most frequently in patients undergoing major cardiovascular surgery or suffering severe trauma, hemorrhage, sepsis, and/or volume depletion (Table 269-1). Ischemic ARF can also complicate milder forms of true hypovolemia or reduced "effective" arterial blood volume if they occur in the presence of other insults (e.g., nephrotoxins or sepsis) or in patients with compromised autoregulatory defense mechanisms or preexisting renal disease.

The course of ischemicARF is typically characterized by three phases: the initiation, maintenance, and recovery phases. The *initiation phase* (hours to days) is the initial period of renal hypoperfusion during which ischemic injury is evolving.GFRdeclines because (1) glomerular ultrafiltration pressure is reduced as a consequence of the fall in renal blood flow, (2) the flow of glomerular filtrate within tubules is obstructed by casts comprising epithelial cells and necrotic debris derived from ischemic tubule epithelium, and (3) there is backleak of glomerular filtrate through injured tubular epithelium (Fig. 269-1). Ischemic injury is most prominent in the terminal medullary portion of the proximal tubule (S_3segment, pars recta) and the medullary portion of the thick ascending limb of the loop of Henle. Both segments have high rates of active (ATP-dependent) solute transport and oxygen consumption and are located in a zone of the kidney (the outer medulla) that is relatively ischemic, even under basal conditions, by virtue of the unique countercurrent arrangement of the medullary vasculature. Cellular ischemia results in a series of alterations in energetics, ion transport, and membrane integrity that ultimately lead to cell injury and, if severe, cell apoptosis or necrosis. These alterations include depletion of ATP, inhibition of active sodium transport and transport of other solutes, impairment of cell volume regulation and cell swelling, cytoskeletal disruption and loss of cell polarity, cell-cell and cell-matrix attachment, accumulation of intracellular calcium, altered phospholipid metabolism, oxygen free radical formation, and peroxidation of membrane lipids. Importantly, renal

injury can be limited by restoration of renal blood flow during this period.

The initiation phase is followed by a *maintenance phase* (typically 1 to 2 weeks) during which renal cell injury is established,GFRstabilizes at its nadir (typically 5 to 10 mL/min), urine output is lowest, and uremic complications arise (see below). The reasons why the GFR remains low during this phase, despite correction of systemic hemodynamics, are still being defined. Putative mechanisms include persistent intrarenal vasoconstriction and medullary ischemia triggered by dysregulated release of vasoactive mediators from injured endothelial cells (e.g., decreased nitric oxide, increased endothelin-1 and platelet-activating factor), congestion of medullary blood vessels, and reperfusion injury induced by reactive oxygen species and other mediators derived from leukocytes or renal parenchymal cells (Fig. 269-1). In addition, epithelial cell injury per se may contribute to persistent intrarenal vasoconstriction by a process termed *tubuloglomerular feedback*. Specialized epithelial cells in the macula densa region of distal tubules detect increases in distal salt (probably chloride) delivery that occur as a consequence of impaired reabsorption by more proximal nephron segments. Macula densa cells in turn stimulate constriction of adjacent afferent arterioles by a poorly defined mechanism and further compromise glomerular perfusion and filtration, thereby contributing to a vicious cycle. A *recovery phase* is characterized by renal parenchymal cell, particularly tubule epithelial cell, repair and regeneration and a gradual return of GFR to or towards premorbid levels. The recovery phase may be complicated by a marked diuretic phase due to excretion of retained salt and water and other solutes, continued use of diuretics, and/or delayed recovery of epithelial cell function (solute and water reabsorption) relative to glomerular filtration (see below).

Etiology and Pathophysiology of Nephrotoxic**ARF**Acute intrinsic renal ARF can complicate exposure to many structurally diverse pharmacologic agents (Table 269-1). With most nephrotoxins, the incidence of ARF is increased in the elderly and in patients with preexisting chronic renal insufficiency, true or "effective" hypovolemia, or concomitant exposure to other toxins.

Intrarenal vasoconstriction is a pivotal event inARFtriggered by *radiocontrast agents* (contrast nephropathy) and *cyclosporine*. In keeping with this pathophysiology, both agents induce ARF that shares features with prerenal ARF: namely, an acute fall in renal blood flow andGFR, a relatively benign urine sediment, and a low fractional excretion of sodium (see below). Severe cases may show clinical or pathologic evidence ofATN. Contrast nephropathy classically presents as an acute (onset within 24 to 48 h) but reversible (peak 3 to 5 days, resolution within 1 week) rise in blood urea nitrogen and creatinine and is most common in individuals with preexisting chronic renal insufficiency, diabetes mellitus, congestive heart failure, hypovolemia, or multiple myeloma. The syndrome appears to be dose-related, and its incidence is only slightly reduced in high-risk individuals by use of more expensive low osmolality, nonionic contrast agents. Endothelin-1, a potent vasoconstrictor peptide released from endothelial cells, is an important mediator of intrarenal vasoconstriction and mesangial cell contraction in this setting. Endothelin-1 has also been implicated as an important mediator of cyclosporine-induced ARF.

Direct toxicity to tubule epithelial cells and/or intratubular obstruction are major pathophysiologic events inARFinduced by many antibiotics and anticancer drugs.

Frequent offenders are the antimicrobial agents, such as acyclovir, foscarnet, aminoglycosides, amphotericin B, and pentamidine, and chemotherapeutic agents, such as cisplatin and ifosfamide. ARF complicates 10 to 30% of courses of *aminoglycoside antibiotics*, even in the presence of therapeutic levels. *Amphotericin B* causes dose-related ARF through intrarenal vasoconstriction and direct toxicity to proximal tubule epithelium. Cisplatin, like the aminoglycosides, is accumulated by proximal tubule cells and typically provokes ARF after 7 to 10 days of exposure by inducing mitochondrial injury, inhibition of ATPase activity and solute transport, free radical-mediated injury to cell membranes, apoptosis and/or necrosis.

The most common endogenous nephrotoxins are calcium, myoglobin, hemoglobin, urate, oxalate, and myeloma light chains. Hypercalcemia can compromiseGFR, predominantly by inducing intrarenal vasoconstriction. Calcium phosphate deposition within the kidney may also contribute. Both *rhabdomyolysis* and *hemolysis* can induceARF, particularly in hypovolemic or acidotic individuals. Myoglobinuric ARF complicates approximately 30% of cases of rhabdomyolysis. Common causes of the latter include traumatic crush injury, acute muscle ischemia, seizures, excessive exercise, heat stroke or malignant hyperthermia, intoxications (e.g., alcohol, cocaine), and infectious or metabolic disorders. ARF due to hemolysis is relatively rare and is observed following massive blood transfusion reactions. It has been postulated that myoglobin and hemoglobin or other compounds released from muscle or red blood cells cause ARF via toxic effects on tubule epithelial cells or by inducing intratubular cast formation. Hypovolemia or acidosis may contribute to the pathogenesis of ARF in this setting by promoting intratubular cast formation. In addition, both hemoglobin and myoglobin are potent inhibitors of nitric oxide bioactivity and may trigger intrarenal vasoconstriction and ischemia in patients with borderline renal hypoperfusion. The formation of intratubular casts containing filtered immunoglobulin light chains and other proteins, including Tamm-Horsfall protein produced by thick ascending limb cells, is the major trigger for ARF in patients with *multiple myeloma* (myeloma cast nephropathy). Light chains may also be directly toxic to tubule epithelial cells. Intratubular obstruction may also be an important cause of ARF in patients with severe *hyperuricosuria* or *hyperoxaluria*. Acute uric acid nephropathy typically complicates treatment of lymphoproliferative or myeloproliferative disorders but occasionally occurs in other forms of primary or secondary hyperuricemia if the urine is concentrated.

Pathology of Ischemic and Nephrotoxic ARF The classic pathologic features of ischemic ARF are patchy and focal necrosis of tubule epithelium with detachment from its basement membrane and occlusion of tubule lumens with casts composed of intact or degenerating epithelial cells, cellular debris, Tamm-Horsfall mucoprotein, and pigments. Leukocyte accumulation is frequently observed in vasa recta; however, the morphology of the glomeruli and renal vasculature is characteristically normal. Necrosis is most severe in the straight portion (pars recta) of proximal tubules but may also affect the medullary thick ascending limb of the loop of Henle.

In nephrotoxicARF, morphologic changes tend to be most prominent in both the convoluted and straight portions of proximal tubules. Tubule cell necrosis is less pronounced than in ischemic ARF.

Other Causes of Intrinsic Renal ARF Patients with advanced atherosclerosis can

develop ARF after manipulation of the aorta or renal arteries at surgery or angiography, following trauma, or, rarely, spontaneously due to embolization of cholesterol crystals to the renal vasculature (atheroembolic ARF). Cholesterol crystals lodge in small- and medium-sized arteries and incite a giant cell and fibrotic reaction in the vessel wall with narrowing or obstruction of the vessel lumen. Atheroembolic ARF is frequently irreversible. A myriad of structurally diverse pharmacologic agents induce ARF by triggering allergic interstitial nephritis, a disease characterized by infiltration of the tubulointerstitium by granulocytes (typically but not invariably eosinophils), macrophages, and/or lymphocytes and by interstitial edema. The most common offenders are antibiotics (e.g., penicillins, cephalosporins, trimethoprim, sulfonamides, rifampicin) and NSAIDs (Table 269-1).

POSTRENALARF(See also Chap. 281)

Urinary tract obstruction accounts for fewer than 5% of cases of ARF. Since one kidney has sufficient clearance capacity to excrete nitrogenous waste products, ARF from obstruction requires either obstruction to urine flow between the external urethral meatus and bladder neck, bilateral ureteric obstruction, or unilateral ureteric obstruction in a patient with one functioning kidney or preexisting chronic renal insufficiency. Bladder neck obstruction represents the most common cause of postrenal ARF and is usually due to prostatic disease (e.g., hypertrophy, neoplasia, or infection), neurogenic bladder, or therapy with anticholinergic drugs. Less common causes of acute lower urinary tract obstruction include blood clots, calculi, and urethritis with spasm. Ureteric obstruction may result from intraluminal obstruction (e.g., calculi, blood clots, sloughed renal papillae), infiltration of the ureteric wall (e.g., neoplasia), or external compression (e.g., retroperitoneal fibrosis, neoplasia or abscess, inadvertent surgical ligature). During the early stages of obstruction (hours to days), continued glomerular filtration leads to increased intraluminal pressure upstream to the site of obstruction. As a result there are gradual distention of proximal ureter, renal pelvis, and calyces and a fall inGFR. Acute obstruction is initially associated with modest increase in renal blood flow, but arteriolar vasoconstriction soon supervenes, leading to a further decline in glomerular filtration.

CLINICAL FEATURES AND DIFFERENTIAL DIAGNOSIS

Patients presenting with renal failure should be assessed initially to determine if the decline inGFR is acute or chronic. An acute process is easily established if a review of laboratory records reveals a recent rise in blood urea and creatinine levels, but previous measurements are not always available. Findings that suggest chronic renal failure (Chap. 270) include anemia, neuropathy, and radiologic evidence of renal osteodystrophy or small scarred kidneys. However, it should be noted that anemia may also complicateARF (see below), and renal size may be normal or increased in several chronic renal diseases (e.g., diabetic nephropathy, amyloidosis, polycystic kidney disease). Once a diagnosis of ARF has been established, several issues should be addressed promptly: (1) the identification of the cause of ARF, (2) the elimination of the triggering insult (e.g., nephrotoxin) and/or institution of disease-specific therapies, and (3) the prevention and management of uremic complications.

CLINICAL ASSESSMENT

Clinical clues to *prerenal*ARF are symptoms of thirst and orthostatic dizziness and physical evidence of orthostatic hypotension and tachycardia, reduced jugular venous pressure, decreased skin turgor, dry mucous membranes, and reduced axillary sweating. Case records should be reviewed for documentation of a progressive fall in urine output and body weight and treatment with NSAIDs orACEinhibitors. Careful clinical examination may reveal stigmata of chronic liver disease and portal hypertension, advanced cardiac failure, sepsis, or other causes of reduced "effective" arterial blood volume (Table 269-1).

*Intrinsic renal*ARF due to ischemia is likely following severe renal hypoperfusion complicating hypovolemic or septic shock or following major surgery. The likelihood of ischemic ARF is increased further if ARF persists despite normalization of systemic hemodynamics. Diagnosis of nephrotoxic ARF requires careful review of the clinical data and pharmacy, nursing, and radiology records for evidence of recent exposure to nephrotoxic medications or radiocontrast agents or to endogenous toxins (e.g., myoglobin, hemoglobin, uric acid, myeloma protein, or elevated levels of serum calcium).

Although ischemic and nephrotoxicARFaccount for more than 90% of cases of intrinsic renal ARF, other renal parenchymal diseases must be considered (Table 269-2). Flank pain may be a prominent symptom following occlusion of a renal artery or vein and with other parenchymal diseases distending the renal capsule (e.g., severe glomerulonephritis or pyelonephritis). Subcutaneous nodules, livido reticularis, bright orange retinal arteriolar plaques, and digital ischemia, despite palpable pedal pulses, are clues to atheroembolization. ARF in association with oliguria, edema, hypertension, and an "active" urine sediment (nephritic syndrome) suggests acute glomerulonephritis or vasculitis. Malignant hypertension is a likely cause of ARF in patients with severe hypertension and evidence of hypertensive injury to other organs (e.g., left ventricular hypertrophy and failure, hypertensive retinopathy and papilledema, neurologic dysfunction). Fever, arthralgias, and a pruritic erythematous rash following exposure to a new drug suggest allergic interstitial nephritis, although systemic features of hypersensitivity are frequently absent.

*Postrenal*ARFpresents with suprapubic and flank pain due to distention of the bladder and of the renal collecting system and capsule, respectively. Colicky flank pain radiating to the groin suggests acute ureteric obstruction. Prostatic disease is likely if there is a history of nocturia, frequency, and hesitancy and enlargement or induration of the prostate on rectal examination. Neurogenic bladder should be suspected in patients receiving anticholinergic medications or with physical evidence of autonomic dysfunction. Definitive diagnosis of postrenal ARF hinges on judicious use of radiologic investigations and rapid improvement in renal function following relief of obstruction.

URINALYSIS

Anuria suggests complete urinary tract obstruction but may complicate severe cases of prerenal or intrinsic renal ARF. Wide fluctuations in urine output raise the possibility of intermittent obstruction, whereas patients with partial urinary tract obstruction can present with polyuria due to impairment of urine concentrating mechanisms.

In prerenalARF, the sediment is characteristically acellular and contains transparent hyaline casts ("bland," "benign," "inactive" urine sediment). Hyaline casts are formed in concentrated urine from normal constitutents of urine -- principally Tamm-Horsfall protein, which is secreted by epithelial cells of the loop of Henle. Postrenal ARF may also present with an inactive sediment, although hematuria and pyuria are common in patients with intraluminal obstruction or prostatic disease. Pigmented "muddy brown" granular casts and casts containing tubule epithelial cells are characteristic ofATN and suggest ischemic or nephrotoxic ARF. They are usually found in association with microscopic hematuria and mild "tubular" proteinuria (<1 g/d); the latter reflects impaired reabsorption and processing of filtered proteins by injured proximal tubules. Casts are absent, however, in 20 to 30% of patients with ischemic or nephrotoxic ARF and are not a requisite for diagnosis. In general, red blood cell casts indicate glomerular injury or, less often, acute tubulointerstitial nephritis. White cell casts and nonpigmented granular casts suggest interstitial nephritis, whereas broad granular casts are characteristic of chronic renal disease and probably reflect interstitial fibrosis and dilatation of tubules. Eosinophiluria (>5% of urine leukocytes) is a common finding (~90%) in antibiotic-induced allergic interstitial nephritis when studied using Hansel's stain; however, lymphocytes may predominate in allergic interstitial nephritis induced by NSAIDs. Eosinophiluria is also a feature of atheroembolic ARF. Occasional uric acid crystals (pleomorphic in shape) are common in the concentrated urine of prerenal ARF but suggest acute urate nephropathy if seen in abundance. Oxalate (envelope-shaped) and hippurate (needle-shaped) crystals raise the possibility of ethylene glycol ingestion and toxicity.

Increased urine protein excretion, but <1 g/d, is common inATN due to failure of injured proximal tubules to reabsorb filtered protein and excretion of cellular debris ("tubular proteinuria"). Proteinuria of>1 g/d suggests injury to the glomerular ultrafiltration barrier ("glomerular proteinuria") or excretion of myeloma light chains. The latter are not detected by conventional dipsticks (which detect albumin) and must be sought by other means (e.g., sulfosalicylic acid test, immunoelectrophoresis). Heavy proteinuria is also a frequent finding (~80%) in patients who develop combined allergic interstitial nephritis and minimal change glomerulopathy when treated with NSAIDs. A similar syndrome can be triggered by ampicillin, rifampicin, or interferon a. Hemoglobinuria or myoglobinuria should be suspected if urine is strongly positive for heme by dipstick, but contains few red cells, and if the supernatant of centrifuged urine is positive for free heme. Bilirubinuria may provide a clue to the presence of hepatorenal syndrome.

RENAL FAILURE INDICES

Analysis of urine and blood biochemistry is particularly useful for distinguishing prerenalARF from ischemic or nephrotoxic intrinsic renal ARF (Table 269-3). The fractional excretion of sodium (FE_{Na}) is most useful in this regard. The FE_{Na}relates sodium clearance to creatinine clearance. Sodium is reabsorbed avidly from glomerular filtrate in patients with prerenal ARF, in an attempt to restore intravascular volume, but not in patients with ischemic or nephrotoxic intrinsic ARF, as a result of tubular epithelial cell injury. In contrast, creatinine is not reabsorbed in either setting. Consequently, patients with prerenal ARF typically have a FE_{Na} of<1.0% (frequently<0.1%), whereas the FE_{Na} in patients with ischemic or nephrotoxic ARF is usually>1.0%. The *renal failure index* (Table 269-3) provides comparable information, since clinical variations in serum

sodium concentration are relatively small. *Urine sodium concentration* is a less sensitive index for distinguishing prerenal ARF from ischemic and nephrotoxic ARF as values overlap between groups. Similarly, indices of urinary concentrating ability such as urine specific gravity, urine osmolality, urine-to-plasma urea ratio, and blood urea-to-creatinine ratio are of limited value in differential diagnosis.

Many caveats apply when interpreting biochemical renal failure indices. FE_{Na} may be >1.0% in prerenal ARF if patients are receiving diuretics or have bicarbonaturia (accompanied by sodium to maintain electroneutrality), preexisting chronic renal failure complicated by salt wasting, or adrenal insufficiency. In contrast, the FE_{Na} is<1.0% in approximately 15% of patients with nonoliguric ischemic or nephrotoxic ARF. The FE_{Na} is often <1.0% in ARF due to urinary tract obstruction, glomerulonephritis, and vascular diseases.

LABORATORY FINDINGS

Serial measurements of serum creatinine can provide useful pointers to the cause of ARF. Prerenal ARF is typified by fluctuating levels that parallel changes in hemodynamic function. Creatinine rises rapidly (within 24 to 48 h) in patients with ARF following renal ischemia, atheroembolization, and radiocontrast exposure. Peak creatinine levels are observed after 3 to 5 days with contrast nephropathy and return to baseline after 5 to 7 days. In contrast, creatinine levels typically peak later (7 to 10 days) in ischemic ARF and atheroembolic disease. The initial rise in serum creatinine is characteristically delayed until the second week of therapy with many tubule epithelial cell toxins (e.g., aminoglycosides, cisplatin) and probably reflects the need for accumulation of these agents within cells before GFR falls.

Hyperkalemia, hyperphosphatemia, hypocalcemia, and elevations in serum uric acid and creatine kinase (MM isoenzyme) levels at presentation suggest a diagnosis of rhabdomyolysis. Hyperuricemia [>890 umol/L (>15 mg/dL)] in association with hyperkalemia, hyperphosphatemia, and increased circulating levels of intracellular enzymes such as lactate dehydrogenase may indicate acute urate nephropathy and tumor lysis syndrome following cancer chemotherapy. A wide serum anion and osmolal gap (measured serum osmolality minus the serum osmolality calculated from serum sodium, glucose, and urea concentrations) indicate the presence of an unusual anion or osmole in the circulation and are clues to diagnosis of ethylene glycol or methanol ingestion. Severe anemia in the absence of hemorrhage raises the possibility of hemolysis, multiple myeloma, or thrombotic microangiopathy. Systemic eosinophilia suggests allergic interstitial nephritis but is also a feature of atheroembolic disease and polyangiitis nodosa.

RADIOLOGIC FINDINGS

Imaging of the urinary tract by ultrasonography is useful to exclude postrenal ARF. Computed tomography and magnetic resonance imaging are alternative imaging modalities. Whereas pelvicalyceal dilatation is usual with urinary tract obstruction (98% sensitivity), dilatation may be absent immediately following obstruction or in patients with ureteric encasement (e.g., retroperitoneal fibrosis, neoplasia). Retrograde or anterograde pyelography are more definitive investigations in complex cases and

provide precise localization of the site of obstruction. A plain film of the abdomen, with tomography if necessary, is a valuable initial screening technique in patients with suspected nephrolithiasis. Doppler ultrasonography and magnetic resonance flow imaging appear promising for assessment of patency of renal arteries and veins in patients with suspected vascular obstruction; however, contrast angiography is usually required for definitive diagnosis.

RENAL BIOPSY

Biopsy is reserved for patients in whom prerenal and postrenalARF have been excluded and the cause of intrinsic renal ARF is unclear. Renal biopsy is particularly useful when clinical assessment and laboratory investigations suggest diagnoses other than ischemic or nephrotoxic injury that may respond to disease-specific therapy. Examples include glomerulonephritis, vasculitis, hemolytic-uremic syndrome, thrombotic thrombocytopenic purpura, and allergic interstitial nephritis.

COMPLICATIONS

ARFimpairs renal excretion of sodium, potassium, and water and perturbs divalent cation homeostasis and urinary acidification mechanisms. As a result, ARF is frequently complicated by intravascular volume overload, hyponatremia, hyperkalemia, hyperphosphatemia, hypocalcemia, hypermagnesemia, and metabolic acidosis. In addition, patients are unable to excrete nitrogenous waste products and are prone to develop the uremic syndrome (Chap. 270). The speed of development and the severity of these complications reflect the degree of renal impairment and catabolic state of the patient.

Expansion of extracellular fluid volume is an inevitable consequence of diminished salt and water excretion in oliguric or anuric individuals. Whereas milder forms are characterized by weight gain, bibasilar lung rales, raised jugular venous pressure, and dependent edema, continued volume expansion may precipitate life-threatening pulmonary edema. Hypervolemia may be particularly problematic in patients receiving multiple intravenous medications and enteral or parenteral nutrition. Excessive administration of free water either through ingestion and nasogastric administration or as hypotonic saline or isotonic dextrose solutions (dextrose being metabolized) can induce *hypoosmolality* and *hyponatremia*, which, if severe, lead to cerebral edema and neurologic abnormalities, including seizures.

Hyperkalemia is a frequent complication ofARF. Serum potassium typically rises by 0.5 mmol/L per day in oliguric and anuric patients due to impaired excretion of ingested or infused potassium and potassium released from injured tissue. Coexistent metabolic acidosis may exacerbate hyperkalemia by promoting potassium efflux from cells. Hyperkalemia may be particularly severe, even at the time of diagnosis, in patients with rhabdomyolysis, hemolysis, and tumor lysis syndrome. Mild hyperkalemia (<6.0 mmol/L) is usually asymptomatic. Higher levels are typically associated with electrocardiographic abnormalities and/or increased cardiac excitability (Chap. 226).

Metabolism of dietary protein yields between 50 and 100 mmol/d of fixed nonvolatile acids that are normally excreted by the kidneys. Consequently,ARF is typically

complicated by *metabolic acidosis*, often with an increased serum anion gap (Chap. 50). Acidosis can be particularly severe when endogenous production of hydrogen ions is increased by other mechanisms (e.g., diabetic or fasting ketoacidosis; lactic acidosis complicating generalized tissue hypoperfusion, liver disease, or sepsis; metabolism of ethylene glycol or methanol).

Mild *hyperphosphatemia* is an almost invariable complication ofARF. Severe hyperphosphatemia may develop in highly catabolic patients or following rhabdomyolysis, hemolysis, or tumor lysis. Metastatic deposition of calcium phosphate can lead to *hypocalcemia*, particularly when the product of serum calcium (mg/dL) and phosphate (mg/dL) concentrations exceeds 70. Other factors that contribute to hypocalcemia include tissue resistance to the actions of parathyroid hormone and reduced levels of 1,25-dihydroxyvitamin D. Hypocalcemia is often asymptomatic but can cause perioral paresthesias, muscle cramps, seizures, hallucinations and confusion, and prolongation of the QT interval and nonspecific T-wave changes on electrocardiography (Chap. 341).

Anemia develops rapidly inARF and is usually mild and multifactorial in origin. Contributing factors include impaired erythropoiesis, hemolysis, bleeding, hemodilution, and reduced red cell survival time. Prolongation of the *bleeding time* and *leukocytosis* are also common. Common contributors to the bleeding diathesis include mild thrombocytopenia, platelet dysfunction, and/or clotting factor abnormalities (e.g., factor VIII dysfunction), whereas leukocytosis usually reflects sepsis, a stress response, or other concurrent illness. *Infection* is a common and serious complication of ARF, occurring in 50 to 90% of cases and accounting for up to 75% of deaths. It is unclear whether patients with ARF have a clinically significant defect in host immune responses or whether the high incidence of infection reflects repeated breaches of mucocutaneous barriers (e.g., intravenous cannulae, mechanical ventilation, bladder catheterization). *Cardiopulmonary complications* of ARF include arrhythmias, myocardial infarction, pericarditis and pericardial effusion, pulmonary edema, and pulmonary embolism. Mild *gastrointestinal bleeding* is common (10 to 30%) and is usually due to stress ulceration of gastric or small intestinal mucosa.

Protracted periods of severeARF are invariably associated with the development of the *uremic syndrome* (Chap. 270).

A *vigorous diuresis* can occur during the recovery phase ofARF (see above) and lead to intravascular volume depletion and delayed recovery ofGFR by causing secondary prerenal ARF. *Hypernatremia* can also complicate recovery if water losses via hypotonic urine are not replaced or if losses are inappropriately replaced by relatively hypertonic saline solutions. *Hypokalemia*, *hypomagnesemia*, *hypophosphatemia*, and *hypocalcemia* are less common metabolic complications during this period.

TREATMENT

Prevention Because there are no specific therapies for ischemic or nephrotoxicARF, prevention is of paramount importance. Many cases of ischemic ARF can be avoided by close attention to cardiovascular function and intravascular volume in high-risk patients, such as the elderly and those with preexisting renal insufficiency. Indeed, aggressive

restoration of intravascular volume has been shown to reduce the incidence of ischemic ARF dramatically after major surgery or trauma, burns, or cholera. The incidence of nephrotoxic ARF can be reduced by tailoring the dosage of potential nephrotoxins to body size andGFR; for example, reducing the dose or frequency of administration of drugs in patients with preexisting renal impairment. In this regard, it should be noted that serum creatinine is a relatively insensitive index of GFR and may overestimate GFR considerably in small or elderly patients. For purposes of drug dosing, it is advisable to estimate the GFR using the Cockcroft-Gault formula, which factors in the variables of age and weight (Chap. 47). Adjusting drug dosage according to circulating drug levels also appears to limit renal injury in patients receiving aminoglycoside antibiotics or cyclosporine. Diuretics, cyclooxygenase inhibitors,ACEinhibitors, and other vasodilators should be used with caution in patients with suspected true or "effective" hypovolemia or renovascular disease as they may precipitate prerenal ARF or convert the latter to ischemic ARF. Hypovolemia should be avoided in patients receiving nephrotoxic medications as renal hypoperfusion potentiates the toxicity of most nephrotoxins. Allopurinol and forced alkaline diuresis are useful in patients at high risk for acute urate nephropathy (e.g., cancer chemotherapy in hematologic malignancies) to limit uric acid generation and prevent precipitation of urate crystals in renal tubules. Forced alkaline diuresis may also prevent or attenuate ARF in patients receiving high-dose methotrexate or suffering from rhabdomyolysis. *N*-acetylcysteine limits acetaminophen-induced renal injury if given within 24 h of ingestion. Dimercaprol, a chelating agent, may prevent heavy metal nephrotoxicity. Ethanol inhibits ethylene glycol metabolism to oxalic acid and other toxic metabolites and is an important adjunct to hemodialysis in the emergency management of ethylene glycol intoxication.

Specific Therapies By definition, prerenalARF is rapidly reversible upon correction of the primary hemodynamic abnormality, and postrenal ARF resolves upon relief of obstruction. To date, there are no specific therapies for established intrinsic renal ARF due to ischemia or nephrotoxicity. Management of these disorders should focus on elimination of the causative hemodynamic abnormality or toxin, avoidance of additional insults, and prevention and treatment of complications. Specific treatment of other causes of intrinsic renal ARF depends on the underlying pathology.

Prerenal ARF The composition of replacement fluids for treatment of prerenal ARF due to hypovolemia must be tailored according to the composition of the lost fluid. Severe hypovolemia due to hemorrhage should be corrected with packed red blood cells, whereas isotonic saline is usually appropriate replacement for mild to moderate hemorrhage or plasma loss (e.g., burns, pancreatitis). Urinary and gastrointestinal fluids can vary greatly in composition but are usually hypotonic. Hypotonic solutions (e.g., 0.45% saline) are usually recommended as initial replacement in patients with prerenal ARF due to increased urinary or gastrointestinal fluid losses, although isotonic saline may be more appropriate in severe cases. Subsequent therapy should be based on measurements of the volume and ionic content of excreted or drained fluids. Serum potassium and acid-base status should be monitored carefully, and potassium and bicarbonate supplemented as appropriate. Cardiac failure may require aggressive management with positive inotropes, preload and afterload reducing agents, antiarrhythmic drugs, and mechanical aids such as intraaortic balloon pumps. Invasive hemodynamic monitoring may be required to guide therapy for complicated conditions in patients in whom clinical assessment of cardiovascular function and intravascular

volume proves unreliable.

Fluid management may be particularly difficult in patients with cirrhosis complicated by ascites. In this setting, it is important to distinguish between full-blown hepatorenal syndrome (Chap. 299), which carries a grave prognosis, and reversibleARF due to true or "effective" hypovolemia induced by overzealous use of diuretics or sepsis (e.g., spontaneous bacterial peritonitis). The contribution of hypovolemia to ARF can be definitively assessed only by administration of a fluid challenge. Fluids should be administered slowly and titrated against jugular venous pressure and, if necessary, central venous and pulmonary capillary wedge pressure, abdominal girth, and urine output. Patients with a reversible prerenal component typically have an increase in urine output and fall in serum creatinine, whereas patients with hepatorenal syndrome do not and may suffer increased ascites formation and pulmonary compromise if not monitored closely. Large volumes of ascitic fluid can usually be drained by paracentesis without deterioration in renal function if intravenous albumin is administered simultaneously. Indeed, "large-volume paracentesis" may afford an increase inGFR, possibly by lowering intraabdominal pressure and improving flow in renal veins. Shunting of ascitic fluid from the peritoneum to a central vein (peritoneojugular shunt, LeVeen or Denver shunts) is an alternative approach in refractory cases but has not been shown to improve survival in controlled trials. The efficacy of the newer technique of transjugular intrahepatic portosystemic shunting (TIPS procedure) is currently undergoing rigorous clinical assessment. Shunting can also improve GFR and sodium excretion transiently, probably because the increase in central blood volume stimulates release of atrial natriuretic peptides and inhibits secretion of aldosterone and norepinephrine.

Intrinsic renal ARF Many different approaches have been tested for their ability to attenuate injury or hasten recovery in ischemic and nephrotoxic ARF. These include atrial natriuretic peptide (ANP), low-dose dopamine, loop-blocking diuretics, calcium channel blockers, a-adrenoreceptor blockers, prostaglandin analogues, antioxidants, antibodies against leukocyte adhesion molecules, and insulin-like growth factor. Whereas many of these are beneficial in experimental models of ischemic or nephrotoxic ARF, they have either failed to confer consistent benefit or proved ineffective in humans.

ARFdue to other intrinsic renal diseases such as acute glomerulonephritis or vasculitis may respond to glucocorticoids, alkylating agents, and/or plasmapheresis, depending on the primary pathology. Glucocorticoids also hasten remission in some cases of allergic interstitial nephritis. Aggressive control of systemic arterial pressure is of paramount importance in limiting renal injury in malignant hypertensive nephrosclerosis, toxemia of pregnancy, and other vascular diseases. Hypertension and ARF due to scleroderma may be exquisitely sensitive to treatment withACEinhibitors.

Postrenal ARF Management of postrenal ARF requires close collaboration between nephrologist, urologist, and radiologist. Obstruction of the urethra or bladder neck is usually managed initially by transurethral or suprapubic placement of a bladder catheter, which provides temporary relief while the obstructing lesion is identified and treated definitively. Similarly, ureteric obstruction may be treated initially by percutaneous catheterization of the dilated renal pelvis or ureter. Indeed, obstructing lesions can often be removed percutaneously (e.g., calculus, sloughed papilla) or bypassed by insertion

of a ureteric stent (e.g., carcinoma). Most patients experience an appropriate diuresis for several days following relief of obstruction. Approximately 5% of patients develop a transient salt-wasting syndrome that may require administration of intravenous saline to maintain blood pressure.

Supportive Measures (Table 269-4) Following correction of hypovolemia, salt and water intake are tailored to match losses. Hypervolemia can usually be managed by restriction of salt and water intake and diuretics. Indeed, there is, as yet, no proven rationale for administration of diuretics inARFexcept to treat this complication. High doses of loop-blocking diuretics such as furosemide (up to 200 to 400 mg intravenously) or bumetanide (up to 10 mg intravenously administered as a bolus or by continuous infusion) may promote diuresis in patients who fail to respond to conventional doses. Subpressor doses of dopamine are claimed to promote salt and water excretion by increasing renal blood flow andGFR and by inhibiting tubule sodium reabsorption; however, subpressor ("low-dose," "renal-dose,") dopamine has proved ineffective in clinical trials and may trigger arrythmias and sudden cardiac death in critically ill patients. Ultrafiltration or dialysis is used to treat severe hypervolemia when conservative measures fail. Hyponatremia and hypoosmolality can usually be controlled by restriction of free water intake. Conversely, hypernatremia is treated by administration of water or intravenous hypotonic saline or isotonic dextrose-containing solutions.

**The management of hyperkalemia is described in Chap. 49.*

Metabolic acidosis is not treated unless serum bicarbonate concentration falls below 15 mmol/L or arterial pH falls below 7.2. More severe acidosis is corrected by oral or intravenous sodium bicarbonate. Initial rates of replacement are guided by estimates of bicarbonate deficit and adjusted thereafter according to serum levels (Chap. 50). Patients are monitored for complications of bicarbonate administration such as hypervolemia, metabolic alkalosis, hypocalcemia, and hypokalemia. From a practical point of view, most patients requiring sodium bicarbonate need emergency dialysis within days. Hyperphosphatemia is usually controlled by restriction of dietary phosphate and by oral aluminum hydroxide or calcium carbonate, which reduce gastrointestinal absorption of phosphate. Hypocalcemia does not usually require treatment unless severe, as may occur with rhabdomyolysis or pancreatitis or following admininstration of bicarbonate. Hyperuricemia is typically mild [<890 umol/L (< 15 mg/dL)] and does not require intervention.

The objective of *nutritional management* during the maintenance phase ofARF is to provide sufficient calories to avoid catabolism and starvation ketoacidosis, while minimizing production of nitrogenous waste. This is best achieved by restricting dietary protein to approximately 0.6 g/kg per day of protein of high biologic value (i.e., rich in essential amino acids) and to provide most calories as carbohydrate (approximately 100 g daily). Nutritional management is easier in nonoliguric patients and following institution of dialysis. Vigorous parenteral hyperalimentation is claimed to improve prognosis; however, convincing benefit has yet to be demonstrated in controlled trials.

Anemia may necessitate blood transfusion if severe or if recovery is delayed. In contrast to chronic renal failure, recombinant human erythropoietin is rarely used inARFbecause

bone marrow resistance to erythropoietin is common, more immediate treatment of anemia (if any) is required, and renal failure is usually self-limiting. Uremic bleeding usually responds to correction of anemia, administration of desmopressin or estrogens, or dialysis. Regular doses of antacids appear to reduce the incidence of gastrointestinal hemorrhage significantly and may be more effective in this regard than H_2antagonists, or proton pump inhibitors. Meticulous care of intravenous cannulae, bladder catheters, and other invasive devices is mandatory to avoid infections. Unfortunately, prophylactic antibiotics have not been shown to reduce the incidence of infection in these high-risk patients.

Indications and Modalities of Dialysis Dialysis replaces renal function until regeneration and repair restore renal function. Hemodialysis and peritoneal dialysis appear equally effective for management ofARF. Thus, the dialysis modality is chosen according to the needs of individual patients (e.g., peritoneal dialysis may be preferable if the patient is hemodynamically unstable, and hemodialysis after abdominal surgery involving the peritoneum), the expertise of the nephrologist, and the facilities of the institution. Vascular access for conventional intermittent hemodialysis is best achieved by insertion of a temporary double-lumen hemodialysis catheter into the internal jugular vein. The subclavian and femoral veins are alternative access sites. Peritoneal dialysis is achieved by insertion of a single-lumen cuffed catheter into the peritoneal cavity. Absolute indications for dialysis include symptoms or signs of the uremic syndrome and management of refractory hypervolemia, hyperkalemia, or acidosis. Many nephrologists also initiate dialysis empirically for blood urea levels of >100 mg/dL, even in the absence of clinical uremia; however, this approach has yet to be validated in controlled clinical trials. Nor is it clear whether intensive dialysis prescribed to maintain blood urea and creatinine below a certain level is beneficial. The latter are important issues since unnecessary or intensive hemodialysis can exacerbateATN and delay renal recovery by triggering hypotension and repeated renal hypoperfusion. Moreover, an expanding body of evidence suggests that leukocytes, activated directly by contact with hemodialysis membranes or as a result of membrane-triggered complement activation, then travel to the already-compromised renal microcirculation where they further exacerbate renal injury.

Continuous arteriovenous hemodiafiltration (CAVH) and continuous venovenous hemodiafiltration (CVVH) are alternatives to conventional intermittent hemodialysis techniques for treatment of ARF. They are particularly valuable techniques in patients in whom intermittent hemodialysis fails to control hypervolemia or uremia and for those who do not tolerate intermittent hemodialysis and in whom peritoneal dialysis is not possible. CAVH requires both arterial and venous access. The patient's own blood pressure generates an ultrafiltrate of plasma across a porous biocompatible dialysis membrane. A physiologic crystalloid solution is passed along the other side of the membrane to achieve diffusive clearance. CVVH, in contrast, requires only a double-lumen venous catheter as a blood pump generates ultrafiltration pressure across the dialysis membrane. These newer continuous techniques have not been compared to conventional intermittent hemodialysis in prospective, adequately controlled trials, and the choice of technique is currently tailored to the specific needs of the patient, the resources of the institution, and the expertise of the physician. Potential disadvantages of continuous hemodialysis techniques are the need for prolonged immobilization in bed, systemic anticoagulation, arterial cannulation (in CAVH), and prolonged exposure

of blood to synthetic, albeit relatively biocompatible, dialysis membranes.

OUTCOME AND LONG-TERM PROGNOSIS

The mortality rate among patients withARFapproximates 50% and has changed little over the past 30 years. It should be stressed, however, that patients usually die from sequelae of the primary illness that induced ARF and not from ARF itself. Indeed, the kidney is one of the few organs whose function can be replaced artificially (i.e., by dialysis) for protracted periods of time. In agreement with this interpretation, mortality rates vary greatly depending on the cause of ARF: ~15% in obstetric patients, ~30% in toxin-related ARF, and ~60% following trauma or major surgery. Oliguria (<400 mL/d) at time of presentation and a rise in serum creatinine of >265 umol/L (>3 mg/dL) are associated with a poor prognosis and probably reflect the severity of renal injury and of the primary illness. Mortality rates are higher in older debilitated patients and in those with multiple organ failure. Most patients who survive an episode of ARF recover sufficient renal function to live normal lives. However, 50% have subclinical impairment of renal function or residual scarring on renal biopsy. Approximately 5% of patients never recover function and require long-term renal replacement with dialysis or transplantation. An additional 5% suffer progressive decline inGFR, following an initial recovery phase, probably due to hemodynamic stress and sclerosis of remnant glomeruli (Chap. 273).

270. CHRONIC RENAL FAILURE - *Karl Skorecki*, *Jacob Green*, *Barry M. Brenner*

MECHANISMS OF CHRONIC RENAL FAILURE

DEFINITIONS

Chronic renal disease (CRD) is a pathophysiologic process with multiple etiologies, resulting in the inexorable attrition of nephron number and function, and frequently leading to *end-stage renal disease (ESRD)*. In turn, ESRD represents a clinical state or condition in which there has been an irreversible loss of endogenous renal function, of a degree sufficient to render the patient permanently dependent upon renal replacement therapy (dialysis or transplantation) in order to avoid life-threatening *uremia*. Uremia is the clinical and laboratory syndrome, reflecting dysfunction of all organ systems as a result of untreated or undertreated acute or chronic renal failure. Given the capacity of the kidneys to regain function following acute injury (Chap. 269), the vast majority (>90%) of patients with ESRD have reached this state as a result of CRD.

PATHOPHYSIOLOGY OF CRD

The pathophysiology ofCRDinvolves initiating mechanisms specific to the underlying etiology as well as a set of progressive mechanisms that are a common consequence following long-term reduction of renal mass, irrespective of etiology. Such reduction of renal mass causes structural and functional hypertrophy of surviving nephrons. This compensatory hypertrophy is mediated by vasoactive molecules, cytokines, and growth factors and is due initially to adaptive hyperfiltration, in turn mediated by increases in glomerular capillary pressure and flow. Eventually, these short-term adaptations prove maladaptive, in that they predispose to sclerosis of the remaining viable nephron population. This final common pathway for inexorable attrition of residual nephron function may persist even after the initiating or underlying disease process has become inactive. Increased intrarenal activity of the renin-angiotensin axis appears to contribute both to the initial adaptive hyperfiltration and to the subsequent maladaptive hypertrophy and sclerosis. These maladaptive long-term actions of renin-angiotensin axis activation are mediated in part through downstream growth factors such as transforming growth factor b. Interindividual variability in the risk and rate of CRD progression can be explained in part by variations in the genes encoding components of these and other pathways involved in glomerular and tubulointerstitial fibrosis and sclerosis (see "Genetic Considerations in the Progression of CRD," below).

The earliest stage common to all forms of CRDis a loss of renal reserve. When kidney function is entirely normal, glomerular filtration rate (GFR) can be augmented by 20 to 30% in response to the stimulus of a protein challenge. During the earliest stage of loss of renal reserve, basal GFR may be normal or even elevated (hyperfiltration), but the expected further rise in response to a protein challenge is attenuated. This early stage is particularly well documented in diabetic nephropathy. At this stage, the only clue may be at the level of laboratory measurements, which estimate GFR. The most commonly utilized laboratory measurements are the serum urea and creatinine concentrations. By the time serum urea and creatinine concentrations are even mildly elevated, substantial chronic nephron injury has already occurred.

AsGFRdeclines to levels as low as 30% of normal, patients may remain asymptomatic with only biochemical evidence of the decline in GFR, i.e., rise in serum concentrations of urea and creatinine. However, careful scrutiny usually reveals early additional clinical and laboratory manifestations of renal insufficiency. These may include nocturia, mild anemia and loss of energy, decreasing appetite and early disturbances in nutritional status, and abnormalities in calcium and phosphorus metabolism (*moderate renal insufficiency*). As GFR falls to below 30% of normal, an increasing number and severity of uremic clinical manifestations and biochemical abnormalities supervene (*severe renal insufficiency*). At the stages of mild and moderate renal insufficiency, intercurrent clinical stress may compromise renal function still further, inducing signs and symptoms of overt uremia. Such intercurrent clinical conditions to which patients withCRD may be particularly susceptible include infection (urinary, respiratory, or gastrointestinal), poorly controlled hypertension, hyper- or hypovolemia, and drug or radiocontrast nephrotoxicity, among others. When GFR falls below 5 to 10% of normal(ESRD), continued survival without renal replacement therapy becomes impossible.

ETIOLOGY

There has been a dramatic increase in the incidence ofESRD as well as a shift in the relative incidence of etiologies ofCRDduring the past two decades. Whereas glomerulonephritis was the leading cause of CRD in the past, diabetic and hypertensive nephropathy are now much more frequent underlying etiologies (Table 270-1). This may be a consequence of more effective prevention and treatment of glomerulonephritis or of diminished mortality from other causes among individuals with diabetes and hypertension. Greater overall longevity and diminished premature cardiovascular mortality have also increased the mean age of patients presenting with ESRD. Hypertension is a particularly common cause of CRD in the elderly, in whom chronic renal ischemia due to renovascular disease may be an underrecognized additional contribution to the pathophysiologic process. Many patients present at an advanced stage of CRD, precluding definitive determination of etiology.

GENETIC CONSIDERATIONS

Progression of CRD Disorders with clear-cut monogenic inheritance comprise a small but important component among the etiologies of CRD. Among these, autosomal dominant polycystic kidney disease is the most common on a world-wide basis (Chap. 276). Alport's hereditary nephritis (Chap. 275) is a less common cause of both benign hematuria without progression to CRD and more severe nephron injury with progression toESRD, and it usually displays an X-linked pattern of inheritance. In contrast, the two most common etiologies of CRD (Table 270-1), namely diabetes mellitus (both types 1 and 2) and essential hypertension, display complex polygenic patterns of inheritance. Both candidate locus and genome-wide strategies have been used to pinpoint genes that contribute to the risks for development of these disorders. Recent evidence also suggests that reflux nephropathy may have a heritable basis, again involving the contribution of several genetic loci.

Striking interindividual variability in the rate of progression toESRD is a characteristic feature among patients with either inherited or acquired causes of CRD, irrespective of underlying etiology. This interindividual variability has an important heritable component,

clarification of which may help guide therapeutic approaches. A number of genetic loci that contribute to the progression of CRD have been identified. Most extensively studied has been an insertion/deletion polymorphism of the angiotensin-converting enzyme (ACE) gene, previously shown to contribute to cardiovascular disease risk. Studies in a wide variety of disorders, including diabetic nephropathy, glomerulonephritis, polycystic kidney disease, and CRD caused by urologic abnormalities, have revealed an important contribution of this locus to progressive deterioration of renal function. The two different alleles defined by this polymorphism of the ACE gene are associated with corresponding differences in the endogenous activity of the encoded enzyme. The homozygous deletion (D/D) variant is associated with the highest expression of endogenous ACE activity and a greater risk of CRD progression. This finding has important therapeutic implications and leads to the prediction that ACE inhibitor therapy might be most effective in patients who are homozygous for the "at-risk" allele. Similar conclusions have been reached with respect to genes encoding other components of the renin-angiotensin axis, including the angiotensinogen gene, and the angiotensin receptor. These findings are consistent with the important role of intraglomerular hemodynamic perturbations in progressive renal injury.

PATHOPHYSIOLOGY AND BIOCHEMISTRY OF UREMIA

The uremic syndrome results from functional derangements of many organ systems, although the prominence of specific symptoms varies among patients. *Azotemia* refers to the retention of nitrogenous waste products as renal insufficiency develops. *Uremia* refers to the more advanced stages of progressive renal insufficiency when the complex, multiorgan system derangements become clinically manifest. The term uremia was adopted originally because of the presumption that all of the abnormalities result from retention in the blood of end products of metabolism normally excreted in the urine. The most likely candidates as toxins in uremia are the by-products of protein and amino acid metabolism. Unlike fats and carbohydrates, which are eventually metabolized to carbon dioxide and water -- substances readily excreted even in uremic subjects via lungs and skin -- the products of protein and amino acid metabolism depend primarily on the kidneys for excretion. Although a number of such products have been identified (Table 270-2), the clinical symptoms of uremia correlate poorly with the blood levels of these products. This is because uremia involves more than renal excretory failure alone. A host of metabolic and endocrine functions normally subserved by the kidney are also impaired, resulting in anemia; malnutrition; impaired metabolism of carbohydrates, fats, and proteins; defective utilization of energy; and metabolic bone disease. Thus, the pathophysiology of the uremic syndrome can be divided into those sets of abnormalities consequent to the accumulation of products of protein metabolism on the one hand, and on the other hand, abnormalities consequent to the loss of other renal functions, such as fluid and electrolyte homeostasis and synthesis of certain hormones [e.g., erythropoietin (EPO), 1.25-dihydroxycholecalciferol].

Although not the major cause of overt uremic toxicity, urea may contribute to some of the clinical abnormalities, including anorexia, malaise, vomiting, and headache. Elevated levels of plasma *guanidinosuccinic acid*, by interfering with activation of platelet factor III by ADP, contribute to the impaired platelet function inCRD. *Creatinine* may cause adverse effects following conversion to metabolites such as sarcosine and methylguanidine. Nitrogenous compounds with a molecular mass of 500 to 12,000 Da

(so-called middle molecules) are also retained in CRD and similarly are believed to contribute to morbidity and mortality in uremic subjects. Decreased renal excretion is not the only reason why such middle-sized molecules, along with various cytokines and growth factors, accumulate in uremic plasma. The kidney normally catabolizes a number of circulating plasma proteins and polypeptides; with reduced renal mass, this capacity is impaired. Furthermore, plasma levels of many polypeptide hormones, including parathyroid hormone (PTH) insulin, glucagon, luteinizing hormone, and prolactin, rise with renal failure, not only because of impaired renal catabolism but also because of enhanced glandular secretion. Of these, excessive PTH has been suggested to be an important uremic "toxin" because of its adverse effect of elevating cellular cytosolic Ca^{2+}levels in several tissues and organs.

CLINICAL AND LABORATORY MANIFESTATIONS OF CHRONIC RENAL FAILURE AND UREMIA

Uremia leads to disturbances in the function of every organ system. Chronic dialysis (Chap. 271) reduces the incidence and severity of these disturbances, so that, where modern medicine is practiced, the overt and florid manifestations of uremia have largely disappeared. Unfortunately, as indicated in Table 270-3, even optimal dialysis therapy is not a panacea, because some disturbances resulting from impaired renal function fail to respond fully, while others continue to progress.

FLUID, ELECTROLYTE, AND ACID-BASE DISORDERS (See also Chaps. 49 and50)

Sodium and Water Homeostasis When theGFR is normal, >24,000 mmol of Na^+ are filtered per day. An overwhelming fraction of this Na^+ load is reabsorbed by the tubules, leaving only a small fraction (usually<1%) to be excreted. Thus, even when the GFR falls markedly to levels as low as 10% of normal, the filtered load of Na^+still far exceeds daily requirements for urinary Na^+excretion. Therefore, any abnormalities in overall Na^+balance will reflect the relationship between the filtered load and fractional reabsorption (glomerulotubular balance). Progressive nephron injury can be associated with a tendency to Na^+retention, Na^+wasting, or maintenance of Na^+balance, depending in part on the underlying etiology (glomerular vs. tubulointerstitial disease), ongoing diuretic treatment, and comorbid conditions that affect Na^+balance, such as cardiac failure or cirrhosis. Osmotic regulation of vasopressin release and of thirst are also preserved. Even when tubule response to vasopressin is diminished, normal thirst mechanisms and access to H_2O generally prevent hypernatremia. However, a compromised capacity to excrete a maximally dilute urine with progressiveCRD may lead to hyponatremia.

In most patients with stableCRD, the total body contents of Na^+ and H_2O are increased modestly, although this may not be clinically apparent. The underlying etiologic disease process may itself disrupt glomerulotubular balance and promote Na^+retention (e.g., glomerulonephitis), or excessive Na^+ingestion may lead to cumulative positive Na^+balance and attendant extracellular fluid volume (ECFV) expansion. Such ECFV expansion contributes to hypertension, which in turn accelerates further the progression of nephron injury. As long as water intake does not exceed the capacity for free water clearance, the ECFV expansion will be isotonic and the patient will remain normonatremic. On the other hand, hyponatremia will be the consequence of excessive

water ingestion. However, in view of the concomitant impairment in urinary concentrating mechanism, severe hyponatremia is not usual in predialysis patients, and water restriction is only necessary when hyponatremia is documented. In such patients, a daily intake of fluid equal to the urine volume per day plus about 500 mL usually maintains the serum Na^+ concentration at normal levels.

Weight gain usually associated with volume expansion may be offset in patients with CRD by concomitant loss of lean body mass. In the CRD patient who is not yet on dialysis but has clear evidence of ECFV expansion, administration of loop diuretics coupled with restriction of salt intake are the mainstays of therapy. It should be noted that resistance to loop diuretics in renal failure often mandates use of higher doses than those usually used when GFR is well preserved. The combination of loop diuretics with metalozone, which inhibits the Na-Cl cotransporter of the distal convoluted tubule, can sometimes overcome diuretic resistance. When the GFR falls to<5 to 10 mL/min, even high doses of combination diuretics are ineffective. ECFV expansion under these circumstances usually means that dialysis is indicated. In dialysis patients with volume expansion, management should include ultrafiltration and restriction of salt and water intake between dialysis treatments.

Patients with CRD also have impaired renal mechanisms for conserving Na^+ and H_2O (Chap. 268). When an *extrarenal* cause for fluid loss is present (e.g., vomiting, diarrhea, sweating, fever), these patients are prone to volume depletion. Depletion of ECFV may compromise residual renal function with resulting signs and symptoms of overt uremia. Because of impaired renal Na^+ and H_2O conservation mechanisms, the usual indices of prerenal azotemia (oliguria, high urine osmolality, low urinary Na^+ concentration, and low fractional excretion of Na^+) are not useful. Cautious volume repletion, usually with normal saline, returns ECFV to normal and usually restores renal function to prior levels.

Potassium Homeostasis (See also Chap. 49) When GFR is normal, the approximate daily filtered load of K^+ is 700 mmol. The majority of this filtered load is reabsorbed in tubule segments prior to the cortical collecting tubule, and most of the K^+ excreted in the final urine reflects events governing K^+ handling at the level of the cortical collecting tubule and beyond. These factors include the flow of luminal fluid and the delivery and reabsorption of Na^+, which generates the lumen-negative electromotive force for K^+ secretion at the aldosterone-responsive distal nephron sites. In CRD, these factors may be well preserved, such that a decline in GFR is not necessarily accompanied by a concomitant and proportionate decline in urinary K^+ excretion. In addition, K^+ excretion in the gastrointestinal tract is augmented in patients with CRD. However, hyperkalemia may be precipitated in a number of clinical situations, including augmented dietary intake, protein catabolism, hemolysis, hemorrhage, transfusion of stored red blood cells, metabolic acidosis, and following the exposure to a variety of medications that inhibit K^+ entry into cells or K^+ secretion in the distal nephron. Most commonly encountered medications in this regard are beta blockers, ACE inhibitors, K^+-sparing diuretics (amiloride, triamterene, spironolactone), and nonsteroidal anti-inflammatory drugs (NSAIDs). In addition, certain etiologies of CRD may be associated with earlier and more severe disruption of K^+ secretory mechanisms in the distal nephron, relative to the reduction in GFR. Most important are conditions associated with hyporeninemic hypoaldosteronism (e.g., diabetic nephropathy and certain forms of distal renal tubular acidosis; Chap. 49).

Most commonly, clinically significant hyperkalemia does not occur until the GFR falls to below 10 mL/min or unless there is exposure to a K^+ load, either endogenous (e.g., hemolysis, trauma, infection) or exogenous (e.g., administration of stored blood, K^+-containing medications, K^+-containing dietary salt substitute). In kidney transplant recipients, cyclosporine is another common cause of increased plasma K^+ concentration. Hyperkalemia in CRD patients may also be induced by abrupt falls in plasma pH, since acidosis is associated with efflux of K^+ from the intracellular to the extracellular fluid compartment.

Although total-body K^+ is frequently reduced in CRD, *hypokalemia* is uncommon. The occurrence of hypokalemia usually reflects markedly reduced dietary K^+ intake, in association with excessive diuretic therapy or gastrointestinal losses. Hypokalemia occurs as a result of primary renal K^+ wasting in association with other solute transport abnormalities, as in Fanconi's syndrome, renal tubular acidosis, or other forms of hereditary or acquired tubulointerstitial diseases. However, even under these circumstances, as GFR declines, the tendency to hypokalemia diminishes and hyperkalemia may supervene. Accordingly, K^+ supplementation and K^+-sparing diuretics should be used with caution as GFR declines.

Metabolic Acidosis (See also Chap. 50) In adults, the metabolism of dietary protein generates approximately 1 mmol/kg per day of H^+. The H^+ must be excreted, primarily by renal mechanisms, if neutral acid-base balance is to be maintained. Acidosis is a common disturbance during the advanced stages of CRD. Although in a majority of patients with CRD the urine can be acidified normally, these patients have a reduced ability to produce ammonia. In part this is a consequence of limited ATP utilization, resulting from diminished Na^+ reabsorption in the proximal tubule. As a result, the use of glutamine as an energy source is limited, which in turn limits proximal tubule ammonia production. Hyperkalemia, when present, further depresses urinary ammonium excretion. The combination of hyperkalemia and hyperchloremic metabolic acidosis (known as type IV renal tubular acidosis or hyporeninemic hypoaldosteronism) is most characteristically seen in patients with diabetes or in those with predominantly tubulointerstitial disease. Treatment of the hyperkalemia frequently improves the acidosis as well.

With advancing renal failure, total urinary net daily acid excretion is usually limited to 30 to 40 mmol; thus, throughout the remainder of their course of CRD, many patients may be in a positive H^+ balance of 20 to 40 mmol/d. The retained H^+ is buffered by bone salts. In the early stages, the accompanying organic anions are excreted in the urine, and the metabolic acidosis is of the non-anion gap variety. However, with advanced renal failure, a fairly large "anion gap" may develop (to approximately 20 mmol/L) with a reciprocal fall in plasma HCO_3^- concentration. In most patients, the metabolic acidosis is mild and the pH is rarely less than 7.35. The metabolic acidosis can usually be corrected by treating the patient with 20 to 30 mmol of sodium bicarbonate or sodium citrate daily. However, the concomitant Na^+ load mandates careful attention to volume status and the potential need for diuretic agents. Also, citrate enhances aluminum absorption in the large bowel, and citrate-containing antacids should be avoided if aluminum-containing drugs are also administered. As with other abnormalities in CRD, severe symptomatic manifestations of acid-base imbalance occur when the patient is

challenged with an excessive endogenous or exogenous acid load or loses excessive alkali (e.g., with diarrhea).

BONE, PHOSPHATE, AND CALCIUM ABNORMALITIES (Fig. 270-1) (See also Chap. 340)

Although clinical symptoms of bone disease are present before dialysis in fewer than 10% of patients with ESRD, radiologic and histologic abnormalities are observed in about 35 and 90%, respectively. Two principal types of bone disorders are observed in patients with ESRD: a high-turnover osteodystrophy, known as *osteitis fibrosa cystica*, and a low-turnover state characterized initially by *osteomalacia* and subsequently by *adynamic bone disease*. In osteitis fibrosa, the number and size of the osteoclasts are increased, as are the number and depth of the osteoclastic resorption lacunae. Collagen deposition is less ordered, and the rate of bone turnover is markedly increased. In osteomalacia, the rate of mineralization is slower than that of collagen synthesis, resulting in excessive accumulation of unmineralized osteoid and widened osteoid seams. In adynamic uremic osteodystrophy, a parallel marked reduction in the rate of mineralization and collagen synthesis results in osteoid seams of normal width. While these disorders are often discussed as if they were distinct, they commonly overlap in a given patient with ESRD.

High-Turnover Uremic Osteodystrophy This condition is associated with elevated PTH levels. The hyperparathyroid state is attributable both to hyperplastic growth of the parathyroid glands and to augmented release of hormone from each individual parathyroid cell. The main factors responsible for deranged PTH synthesis in CRD are related to altered metabolism of phosphate, calcitrol [1,25(OH)$_2$D$_3$], and Ca^{2+}.

Phosphate (PO_4^{3-}) Hyperphosphatemia is a feature of advanced renal failure. The serum phosphate concentration rises in patients with a GFR < 20 mL/min, but retention of PO_4^{3-} can be documented in balance studies with even less severe declines in GFR. The retained PO_4^{3-} is a major cause of the development of secondary hyperparathyroidism in CRD. PO_4^{3-} exerts indirect effects on PTH secretion by decreasing renal production of calcitriol (see below) and by lowering plasma ionized Ca^{2+}. Recent studies also suggest a direct stimulatory role of PO_4^{3-} at the level of the parathyroid gland, in the absence of changes in serum Ca^{2+} or calcitriol levels. Dietary restriction of PO_4^{3-} as well as gastrointestinal PO_4^{3-} binders may prevent hyperphosphatemia, thereby mitigating the rise in PTH levels.

Calcitriol Under normal conditions, calcitriol exerts negative feedback control on the parathyroid gland through both direct (i.e., diminished transcription of pre-pro PTH mRNA) and indirect mechanisms. The latter act through stimulation of intestinal absorption of Ca^{2+} and the skeletal mobilization of Ca^{2+}, thereby increasing plasma Ca^{2+} and inhibiting PTH secretion. Therefore, reduced synthesis of 1,25(OH)$_2$D$_3$ during CRD plays a key role in the pathogenesis of hyperparathyroidism, both directly and through hypocalcemia. The abnormal vitamin D metabolism may be related to the renal disease itself (since the active vitamin D metabolite is normally produced in the proximal tubule) and to the hyperphosphatemia, which has a suppressive effect on the renal 1a-hydroxylase enzyme. Furthermore, a decrease in the number of calcitriol receptors in the parathyroid tissue of uremic patients has been

reported by several groups. Recent studies have demonstrated a marked decrease in vitamin D-receptor expression in areas of nodular transformation within hyperplastic parathyroid tissue but revealed no such receptor downregulation in diffuse hyperplastic parathyroid tissue. Since vitamin D also has an antiproliferative effect on parathyroid cells, this phenomenon may provide an explanation for the marked PTH secretion as well as the abnormal glandular growth pattern characteristic of nodular hyperparathyroidism.

Calcium The total plasma Ca^{2+}concentration in patients withCRD is often significantly lower than normal. Patients with CRD tolerate the hypocalcemia quite well; rarely is a patient symptomatic from the decreased Ca^{2+}concentration. This may partly be due to the frequent concomitant acidosis, which offsets some of the neuromuscular effects of hypocalcemia. The hypocalcemia in CRD results from decreased intestinal absorption of Ca^{2+} due to vitamin D deficiency (see above). Also, with the increasing serum PO_4^{3-}level, Ca^{2+}phosphate is deposited in soft tissues and serum Ca^{2+}concentration (both total and ionized) declines. In addition, patients with CRD are resistant to the action ofPTH. Hypocalcemia is a potent stimulus to PTH secretion and leads to hyperplasia of the parathyroid gland. Ca^{2+}binds to a specific Ca^{2+}-sensing receptor protein located in the cell membrane. The Ca^{2+}-sensing receptor is linked to several cytoplasmic messenger systems by one or more GTP-binding proteins. These signaling pathways are responsible for either enhanced or suppressed release of PTH during acute hypo- and hypercalcemia, respectively. Several studies have demonstrated the mRNA and protein expression of the Ca^{2+}-sensing receptor to be reduced in primary (adenomas) and secondary hyperparathyroidism (hyperplasia) compared to the expression in normal parathyroid tissue. In secondary hyperparathyroidism, expression of the Ca^{2+}-sensing receptor is often depressed in nodular areas compared with adjacent nonnodular hyperplasia. Thus, decreased Ca^{2+}receptor expression in hyperparathyroidism is compatible with a less efficient control of PTH synthesis and release, in response to varying plasma Ca^{2+}concentration.

In addition to excessive release of PTHfrom individual parathyroid cells, the size of the glands also increases as renal failure progresses. This abnormal growth of the parathyroid glands may assume one of the following patterns: (1) diffuse hyperplasia (polyclonal growth), (2) nodular growth (monoclonal growth) within diffuse hyperplastic tissue, or (3) diffuse monoclonal hyperplasia ("adenoma," or tertiary autonomous hyperparathyroidism). Patients with monoclonal ("autonomous") hyperplasia are especially prone to develop hypercalcemia following successful kidney transplantation, often necessitating parathyroidectomy.

During the initial phase ofCRD, the elevatedPTHlevels may normalize serum levels of Ca^{2+}, PO_4^{3-}, and vitamin D. Therefore hypocalcemia, hyperphosphatemia, and reduced $1,25(OH)_2D_3$are observed only as CRD progresses. However, even at the earliest stages of CRD, the elevated PTH levels adversely affect bone metabolism, causing increased osteoclastic and osteoblastic activity (high-turnover bone disease). Additional detrimental factors include the chronic uremic acidosis, which inhibits osteoblastic bone formation and stimulates osteoclastic bone resorption.

Low-Turnover Uremic Osteodystrophy Originally thought to result solely from vitamin D deficiency, *osteomalacia* (Chap. 342) has now been more closely associated with

aluminum toxicity. Aluminum was first identified as a presumed cause of dialysis dementia in dialysis patients, and shortly thereafter aluminum deposition in bone was shown to be associated with osteomalacia. The sources of aluminum were phosphate binders and the water used in preparing dialysate. Aluminum is no longer present as a contaminant in dialysate, but it still is widely utilized as a phosphate binder in some settings. Approximately one-third of dialysis andCRDpatients ingest at least some aluminum. Aluminum deposition adversely affects mineral deposition at the mineralization front.

Aplastic renal osteodystrophy occurs in many patients who have no evidence of excess aluminum accumulation. These patients have relatively low levels ofPTH. The disorder is associated with the use of supraphysiologic Ca^{2+}concentrations in peritoneal dialysate and the excessive use of oral Ca^{2+} and vitamin D preparations in both hemodialysis and peritoneal dialysis patients. These sources of exogenous Ca^{2+}might lower serum PTH to levels that are inadequate for maintaining normal bone turnover.

Yet another type of skeletal lesion that occurs inESRDpatients after many years of dialysis therapy results from *amyloid deposition* related to the accumulation ofb_2-microglobulin. This syndrome presents as carpal tunnel syndrome, tenosynovitis of the hands, shoulder arthropathy, bone cysts, cervical spondyloarthropathy, and cervical pseudotumors. It is characterized on x-ray films by cysts in the carpal bones and femoral neck. Amyloid tumoral masses may be best appreciated by ultrasound examination or computed tomography.

With high-turnover osteitis fibrosa cystica, vitamin D-deficient and aluminum-induced osteomalacia, and dialysis-related amyloidosis,ESRDpatients are prone to spontaneous fractures, which are slow to heal. The ribs are most commonly involved in the case of osteitis fibrosa cystica. The femoral neck is a frequent site of aluminum-induced osteomalacia and dialysis-related amyloidosis and is also prone to pathologic fractures. Bone pain, even in the absence of fractures, is common. In osteitis fibrosa cystica, a proximal myopathy often coexists, giving rise to gait abnormalities and to impairment of ambulation. Similarly, a myopathy may also accompany amyloid arthropathy. InCRD, there is a tendency to extraosseous or metastatic calcification when the calcium-phosphate product is very high (>70 when expressed as mg/dL). Medium-sized blood vessels; subcutaneous, articular, and periarticular tissues; myocardium; eyes; and lungs are common sites of metastatic calcification. *Calciphylaxis* refers to devastating necrotic extremity soft tissue lesions related to vascular occlusion and metastatic calcification.

The Effect of Uremic Acidosis on Bone Disease As previously noted, in patients withCRD, a decrease in acid excretion leads to unremitting positive H^+balance. If extracellular fluid HCO_3^-were the only H^+buffer available, it would become progressively depleted and the concentration of serum HCO_3^-, and thus pH, would fall to levels incompatible with life. However, during CRD, extracellular fluid $HCO_3^-$and pH remain stable, although reduced, for long periods; thus, either non-HCO_3^-buffers must neutralize the retained hydrogen ions or acid production must decrease. Acid production does not appear to diminish in patients with renal failure; yet such patients excrete only approximately two-thirds of their daily hydrogen ion production. Thus substantial buffering of the retained hydrogen ions almost certainly occurs. Because of its mass and

potential buffering capacity, bone is a likely site for the chronic hydrogen ion buffering.

TREATMENT

Secondary hyperparathyroidism and *osteitis fibrosa* are best prevented and treated by reducing serum PO_4^{3-} concentration through the use of a PO_4^{3-}-restricted diet as well as oral PO_4^{3-}-binding agents. Calcium carbonate and calcium acetate are the preferred PO_4^{3-}-binding agents, but in some rare circumstances a combination of short-term aluminum hydroxide and calcium carbonate is necessary. In such cases, aluminum levels should be monitored, and citrate antacids, which enhance aluminum absorption, should be avoided. Daily oral calcitriol, or intermittent oral or intravenous pulses, appear to exert a direct suppressive effect on PTH secretion, in addition to the indirect effect mediated through raising Ca^{2+} levels. Intravenous pulses are especially convenient for patients on hemodialysis. The use of calcitriol and Ca^{2+} preparations in the predialysis population must take into account potential effects of increased phosphate and Ca^{2+} on the rate of progression of CRD. In the dialysis population, dialysate Ca^{2+}, calcium carbonate, calcium acetate, aluminum hydroxide, and calcitriol must be properly balanced to maintain the serum PO_4^{3-} concentration at approximately 1.4 mmol/L (4.5 mg/dL) and the serum Ca^{2+} at approximately 2.5 mmol/L (10 mg/dL) in an attempt to suppress parathyroid hyperplasia, thus avoiding or reversing osteitis fibrosa cystica, osteomalacia, and myopathy. It is particularly important to maintain the Ca^{2+}-PO_4^{3-} product in the normal range to avoid metastatic calcification. Several analogues of calcitriol are now being evaluated. Such analogues would be beneficial if they had the same effect on PTH mRNA as calcitriol and increased the margin of safety and efficacy by having less hyperphosphatemic and hypercalcemic effects. In this manner, it might be possible to have a greater suppressive effect on PTH transcription because a higher dose could be used safely.

Adynamic bone disease is often a consequence of overzealous treatment of secondary hyperparathyroidism. Therefore, suppression of PTH levels to less than 120 pg/mL in uremic patients may not be desirable. The incidence of aluminum-induced osteomalacia has been greatly reduced with the recognition of aluminum as the principal culprit. Therapy for this disorder is continued avoidance of aluminum, with possible use of a chelating agent such as desferoxamine along with high-flux dialysis. Management of metabolic acidosis should aim to maintain a nearly normal level of plasma HCO_3^-, with the administration of calcium acetate or calcium carbonate in the first instance, and with the addition of $NaHCO_3$ if necessary. Excessive administration of alkali should be avoided to minimize risk of urinary precipitation of calcium phosphate.

At present, there is no good therapy for *dialysis-related amyloidosis*. Local physical therapy, glucocorticoid injections, and NSAIDs constitute current options.

Other Solutes *Uric acid* retention is a common feature of CRD but rarely leads to symptomatic gout. Treatment of hyperuricemia is not necessary unless recurrent gout becomes a problem. When recurrent symptomatic gout occurs, a reduced dose of allopurinol (100 to 200 mg/d) is usually sufficient to inhibit uric acid synthesis. Hypophosphatemia is rare and, when it occurs, is usually a consequence of overzealous oral administration of phosphate-binding gels. Because serum magnesium levels tend to rise in CRD, magnesium-containing antacids and cathartics should be

avoided.

CARDIOVASCULAR AND PULMONARY ABNORMALITIES

Congestive Heart Failure (See also Chap. 232) Salt and water retention in uremia often result in congestive heart failure and/or pulmonary edema. A unique form of pulmonary congestion and edema may occur even in the absence of volume overload and is associated with normal or mildly elevated intracardiac and pulmonary capillary wedge pressures. This entity, characterized radiologically by peripheral vascular congestion giving rise to a "butterfly wing" distribution, is due to increased permeability of alveolar capillary membranes. This "low-pressure" pulmonary edema as well as cardiopulmonary abnormalities associated with circulatory overload usually respond promptly to vigorous dialysis.

Hypertension and Left Ventricular Hypertrophy (See also Chap. 246) Hypertension is the most common complication ofCRD andESRD. When it is not found, the patient may have a salt-wasting form of renal disease (e.g., medullary cystic disease, chronic tubulointerstitial disease, or papillary necrosis), may be receiving antihypertensive therapy, or be volume-depleted, the last condition usually due to excessive gastrointestinal fluid losses or overzealous diuretic therapy. Since volume overload is the major cause of hypertension in uremia, the normotensive state can often be restored by appropriate use of diuretics in the predialysis patient or with aggressive ultrafiltration in dialysis patients. Nevertheless, because of hyperreninemia, some patients remain hypertensive despite rigorous salt and water restriction and ultrafiltration. Rarely, patients develop accelerated or malignant hypertension. Intravenous nitroprusside, labetolol, or more recently approved agents such as fenoldopam or urapidil, together with control ofECFV, generally controls such hypertension. Subsequently, such patients usually require more than one oral antihypertensive drug. Enalaprilat or otherACEinhibitors may also be considered, but in the face of bilateral renovascular disease they have the potential to further reduceGFRabruptly. Administration of erythropoietin (EPO) (p. 1557) may raise blood pressure and increase the requirement for antihypertensive drugs. A high percentage of patients with CRD present with left ventricular hypertrophy or dilated cardiomyopathy. These are among the most ominous risk factors for excess cardiovascular morbidity and mortality in patients with CRD and ESRD and are thought to be related primarily to prolonged hypertension and ECFV overload. In addition, anemia and the surgical placement of an arteriovenous anastomosis for future or ongoing dialysis access may generate a high cardiac output state, which also intensifies the burden placed on the left ventricle.

TREATMENT

Management of hypertension inCRD can be considered in terms of two overall goals: to slow the progression of CRD itself and to prevent the extrarenal complications of hypertension, such as cardiovascular disease and stroke. In all patients with CRD, blood pressure should be controlled to at least the level established in the guidelines of the Joint National Commission on Hypertension Detection Education and Follow-up Program (130/80-85 mmHg). In the elderly, levels of 140 mmHg may be a more realistic target. In predialysis patients with proteinuria> 1 g per 24 hr, blood pressure should be further reduced to a mean arterial pressure of 92 mmHg (equivalent to 125/75 mmHg),

where possible. Volume control is the mainstay of therapy, with addition of antihypertensive agents as needed when hypertension persists despite achievement of a normovolemic state. When salt retention and hypervolemia contribute to hypertension, salt restriction and diuretics are indicated as initial therapy. The choice of additional agents to slow the progression of CRD based upon reduction of intraglomerular hypertension and proteinuria is considered below. In ESRDpatients, considerations related to slowing of nephron injury are less important, and the main goal is to prevent cardiac hypertrophy and stroke. The choice of antihypertensive agents may come from all the major classes, with careful consideration of comorbid conditions. However, powerful direct-acting vasodilators, such as hydralazine or minoxidil, may perpetuate the tendency to cardiac hypertrophy, despite the lowering of blood pressure. Therefore, prolonged use of such agents should be reserved for those very rare patients in whom severe refractory hypertension persists, despite adequate volume reduction and compliance with all other classes of antihypertensives.

Atherosclerotic Coronary and Peripheral Vascular Disease Hypertension, hyperhomocysteinemia, and lipid abnormalities promote atherosclerosis but are potentially treatable complications ofCRD. Ongoing or prior nephrotic syndrome is also associated with hyperlipidemia and hypercoagulability, which increase the risk of occlusive vascular disease. Since diabetes mellitus and hypertension are themselves the two most frequent etiologies of CRD, it is not surprising that cardiovascular disease is the most frequent cause of death inESRDpatients. Therefore, accepted life-style changes and therapeutic measures for cardiac risk reduction (Chap. 242) are especially important in this group of patients. The approach to managing hypertension has been outlined above. Hyperhomocysteinemia may respond to vitamin therapy, which includes folate supplementation to between 1 and 5 mg/d. Hyperlipidemia in patients with CRD and ESRD should be managed aggressively according to the guidelines of the National Cholesterol Education Program (Chaps. 242 and344). If dietary measures are inadequate, the preferred lipid-lowering medications are gemfibrozil and an HMG-CoA reductase inhibitor. However, these two classes of agents ordinarily should not be combined because of an increased risk of myositis and rhabomyolysis in CRD and ESRD patients.

Abnormalities in Ca^{2+} and PO_4^{3-}metabolism (see above) may lead to metastatic vascular calcification and markedly increase the propensity to coronary, cerebral, and peripheral occlusive vascular disease. By careful attention to the guidelines noted above for the management of divalent ion metabolism and bone disease, avoidance of an elevated Ca^{2+}-PO_4^{3-}product may mitigate this effect.

Pericarditis (See alsoChap. 239) With the advent of early initiation of renal replacement therapy, pericarditis is now observed more often in underdialyzed patients than in patients withCRD in whom dialysis has not yet been initiated. Pericardial pain with respiratory accentuation, accompanied by a friction rub, are the hallmarks of uremic pericarditis. The finding of a multicomponent friction rub strongly supports the diagnosis. Furthermore, the usual occurrence of multiple cardiac murmurs, S_3 and S_4 heart sounds, and transmitted bruits from arteriovenous access devices may render precordial auscultation more challenging in this group of patients. Classic electrocardiographic abnormalities include PR-interval shortening and diffuse ST-segment elevation. Pericarditis may be accompanied by the accumulation of

pericardial fluid, readily detected by echocardiography, sometimes leading to cardiac tamponade. Pericardial fluid in uremic pericarditis is more often hemorrhagic than in viral pericarditis.

TREATMENT

Uremic pericarditis is an absolute indication for initiation of dialysis or for intensification of the dialysis prescription in those already on dialysis. Because of the propensity to hemorrhagic pericardial fluid, heparin-free dialysis is indicated. Pericardiectomy should be considered only if more conservative measures fail. Nonuremic causes of pericarditis and pericardial effusion include viral, malignant, and tuberculous pericarditis and pericarditis associated with myocardial infarction; these are also more frequent in patients withESRD and should be managed according to the dictates of the underlying disease process.

HEMATOLOGIC ABNORMALITIES

Anemia ofCRD(See also Chap. 105) A normocytic, normochromic anemia is present in the majority of patients withCRD. It is usually observed when theGFRfalls below 30 mL/min. When untreated, the anemia of CRD is associated with a number of physiologic abnormalities, including decreased tissue oxygen delivery and utilization, increased cardiac output, cardiac enlargement, ventricular hypertrophy, angina, congestive heart failure, decreased cognition and mental acuity, altered menstrual cycles, and impaired immune responsiveness. In addition, anemia may play a role in growth retardation in children. The primary cause of anemia in patients with CRD is insufficient production ofEPO by the diseased kidneys. Additional factors include the following: iron deficiency, either related to or independent of blood loss from repeated laboratory testing, needle punctures, blood retention in the dialyzer and tubing, or gastrointestinal bleeding; severe hyperparathyroidism; acute and chronic inflammatory conditions; aluminum toxicity; folate deficiency; shortened red cell survival; hypothyroidism; and underlying hemoglobinopathies. These potential contributing factors should be considered and addressed.

Before 1989, theEPO-deficient condition characteristic ofCRDcould only be treated with blood transfusions and anabolic steroids, with limited success and substantial complications. The availability of recombinant human EPO, approved by the U.S. Food and Drug Administration in 1989, has been one of the most significant advances in the care of renal patients in the past decade. Considerable debate continues regarding the optimal target hematocrit in dialysis patients receiving EPO. Mortality and hospitalization studies support the National Kidney Foundation Dialysis Outcomes Quality Initiative target hematocrit range of 33 to 36% as providing the best associated outcomes. EPO can be administered either intravenously or subcutaneously. Most studies have shown that administering EPO by the subcutaneous route has a sparing effect, with the target hematocrit achieved at a lower EPO dose. ManagementGuidelinesfor the correction of anemia in CRD are as follows.

The iron status of the patient withCRD must be assessed, and adequate iron stores should be available before treatment withEPO is initiated. Iron supplementation is usually essential to ensure an adequate response to EPO in patients with CRD,

because the demands for iron by the erythroid marrow frequently exceed the amount of iron that is immediately available for erythropoiesis (as measured by percent transferrin saturation) as well as iron stores (as measured by serum ferritin). In most cases, intravenous iron will be required to achieve and/or maintain adequate iron. However, excessive iron therapy may be associated with a number of complications, including hemosiderosis, accelerated atherosclerosis, increased susceptibility to infection, and possibly an increased propensity to the emergence of malignancies. In addition to iron, an adequate supply of the other major substrates and cofactors for erythrocyte production must be assured, especially vitamin B_{12} and folate. Anemia resistant to recommended doses of EPO in the face of adequate availability of iron and vitamin factors often suggests inadequate dialysis; uncontrolled hyperparathyroidism; aluminum toxicity; chronic blood loss or hemolysis; and associated hemoglobinopathy, malnutrition, chronic infection, multiple myeloma, or another malignancy. Blood transfusions may contribute to suppression of erythropoiesis in CRD; because they increase the risk of hepatitis, hemosiderosis, and transplant sensitization, they should be avoided unless the anemia fails to respond to EPO and the patient is symptomatic.

Abnormal Hemostasis Abnormal hemostasis is common inCRD and is characterized by a tendency to abnormal bleeding and bruising. Bleeding from surgical wounds and spontaneous bleeding into the gastrointestinal tract, pericardial sac, or intracranial vault (in the form of subdural hematoma or intracerebral hemorrhage) are of greatest concern. Prolongation of bleeding time, decreased activity of platelet factor III, abnormal platelet aggregation and adhesiveness, and impaired prothrombin consumption contribute to the clotting defects. The abnormality in platelet factor III correlates with increased plasma levels of guanidinosuccinic acid and can be corrected by dialysis. Prolongation of the bleeding time is common even in well-dialyzed patients. Abnormal bleeding times and coagulopathy in patients with renal failure may be reversed with desmopressin, cryoprecipitate, conjugated estrogens, and blood transfusions, as well as by the use ofEPO.

Enhanced Susceptibility to Infection Changes in leukocyte formation and function in uremia lead to enhanced susceptibility to infection. Lymphocytopenia and atrophy of lymphoid structures occur, whereas neutrophil production is relatively unimpaired. Nevertheless, the function of all leukocyte cell types may be affected adversely by uremic serum. Alterations in monocyte, lymphocyte, and neutrophil function cause impairment of acute inflammatory responses, decreased delayed hypersensitivity, and altered late immune function.

There is a tendency for uremic patients to have less fever in response to infection, perhaps because of the effects of uremia on the hypothalamic temperature control center. Leukocyte function may also be impaired in patients withCRDbecause of coexisting acidosis, hyperglycemia, protein-calorie malnutrition, and serum and tissue hyperosmolarity (due to azotemia). In patients treated with hemodialysis, leukocyte function is disturbed because of the effects of the bioincompatibility of various dialysis membranes. Activation of cytokine and complement cascades likewise occurs when blood comes in contact with dialysis membranes. These substances in turn alter inflammatory and immune responses of the uremic patient. Mucosal barriers to infection may also be defective, and, in dialysis patients, vascular and peritoneal access devices are common portals of entry for pathogens, especially staphylococci. Glucocorticoids

and immunosuppressive drugs used for various renal diseases and renal transplantation further increase the risk of infection.

NEUROMUSCULAR ABNORMALITIES

Subtle disturbances of central nervous system function, including inability to concentrate, drowsiness, and insomnia, are among the early symptoms of uremia. Mild behavioral changes, loss of memory, and errors in judgment soon follow and may be associated with neuromuscular irritability, including hiccoughs, cramps, and fasciculations/twitching of muscles. Asterixis, myoclonus, and chorea are common in terminal uremia, as are stupor, seizures, and coma. Peripheral neuropathy is also common in advancedCRD. Initially, sensory nerves are involved more than motor nerves, lower extremities more than upper, and distal portions of the extremities more than proximal. The "restless legs syndrome" is characterized by ill-defined sensations of discomfort in the feet and lower legs requiring frequent leg movement. If dialysis is not instituted soon after onset of sensory abnormalities, motor involvement follows, including loss of deep tendon reflexes, weakness, peroneal nerve palsy (foot drop), and, eventually, flaccid quadriplegia. Accordingly, evidence of peripheral neuropathy is a firm indication for the initiation of dialysis or transplantation. Some of the central nervous system and neuromuscular complications of advanced uremia resolve with dialysis, although nonspecific electroencephalographic abnormalities may persist (Table 270-3). Successful transplantation may reverse residual peripheral neuropathy.

Two types of neurologic disturbances are unique to patients on chronic dialysis (Chap. 271). *Dialysis dementia* may occur in patients who have been on dialysis for many years and is characterized by speech dyspraxia, myoclonus, dementia, and eventually seizures and death. Aluminum intoxication is probably the major contributor to this syndrome, but other factors, such as viral infections, may play a role since not all patients with aluminum exposure develop the syndrome. *Dialysis disequilibrium*, which occurs during the first few dialyses in association with rapid reduction of blood urea levels, manifests clinically with nausea, vomiting, drowsiness, headache, and, rarely, seizures. The syndrome has been attributed to cerebral edema and increased intracranial pressure due to the rapid (dialysis-induced) shifts of omsolality and pH between extracellular and intracellular fluids. This complication can often be anticipated and prevented in patients who present with markedly elevated concentrations of plasma urea, by prescribing an initial dialysis regimen that produces slower solute removal.

GASTROINTESTINAL ABNORMALITIES

Anorexia, hiccoughs, nausea, and vomiting are common early manifestations of uremia. Protein restriction is useful in diminishing nausea and vomiting late in the course of renal failure. However, protein restriction should not be implemented in patients with early signs of protein-calorie malnutrition. *Uremic fetor*, a uriniferous odor to the breath, derives from the breakdown of urea to ammonia in saliva and is often associated with an unpleasant metallic taste sensation. Mucosal ulcerations leading to blood loss can occur at any level of the gastrointestinal tract in the very late stages ofCRD. Peptic ulcer disease is common in uremic patients. Whether this high incidence is related to altered gastric acidity, enhanced colonization by *Helicobacter pylori*, or hypersecretion of gastrin is unknown. Patients with CRD, particularly those with polycystic kidney disease,

have an increased incidence of diverticulosis. Pancreatitis and angiodysplasia of the large bowel with chronic bleeding have been noted more commonly in dialysis patients. Hepatitis B antigenemia was very common in the past, but it is much less so now because of the implementation of universal precautions, the use of hepatitis B vaccine, and the diminished need for blood transfusions resulting from the introduction of EPO. There is a higher incidence of hepatitis C virus infection in patients treated with chronic hemodialysis. Unlike hepatitis B, this infection is most often persistent. Although it does not seem to cause significant liver disease in most patients, it is a definite concern in patients who subsequently undergo transplantation and immunosuppression, in whom the incidence of active chronic hepatitis and cirrhosis is considerably higher than in those without hepatitis C infection.*The role of interferon and antiviral treatment in both hepatitis B and C infections is discussed in Chap. 295.

ENDOCRINE-METABOLIC DISTURBANCES

Disturbances in parathyroid function, protein-calorie and lipid metabolism, and overall nutritional abnormalities of uremia have already been considered.

Glucose metabolism is impaired, as evidenced by a slowing of the rate at which blood glucose levels decline after a glucose load. Fasting blood glucose is usually normal or only slightly elevated, and the mild glucose intolerance related to uremia per se, when present, does not require specific therapy. Because the kidney contributes significantly to insulin removal from the circulation, plasma levels of insulin are slightly to moderately elevated in most uremic subjects, both in the fasting and post-prandial states. However, the response to insulin and glucose utilization is impaired inCRD. Many renal hypoglycemic drugs require dose reduction in renal failure, and some, such as metformin, are contraindicated whenGFR has diminished by more than approximately 25 to 50%.

In women, *estrogen levels* are low, and amenorrhea and inability to carry pregnancies to term are common manifestations of uremia. WhenGFR has declined by approximately 30%, pregnancy may hasten the progression ofCRD. In women withESRD, the reappearance of menses is a sign of efficient renal replacement therapy and is a frequent occurrence after an adequate chronic dialysis regimen has been established. Successful pregnancies are rare. In men with CRD, including those receiving chronic dialysis, impotence, oligospermia, and germinal cell dysplasia are common, as are reduced plasma testosterone levels. Like growth, sexual maturation is often impaired in adolescent children with CRD, even among those treated with chronic dialysis. Many of these abnormalities improve or reverse with successful renal transplantation.

DERMATOLOGIC ABNORMALITIES

The skin may show evidence of anemia (pallor), defective hemostasis (ecchymoses and hematomas), calcium deposition and secondary hyperparathyroidism (pruritus, excoriations), dehydration (poor skin turgor, dry mucous membranes), and the general cutaneous consequences of protein-calorie malnutrition. A sallow, yellow cast may reflect the combined influences of anemia and retention of a variety of pigmented metabolites, or *urochromes*. The gray to bronze discoloration of the skin related to

transfusional hemochromatosis has now become uncommon with the availability and usage ofEPO. In advanced uremia, the concentration of urea in sweat may be so high that, after evaporation, a fine white powder can be found on the skin surface -- so-called uremic (urea) frost. Although many of these cutaneous abnormalities improve with dialysis, *uremic pruritus* often remains a problem. The first lines of management are to rule out unrelated skin disorders, to adjust the dialysis prescription so as to ensure adequacy of dialysis, and to control PO_4^{3-}concentration with avoidance of an elevated Ca^{2+}-PO_4^{3-}product. Occasionally, pruritus remains refractory to these measures and to other nonspecific systemic and topical therapies. The latter has itself been reported to improve pruritus. Skin necrosis can occur as part of the calciphylaxis syndrome, which also includes subcutaneous, vascular, joint, and visceral calcification in patients with poorly controlled calcium-phosphate product.

DIAGNOSTIC APPROACH

The most important initial step in the evaluation of a patient presenting de novo with biochemical or clinical evidence of renal failure is to distinguishCRD, which may be first coming to clinical attention, from true acute renal failure. The demonstration of evidence of chronic metabolic bone disease and anemia and the finding of bilaterally reduced kidney size by imaging studies strongly favor a long-standing process consistent with CRD. However, these findings do not rule out the superimposition of an acute and reversible exacerbating factor that has accelerated the decline inGFR (see below). Having established that the patient suffers from CRD, in the early stages it is often possible to establish the underlying etiology. However, when the CRD process is quite advanced, then definitively establishing an underlying etiology becomes less feasible in many cases and also of less therapeutic significance.

ESTABLISHING THE ETIOLOGY

Of special importance in establishing the etiology ofCRD are a history of hypertension; diabetes; systemic infectious, inflammatory, or metabolic diseases; exposure to drugs and toxins; and a family history of renal and urologic disease. Drugs of particular importance include analgesics (usage frequently underestimated or denied by the patient),NSAIDs, gold, penicillamine, antimicrobials, lithium, andACEinhibitors. In evaluating the uremic syndrome, questions about appetite, diet, nausea, vomiting, hiccoughing, shortness of breath, edema, weight change, muscle cramps, bone pain, mental acuity, and activities of daily living are especially helpful.

Physical Examination Particular attention should be paid to blood pressure, fundoscopy, precordial examination, examination of the abdomen for bruits and palpable renal masses, extremity examination for edema, and neurologic examination for the presence of asterixis, muscle weakness, and neuropathy. In addition, the evaluation of prostate size in men and potential pelvic masses in women should be undertaken by appropriate physical examination.

Laboratory Investigations These should also focus on a search for clues to an underlying disease process and its continued activity. Therefore, if the history and physical examination warrant, immunologic tests for systemic lupus erythematosus and vasculitis might be considered. Serum and urinary protein electrophoresis should be

undertaken in all patients over the age of 40 with unexplainedCRD and anemia, to rule out paraproteinemia. Other tests to determine the severity and chronicity of the disease include serial measurements of serum creatinine and blood urea nitrogen, hemoglobin, calcium, phosphate, and alkaline phosphatase to assess metabolic bone disease. Urine analysis may be helpful in assessing the presence of ongoing activity of the underlying inflammatory or proteinuric disease process, and when indicated should be supplemented by a 24-h urine collection for quantifying protein excretion. The latter is particularly helpful in guiding management strategies aimed at ameliorating the progression of CRD. The presence of *broad casts* on examination of the urinary sediment is a nonspecific finding seen with all diverse etiologies and reflects chronic tubulointerstitial scarring and tubular atrophy with widened tubule diameter, usually signifying an advanced stage of CRD.

Imaging Studies The most useful among these is renal sonography. An ultrasound examination of the kidneys verifies the presence of two symmetric kidneys, provides an estimate of kidney size, and rules out renal masses and obstructive uropathy. The documentation of symmetric small kidneys supports the diagnosis of progressiveCRD with an irreversible component of scarring. The occurrence of normal kidney size suggests the possibility of an acute rather than chronic process. However, polycystic kidney disease, amyloidosis, and diabetes may lead to CRD with normal-sized or even enlarged kidneys. Documentation of asymmetric kidney size suggests either a unilateral developmental or urologic abnormality or chronic renovascular disease. In the latter case, a vascular imaging procedure, such as duplex Doppler sonography of the renal arteries, radionuclide scintigraphy, or magnetic resonance angiography should be considered. A computed tomographic scan without contrast may be useful in assessing kidney stone activity, in the appropriate clinical context. Voiding cystourethrography to rule out reflux may be indicated in some younger patients with a history of enuresis or with a family history of reflux. However, in most cases, by the time CRD is established, reflux has resolved; even if present, its repair may not stabilize renal function. In any case, imaging studies should avoid exposure to intravenous radiocontrast dye where possible because of its nephrotoxicity.

Differentiation of CRD from Acute Renal Failure The most classic constellation of laboratory and imaging findings that distinguishes progressiveCRD from acute renal failure are bilaterally small (<8.5 cm) kidneys, anemia, hyperphosphatemia and hypocalcemia with elevatedPTHlevels, and a urinary sediment that is inactive or reveals proteinuria and broad casts. Furthermore, integration of a particular constellation of clinical, laboratory, and imaging findings based on the approach noted above strongly supports a particular presumed underlying etiologic disease process. For example, in a patient with insulin-dependent type 1 diabetes mellitus of 15 to 20 years' duration, diabetic retinopathy, and nephrotic-range albuminuria without hematuria, the diagnosis of diabetic nephropathy is likely. The diagnosis of chronic hypertensive nephrosclerosis (Chap. 278) requires a history of long-standing hypertension, in the absence of evidence for another renal disease process, and hence is usually a diagnosis of exclusion. Usually, proteinuria is mild to moderate (<3 g/d) and the urine sediment inactive. In many cases of presumed hypertensive nephrosclerosis, renovascular disease may not only be the cause of hypertension but also may cause ischemic renal damage. Bilateral renovascular ischemic disease may be a greatly underdiagnosed cause of CRD. This is of therapeutic significance from two points of view: (1)

documentation of ischemic renal disease may prompt revascularization therapy in some patients, with occasional dramatic stabilization or improvement in renal function; and (2) renovascular ischemic disease is a contraindication toACEinhibitor therapy in most cases. Analgesic-associated chronic tubulointerstitial nephropathy is also an underdiagnosed cause of CRD. Imaging studies, including computed tomography, often reveal pathognomonic features such as papillary calcification and necrosis. Under such circumstances, cessation of analgesic exposure may dramatically stabilize renal function.

Kidney Biopsy This procedure should be reserved for patients with near-normal kidney size, in whom a clear-cut diagnosis cannot be made by less invasive means, and when the possibility of a reversible underlying disease process remains tenable so that clarification of the underlying etiology may alter management. The extent of tubulointerstitial scarring on kidney biopsy generally provides the most reliable pathologic correlate indicating prognosis for continued deterioration towardESRD. Contraindications to renal biopsy include bilateral small kidneys, polycystic kidney disease, uncontrolled hypertension, urinary tract or perinephric infection, bleeding diathesis, respiratory distress, and morbid obesity.

TREATMENT

This refers to all of the preventive and therapeutic measures that precede and aim to prevent or postponeESRD and renal replacement therapy.

Specific Therapy The optimal time for specific therapy aimed at the underlying disease process is usually well before there has been a measurable decline in baselineGFR, and usually well beforeCRD is established. When kidney size remains well preserved, renal biopsy results may provide an index of chronicity versus disease activity, which might help in guiding therapeutic decisions. In contrast, by the time CRD is established and GFR has irreversibly declined to less than 20 to 30% of normal, the risks of immunomodulatory and other therapies aimed at treating an underlying past or ongoing disease process may outweigh the benefits.

Superimposed Factors It is of benefit to follow and plot the rate of decline inGFR in patients withCRD. Any acceleration in the rate of decline should prompt a search for a superimposed acute process. The differential diagnosis should be developed in a systematic manner, as for any patient with acute renal failure (Chap. 269). Particular attention should be directed to factors that more commonly lead to an acute and reversible decline in GFR in patients with CRD. These include superimposed volume depletion, accelerated and uncontrolled hypertension, urinary tract infection, superimposed obstructive uropathy (e.g., due to stone disease, papillary necrosis), nephrotoxic effect of medications (e.g.,NSAIDs) and radiocontrast agents, and reactivation or flare of the original underlying etiologic disease process.

Measures to Mitigate Hyperfiltration Injury The two major therapeutic tools currently available in the mitigation of hyperfiltration injury are: (1) dietary protein restriction, and (2) pharmacologic management of intraglomerular hypertension.

Protein Restriction inCRDManagement guidelines for protein restriction in CRD are

shown in theGuidelines. In contrast to fat and carbohydrates, protein in excess of the daily requirement is not stored but is degraded to form urea and other nitrogenous wastes, which are principally excreted by the kidney. In addition, protein-rich foods contain hydrogen ions, PO_4^{3-}, sulfates, and other inorganic ions that are also eliminated by the kidney. Therefore, when patients with CRD consume excessive dietary protein, nitrogenous wastes and inorganic ions accumulate, resulting in the clinical and metabolic disturbances characteristic of uremia. Restricting dietary protein can ameliorate many uremic symptoms and may slow the actual rate of nephron injury. The effectiveness of protein restriction in slowing the progression of CRD has been evaluated in a number of controlled clinical trials. The Modification of Diet in Renal Disease (MDRD) Study was the most extensive trial devoted to this question, but it nevertheless yielded an ambiguous result, although positive trends emerged when it ended after an average follow-up of only 2.2 years. In a separate study of patients with insulin-dependent diabetic nephropathy, protein restriction was shown to slow progression significantly in one well-controlled study. Two meta-analyses of studies of the effects of protein restriction on progression concluded that low-protein diets slow progression of both diabetic and nondiabetic renal disease.

It is crucial that protein restriction be carried out in the context of an overall dietary program that optimizes nutritional status and avoids malnutrition, especially as patients near dialysis or transplantation. Measurements of urinary nitrogen appearance, anthropometric and biochemical measurements, as well as dietary consultation are mandatory to preempt malnutrition. Among the most readily available and useful indices of malnutrition are plasma concentrations of albumin (<3.8 g/dL), pre-albumin (<18 mg/dL), and transferrin (<180 ug/dL). Metabolic and nutritional studies indicate that protein requirements for patients withCRD are similar to those for normal adults, approximately 0.6 g/kg per day. However, there is a particular requirement in patients with CRD that the composition of dietary protein be higher in essential amino acids, and that this be combined with an overall energy supply sufficient to mitigate a catabolic state. Energy requirements in the range of 35 kcal/kg per day are recommended.

Fortunately, even patients with advancedCRD are able to activate the same adaptive responses to dietary protein restriction as healthy individuals, i.e., a postprandial suppression of whole-body protein degradation and a marked inhibition of amino acid oxidation. After at least 1 year of therapy with a low-protein diet (range 12 to 24 months) these same adaptive responses persist, indicating that the compensatory responses to dietary protein restriction are sustained during long-term therapy. Further evidence that low-protein diets are safe in CRD patients is provided by the finding that nutritional indices remain normal during long-term therapy.

Pharmacologic Management of Intraglomerular Hypertension In addition to reduction of cardiovascular disease risk, antihypertensive therapy in patients withCRD also aims to slow the progression of nephron injury by ameliorating intraglomerular hypertension and hypertrophy. Progressive renal injury in CRD appears to be most closely related to the height of intraglomerular pressure and/or the extent of glomerular hypertrophy. TheMDRD and other studies demonstrated that control of hypertension is as important as dietary protein restriction in slowing the progression of CRD. Furthermore, the target for pharmacologic therapy was highly dependent on the level of proteinuria. Indeed, proteinuria is now considered a risk factor for progressive nephron

injury; the prior level of proteinuria correlates with the subsequent rate ofGFRdecline. Elevated blood pressure increases proteinuria due to the transmission to the glomeruli of the elevated systemic pressure. Conversely, the protective effect of antihypertensive medications is evident through the curtailment of proteinuria. Thus, the more effective a given treatment is in lowering proteinuria, the greater the subsequent impact on protection from GFR decline.

Some antihypertensive agents, particularly theACEinhibitors, may be superior to others in affording renal protection. The advantage of this pharmacologic class is thought to relate to salutary modulation of intraglomerular hemodynamics over and above effects on systemic blood pressure. Several well-designed studies have now established favorable outcomes for ACE inhibitors in slowing the progression of diabetic nephropathy. ACE inhibitors have been shown to be more effective than diuretics, beta blockers, and calcium antagonists in reducing urinary albumin excretion in both hypertensive and diabetic patients. Furthermore, these drugs have been shown to facilitate the regression of remodeling more generally in the cardiovascular system and to improve endothelial function in resistance arterioles of humans with hypertension. In nondiabeticCRD, the European AIPRI trial documented a 53% additional reduction in the risk of doubling serum creatinine levels with ACE inhibitor therapy compared to conventional regimens that did not include ACE inhibitors. The reduction in the risk was greater in patients with mild renal insufficiency and in those with proteinuria >1g/d. In a recent meta-analysis, information from all the randomized ACE inhibitor trials in patients with nondiabetic renal disease was combined; the conclusion is that ACE inhibitors are more effective than other antihypertensive agents in reducing the development ofESRD. A similar salutary effect on kidney function as observed with ACE inhibitors has been observed recently with the angiotensin II receptor antagonists, which also possess significant antiproteinuric properties.

Among the calcium channel blockers, diltiazem and verapamil appear to exhibit antiproteinuric and renal protective effects not shared by the dihydropyridines. As a group, these drugs do not adversely affect renal function in patients with nondiabetic renal insufficiency, and they may be more effective in preventing or ameliorating progressive renal injury than some other classes of antihypertensive drugs in this group of patients. Thus, it appears that at least two different categories of responses may exist: one in which progression is strongly associated with systemic and intraglomerular hypertension and with proteinuria (e.g., diabetic nephropathy, glomerular diseases) and in whichACEinhibitors and angiotensin-receptor blockers are likely to be the first choice; and the second in which proteinuria is mild or absent (e.g., adult polycystic kidney disease), probably with a less prominent role for intraglomerular hypertension, and which might respond as well to calcium channel blockers. The level of blood pressure lowering is also of crucial importance in achieving a significant renal protective effect. Clinical practice guidelines are summarized in theGuidelines.

Use of Drugs (See also Chaps. 70 and71) Although the loading dose of most drugs is not affected byCRD, maintenance doses of many drugs need to be adjusted. One exception is digoxin, whose volume of distribution is decreased in CRD, mandating a concomitant reduction in the loading dose in addition to adjustment of the maintenance dose. For those drugs in which >70% excretion is by a nonrenal (e.g., hepatic or intestinal) route, dosage adjustment may not be needed. Some drugs that should be

entirely avoided include meperidine, metformin, and other oral hypoglycemics with a renal route of elimination. Commonly used medications that require either a reduction in dosage or interval include allopurinol, many antibiotics, several hypertensives, and anti-arrhythmics. For a comprehensive detailed and authoritative listing of the recommended dose adjustment for most of the commonly used medications, the reader is referred to the American College of Physicians handbook of "Drug Prescribing in Renal Failure" (seehttp://www.acponline.org).

Preparation for Renal Replacement Therapy Over the past 35 years, renal replacement therapy using dialysis and transplantation has prolonged the lives of hundreds of thousands of patients withESRD. Renal replacement therapy should *not* be initiated when the patient is totally asymptomatic; however, dialysis and/or transplantation should be started sufficiently early to prevent serious complications of the uremic state. Clear indications for initiation of renal replacement therapy include pericarditis, progressive neuropathy attributable to uremia, encephalopathy, muscle irritability, anorexia and nausea that is notameliorated by reasonable protein restriction, and fluid and electrolyte abnormalities that are refractory to conservative measures. The latter include volume overload unresponsive to diuretic therapy, hyperkalemia unresponsive to dietary potassium restriction, and progressive metabolic acidosis that cannot be managed with alkali therapy. Clinical clues indicating the imminent development of uremic complications are a history of hiccoughing, intractable pruritus, morning nausea and vomiting, muscle twitching and cramps, and the presence of asterixis on physical examination. In addition, the patient whose follow-up and compliance with conservative management are questionable should be considered for earlier initiation of renal replacement therapy, lest potentially life-threatening uremic complications or electrolyte disturbances supervene.

The correlation of uremic symptoms with renal function varies from patient to patient depending on the cause of renal disease (earlier onset of symptoms in patients with diabetes mellitus), muscle mass (large, muscular patients tolerate high levels of azotemia), diet, nutritional status, and coexisting conditions. Therefore, it is ill-advised to assign a certain "usual" level of blood urea nitrogen, serum creatinine, or GFR to the need to start dialysis. Nevertheless, in the United States, the Health Care Financing Administration has assigned levels of serum creatinine and creatinine clearance to qualify for reimbursement from Medicare for patients receiving dialysis. Serum creatinine must be ³700 umol/L (³8.0 mg/dL) and the creatinine clearance must be £0.17 mL/s (£10 mL/min).

Patient Education Social, psychological, and physical preparation for the transition to renal replacement therapy and choice of the optimal initial modality is best accomplished with a gradual approach involving a multidisciplinary team. While conservative measures are being carried out in patients withCRD, it is important to prepare them with an intensive educational program, explaining the likelihood and timing of initiation of renal replacement therapy and the various forms of therapy available. The more knowledgeable patients are concerning hemodialysis, peritoneal dialysis, and transplantation, the easier and more appropriate will be their decisions at a later time. Exploration of social service support resources is of great importance. In those who may perform home dialysis or undergo transplantation, early education of family members for selection and preparation as a home dialysis helper or a related

donor for transplantation should occur long before the onset of symptomatic renal failure.

Selection of patients to be treated with various modalities of dialysis or transplantation is a matter of some debate, with considerable variation in different parts of the world. In general, in the United States and some other countries, nearly all patients who have reachedESRD are accepted for dialysis if they or their families desire prolongation of life, irrespective of age.

In terms of dialysis treatment modalities (Chap. 271), large multicenter studies have not shown a consistent or convincing advantage in terms of morbidity or mortality, of one modality over another.

Only kidney transplantation (Chap. 272) offers the potential for nearly complete rehabilitation. This is because dialysis techniques replace only 10 to 15% of normal kidney function at the level of small-solute removal and are even less efficient at the removal of larger solutes. Generally, kidney transplantation follows a prior period of dialysis treatment. All patients in whom an acute reversible component of renal failure has not been completely excluded should be supported with dialysis first, at least for some period of time, to allow for possible return of renal function before consideration of transplantation. Recovery of endogenous renal function in patients treated with dialysis for more than 6 months is a rare occurrence. Usually these are patients in whom the underlying disease process has been acute or subacute -- such as one of the thrombotic microangiopathies, rapidly progressive glomerulonephritis, or obstructive uropathy. Patients approachingESRD in whom a reversible component has been excluded, and who have a good antigenic match with a willing donor, may occasionally be considered for primary transplantation without intervening dialysis.

271. DIALYSIS IN THE TREATMENT OF RENAL FAILURE - *Ajay K. Singh, Barry M. Brenner*

With the widespread availability of dialysis, the lives of hundreds of thousands of patients with end-stage renal disease (ESRD) have been prolonged. In the United States alone, there are now approximately 300,000 patients with ESRD. The overall incidence of ESRD is 242 cases per million population per year. The incident population of patients with ESRD is increasing at approximately 8% each year. The incidence of ESRD is disproportionately higher in African Americans (758 per million population per year) as compared with white Americans (180 per million population per year). In the United States, the leading cause of ESRD is diabetes mellitus, accounting for more than 40% of newly diagnosed cases of ESRD. The second most common cause is hypertension, which is estimated to cause 30% of ESRD cases. Other causes of ESRD include glomerulonephritis, polycystic kidney disease, and obstructive uropathy.

Dialysis care in the United States is funded through the Medicare End-Stage Renal Dialysis program; the cost was approximately $13.5 billion in 1997. Although the total program expense has increased dramatically, the cost for treating individual patients in inflation-adjusted terms has gone down. In addition, quality and outcomes have improved through better management of dialysis dose, improved nutrition, management of anemia, and control of hypertension. The cost of dialysis, which ranges from $45,000 to $65,000 per year, has been demonstrated to vary according to the presence or absence of diabetes mellitus and whether the treatment modality is hemodialysis or peritoneal dialysis. The mortality of patients withESRD is lowest in Europe and Japan but is very high in the developing world because of the limited availability of dialysis. In the United States, the mortality rate of patients on dialysis is approximately 18% per year. Deaths are due mainly to cardiovascular diseases and infections (approximately 50% and 15% of deaths, respectively).

TREATMENT OPTIONS FOR ESRD PATIENTS

Commonly accepted criteria for putting patients on dialysis include: the presence of the uremic syndrome; the presence of hyperkalemia unresponsive to conservative measures; extracellular volume expansion; acidosis refractory to medical therapy; a bleeding diathesis; and a creatinine clearance of<10 cc/min per 1.73m_2. There is emerging consensus that patients with ESRD should be started on dialysis early. Although vigorous protein restriction can maintain the blood urea nitrogen at an acceptable level in these patients, it may come at the price of significant malnutrition, which in turn correlates with mortality on dialysis. In addition to carefully evaluating patients for the onset of uremia (Chap. 270), regular measurement of renal function is important.

Renal function can be assessed by measurement of serum creatinine and blood urea nitrogen or of creatinine and urea clearance, or the direct measurement of glomerular filtration rate (GFR) using a radioisotope such as iothalamate. Creatinine clearance usually overestimates glomerular filtration rate because a substantial fraction of creatinine excretion in advanced renal failure occurs as a consequence of proximal tubular secretion. On the other hand, urea clearance invariably underestimates GFR because urea is reabsorbed in the distal nephron. Thus, when measurement of GFR by

a direct test is not available, the average of the sum of the creatinine and urea clearance, or a cimetidine-blocked creatinine clearance (cimetidine blocks proximal tubular secretion), is recommended. Early referral to a nephrologist for advanced planning and creation of a dialysis access, education aboutESRDtreatment options, and the aggressive management of the complications of chronic renal failure, including acidosis, anemia, and hyperparathyroidism, are important.

The treatment options available for patients with renal failure depend on whether it is acute or chronic (Fig. 271-1). In acute renal failure, treatments include hemodialysis, continuous renal replacement therapies (see p. 1565), and peritoneal dialysis. In chronic renal failure(ESRD)the options include hemodialysis (in center or at home); peritoneal dialysis, either as continuous ambulatory peritoneal dialysis (CAPD) or continuous cyclic peritoneal dialysis (CCPD); or transplantation (Chap. 272). Although there are geographic variations, hemodialysis remains the most common therapeutic modality for ESRD (>80% of patients in the United States). The choice between hemodialysis and peritoneal dialysis involves the interplay of various factors that include the patient's age, the presence of comorbid conditions, the ability to perform the procedure, and the patient's own conceptions about the therapy. Peritoneal dialysis is favored in younger patients because of their better manual dexterity and greater visual acuity, and because younger patients prefer the independence and flexibility of home-based peritoneal dialysis treatment. In contrast, larger patients (>80 kg), patients with no residual renal function, and patients who have truncal obesity with or without prior abdominal surgery are more suited to hemodialysis. Larger patients with no residual renal function are more appropriate for hemodialysis because these patients have a large volume of distribution of urea and require significantly higher amounts of peritoneal dialysis, which may be difficult to achieve because of the limited willingness of patients to perform more than four exchanges each day. In some patients, the inability to obtain vascular access predicates a switch from hemodialysis to peritoneal dialysis.

HEMODIALYSIS

This consists of diffusion that occurs bi-directionally across a semipermeable membrane. Movement of metabolic waste products takes place down a concentration gradient from the circulation into the dialysate, and in the reverse direction. The rate of diffusive transport increases in response to several factors, including the magnitude of the concentration gradient, the membrane surface area, and the mass transfer coefficient of the membrane. The latter is a function of the porosity and thickness of the membrane, the size of the solute molecule, and the conditions of flow on the two sides of the membrane. According to the laws of diffusion, the larger the molecule, the slower its rate of transfer across the membrane. A small molecule such as urea (60 Da) undergoes substantial clearance, whereas a larger molecule such as creatinine (113 Da), is cleared much less efficiently. In addition to diffusive clearance, movement of toxic materials such as urea from the circulation into the dialysate may occur as a result ofultrafiltration. Convective clearance occurs because of solvent drag with solutes getting swept along with water across the semipermeable dialysis membrane.

THE DIALYZER

There are three essential components to dialysis: the dialyzer, the composition and

delivery of the dialysate, and the blood delivery system (Fig. 271-2). The dialyzer consists of a plastic device with the facility to perfuse blood and dialysate compartments at very high flow rates. The surface area of dialysis membranes in adult patients is usually in the range of 0.8 to 1.2 m_2.

There are currently two geometric configurations for dialyzers: hollow fiber and flat plate. The hollow fiber dialyzer is the most common in use in the United States. These dialyzers are composed of bundles of capillary tubes through which blood circulates while dialysate travels on the outside of the fiber bundle. In contrast, the less frequently utilized flat plate dialyzers are composed of sandwiched sheets of membrane in a parallel plate configuration. The advantage of the hollow fiber construction is the lower priming volume (60 to 90 mL vs 100 to 120 mL for the flat plate) and easier reprocessing of the filter for reuse in future dialysis treatments.

Recent advances have led to the development of many different types of membrane material. Broadly, there are four categories of dialysis membranes: cellulose, substituted cellulose, cellulosynthetic, and synthetic. Over the past two decades, there has been a gradual switch from cellulose-derived to synthetic membranes, because the latter are more biocompatible. Bioincompatibility may be defined as the ability of the membrane to activate the complement cascade. Cellulosic membranes are bioincompatible because of the presence of free hydroxyl groups on the membrane surface. In contrast, with the substituted cellulose membranes (e.g., cellulose acetate) or the cellulosynthetic membranes, the hydroxyl groups are chemically bonded to either acetate or tertiary amino groups, resulting in limited complement activation. Synthetic membranes, such as polysulfone, polymethylmethacrylate, and polyacrylonitrile membranes are more biocompatible because of the absence of these hydroxyl groups. Polysulfone membranes are now used in over 60% of the dialysis treatments in the United States.

Reprocessing and reuse of hemodialyzers is employed for patients on chronic hemodialysis in nearly 80% of dialysis centers in the United States, in large part because of the expense of individual dialyzers. Evidence also suggests that reuse reduces complement activation, the incidence of anaphylactoid reactions to the membrane (first-use syndrome), and, in some studies, mortality rates among dialysis patients. In most centers, only the dialyzer unit is reprocessed and reused, whereas in the developing world blood lines are also frequently reused. The reprocessing procedure can be either manual or automated. It consists of the sequential rinsing of the blood and dialysate compartments with water, a chemical cleansing step with reverse ultrafiltration from the dialysate to the blood compartment, the testing of the patency of the dialyzer, and, finally, disinfection of the dialyzer. Formaldehyde, peracetic acid-hydrogen peroxide, and glutaraldehyde are the most frequently used reprocessing agents, with peracetic acid-hydrogen peroxide being the most common.

DIALYSATE

The composition of dialysate is listed inTable 271-1. Bicarbonate has replaced acetate as the preferred buffer in the United States. This change has resulted in fewer episodes of hypotension during dialysis. The potassium concentration of dialysate may be varied from 0 to 4 mmol/L depending on the predialysis plasma potassium concentration. The usual dialysate calcium concentration is 1.25 mmol/L (2.5 meq/L). The usual dialysate

sodium concentration is 140 mmol/L. Lower dialysate sodium concentrations are associated with a higher frequency of hypotension, cramping, nausea, vomiting, fatigue, and dizziness. In patients who frequently develop hypotension during their dialysis run, sodium modeling to counterbalance urea-related osmolar gradients is now widely used. In this technique, the dialysate sodium concentration is gradually lowered from the range of 148 to 160 meq/L to isotonic levels (140 meq/L) near the end of the dialysis treatment. A dialysate glucose concentration of 200 mg/dL (11 mmol/L) is used to optimize blood glucose concentrations. Because patients are exposed to approximately 120 L of water during each dialysis treatment, untreated water could expose them to a variety of environmental contaminants. Therefore, in 98% of U.S. dialysis centers, water used for the dialysate is subjected to filtration, softening, deionization, and, ultimately, reverse osmosis. During the reverse osmosis process, water is forced through a semipermeable membrane at very high pressure to remove microbiologic contaminants and more than 90% of dissolved ions.

BLOOD DELIVERY SYSTEM

This is composed of the extracorporeal circuit in the dialysis machine and the dialysis access. The dialysis machine consists of a blood pump, dialysis solution delivery system, and various safety monitors. The blood pump, using a roller mechanism, moves blood from the access site, through the dialyzer, and back to the patient. The blood flow rate may range from 250 to 500 mL/min. Negative hydrostatic pressure on the dialysate side can be manipulated to achieve desirable fluid removal, so-called *ultrafiltration*. Dialysis membranes have different ultrafiltration coefficients (i.e., mL removed/min per mmHg) so that along with hydrostatic changes, fluid removal can be varied. The dialysis solution delivery system dilutes the dialysate concentrate with water, and monitors the temperature, conductivity, and flow of dialysate. The dialysate may be delivered to the dialyzer from a storage tank or a proportioning system that manufactures dialysate online.

Dialysis Access The fistula, graft, or catheter through which blood is obtained for hemodialysis is often referred to as a *dialysis access*. A native fistula created by the anastomosis of an artery to a vein (e.g., the Cimino-Breschia fistula, in which the cephalic vein is anastomosed to the radial artery) results in arterialization of the vein. This faciliates its subsequent use in the placement of large needles (typically 15 gauge) to access the circulation. Although fistulas have a high patency rate (approximately 80% are patent at 3 years following creation), fistulas are created in only approximately 30% of patients in the United States. In the majority of U.S. dialysis patients, the dialysis access consists of an arteriovenous graft which interposes prosthetic material, such as polytetrafluoroethylene, between an artery and a vein. Such grafts have a 3-year patency rate of only 20%. Reasons for the higher rates of graft placement include the late referral of patients to vascular access surgeons so that by the time surgery is planned, the patient's arm veins have already been obliterated through multiple blood draws; the high prevalence of patients with diabetes mellitus and its associated microvascular disease; and the greater surgical skill required in creating a fistula. The most common access-related complication is thrombosis due to intimal hyperplasia, which results in stenosis proximal to the venous anastomosis.

A double lumen cuffed catheter may be a reasonable alternative to either a native

arteriovenous fistula or a graft in selected patients in whom dialysis is required relatively urgently, such as patients who manifest delayed recovery from acute renal failure, or where a further permanent access procedure (e.g., arteriovenous fistula or arteriovenous graft) is not feasible for anatomic reasons. Although double lumen catheters may permit blood flows comparable to a permanent arteriovenous access, these catheters are prone to infection and to occlusion because of thrombosis. Temporary double lumen catheters in either the femoral vein or the internal jugular or subclavian vein are usually employed in patients with acute renal failure. The jugular is preferred to the subclavian vein because, for unclear reasons, a catheter placed in a subclavian vein appears to be associated with a higher rate of venous stenosis. Temporary access can be used for 2 to 3 weeks. Thromobosis, low blood flow, and infection limit the life of the catheter.

GOALS OF DIALYSIS

The hemodialysis procedure is targeted at removing both small and large molecular weight solutes. The procedure consists of pumping heparinized blood through the dialyzer at a flow rate of 300 to 500 mL/min, while dialysate flows in an opposite *counter-current* direction at 500 to 800 mL/min. The clearance of urea ranges from 200 to 350 mL/min, while the clearance of$b_2$microglobulin is more modest and ranges from 20 to 25 mL/min. The efficiency of dialysis is determined by blood and dialysate flow through the dialyzer, as well as dialyzer characteristics (i.e., its efficiency in removing solute). The *dose* of dialysis, which is defined as the magnitude of urea clearance during a single dialysis treatment, is further governed by patient size, residual renal function, dietary protein intake, the degree of anabolism or catabolism, and the presence of comorbid conditions. Since the landmark studies of Sargent and Gatch relating the measurement of the dose of dialysis using urea concentration with patient outcome, the *delivered* dose of dialysis has been correlated with morbidity and mortality. This has led to the development of two major models for assessing the adequacy of the dialysis dose. Fundamentally, these two widely used measures of the adequacy of dialysis are calculated from the decrease in the blood urea nitrogen concentration during the dialysis treatment -- that is, the urea reduction ratio (URR), and *KT/V*, an index based on the urea clearance rate, *K*, and the size of the urea pool, represented as the urea distribution volume, *V*. K, which is the sum of clearance by the dialyzer plus renal clearance, is multiplied by the time spent on dialysis, *T*. Increasingly, KT/V has become the preferred marker for dialysis adequacy. Currently, a URR of 65% and a KT/V of 1.2 per treatment are minimal standards for adequacy; lower levels of dialysis treatment are associated with increased morbidity and mortality.

For the majority of patients with chronic renal failure, between 9 and 12 h of dialysis is required each week, usually divided into three equal sessions. However, the dialysis dose must be individualized. The measurement of dialysis adequacy using KT/V or theURRserve only as a guide; body size, residual renal function, dietary intake, complicating illness, degree of anabolism or catabolism, and the presence of large interdialytic fluid gains are important factors in consideration of the dialysis prescription.

COMPLICATIONS DURING HEMODIALYSIS

Hypotension is the most common acute complication of hemodialysis. Numerous factors

appear to increase the risk of hypotension, including excessive ultrafiltration with inadequate compensatory vascular filling, impaired vasoactive or autonomic responses, osmolar shifts, food ingestion, impaired cardiac reserve, the use of antihypertensive drugs, and vasodilation due to the use of warm dialysate. Because of the vasodilatory and cardiodepressive effects of acetate, the use of acetate as the buffer in dialysate was once a common cause of hypotension. Since the introduction of bicarbonate-containing dialysate, dialysis-associated hypotension has become common. The management of hypotension during dialysis consists of discontinuing ultrafiltration, the administration of 100 to 250 cc of isotonic saline, and, in patients with hypoalbuminemia, administration of salt-poor albumin. Hypotension during dialysis can frequently be prevented by careful evaluation of the dry weight, holding of antihypertensive medications on the day prior to and on the day of dialysis, and avoiding heavy meals during dialysis. Additional maneuvers include the performance of sequential ultrafiltration followed by dialysis and cooling of the dialysate during dialysis treatment.

Muscle cramps during dialysis are also a common complication of the procedure. However, since the introduction of volumetric controls on dialysis machines and sodium modelling, the incidence of cramps has fallen. The etiology of dialysis-associated cramps remains obscure. Changes in muscle perfusion because of excessively aggressive volume removal, particularly below the estimated dry weight and the use of low sodium containing dialysate, have been proposed as precipitants of dialysis-associated cramps. Strategies that may be used to prevent cramps include reducing volume removal during dialysis, the use of higher concentrations of sodium in the dialysate, and the use of quinine sulfate (260 mg 2 h before treatment).

Anaphylactoid reactions to the dialyzer, particularly on its first use, have been reported most frequently with the bioincompatible cellulosic-containing membranes. With the gradual phasing out of cuprophane membranes in the United States, the first use syndrome has become relatively uncommon. The first use syndrome consists of either an intermediate hypersensitivity reaction due to an IgE mediated reaction to ethylene oxide used in the sterilization of new dialyzers, or a symptom complex of nonspecific chest and back pain, which appears to result from complement activation and cytokine release.

The major cause of death in patients withESRDreceiving chronic dialysis is cardiovascular disease. The rate of death from cardiac disease is higher in patients on hemodialysis as compared to patients on peritoneal dialysis and renal transplantation. The underlying cause of cardiovascular disease is unclear but may be related to the inadequate treatment of hypertension; the presence of hyperlipidemia, homocystinemia and anemia; the calcification of coronary arteries in patients with an elevated calcium-phosphorus product; and perhaps alterations in cardiovascular dynamics during the dialysis treatment. Intensive investigation of the mechanisms and potential interventions that could impact on reducing the mortality from cardiovascular causes is currently underway.

CONTINUOUS RENAL REPLACEMENT THERAPY

Continuous renal replacement therapies (CRRT) have become increasingly prevalent in

the intensive care unit setting for management of acute renal failure. The advantages of CRRT over intermittent hemodialysis are that it is usually better tolerated hemodynamically; it facilitates gradual correction of biochemical abnormalities; it is highly effective in removing fluid; and it is technically simple to perform. Clearance of toxic materials (using urea as the marker) can occur with CRRT from convective clearance alone if the ultrafiltration rate is high and with diffusive clearance if dialysis accompanies ultrafiltration. CRRT techniques include continuous arteriovenous hemodiafiltration (CAVH/D) with or without dialysis, and continuous veno-venous hemodiafiltration (CVVH/D) with or without dialysis. Veno-venous therapies differ fundamentally from arteriovenous therapies in that veno-venous therapies do not require arterial access. This allows obtaining less risky and easier vascular access. However, because there is no systemic arterial pressure to drive hemofiltration, veno-venous therapies require a blood pump in the extracorporeal circuit. Veno-venous therapies such as CVVH provide substantial flexibility because changing the blood flow rate in the pump can change the ultrafiltration and clearance rates. In contrast, arterio-venous therapies such as CAVH are associated with variable efficiency because the systemic blood pressure is frequently low or unstable in patients with acute renal failure. Furthermore, low blood flow with CAVH may also result in clotting of the extracorporeal circuit. CAVH often results in clearance rates as low as 10 to 15 mL/min, whereas CVVH may generate clearances in the range of 30 to 40 mL/min. Thus, in light of these advantages of CVVH, many centers have completely switched from arteriovenous to veno-venous therapies in patients with acute renal failure in the ICU setting.

Vascular access in patients onCVVH is usually achieved by the insertion of a double-lumen catheter into the femoral vein. The blood pump is typically set to deliver approximately 150 to 180 mL/min. In automated systems, (e.g., the Cobe Prisma system), the treatment is volumetrically governed by continuously weighing the effluent and replacement solutions and using a servomechanism to drive the replacement fluid pump at a rate computed either to balance the inflow and loss of fluid or to maintain a predetermined rate of fluid loss. Anticoagulation of the extracorporeal circuit is via a heparin infusion (200 to 1600 U/h) through the inflow side of the circuit. Alternatively, citrate can be used to chelate calcium in the extracorporeal circuit to provide regional anticoagulation in selected patients who cannot undergo systemic heparinization. The replacement solution in continuous therapies is designed specifically to replace calcium, magnesium, and bicarbonate. In place of bicarbonate, lactate or citrate is the buffer in the replacement solution. However, bicarbonate-based replacement fluid is the preferred option in patients with liver failure because of the impaired ability of the liver to metabolize either lactate or acetate into bicarbonate.

PERITONEAL DIALYSIS

This consists of infusing 1 to 3 L of a dextrose-containing solution into the peritoneal cavity and allowing the fluid to dwell for 2 to 4 h. As with hemodialysis, toxic materials are removed through a combination of convective clearance generated through ultrafiltration, and diffusive clearance down a concentration gradient. The clearance of solute and water during a peritoneal dialysis exchange depends on the balance between the movement of solute and water into the peritoneal cavity versus absorption from the peritoneal cavity. The rate of diffusion diminishes with time and eventually

stops when equilibriation between plasma and dialysate is reached. Absorption of solutes and water from the peritoneal cavity occurs across the peritoneal membrane into the peritoneal capillary circulation and via peritoneal lymphatics into the lymphatic circulation. The rate of peritoneal solute transport varies from patient to patient and may be altered by the presence of infection (peritonitis), drugs such as beta blockers and calcium channel blockers, and by physical factors such as position and exercise.

FORMS OF PERITONEAL DIALYSIS

Peritoneal dialysis may be carried out as continuous ambulatory peritoneal dialysis (CAPD),continuous cyclic peritoneal dialysis (CCPD), or nocturnal intermittent peritoneal dialysis (NIPD). In CAPD, dialysis solution is manually infused into the peritoneal cavity during the day and exchanged 3 to 4 times daily. A nighttime dwell is frequently instilled at bedtime and remains in the peritoneal cavity through the night. The drainage of spent dialysate (effluence) is performed manually with the assistance of gravity to move fluid out of the abdomen. In CCPD, exchanges are performed in an automated fashion, usually at night; the patient is connected to the automated cycler, which then performs 4 to 5 exchange cycles while the patient sleeps. Peritoneal dialysis cyclers automatically cycle dialysate in and out of the abdominal cavity. In the morning the patient, with the last exchange remaining in the abdomen, is disconnected from the cycler and goes about his regular daily activities. In NIPD, the patient is given approximately 10 h of cycling each night, with the abdomen left dry during the day.

Peritoneal dialysis solutions are available in various volumes ranging from 0.5 to 3.0 L. The electrolyte composition is shown inTable 271-2. Lactate is the preferred buffer in peritoneal dialysis solutions. Acetate in peritoneal dialysis solutions appears to accelerate peritoneal sclerosis, whereas use of bicarbonte results in precipitation of calcium and caramelization of glucose. The most common additives to peritoneal dialysis solutions are heparin and antibiotics during an episode of acute peritonitis. Insulin may also be added in patients with diabetes mellitus.

ACCESS TO THE PERITONEAL CAVITY

This is obtained through a peritoneal catheter. These are either *acute* catheters, used to perform acute continuous peritoneal dialysis, usually in an emergency setting, or *chronic* catheters, which have either one or two Dacron cuffs and are tunneled under the skin into the peritoneal cavity. An acute catheter consists of a straight or slightly curved rigid tube with several holes at its distal end. Catheters can be inserted at the bedside by making a small incision in the anterior abdominal wall; the catheter is inserted with the assistance of a guidewire or stylet. Acute catheters are anchored externally with adhesives or sutures and are usually reserved for temporary use because of the risk of infection, which increases after 72 h of use. In contrast, chronic catheters are flexible and made of silicon rubber with numerous side holes at the distal end. These chronic catheters usually have two Dacron cuffs to promote fibroblast proliferation, granulation and invasion of the cuff. The scarring that occurs around the cuffs anchors the catheter and seals it from bacteria tracking from the skin surface into the peritoneal cavity; it also prevents the external leakage of fluid from the peritoneal cavity. The cuffs are placed in the preperitoneal plane and approximately 2 cm from the skin surface. The most common chronic peritoneal dialysis catheter in use is the Tenckhoff catheter, which

contains two cuffs.

The initialCAPDprescription consists of the infusion of a 2-L volume of a 1.5% dextrose concentration peritoneal dialysis solution into the peritoneal cavity over 10 min and allowing it to dwell for 2.5 h. The effluent solution is then drained over 20 min before the next exchange. Three daytime exchanges are accompanied by a 2 L nighttime dwell as the standard prescription. Because peritoneal membrane characteristics vary from one individual to another, the peritoneal equilibrium test should be employed within 2 months of a patient initiating peritoneal dialysis. This test measures the peritoneal membrane transfer rate for solutes (usually urea and creatinine) based on the ratio of their concentration in dialysate and plasma at specific times during the dialysate dwell. It allows patients to be classified as low, low-average, high-average, and high transporters. Approximately 10 to 17% of patients are high transporters, 50% high-average transporters, 25 to 30% low-average transporters, and 1 to 5% low transporters. Identifying the high transporters early is important, since these patients not only demonstrate excellent solute removal, they also absorb glucose rapidly; maximum ultrafiltration occurs early in the dwell, followed by reabsorption of water back into the circulation over the course of the dwell. Such patients benefit from eitherNIPD or CAPD without a nighttime dwell.

The dose of peritoneal dialysis required to provide adequate or optimal dialysis as measured by patient outcomes is not known. However, there is emerging consensus that the weekly KT/V should be >2.0 and the creatinine clearance >65 L/week per 1.73 m_2. The most frequently utilized approach to calculating a weekly KT/V and creatinine clearance is by collecting the spent dialysate and urine over a 24-h period. The peritoneal dialysis prescription can be tailored to improve suboptimal clearance values by either increasing the volume of individual exchanges, increasing the number of exchanges, or by combining theCAPD andCCPDtechniques. In combining these techniques, the CAPD patient hooks up to a cycler at night and the machine automatically performs one or two nocturnal exchanges, whereas the CCPD patient makes an additional manual daytime exchange.

272. TRANSPLANTATION IN THE TREATMENT OF RENAL FAILURE - *Charles B. Carpenter*, *Edgar L. Milford*, *Mohamed H. Sayegh*

Transplantation of the human kidney is frequently the most effective treatment of advanced chronic renal failure. Worldwide, tens of thousands of such procedures have been performed. When azathioprine and prednisone were initially used as immunosuppressive drugs in the 1960s, the results with properly matched familial donors were superior to those with organs from cadaveric donors, namely, 75 to 90% compared with 50 to 60% graft survival rates at 1 year. During the 1970s and 1980s, the success rate at the 1-year mark for cadaveric transplants rose progressively. By the time cyclosporine was introduced in the early 1980s, cadaveric donor grafts had a 70% 1-year survival and reached the 80 to 85% level in the mid 1990s (Fig. 272-1). After the first year, graft survival curves show an exponential decline in numbers of functioning grafts from which a half-life ($t_{1/2}$) in years is calculated (Fig. 272-1). Mortality rates after transplantation are highest in the first year and are age-related: 2% for ages 6 to 45 years, 7% for ages 46 to 60 years, and 10% for ages over 60 years, and lower thereafter. These rates compare favorably to those in the chronic dialysis population, even after risk adjustments for age, diabetes, and cardiovascular status. Occasionally, acute irreversible rejection may occur after many months of good function, especially if the patient neglects to take the immunosuppressive drugs. Most grafts, however, succumb at varying rates to a chronic vascular and interstitial obliterative process termed *chronic rejection*, although its pathogenesis is incompletely understood. Overall, transplantation returns the majority of patients to an improved life-style and an improved life expectancy, as compared to patients on dialysis; however, careful prospective cohort studies have yet to be reported.

RECIPIENT SELECTION

Transplantation should be undertaken only when there is a state of irreversible renal failure. When a living donor is available, a period of chronic dialysis may be avoided. When end-stage renal disease is the result of diabetes mellitus, there is special merit in having a transplant before it is necessary to initiate maintenance dialysis in order to minimize progression of cardiovascular complications of diabetes, which are frequently accelerated during chronic dialysis. In patients who must wait for a cadaveric donor kidney, a dialysis program must be established since the waiting time will be in the 3 to 4 year range for most patients. Each candidate must have a careful risk/benefit evaluation. Elderly patients over age 70, patients with metastatic malignancy, or those with advanced cardiopulmonary disease are generally poor operative risks and are also more susceptible to infections in the setting of immunosuppressive medications. Coronary artery revascularization may be indicated in select patients prior to transplantation. Because of the growing shortage of available cadaveric organs in relation to the expanding chronic dialysis population, patients who do not have a life expectancy of at least 5 years are generally not placed on the national waiting list in the United States.

DONOR SELECTION

Donors can be cadavers or volunteer living donors. The latter are usually family members selected to have at least partial compatibility for HLA antigens. Living

volunteer donors should be normal on physical examination and of the same major ABO blood group, because crossing major blood group barriers prejudices survival of the allograft. It is possible, however, to transplant a kidney of a type O donor into an A, B, or AB recipient. Selective renal arteriography should be performed on donors to rule out the presence of multiple or abnormal renal arteries, because the surgical procedure is difficult and the ischemic time of the transplanted kidney long when vascular abnormalities exist. Cadaveric donors should be free of malignant neoplastic disease, hepatitis, and HIV because of possible transmission to the recipient. Increased risk of graft failure exists when the donor is elderly or has renal failure and when the kidney has a prolonged period of ischemia and storage.

In the United States, there is a coordinated national system (United Network for Organ Sharing) of regulations, allocation support, and outcomes analysis for kidney transplantation. It is now possible to remove cadaver kidneys and to maintain them for up to 48 h on cold pulsatile perfusion or simple flushing and cooling. This permits adequate time for typing, cross-matching, transportation, and selection problems to be solved.

TISSUE TYPING AND CLINICAL IMMUNOGENETICS

Matching for antigens of the HLA major histocompatibility gene complex (Chap. 306) is an important criterion for selection of donors for renal allografts. Each mammalian species has a single chromosomal region that encodes the strong, or major, transplantation antigens, and this region on the human sixth chromosome is called *HLA*. HLA antigens have been classically defined by serologic techniques, but methods to define specific nucleotide sequences in genomic DNA are increasingly being used. Other antigens, called "minor," may nevertheless play crucial roles, in addition to the ABH(O) blood groups and endothelial antigens that are not shared with lymphocytes. The Rh system is not expressed on graft tissue. Evidence for designation of HLA as the genetic region encoding major transplantation antigens comes from the success rate in living related donor renal and bone marrow transplantation, with superior results in HLA-identical sibling pairs. Nevertheless, 5% of HLA-identical renal allografts are rejected, often within the first weeks after transplantation. These failures represent states of prior sensitization to non-HLA antigens. Non-HLA antigens are relatively weak when initially encountered and are therefore suppressible by conventional immunosuppressive therapy. Once priming has occurred, however, secondary responses are much more refractory to treatment. ABO incompatibilities are hazardous because of the presence of natural anti-A and anti-B antibodies in recipients and the normal expression of A and B blood group substances on endothelium, resulting in immediate vascular injury.

Living Donors When first-degree relatives are donors, graft survival rates at 1 year are slightly greater than those for cadaver grafts, with the exception of HLA-identical donors where 1-year results are approximately 95%. After the first year, the long-term survival rates as defined by the $t_{1/2}$still favor the partially matched (one HLA haplotype) family donor over a randomly selected cadaver donor (Table 272-1). In addition, living donors provide the advantage of immediate availability. Waiting lists for cadaveric kidneys have grown faster than the available organ supply, to the point where most new patients with end-stage renal disease wait for more than 4 years. In response to this increasing

disparity between cadaver donor supply and patient demand, living unrelated volunteers, usually spouses or close friends, are being accepted as donors in increasing numbers. It is illegal in the United States to purchase organs for transplantation. The results of transplantation using living unrelated donors have been most satisfactory, with initial and long-term survival rates the same as for partial HLA-matched family donors and better than for partially matched cadaveric donors (Table 272-1).

Concern has been expressed regarding the potential risk to a volunteer kidney donor of premature renal failure after several years of increased blood flow and hyperfiltration per nephron in the remaining kidney. There are a few reports of the development of hypertension, proteinuria, and even lesions of focal segmental sclerosis in donors under long-term follow-up. Difficulties in donors followed for 20 or more years are unusual, however, and it may be that having a single kidney becomes significant only when another condition, such as hypertension, is superimposed. It is also desirable to consider the risk of development of type 1 diabetes mellitus in a family member who is a potential donor to a diabetic renal failure patient. Anti-insulin and anti-islet antibodies should be measured, and glucose tolerance tests should be performed in such donors to rule out a prediabetic state.

HLA Matching and Cadaveric Donors The question of whether matching of HLA antigens in unrelated donor-recipient pairs would approximate the high initial success rates and slow rates of subsequent graft loss with HLA-identical sib pairs could not be answered until the late 1980s when reliable class II histocompatibility (DR) typing became widely available. Now that pooled data on tens of thousands of cadaveric renal transplants from all over the world are available, the HLA-matching effect can be clearly seen, especially in the long-term $t_{1/2}$half-life survival figures. It is shown inTable 272-1 that there is an overall beneficial effect of HLA matching in first cadaveric grafts. When compared with HLA-identical transplants, in which the 1-year graft survival rate is 95% and the subsequent half-life is 25 years, one-HLA-haplotype-matched family donor transplants have 1-year survival rates of 85% with a 12-year half-life (Table 272-1). With increasing numbers of mismatches for cadaveric donors, the half-life decreases from 20 to 7.7 years. The survival rates at the 10-year mark are projected to range from 65 (zero mismatches) to 34% (six mismatches). Many centers now report 1-year graft survival rates in the 85 to 90% range for all renal transplants (Fig. 272-1), possibly the result of heavy initial immunosuppression, but the subsequent half-lives are similar to those above. There is controversy regarding the value of cadaveric organ-sharing rules that are based entirely upon the numbers of HLA mismatches. Avoidance of mismatching for six antigens Table 272-1) is a top priority in the United States, however, and 20% of kidneys are transplanted on this basis.Table 272-1 also shows the interaction of HLA matching and graft ischemia on results; namely, kidneys from HLA-incompatible spousal donors do better than those from similarly mismatched cadaver donors, suggesting that the additional ischemic injury of organ storage is important. When such a cadaveric donor is HLA-compatible, however, ischemia and storage do not impede the matching benefit.

Presensitization A positive cross match of recipient serum with donor T lymphocytes representing anti-HLA class I is usually predictive of an acute vasculitic event termed *hyperacute rejection*. Patients with anti-HLA antibodies can be safely transplanted if careful cross matching of donor blood lymphocytes with recipient serum is performed.

Patients sustained by dialysis often show fluctuating antibody titers and specificity patterns. At the time of assignment of a cadaveric kidney, cross matches are performed with at least a current serum. Previously analyzed antibody specificities and additional cross matches are performed accordingly. Techniques for cross matching are not universally standardized; however, at least two techniques are employed in most laboratories. The minimal purpose for the cross match is avoidance of hyperacute rejection mediated by recipient antibodies to donor HLA class I antigens. Sensitive tests, such as the use of flow cytometry, can be useful for avoidance of accelerated, and often untreatable, early graft rejection in patients receiving second or third transplants. Donor T lymphocytes, which express only class I antigens, are used as targets for detection of anti-class I (HLA-A and -B) antibodies. Anti-class II (HLA-DR) antibodies do not contraindicate transplantation, unless present in high titer. B lymphocytes expressing both class I and class II antigens are used in these assays. Non-HLA antigens restricted in expression to endothelium and sometimes monocytes have been described, but clinical relevance is not well established.

Blood Transfusions Exposure to leukocyte HLA antigens during transfusions is a major cause of sensitization that limits transplantation access and increases the risk of early graft rejection. In the 1970s, attempts to avoid all blood exposure in dialysed patients paradoxically increased the risk of graft rejection. The beneficial "transfusion effect" was never fully explained, and it almost disappeared in the 1980s as overall management of patients improved with the use of cyclosporine and more effective means of rejection treatment. Currently, with the use of erythropoietin the need for transfusion is much reduced. It has been noted, however, that nontransfused patients do have more rejection activity.

IMMUNOLOGY OF REJECTION

Knowledge of the immunology of tissue transplantation stems largely from animal experimentation. However, enough evidence has accumulated in humans to indicate that the mechanisms are not qualitatively different from those found in other areas of immunology (Chap. 305). Early rejection is associated with activation of T lymphocytes having direct specificity against donor antigens. These may be cytotoxic cells (CD8+ or CD4+) or cells that mediate delayed hypersensitivity (CD4+); however, significant numbers of B lymphocytes, natural killer cells, and macrophages appear in the early infiltrate, and cells capable of mediating antibody-dependent cell-mediated cytotoxicity are also present. Many of the B lymphocytes produce immunoglobulins. The spectrum of cellular and humoral response and graft injury is quite varied, depending on specific genetic differences between donor and recipient and states of presensitization. The greater the degree of presensitization, the more likely it is that one will find antibody-mediated vascular lesions. All the processes shown inFig. 272-2 are possible, but their relative contribution varies from case to case. Monitoring of peripheral blood lymphocyte subsets utilizing monoclonal antibodies to functionally related surface molecules, such as CD4 (T helper cells) and CD8 (T cytotoxic cells), has been related to the degree of rejection activity in some surveys. Since the principal role of the CD4 molecule is to promote interaction of T cells with class II HLA molecules on antigen-presenting cells and similarly CD8 interacts with class I HLA (Chap. 305), it is not surprising that both types of T cells are usually present. Finally, the cytokine mediators of the cellular immune response [interleukin (IL) 1 to IL-4, IL-6, IL-10, IL-12,

tumor necrosis factor (TNF), and interferon g] are involved in the control and expression of the alloimmune rejection response. For example, T cell production of interferon g causes increased expression of HLA antigens on endothelial cells. In normal immunobiology this effect may be to promote more efficient presentation of foreign antigen, while in transplantation it enhances the immunogenicity of the vascularized transplant. Also, IL-2, the major growth factor for expansion of effector T cells, is the product of a major subset of CD4 cells (Th1), while other CD4 cells (Th2) produce B cell growth factors, such as IL-4.

The failure of transplanted kidneys after several years of adequate function is said to be due to "chronic rejection." In such kidneys, the development of nephrosclerosis, with proliferation of the vascular intima of renal vessels, and intimal fibrosis, with marked decrease in the lumen of the vessels, takes place (Fig. 272-3). The result is renal ischemia, hypertension, tubular atrophy, interstitial fibrosis, and glomerular atrophy with eventual renal failure. It is not established, however, whether slow deterioration of graft function over years is due to the same mechanisms in all cases. In addition to the established influence of HLA incompatibility, the age, number of nephrons, and ischemic history of a donor kidney may contribute to ultimate progressive renal failure in transplanted patients.

IMMUNOSUPPRESSIVE TREATMENT

Immunosuppressive therapy, as presently available, generally suppresses all immune responses, including those to bacteria, fungi, and even malignant tumors. In the 1950s when clinical renal transplantation began, sublethal total-body irradiation was employed. We have now reached the point where sophisticated pharmacologic immunosuppression is available, but it still has the hazard of promoting infection and malignancy. In general, all clinically useful drugs are more selective to primary than to memory immune responses. Agents to suppress the immune response are discussed in the following paragraphs, and those currently in clinical use are listed inTable 272-2.

Drugs *Azathioprine*, an analogue of mercaptopurine, was for two decades the keystone to immunosuppressive therapy in humans. This agent can inhibit synthesis of DNA, RNA, or both. Because cell division and proliferation are a necessary part of the immune response to antigenic stimulation, suppression by this agent may be mediated by the inhibition of mitosis of immunologically competent lymphoid cells, interfering with synthesis of DNA. Alternatively, immunosuppression may be brought about by blocking the synthesis of RNA (possibly messenger RNA), inhibiting processing of antigens prior to lymphocyte stimulation. Therapy with azathioprine in doses of 1.5 to 2.0 mg/kg per day is generally added to cyclosporine as a means of decreasing the requirements for the latter. Because azathioprine is rapidly metabolized by the liver, its dosage need not be varied directly in relation to renal function, even though renal failure results in retention of the metabolites of azathioprine. Reduction in dosage is required because of leukopenia and occasionally thrombocytopenia. Excessive amounts of azathioprine may also cause jaundice, anemia, and alopecia. If it is essential to administer allopurinol concurrently, the azathioprine dose must be reduced, since inhibition of xanthine oxidase delays degradation. This combination is best avoided.

Mycophenolate mofetil is now used in place of azathioprine in many centers. It has a

similar mode of action and a mild degree of gastrointestinal toxicity but produces minimal bone marrow suppression. Its advantage is its increased potency in preventing or reversing rejection.

Glucocorticoids are important adjuncts to immunosuppressive therapy. Of all the agents employed, prednisone has effects that are easiest to assess, and in large doses it is usually effective for the reversal of rejection. In general, 200 to 300 mg prednisone is given immediately prior to or at the time of transplantation, and the dosage is reduced to 30 mg within a week. The side effects of the glucocorticoids, particularly impairment of wound healing and predisposition to infection, make it desirable to taper the dose as rapidly as possible in the immediate postoperative period. Customarily, methylprednisolone, 0.5 to 1.0 g intravenously, is administered immediately upon diagnosis of beginning rejection and continued once daily for 3 days. When the drug is effective, the results are usually apparent within 96 h. Such "pulse" doses are not effective in chronic rejection. Most patients whose renal function is stable after 6 months or a year do not require large doses of prednisone; maintenance doses of 10 to 15 mg/d are the rule. Many patients tolerate an alternate-day course of steroids without an increased risk of rejection.

A major effect of steroids is on the monocyte-macrophage system, preventing the release ofIL-6 and IL-1. Lymphopenia after large doses of glucocorticoids is primarily due to sequestration of recirculating blood lymphocytes to lymphoid tissue.

Cyclosporine is a fungal peptide with potent immunosuppressive activity. It acts on the calcineurin pathway to block transcription of mRNA for IL-2 and other proinflammatory cytokines, thereby inhibiting T cell proliferation. Although it works alone, cyclosporine is more effective in conjunction with glucocorticoids. Since cyclosporine blocks production of IL-2 by T cells, its combination with steroids is expected to produce a double block in the macrophage ®IL-6/IL-1 ® T cell ®IL-2 sequence. As noted, clinical results with tens of thousands of renal transplants have been impressive. Of its toxic effects (nephrotoxicity, hepatoxicity, hirsutism, tremor, gingival hyperplasia, diabetes), only nephrotoxicity presents a serious management problem and is further discussed below.

Tacrolimus (FK-506) is a fungal macrolide that has the same mode of action, and a similar side effect profile, as cyclosporine. It does not produce hirsutism or gingival hyperplasia, however. De novo induction of diabetes mellitus is more common with tacrolimus. The drug was first used in liver transplantation, and may substitute for cyclosporine entirely, or be tried as an alternative in renal patients whose rejections are poorly controlled by cyclosporine.

Sirolimus (previously called rapamycin) is another fungal macrolide but has a different mode of action: namely, it inhibits T cell growth factor pathways, preventing the response toIL-2 and other cytokines. It shows some promise in clinical trials in combination with cyclosporine.

Antibodies to Lymphocytes When serum from animals made immune to host lymphocytes is injected into the recipient, a marked suppression of cellular immunity to the tissue graft results. The action on cell-mediated immunity is greater than on humoral immunity. A globulin fraction of serum [antilymphocyte globulin (ALG)] is the agent

generally employed. For use in humans, peripheral human lymphocytes, thymocytes, or lymphocytes from spleens or thoracic duct fistulas have been injected into horses, rabbits, or goats to produce antilymphocyte serum, from which the globulin fraction is then separated. Monoclonal antibodies against defined lymphocyte subsets offer a more precise and standardized form of therapy. OKT3 is directed to the CD3 molecules that form a portion of the T cell antigen-receptor complex; hence CD3 is expressed on all mature T cells. CD4 or CD8 molecules also form part of the fully activated cluster of molecules, and monoclonal antibodies to these offer the potential for more selective targeting of T cell subsets. Another approach to more selective therapy is to target the 55-kDa alpha chain of theIL-2 receptor, expressed only on T cells that have been recently activated. The problem with such mouse antibodies is the potential for developing human antimouse antibodies (HAMA), an event that limits the effective period of use. Genetically engineered monoclonal antibodies can solve this problem. Two such antibodies to the IL-2 receptor, in which either a chimeric protein has been made between mouse Fab with human Fc (basiliximab) or "humanized" by splicing the combining sites of the mouse into a molecule that is 90% human IgG (daclizumab), have been approved for use, after clinical evidence of reduction of rejection episodes. Their precise clinical role is under study.

CLINICAL COURSE AND MANAGEMENT OF THE RECIPIENT

Adequate hemodialysis should be performed within 48 h of surgery, and care should be taken that the serum potassium level is not markedly elevated so that intraoperative cardiac arrhythmias can be averted. The diuresis that commonly occurs postoperatively must be carefully monitored; in some instances it may be massive, reflecting the inability of ischemic tubules to regulate sodium and water excretion; with large diureses, massive potassium losses may occur. Most chronically uremic patients have some excess of extracellular fluid, and it is useful to maintain an expanded fluid volume in the immediate postoperative period. Acute tubular necrosis (ATN) may cause immediate oliguria or may follow an initial short period of graft function. ATN is most likely when cadaveric donors have been hypotensive or if the interval between cessation of blood flow and organ harvest (warm ischemic time) is more than a few minutes. Recovery usually occurs within 3 weeks, although periods as long as 6 weeks have been reported. Superimposition of rejection on ATN is common, and the differential diagnosis may be difficult without a graft biopsy. Cyclosporine therapy prolongs ATN, and some patients do not diurese until the dose is drastically reduced. Many centers avoid starting cyclosporine for the first several days, usingALG or a monoclonal antibody along with mycophenolate mofetil and prednisone until renal function is established.

The Rejection Episode Early diagnosis of rejection allows prompt institution of therapy to preserve renal function and prevent irreversible damage. Clinical evidence of rejection is rarely characterized by fever, swelling, and tenderness over the allograft. Rejection may present only with a rise in serum creatinine, with or without a reduction in urine volume. The focus should be on ruling out other causes of functional deterioration.

Arteriography and radioactive iodohippurate sodium renograms of the transplanted kidney may be useful in ascertaining changes in the renal vasculature and in renal blood flow, even in the absence of urinary flow. Thrombosis of the renal vein occurs rarely; it may be reversible if caused by technical factors and intervention is prompt. Diagnostic

ultrasound is the procedure of choice to rule out urinary obstruction or to confirm the presence of perirenal collections of urine, blood, or lymph. When renal function has been good initially, a rise in the serum creatinine level is the most sensitive and reliable indicator of possible rejection and may be the only sign.

Calcineurin inhibitors (cyclosporine or tacrolimus) may cause deterioration in renal function in a manner similar to a rejection episode. In fact, rejection processes tend to be more indolent with these inhibitors, and the only way to make a diagnosis may be by renal biopsy. Calcineurin inhibitors have an afferent arteriolar constrictor effect on the kidney and may produce permanent vascular and interstitial injury after sustained high-dose therapy. Addition of angiotensin-converting enzyme (ACE) inhibitors or nonsteroidal anti-inflammatory drugs are likely to raise serum creatinine levels. The former are generally safe to use after the early months, while the latter are best avoided in all renal transplant patients. There is no universally accepted lesion(s) that makes a diagnosis of calcineurin inhibitor toxicity, although interstitial fibrosis, isometric tubular vacuolization, and thickening of arteriolar walls have been noted by some. Basically, if the biopsy does not reveal moderate and active cellular rejection activity, the serum creatinine will most likely respond to a reduction in dose. Blood levels of drug can be useful if very high or very low but do not correlate precisely with renal function, although serial changes in a patient can be useful. If rejection activity is present in the biopsy, appropriate therapy is indicated. The first rejection episode is usually treated with intravenous administration of methylprednisolone, 500 to 1000 mg daily for 3 days. Failure to respond is indication for antibody therapy, usually with OKT3.

OKT3 monoclonal antibody, given intravenously for 10 to 14 days, is effective in more than 90% of first rejections, and less so if methylprednisolone pulses have failed and in cases of severe recurrent rejection activity. A major problem with OKT3 is that severe systemic reactions may be produced during the first day or two of therapy. Chills, fever, hypotension, and headache are the direct result of the antibody effects on the targeted T cells, most likely related to the known potential of OKT3 to activate T cells nonspecifically with release of cytokines, especially TNF-a. If the antibody is administered to overhydrated oliguric patients, pulmonary edema may be induced. These reactions are not characteristic of other monoclonal antibodies, such as those to theIL-2 receptor. Recurrent or rebound rejection activity may require additional therapy. In such circumstances, methylprednisolone may be effective even though it failed initially. Second courses of OKT3 may be given in spite ofHAMAgenerated in response to the first course if the titers are low and the human antibodies are not directed to the combining-site region (idiotype) of the OKT3.

Management Problems The usual clinical manifestations of infection in the posttransplant period are blunted by immunosuppressive therapy. The major toxic effect of azathioprine is bone marrow suppression, which is less likely with mycophenolate mofetil, while calcineurin inhibitors have no marrow effects. All drugs predispose to unusual opportunistic infections, however. The signs and symptoms of infection may be masked and distorted, and fever without obvious cause is common. Only after days or weeks it may become apparent that it has a viral or fungal origin. Bacterial infections are most common during the first month after transplantation. The importance of blood cultures in such patients cannot be overemphasized, because systemic infection without obvious foci is frequent, although wound infections with or without urinary fistulas are

most common. Particularly ominous are rapidly occurring pulmonary lesions, which may result in death within 5 days of onset. When these become apparent, immunosuppressive agents should be discontinued, except for maintenance doses of prednisone. Aggressive diagnostic procedures, including transbronchial and open lung biopsy, are frequently indicated. In the case of *Pneumocystis carinii* (Chap. 209) infection, trimethoprim-sulfamethoxazole is the treatment of choice; amphotericin B has been used effectively in systemic fungal infections. Prophylaxis against *P. carinii* with daily, or alternate day, low-dose trimethoprim-sulfamethoxazole is very effective. Involvement of the oropharynx with *Candida* (Chap. 205) may be treated with local nystatin. Tissue-invasive fungal infections require treatment with systemic agents such as fluconazole. Small doses (a total of 300 mg) of amphotericin given over a period of 2 weeks may be effective in fungal infections refractory to fluconazole. Macrolide antibiotics, especially ketoconazole and erythromycin, and some calcium channel blockers (diltiazem, verapamil) compete with calcineurin inhibitors for P450 catabolism and cause elevated levels of these immunosuppressive drugs. Analeptics, such as phenytoin and carbamazepine, will increase catabolism to result in low levels. *Aspergillus* (Chap. 206), *Nocardia* (Chap. 165), and cytomegalovirus (CMV) (Chap. 185) infections also occur.

CMVis a common and dangerous infection in transplant recipients. It does not generally appear until the end of the first posttransplant month. Active CMV infection is sometimes associated, or occasionally confused, with rejection episodes. Patients at highest risk for severe CMV disease are those without anti-CMV antibodies who receive a graft from a CMV antibody-positive donor (15% mortality). Serial intravenous administration of high-titer CMV immune globulin is effective in reducing this risk. Prophylactic use of ganciclovir is an effective alternative. Early diagnosis in a febrile patient can be made by detecting CMV antigens in the blood. A rise in IgM antibodies to CMV is also diagnostic. Culture of CMV from blood may be less sensitive. Tissue invasion of CMV is common in the gastrointestinal tract and lungs. CMV retinopathy occurs late in the course, if untreated. Treatment of active CMV disease with ganciclovir is always indicated. Many patients immune to CMV can activate the virus after heavy immunosuppression, such as with OKT3. Concurrent treatment with ganciclovir during OKT3 administration appears to be effective for prophylaxis of CMV activation. The complications of glucocorticoid therapy are well known and include gastrointestinal bleeding, impairment of wound healing, osteoporosis, diabetes mellitus, cataract formation, and hemorrhagic pancreatitis. The treatment of unexplained jaundice in transplant patients should include cessation or reduction of immunosuppressive drugs if hepatitis or drug toxicity is suspected. It is surprising that cessation of azathioprine or calcineurin inhibitor therapy in such circumstances often does not result in rejection of a graft, at least for several weeks. Acyclovir is effective in therapy of herpes simplex virus infections.

Antiplatelet agents and anticoagulants, although effective in theory, have not been successful in the prevention of the "chronic rejection" vascular lesions. Persistent elevation of serum creatinine levels above 220 umol/L (2.5 mg/dL) in patients on calcineurin inhibitor is an indication for dose reduction, particularly if calcineurin inhibitor blood levels are elevated. The risk of long-term cumulative toxicity to the kidney now seems to be low. In general, minimal or no rejection during the first 6 months after transplantation is a predictor of safety in reducing immunosuppression therapy over subsequent months to years, but chronic progressive vasculopathy may still occur.

Despite the potential teratogenic effects of immunosuppressive agents, both women and men have become parents after transplantation. The incidence of congenital abnormalities in the offspring is not increased.

Glomerular Lesions Glomerular lesions occur in 10 to 15% of allografts, even when the original disease was accidental removal of a solitary kidney. The pathogenesis is related to a chronic rejection process. In some cases the lesions resemble those of the original glomerular disease. In most instances, the recurrence of the original renal lesions represents no threat to the immediate prognosis, and a primary diagnosis of glomerulonephritis is rarely a contraindication to transplantation. Focal segmental glomerulosclerosis may recur up to 30% of the time, with one-third of these patients losing graft function. Hemolytic uremic syndrome also has a high recurrence rate.

Malignancy The incidence of tumors in patients on immunosuppressive therapy is 5 to 6%, or approximately 100 times greater than that in the general population of the same age range. The most common lesions are cancer of the skin and lips and carcinoma in situ of the cervix, as well as lymphomas, such as non-Hodgkin's lymphomas. The risks are increased in proportion to the total immunosuppressive load administered and time elapsed since transplantation. Surveillance for skin and cervical cancers is necessary.

Other Complications *Hypercalcemia* after transplantation may indicate failure of hyperplastic parathyroid glands to regress. Aseptic necrosis of the head of the femur is probably due to preexisting hyperparathyroidism, with aggravation by glucocorticoid treatment. With improved management of calcium and phosphorus metabolism during chronic dialysis, the incidence of parathyroid-related complications has fallen dramatically. Persistent hyperparathyroid activity may require subtotal parathyroidectomy.

Hypertension may be caused by (1) native kidneys; (2) rejection activity in the transplant; (3) renal artery stenosis, if an end-to-end anastomosis was constructed with an iliac artery branch; and (4) renal calcineurin inhibitor toxicity. The latter may improve with reduction in dose. WhereasACEinhibitors may be useful, calcium channel blockers are more frequently used initially. Amelioration of hypertension to the 120-130/70-80 mmHg range should be the goal in all patients.

Chronic hepatitis, particularly when due to hepatitis B virus, can be a progressive, fatal disease over a decade or so. Patients who are persistently hepatitis B surface antigen-positive are at higher risk, according to some studies, but the presence of hepatitis C virus is also a concern when one embarks on a course of immunosuppression in a transplant recipient.

Both chronic dialysis and renal transplant patients have a higher incidence of death from myocardial infarction and stroke than in the population at large, and this is particularly true in diabetic patients. Contributing factors are the use of glucocorticoids, hypertension, and hypertriglyceridemia. Increased low-density lipoprotein cholesterol and depressed high-density lipoprotein cholesterol concentrations may be exaggerated after transplantation and require treatment. Recipients of renal transplants have a high prevalence of coronary artery and peripheral vascular diseases. The percentage of

deaths from these causes has been slowly rising as the numbers of transplanted diabetic patients and the average age of all recipients increase. More than 50% of renal recipient mortality is attributable to cardiovascular disease. In addition to strict control of blood pressure and blood lipid levels, close monitoring of patients for indications of further medical or surgical intervention is an important part of management.

273. PATHOGENESIS OF GLOMERULAR INJURY - *Hugh R. Brady*, *Barry M. Brenner*

The glomerulus is a modified capillary network that delivers an ultrafiltrate of plasma to Bowman's space, the most proximal portion of the renal tubule. Approximately 1.6 million glomeruli are present in two mature kidneys (range 0.5 to 2.4 million) and collectively they produce 120 to 180 L of ultrafiltrate daily. Glomerular filtration rate (GFR) is dependent on glomerular blood flow, ultrafiltration pressure, and surface area. These parameters are tightly regulated through changes in afferent and efferent arteriolar tone (for blood flow and ultrafiltration pressure) and mesangial cell contractility (for filtration surface area). Arteriolar tone and mesangial cell contractility are, in turn, modulated by neurohumoral factors, local myenteric reflexes, and endothelium-derived vasoactive substances, such as nitric oxide, prostacyclin, and endothelins. In health, glomerular endothelium is also antithrombotic and antiadhesive for leukocytes and platelets, thereby preventing inappropriate vascular thrombosis and inflammation during the filtration process. Filtration of most plasma proteins and all blood cells is normally prevented as a consequence of the physiochemical and electrostatic charge characteristics of the glomerular filtration barrier, the latter being composed of fenestrated glomerular endothelium, basement membrane, and the foot processes and slit diaphragms of visceral epithelial cells (podocytes). Parietal epithelium facilitates glomerular filtration by maintaining the integrity of Bowman's space. In keeping with the physiologic functions of the glomerulus outlined above, virtually all glomerular injury results in impairment of glomerular filtration and/or the inappropriate appearance of plasma proteins and blood cells in the urine.

CLINICOPATHOLOGIC CORRELATES IN GLOMERULAR DISEASE

The major glomerulopathies are described in Chap. 274, and major morphologic patterns of glomerular disease and their clinical features are summarized in Table 273-1. These clinicopathologic entities can be induced by a variety of different pathogenetic mechanisms. Thus, prompt diagnosis, optimal management, and accurate prognostication is a multistep process that requires (1) recognition of the presenting clinical syndrome, (2) delineation of the underlying morphologic pattern of glomerular injury, and (3) elucidation of the specific renal-limited or systemic disease that triggered glomerular dysfunction.

NOMENCLATURE

The terms *glomerulonephritis* and *glomerulopathy* are usually used interchangeably to denote glomerular injury, although some authorities reserve the former term for injury with evidence of inflammation such as leukocyte infiltration, antibody deposition, and/or complement activation. Glomerular diseases are classified as *primary* when the pathology is confined to the kidney and any systemic features are a direct consequence of glomerular dysfunction (e.g., pulmonary edema, hypertension, the uremic syndrome). Usually, but not always, the term primary is synonymous with *idiopathic*. Glomerular diseases are classified as *secondary* when part of a multisystem disorder. In general, *acute* refers to glomerular injury occurring over days or weeks, *subacute* or *rapidly progressive* over weeks or a few months, and *chronic* over many months or years. Lesions are classified as *focal* or *diffuse* when they involve the minority (<50%) or

majority (³50%) of glomeruli, respectively. Lesions are termed *segmental* or *global* when they involve part of or almost all of the glomerular tuft, respectively. *Proliferative* is used to describe an increase in glomerular cell number, which can be due to infiltration by leukocytes or proliferation of resident glomerular cells. Proliferation of resident glomerular cells is classified as *intracapillary* or *endocapillary* when referring to endothelial or mesangial cells and *extracapillary* when referring to cells in Bowman's space. A *crescent* is a half-moon-shaped collection of cells in Bowman's space, usually composed of proliferating parietal epithelial cells and infiltrating monocytes. Because crescentic glomerulonephritis is often associated with renal failure that progresses rapidly over week to months, the clinical term *rapidly progressive glomerulonephritis* and pathologic term *crescentic glomerulonephritis* are often used interchangeably. The description *membranous* is applied to glomerulonephritis dominated by expansion of the glomerular basement membrane (GBM) by immune deposits. *Sclerosis* refers to an increase in the amount of homogeneous nonfibrillar extracellular material of the same ultrastructural appearance and chemical composition as GBM and mesangial matrix. This process is distinct from *fibrosis*, which involves deposition of collagens type I and III and is more commonly a consequence of healing of crescents or tubulointerstitial inflammation.

MAJOR CLINICOPATHOLOGIC ENTITIES

Most glomerulopathies are still classified and named according to their morphologic features (Table 273-1). The major *inflammatory glomerulopathies* are focal proliferative glomerulonephritis (termed *mesangial proliferative* if the proliferating cells are predominantly mesangial cells), diffuse proliferative glomerulonephritis, and crescentic glomerulonephritis. These diseases typically present with a *nephritic-type* "active" urine sediment characterized by the presence of red blood cells, red blood cell casts, leukocytes, and *subnephrotic* proteinuria of <3 g/24 h. The severity of renal insufficiency varies in proportion to the degree of proliferation and necrosis.

The major morphologic patterns affecting the glomerular filtration barrier for proteins, namely theGBM and visceral epithelial cells, are membranous glomerulopathy, minimal change disease, and focal and segmental glomerulosclerosis. These entities typically present with *nephrotic-range* proteinuria of>3 g/24 h and the presence of few red blood cells, leukocytes, or cellular casts. As a consequence of the heavy proteinuria, nephrotic syndrome is associated with hypoalbuminemia, edema, hyperlipidemia, and lipiduria. Membranoproliferative glomerulonephritis, as the name suggests, is a hybrid lesion that presents with a combination of nephritic and nephrotic features.

The *glomerular deposition diseases* are a group of disorders characterized by prominent extravascular deposition of a paraprotein or fibrillar material. These diseases can also trigger nephritic-type and nephrotic-type responses (or a combination of both) and thus show marked clinical and morphologic overlap with the entities described above.

The *thrombotic microangiopathies* are a family of diseases in which the pathologic presentation is dominated by thrombi within the renal microvasculature, often leading to renal insufficiency.

MAJOR DETERMINANTS OF GLOMERULAR INJURY

Important determinants of the severity of glomerular injury include (1) the nature of the primary insult and the secondary mediator systems that it invokes, (2) the site of injury within the glomerulus; and (3) the speed of onset, extent, and intensity of disease.

PRIMARY INSULT

Glomeruli are susceptible to a variety of inflammatory, metabolic, hemodynamic, toxic, and infectious insults (Table 273-2). Most human glomerular disease is triggered by immune attack, diabetes mellitus, or hypertension. Diverse insults can induce similar clinicopathologic presentations, suggesting marked overlap among downstream molecular and cellular responses. For example, infections (e.g., streptococcal pharyngitis, bacterial endocarditis) and vasculitides (e.g., Henoch-Schonlein purpura, microscopic polyarteritis) can each trigger acute proliferative glomerulonephritis with the nephritic syndrome. Similarly, metabolic (e.g., diabetes mellitus) and deposition diseases (e.g., amyloid) can each induce glomerulosclerosis with nephrotic syndrome. An important corollary is that pharmacologic agents that inhibit common secondary mediator systems may prove effective in treating glomerular diseases of diverse etiologies (see below).

SITE OF INJURY

The consequences of injury at different sites within the glomerulus can be predicted from the physiologic functions of the cells within the local milieu (Table 273-3). The major sequelae of injury to the *endothelium* and *subendothelial aspect of theGBM*are (1) recruitment of leukocytes leading to inflammatory glomerulonephritis, (2) perturbed hemostasis leading to thrombotic microangiopathy, and (3) vasoconstriction and mesangial cell contraction leading to acute renal failure. It is usual for one of these phenotypes to dominate the presentation of specific diseases. *Mesangial* injury is usually immunologic in origin and, being more localized, induces less dramatic impairment of glomerular filtration. Patients typically present with asymptomatic abnormalities of the urinary sediment and mild renal insufficiency. Proteinuria dominates the clinical presentation of injury to the *subepithelial aspect of the GBM* and *visceral epithelial cells*. As with mesangial injury,GFR is often only mildly compromised in this setting. The classic pathologic manifestation of *parietal epithelial cell* injury is crescent formation. Crescents can be the dominant morphologic presentation of glomerular disease or complicate proliferative or membranous lesions.

SPEED OF ONSET, INTENSITY, AND EXTENT OF INJURY

To illustrate the importance of the speed of onset, extent, and intensity of glomerular injury, it is instructive to compare two forms of immune complex glomerulonephritis, namely, acute postinfectious glomerulonephritis and IgA nephropathy. Postinfectious glomerulonephritis is characterized by rapid and extensive formation of immune complexes throughout the glomerular capillary wall, which often provokes acute renal failure with the classic hallmarks of acute inflammation: complement activation, leukocyte recruitment, lysosomal enzyme release, free radical generation, and perturbation of vascular tone and permeability. In contrast, IgA nephropathy is characterized by slow, but sustained, formation of immune complexes, largely confined

to the mesangium; less dramatic activation of complement and other secondary mediator systems; and either stability ofGFR or progressive renal insufficiency over 10 to 20 years.

IMMUNOLOGIC GLOMERULAR INJURY

Immune-mediated glomerulonephritis (Chaps. 274 and275) accounts for a large fraction of acquired renal disease. The majority of cases are associated with the deposition of antibodies, often autoantibodies, within the glomerular tuft, indicating dysregulation of humoral immunity. Cellular immune mechanisms also contribute to the pathogenesis of antibody-mediated glomerulonephritis by modulating antibody production and through antibody-dependent cell cytotoxicity (see below). In addition, cellular immune mechanisms probably play a primary role in the pathophysiology of "pauci-immune" glomerulonephritides, notable for robust glomerular inflammation in the absence of immunoglobulin deposition.

ANTIBODY-MEDIATED INJURY (Fig. 273-1)

Most antibody-mediated glomerulonephritis in humans is initiated by reactivity of circulating antibodies with auto- or "planted" antigens within the glomerulus. The major mechanisms of antibody deposition within the glomerulus are (1) reactivity of circulating autoantibodies with intrinsic autoantigens that are components of normal glomerular parenchyma, (2) in situ formation of immune complexes through interaction of circulating antibodies with extrinsic antigens that have been planted within the glomerulus, and (3) intraglomerular trapping of immune complexes that have formed in the systemic circulation. Autoantibodies against neutrophil cytoplasmic antigens in the circulation may represent an additional mechanism of antibody-mediated glomerular injury in patients without discernible immune complexes in the glomerular parenchyma (see below).

Generation of Nephritogenic Antibodies Exposure of the host to a foreign antigen (e.g., a prodromal infection) has been implicated as the trigger for the generation of nephritogenic autoantibodies in several forms of glomerulonephritis. Foreign antigens can provoke autoantibody formation through several mechanisms. First, a foreign antigen, whose structure resembles that of a host glomerular antigen, may stimulate the production of autoantibodies that cross-react with the intrinsic glomerular antigen ("molecular mimickry"). Second, the foreign antigen may trigger aberrant expression of major histocompatibility complex class II molecules on glomerular cells which present previously "invisible" autoantigens to T lymphocytes and thereby generate an autoimmune response. Third, the foreign antigen can trigger polyclonal activation of B lymphocytes, some of which generate nephritogenic antibodies. Alternatively, individuals may suffer a breakdown of immune tolerance through other mechanisms (e.g., genetically programmed). Autoreactive B cells are usually deleted in the thymus during development (clonal deletion) or rendered anergic in peripheral lymphoid tissue (clonal anergy). Similar tolerogenic mechanisms exist for deleting or anergizing autoreactive T helper cells that modulate immunoglobulin production by autoreactive B cells. Perturbation of either of these tolerogenic mechanisms could drive immunoglobulin production in some forms of autoimmune glomerulonephritis. Indeed, defective clonal deletion of autoreactive T cells has been demonstrated in experimental

lupus nephritis due to defective synthesis of Fas, a cell-surface receptor that modulates T cell deletion through apoptosis (programmed cell death) within the thymus.

Deposition of Nephritogenic Antibodies within the Glomerulus (Fig. 273-1)
Anti-GBMantibody disease (p. 1583) is the classic nephritis initiated by interaction of autoantibody with intrinsic glomerular antigen. Afflicted patients have a circulating antibody directed at a 28-kDa antigen (Goodpasture antigen) located in the noncollagenous NC1 domain of the a3 chain of type IV collagen. This type of collagen is preferentially expressed in glomerular and pulmonary alveolar basement membranes. Autoantibodies against mesangial cell antigens have been detected in the serum of patients with IgA nephropathy, the most common form of glomerulonephritis in humans; however, the pathogenicity of these autoantibodies has yet to be defined. Poststreptococcal glomerulonephritis and lupus nephritis are examples of glomerulonephritides that are probably initiated by interaction of circulating antibodies with planted antigens. Several streptococcal antigens have been isolated from immune deposits of kidneys with poststreptococcal glomerulonephritis, including nephritis strain-associated antigen and a cytoplasmic protein endostreptosin. In addition, patients with poststreptococcal glomerulonephritis can have circulating antibodies against laminin, type IV collagen, and heparan sulphate proteoglycans, suggesting that molecular mimickry may also contribute. Similar findings have been reported in experimental and human lupus nephritis. Here, circulating anti-DNA antibodies may potentially induce immune complex glomerulonephritis by reacting with DNA bound to GBM or with planted DNA-histone complexes (nucleosomes). However, it should be noted that patients with systemic lupus erythematosus have a variety of circulating autoantibodies, and the pathogenetic culprit(s) in lupus nephritis have yet to be identified definitively. Cryoglobulinemia, due to chronic hepatitis C infection, is an example of glomerulonephritis initiated by trapping of immune complexes. These patients have circulating and intraglomerular immune complexes composed of hepatitis C antigens, polyclonal antihepatitis C IgG, and a second antibody, usually a monoclonal IgM, directed against the IgG. In support of the pathogenicity of circulating cryoglobulins, their injection into laboratory mice induces glomerulonephritis with many of the hallmarks of human disease.

Site of Antibody Deposition The site of antibody deposition within the glomerulus is a critical determinant of the clinicopathologic presentation. Among the factors that determine the site of deposition are the avidity, affinity, and quantity of the antibody; the size, charge, and site of the antigen; the size of the immune complexes; the efficiency of the clearance mechanisms for immune complexes; and local hemodynamic factors. Relatively anionic antigens are repelled by theGBM, which is negatively charged, and tend to be trapped in the subendothelial cell space and mesangium. In contrast, relatively cationic antigens tend to permeate the GBM and deposit within the GBM or in the subepithelial space. Acute deposition of antibody in the subendothelial cell space or mesangium typically triggers a nephritic-type response characterized by rapid recruitment of leukocytes and platelets, probably because inflammatory mediators generated at these sites are strategically positioned to activate endothelial and hematogenous cells. Inflammation is more severe when antibody is deposited in the subendothelial space, as compared with mesangium, at least in part because the mesangium abuts only 25 to 33% of the capillary wall. Antibody deposition in the subepithelial cell space typically induces a nephrotic-type response characterized by

proteinuria without a pronounced inflammatory cell infiltrate, probably because the immune complexes are shielded from circulating inflammatory cells by the GBM and because the large fluid flux from blood to Bowman's space minimizes back-diffusion of inflammatory mediators towards the endothelium and vascular lumen.

Recruitment of Inflammatory Cells (Fig. 273-1) Leukocytes and platelets are important mediators of injury in most forms of acute and subacute glomerulonephritis. Immunoglobulin can provoke recruitment of leukocytes through several mechanisms. Many antibody subclasses activate the complement cascade, and complement proteins such as C3a, C5a, and C5b-9 (membrane attack complex) are potent stimuli for leukocyte recruitment, either through their direct effects on leukocytes (C3a, C5a) or by increasing endothelial cell adhesiveness for leukocytes (C5b-9). Complement-independent mechanisms also contribute. Leukocytes express Fc receptors that can directly engage the Fc portion of immunoglobulin. Resident glomerular macrophages, endothelial cells, and mesangial cells also express Fc receptors, engagement of which can trigger release of an array of inflammatory mediators and chemotactic cytokines (chemokines) that promote directed locomotion of leukocytes (chemotaxis), binding of leukocytes to inflamed endothelium through cell surface leukocyte adhesion molecules, and diapedesis of leukocytes to the extravascular space.

The mechanisms of platelet recruitment in glomerulonephritis are less well defined. Potential mechanisms include direct binding of platelet Fc receptors with immunoglobulin, and interactions of platelets with endothelium, trapped leukocytes, collagen, and other components of exposedGBM, and with products of the coagulation cascade such as fibrin.

Mediators of Glomerular Injury (Fig. 273-2) *Nephritic-type antibody-mediated glomerular injury* is a vivid example of host defense gone awry. In normal host defense, leukocytes engulf microorganisms into phagosomes, which then fuse with intracellular lysosomes. Microorganisms are destroyed within phagolysosomes through the actions of free radicals, proteolytic enzymes, and other toxic molecules. This process facilitates killing with relative protection and preservation of host tissue. When host defense is inappropriately activated in autoimmune diseases, the inciting antigens are often fixed to (planted antigens) or are a component of host tissue (autoantigen). As a result, phagocytosis is less efficient ("frustrated phagocytosis"), and there is release of toxic moieties such as oxidants and proteases into the parenchyma where they destroy host cells and matrix components. In addition, cytotoxic T lymphocytes and natural killer cells can damage resident glomerular cells by releasing toxic compounds, such as perforins, a process that is facilitated by binding of these cytotoxic cells to glomerular cells through HLA molecules, Fc portions of immunoglobulin (antibody-dependent cell cytotoxicity), and other immune recognition systems. Platelets promote nephritic injury by promoting leukocyte recruitment and intrarenal vasoconstriction and by triggering microthrombi formation. Cytokines, such as tumor necrosis factor a, interleukin 1b, and interferong, play a key role in the amplification and maintenance of glomerular inflammation by inducing de novo synthesis of leukocyte adhesion molecules, chemokines, and other inflammatory mediators.

Leukocytes play a lesser role in *nephrotic-type antibody-mediated glomerular injury*

(Chap. 274). Membranous glomerulopathy is the prototypic entity and is initiated by the formation of subepithelial immune complexes; these provoke production of "spikes" of new basement membrane that eventually encircle and incorporate the immune complexes into theGBM. The antigenic targets in human membranous glomerulopathy have not been determined but may be planted antigens or autoantigens shed from parietal epithelial cells. The frequent association with infections, malignancies, and drugs suggests involvement of planted antigens or molecular mimickry (see above); however, many cases may represent a true loss of tolerance against autoantigens. The membrane attack complex of complement (C5b-9) appears to be a major effector of injury to the glomerular filtration barrier in this setting.

CELL PROLIFERATION AND ACCUMULATION OF EXTRACELLULAR MATRIX

A hallmark of the nephritic-type proliferative glomerulopathies is an increase in glomerular cell number. Initially, this hypercellularity is due predominantly to infiltration of the glomerular tuft by leukocytes. Subsequently, resident glomerular cells proliferate in response to growth factors [e.g., epidermal growth factor, platelet-derived growth factor (PDGF), thrombospondin] released into the local inflammatory milieu. The proliferating cells are typically mesangial in mesangioproliferative glomerulonephritis and both endothelial and mesangial cells in diffuse proliferative glomerulonephritis. The visceral epithelial cell is, for the most part, a terminally differentiated cell that does not proliferate rapidly, even when injured.

Whereas acute antibody-mediated glomerulonephritis typically induces acute diffuse proliferative glomerulonephritis and acute renal failure over days to weeks (nephritic syndrome), subacute immune injury often induces the formation of glomerular crescents and renal failure over weeks-to-months (termed *rapidly progressive glomerulonephritis*). As discussed above, crescents are extracapillary proliferations of cells in Bowman's space, composed of infiltrating monocytes, proliferating parietal epithelial cells, and fibrin.

Sustained low level immune complex deposition over months to years can provoke a marked increase in basement membrane or mesangial matrix production. Mild to moderate accumulation of matrix usually manifests as proteinuria due to disruption of the glomerular filtration barrier; however, in its most severe form, matrix accumulation causes glomerulosclerosis and chronic renal insufficiency.

RESOLUTION, REPAIR, AND SCARRING

Glomerular inflammation can resolve with complete recovery of renal function or with a variable amount of scarring and chronic renal insufficiency. Acute poststreptococcal glomerulonephritis (p. 1582), for example, usually resolves spontaneously and fully in children, whereas adults are frequently left with residual renal impairment. The resolution process requires cessation of further antibody production and immune complex formation, removal of deposited and circulating immune complexes, inhibition of further recruitment of inflammatory cells, dissipation of the gradients of inflammatory mediators, restoration of normal endothelial adhesiveness and permeability, normalization of vascular tone, and clearance of infiltrating inflammatory cells and proliferating resident glomerular cells (Fig. 273-1).

Unfortunately, the resolution phase of most inflammatory glomerulopathies in adults terminates in some glomerular scarring. This is particularly true in patients with crescentic glomerulopathies who may be left with end-stage renal failure requiring dialysis or transplantation. Transforming growth factor (TGF)b, a cytokine, stimulates production of extracellular matrix by most glomerular cells, inhibits synthesis of tissue proteases that normally degrade matrix proteins, and is a potent stimulus for scar formation immediately following glomerular injury.

Moderate-to-severe glomerulonephritis is usually associated with a variable degree of tubulointerstitial inflammation and scarring in addition to glomerular injury. Indeed, the severity of tubulointerstitial injury usually correlates closely with long-term impairment of renal function. The pathogenesis of tubulointerstitial inflammation in this setting is unclear. Potential mechanisms include: (1) primary involvement of both the glomeruli and the tubulointerstitium in autoimmune disease; (2) induction of tubulointerstitial inflammation by mediators generated by diseased glomeruli which then diffuse into the tubulointerstitium via blood, tubular fluid, or the interstitial space; (3) injury to tubule epithelial cells by excessive filtered proteins ("protein overload" hypothesis); and (4) ischemia to areas of the tubulointerstitium downstream to areas of robust glomerular inflammation or severe glomerulosclerosis.

OTHER MECHANISMS OF ANTIBODY-MEDIATED INJURY

Several other autoantibodies have been implicated as mediators of renal injury in patients with glomerulonephritis.

Antineutrophil Cytoplasmic Antibodies (ANCA) Immunoglobulin is not detected in the glomerulus in approximately 40% of patients with rapidly progressive glomerulonephritis ("pauci-immune crescentic glomerulonephritis"). The majority of these patients have Wegener's granulomatosis, microscopic polyangiitis nodosa, or renal-limited crescentic glomerulonephritis and have autoantibodies against neutrophil cytoplasmic antigens in their circulation. When reactive with ethanol-fixed neutrophils isolated from healthy volunteers, ANCA stain results in either a cytoplasmic pattern (c-ANCA) or perinuclear pattern (p-ANCA). In the case of c-ANCA, the neutrophil antigen is usually proteinase-3, a constituent of neutrophil primary granules. In the case of p-ANCA, the antigen is usually myeloperoxidase, another granule constituent that migrates to the perinuclear area upon ethanol fixation. Whereas a greater number of patients with Wegener's granulomatosis have c-ANCA and a greater proportion of patients with renal-limited disease have p-ANCA, the morphologic features, response to treatment, and overall prognosis appear to be similar in patients with either c-ANCA or p-ANCA. ANCA stimulate cytokine-primed human neutrophils to generate reactive oxygen species and injure endothelium in vitro. These findings raise the possibility that ANCA may be pathogenetic in vivo in the presence of circulating cytokines, as may occur following a prodromal infection.

Antiendothelial Cell Antibodies Circulating antibodies against endothelial antigens have been reported in several inflammatory vasculitides and glomerulonephritides. Their titers tend to correlate with disease activity, and some activate endothelial cells and increase their adhesiveness for leukocytes, suggesting a pathogenetic role.

C3 Nephritic Factor Some patients with membranoproliferative glomerulonephritis (Chap. 273) have large deposits of electron-dense material within theGBM that does not stain for immunoglobulin (dense deposit disease; membranoproliferative glomerulonephritis type II). Intriguingly, most of these patients have a circulating IgG, termed the *C3 nephritic factor*, directed at C3bBb (C3 convertase) of the alternative pathway of complement.

CELL-MEDIATED INJURY

Although cell-mediated injury is, as yet, less well defined than antibody-mediated glomerular injury, T cells have also been implicated as independent mediators of glomerular injury and as modulators of the production of nephritogenic antibodies. T cells may be particularly important as initiators of injury in pauci-immune glomerulonephritis. T cells interact, through their cell-surface T cell receptor/CD3 complex, with antigens presented in the groove of major histocompatibility complex molecules of resident glomerular endothelial, mesangial, and epithelial cells, a process that is facilitated by cell-cell adhesion and costimulatory molecules. Cytokines and other mediators released by activated T cells are potent stimuli for further leukocyte recruitment, cytotoxicity, and fibrogenesis. CD4 T lymphocytes are important recruiters of macrophages and trigger clonal expansion of autoreactive B cells; they also promote glomerular cell injury by CD8 cytotoxic T lymphocytes and natural killer cells and through antibody-dependent cell cytotoxicity. Soluble factors derived from T cells have also been implicated in the pathogenesis of proteinuria in minimal change disease and primary focal segmental glomerulosclerosis. The identity and molecular characterization of these nonimmunoglobulin circulating permeability factors remain to be determined.

NONIMMUNOLOGIC GLOMERULAR INJURY

METABOLIC

Diabetic Nephropathy (See also Chaps. 275 and333) Nephropathy complicates approximately 30% of cases of type 1 and type 2 diabetes mellitus and is characterized clinically by proteinuria and progressive renal insufficiency. The typical glomerular lesion is glomerulosclerosis due to thickening of theGBM and expansion of the mesangium with extracellular matrix. Factors implicated as triggers for increased matrix production include glomerular hypertension; the direct effects of hyperglycemia on mesangial cells; advanced glycosylation end-products; growth factors such as growth hormone, insulin-like growth factor 1, and angiotensin II; cytokines such asTGF-b; hyperlipidemia; and cell sorbitol accumulation.

Complementary clinical and laboratory approaches suggest a central role for hemodynamic factors. Glomerular hydrostatic pressure andGFRincrease within months of the development of hyperglycemia. The mechanism by which diabetes mellitus induces glomerular hypertension is still being defined but appears to involve atrial natriuretic peptide. In this framework, glycosuria triggers increased reabsorption of glucose coupled to sodium in the proximal tubule, thereby increasing total-body sodium and extracellular fluid volume. As a compensatory response, atrial natriuretic peptide is released from cardiac myocytes and induces natriuresis in part by triggering afferent

arteriolar dilatation and thereby increasing intraglomerular pressure and GFR. Whereas this compensatory response is appropriate in the short term, sustained glomerular hypertension provokes thickening of theGBM, increased mesangial matrix production, and glomerulosclerosis and disruption of barrier function. In keeping with a central role for intra-glomerular pressure in the pathogenesis of diabetic nephropathy, angiotensin-converting enzyme inhibitors, which lower intraglomerular pressure, slow the progression of diabetic nephropathy, even in normotensive patients. It remains to be determined why diabetes mellitus and glomerular hypertension include glomerulosclerosis in some but not all individuals. Epidemiologic studies and studies of disease concordance in identical twins suggest that important, but as yet unidentified, genetic factors may play a role. It is likely that hemodynamic and metabolic factors act in concert to generate the final glomerulosclerotic phenotype in genetically predisposed patients.

Other Metabolic Diseases Several rare inherited lysosomal enzyme defects induce focal segmental glomerulosclerosis, probably by allowing accumulation of toxic metabolites in renal cells. *Fabry's disease* (a-galactosidase deficiency;Chap. 349) and *sialidosis* (*N*-acetylneuraminic acid hydrolase deficiency;Chap. 349) are the major culprits in this regard. Both tend to induce focal segmental or global glomerulosclerosis by preferentially affecting visceral epithelial cells, probably because these are terminally differentiated cells with a very slow replication rate. *Partial lipodystrophy* is a rare metabolic disorder characterized by lipoatrophy affecting the arms, neck, and chest, often with redistribution of fat to the hips and legs. Approximately one-third of patients develop glomerular disease, usually type II membranoproliferative glomerulopathy (dense deposit disease;Chap. 274).

HEMODYNAMIC GLOMERULAR INJURY

High intraglomerular pressure is a major cause of glomerular injury in humans and can result from systemic hypertension or a local change in glomerular hemodynamics (glomerular hypertension).

Systemic Hypertension (See also Chap. 246) Although the kidneys have evolved sophisticated mechanisms for autoregulating glomerular blood flow and pressure, marked or sustained increments in systemic blood pressure can overwhelm these compensatory systems and perturb glomerular morphology and function. In its most dramatic form, namely malignant hypertension, hemodynamic stress causes massive fibrinoid necrosis of afferent arterioles and glomeruli, thrombotic microangiopathy, acute renal failure, and a nephritic urinary sediment. Chronic sustained hypertension typically leads to arteriolar vasoconstriction and sclerosis, which, in turn, cause secondary atrophy and sclerosis of glomeruli and the tubulointerstitium. A variety of molecular signals appear to couple elevations in intravascular pressure to myointimal proliferation and eventually sclerosis of the vessel wall. These include growth factors such as angiotensin II, epidermal growth factor, andPDGF; cytokines such asTGF-b; and activation of stretch activated ion channels and early response genes.

Glomerular Hypertension The pathophysiology of diabetic nephropathy, discussed above, illustrates the importance of intraglomerular pressure as a stimulus for mesangial matrix production and glomerulosclerosis. Glomerular hypertension is also a key factor

in the pathogenesis of the progressive glomerulosclerosis and renal failure that complicate the adaptive response of remnant nephrons to increased workload following loss of the other nephrons from any cause, including chronic allograft failure (see below). Importantly, these changes in glomerular hemodynamics and pressure appear to precede the development of systemic hypertension and are independent risk factors for glomerular injury.

TOXIC GLOMERULOPATHIES

The renal microvasculature is a relatively uncommon site for toxic injury, by comparison with the tubular interstitium; however, there are a few important exceptions. Verotoxin, derived from *Escherichia coli* during bouts of infective diarrhea, is directly toxic to renal endothelium and induces the hemolytic-uremic syndrome. In this setting, verotoxin interacts with a specific cell membrane receptor, perturbs the antithrombotic phenotype of endothelium, and triggers the development of thrombotic microangiopathy. Irradiation, mitomycin, cyclosporine, and anovulants can also induce thrombotic microangiopathy through poorly defined mechanisms. Nonsteroidal anti-inflammatory drugs, rifampin, ampicillin, and interferon-a can induce an unusual combination of acute renal failure with nephrotic syndrome. The characteristic pathologic correlates of this syndrome are allergic interstitial nephritis and fusion of the foot processes of the visceral epithelial cells, the latter accounting for the marked proteinuria. How these structurally diverse agents induce epithelial cell injury is unclear.

DEPOSITION DISEASES

The glomerular deposition diseases are a group of diverse conditions in which abnormal proteins are deposited in glomeruli, where they provoke an inflammatory reaction and/or glomerulosclerosis. The major glomerular deposition diseases are cryoglobulinemia, amyloidosis, light and heavy chain deposition disease, and fibrillary/immunotactoid glomerulopathy. *Cryoglobulins* (Chap. 317) are immunoglobulins that precipitate in the cold and can be composed of either monoclonal immunoglobulin, usually generated by a lymphoproliferative malignancy (type I); a mixture of polyclonal immunoglobulin (usually IgG) and monoclonal immunoglobulin (usually IgM) directed to epitopes on polyclonal IgG (type II); or a mixture of polyclonal antibodies, one or more having anti-IgG activity (type III). As discussed above, cryoglobulins can induce nephritic-type and nephrotic-type injury depending on the rapidity, severity, and site of immunoglobulin deposition. Most cryoglobulinemic glomerulopathy is associated with type II cryoglobulins, the majority of which are now recognized to be triggered by chronic hepatitis B or C infection. *Glomerular amyloidosis* (Chaps. 275 and319) is one of the five most common causes of nephrotic syndrome in adults and is characterized by extracellular deposition of amyloid fibrils composed, in part, of fragments of immunoglobulin light chains (AL amyloid) or serum amyloid A, the acute-phase reactant (AA amyloid). In light chain deposition diseases, intact immunoglobulin light chains, usually kappa, are deposited in a granular, rather than fibrillary, pattern. The composition of the deposits in *fibrillary/immunotactoid glomerulopathy* is still being defined and may also include immunoglobulin and/or fibronectin-containing cryoglobulins. These different types of deposits, in addition to directly disrupting glomerular architecture, provoke mesangial matrix production and glomerulosclerosis. Fibrillary/immunotactoid glomerulopathy can also present as acute or subacute

glomerular inflammation. How these diverse deposits trigger glomerular matrix production and recruitment of inflammatory cells has yet to be determined.

INFECTIOUS CAUSES OF GLOMERULAR DISEASE

Infectious organisms can induce glomerular disease through several different mechanisms: (1) by direct infection of renal cells, (2) by elaborating nephrotoxins such as *E. coli*-derived verotoxin, (3) by inciting intraglomerular deposition of immune complexes (e.g., postinfectious glomerulonephritis) or cryoglobulins (e.g., hepatitis B or C), and (4) by providing a chronic stimulus for amyloid fibril formation, as in AA amyloidosis. Direct infection of glomerular cells is a relatively rare mechanism of injury but has been implicated in the pathogenesis of nephropathy associated with HIV. This entity is characterized histologically by an aggressive form of focal segmental glomerulosclerosis, microcystic tubular dilatation, and interstitial fibrosis. Viral genome and several proteins have been detected in glomerular and tubular cells in this disease, and infection of glomerular cells induces expression ofTGF-b, a major stimulus for mesangial matrix production and sclerosis.

INHERITED GLOMERULAR DISEASES

Alport's syndrome (hereditary nephritis; Chap. 275), the prototypical inherited glomerular disease, is usually transmitted as an X-linked dominant trait,although autosomal recessive forms have been reported. Patients afflicted with the classic X-linked form have a mutation in the COL4A5 gene that encodes thea5 chain of type IV collagen located on the X chromosome. As a result, theGBM is irregular with longitudinal layering, splitting, or thickening, and patients develop hematuria, progressive glomerulosclerosis, and renal failure. *Thin basement membrane disease* is another relatively common disorder of the GBM. In contrast to Alport's syndrome, this entity is usually inherited as an autosomal dominant or recessive trait and appears to be relatively benign. As the name suggests, the basement membrane is thin but otherwise ultrastructurally normal. Patients typically experience recurrent benign hematuria. The molecular basis for thin basement membrane disease has yet to be elucidated fully; however, defects in the gene encoding the a4 chain of type IV collagen have been reported in some families. Rarer hereditary glomerular diseases include *nail-patella syndrome* (osteoonychodysplasia), which is associated with a relatively benign mottling of the basement membrane with lucent rarefractions; *partial lipodystrophy*, which is associated with type II membranoproliferative glomerulonephritis (dense deposit disease); and *familial lecithin-cholesterol acyltransferase deficiency*, which is associated with distortion of the basement membrane by irregular rounded lucent zones, increased mesangial matrix production, and progressive sclerosis and renal insufficiency.

GLOMERULAR ADAPTATION TO NEPHRON LOSS

Nephron loss, from any cause, is followed by compensatory hyperfiltration in the remaining functional glomeruli. This adaptive response is appropriate in the short-term and maintainsGFR. Over years, however, the hyperfiltering remnant nephrons develop focal and segmental glomerulosclerosis, and eventually global sclerosis, that manifests clinically as proteinuria, hypertension, and progressive renal insufficiency. Sustained glomerular capillary hypertension has been implicated as a major stimulus for

glomerulosclerosis in this setting. Increased glomerular blood flow and ultrafiltration pressure are early findings in remnant nephrons in most experimental models in which the function of more than 50% of nephron mass has been lost through surgical ablation, immunologic or toxic injury, or other mechanisms. Sustained glomerular hypertension is thought to stimulate the accumulation of extracellular matrix by perturbing the function of visceral epithelial and mesangial cells, either directly or by increasing the flux of circulating macromolecules through the glomerular capillary wall. As with most forms of glomerulosclerosis,TGF-bmay be an important regulator of matrix accumulation in remnant nephrons. Angiotensin II,PDGF, and endothelins are other potential modulators of this process. Maneuvers that lower intraglomerular pressure, such as low-protein diet or treatment with angiotensin-converting enzyme inhibitors, slow the development of glomerulosclerosis and renal failure. Glomerular hypertrophy, intracapillary microthrombi, recruited macrophages, and hyperlipidemia are other potential stimuli for glomerulosclerosis. Indeed, glomerular capillary hypertension and hypertrophy appear to be independent risk factors that could act synergistically to cause progressive renal insufficiency. Intriguingly, angiotensin II may trigger TGF-b production in remnant nephrons, suggesting that angiotensin-converting enzyme inhibitors may be renoprotective through complementary effects on glomerular hemodynamics and matrix production.

274. THE MAJOR GLOMERULOPATHIES - *Hugh R. Brady*, *Yvonne M. O'Meara*, *Barry M. Brenner*

Glomerular injury can arise from diverse renal-limited and systemic diseases and is the major cause of end-stage renal disease (ESRD) requiring dialysis and transplantation. In this**chapter**, we describe the epidemiology, clinical presentations, pathology, and treatment of the major glomerulopathies. We focus on the *primary glomerulopathies*, glomerular diseases in which the pathologic process is confined to the kidney and in which systemic features are a direct consequence of impaired glomerular filtration (e.g., hypervolemia, hypertension, uremic syndrome). Considered here are the five major clinical presentations of glomerulopathy: acute nephritic syndrome, rapidly progressive glomerulonephritis (RPGN), nephrotic syndrome, asymptomatic abnormalities of the urinary sediment (hematuria, proteinuria), and chronic glomerulonephritis.**Glomerulopathies associated with systemic diseases (secondary glomerulopathies*) are discussed in Chap. 275. The nomenclature pertaining to the classification and clinicopathologic description of glomerular disease and the pathogenetic mechanisms of glomerular injury are reviewed in Chap. 273.

ACUTE NEPHRITIC SYNDROME AND RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS

CLINICAL FEATURES AND CLINICOPATHOLOGIC CORRELATES

The *acute nephritic syndrome* is the clinical correlate of acute glomerular inflammation. In its most dramatic form, the acute nephritic syndrome is characterized by sudden onset (i.e., over days to weeks) of *acute renal failure* and *oliguria* (<400 mL of urine per day). Renal blood flow and glomerular filtration rate (GFR) fall as a result of obstruction of the glomerular capillary lumen by infiltrating inflammatory cells and proliferating resident glomerular cells. Renal blood flow and GFR are further compromised by intrarenal vasoconstriction and mesangial cell contraction that result from local imbalances of vasoconstrictor (e.g., leukotrienes, platelet-activating factor, thromboxanes, endothelins) and vasodilator substances (e.g., nitric oxide, prostacyclin) within the renal microcirculation. *Extracellular fluid volume expansion*, *edema*, and *hypertension* develop because of impaired GFR and enhanced tubular reabsorption of salt and water. As a result of injury to the glomerular capillary wall, urinalysis typically reveals *red blood cell casts*, dysmorphic red blood cells, leukocytes, and subnephrotic proteinuria of<3.5 g per 24 h ("nephritic urinary sediment"). *Hematuria* is often macroscopic.

The classic pathologic correlate of the nephritic syndrome is *proliferative glomerulonephritis*. The proliferation of glomerular cells is due initially to infiltration of the glomerular tuft by neutrophils and monocytes and subsequently to proliferation of resident glomerular endothelial and mesangial cells (endocapillary proliferation). In its most severe form, the nephritic syndrome is associated with acute inflammation of most glomeruli, i.e., *acute diffuse proliferative glomerulonephritis*. When less vigorous, fewer than 50% of glomeruli may be involved, i.e., *focal proliferative glomerulonephritis*. In milder forms of nephritic injury, cellular proliferation may be confined to the mesangium, i.e., *mesangioproliferative glomerulonephritis*.

RPGNis the clinical correlate of more *subacute glomerular inflammation*. Patients develop renal failure over weeks to months in association with a nephritic urinary sediment, subnephrotic proteinuria and variable oliguria, hypervolemia, edema, and hypertension. The classic pathologic correlate of RPGN is crescent formation involving most glomeruli (*crescentic glomerulonephritis*), crescents being half-moon-shaped lesions in Bowman's space composed of proliferating parietal epithelial cells and infiltrating monocytes (*extracapillary proliferation*). In practice, the clinical term *rapidly progressive glomerulonephritis* and the pathologic term *crescentic glomerulonephritis* are often used interchangeably. In addition to classic crescentic glomerulonephritis, in which crescents dominate the glomerular pathology, crescents can also develop concomitantly with proliferative glomerulonephritis or as a complication of membranous glomerulopathy and other more indolent forms of glomerular inflammation.

The acute nephritic syndrome andRPGN are part of a spectrum of presentations of immunologically mediated proliferative glomerulonephritis. Studies of experimental models suggest that nephritic syndrome and diffuse proliferative glomerulonephritis represent an acute immune response to a sudden large antigen load, whereas RPGN and crescentic glomerulonephritis represent a more subacute immune response to a smaller antigen load in presensitized individuals. At the other end of the spectrum, chronic low-grade immune injury presents with slowly progressive renal insufficiency or asymptomatic hematuria in association with focal proliferative or mesangioproliferative glomerulonephritis. These more indolent forms of immune-mediated glomerulonephritis are discussed later in this**chapter**.

ETIOLOGY AND DIFFERENTIAL DIAGNOSIS

Acute nephritic syndrome andRPGN can result from renal-limited *primary* glomerulopathy or from *secondary* glomerulopathy complicating systemic disease.Figure 274-1 highlights the histopathologic and serologic features that help distinguish among the major causes of nephritic syndrome and RPGN (see also Fig. 274-2). In general, rapid diagnosis and prompt treatment are critical to avoid the development of irreversible renal failure. Renal biopsy remains the "gold standard" for diagnosis. *Immunofluorescence microscopy* is particularly helpful and identifies three major patterns of deposition of immunoglobulin that define three broad diagnostic categories: (1) *granular* deposits of immunoglobulin, a hallmark of *immune-complex glomerulonephritis*; (2) *linear* deposition of immunoglobulin along the glomerular basement membrane (GBM), characteristic of anti-GBM disease; and (3) paucity or absence of immunoglobulin, so-called *pauci-immune glomerulonephritis* (Figs. 273-1 and274-2). Most patients (>70%) with full-blown acute nephritic syndrome have immune-complex glomerulonephritis. Pauci-immune glomerulonephritis is less common in this setting (<30%) and anti-GBM disease is rare (<1%). Among patients with RPGN, immune-complex glomerulonephritis and pauci-immune glomerulonephritis are equally prevalent (~45% each), whereas anti-GBM disease again accounts for a minority of cases (<10%).

Three *serologic markers* often predict the immunofluorescence microscopy findings in nephritic syndrome andRPGN and may obviate the need for renal biopsy in classic cases. They are the serum C3 level and titers of anti-GBMantibody and antineutrophil cytoplasmic antibody (ANCA) (Fig. 274-1). As discussed inChap. 273, the kidney is host

to immune attack in immune-complex glomerulonephritis, most cases being initiated either by in situ formation of immune complexes or less commonly by glomerular trapping of circulating immune complexes. These patients typically have hypocomplementemia (low C3 and CH_{50} in 90%) and negative anti-GBM and ANCA serology. The glomerulus is the direct target of immune attack in anti-GBM disease, glomerular inflammation being initiated by an autoantibody directed at a 28-kDa autoantigen on thea3 chain of type IV collagen. Approximately 90 to 95% of patients with anti-GBM disease have circulating anti-GBM autoantibodies detectable by immunoassay; serum complement levels are typically normal, and ANCA are usually not detected. The pathogenesis of pauci-immune glomerulonephritis is still being defined; however, most patients have circulating ANCA, implicating dysregulation of humoral immunity. The presence of mononuclear leukocytes in glomeruli and the paucity of glomerular immune deposits suggest that cellular mechanisms are also involved. Serum complement levels are typically normal, and anti-GBM titers are usually negative in ANCA-associated renal disease.

IMMUNE-COMPLEX GLOMERULONEPHRITIS

Immune-complex glomerulonephritis may (1) be idiopathic, (2) represent a response to a known antigenic stimulus (e.g., postinfectious glomerulonephritis), or (3) form part of a multisystem immune-complex disorder (e.g., lupus nephritis, Henoch-Schonlein purpura, cryoglobulinemia, bacterial endocarditis;Fig. 274-1). Here, we focus on *postinfectious glomerulonephritis*, the best characterized *primary* immune-complex glomerulonephritis. The major *secondary* immune-complex glomerulonephritides are discussed inChap. 275. Nephritic syndrome andRPGNoccasionally complicate two other primary glomerulopathies, namely, membranoproliferative glomerulonephritis (MPGN) and IgA nephropathy when there is a florid proliferative component. Because nephrotic syndrome and asymptomatic hematuria are more common presentations of MPGN and IgA nephropathy, respectively, these glomerulopathies are discussed in later sections on nephrotic syndrome and asymptomatic urinary abnormalities.

POSTSTREPTOCOCCAL GLOMERULONEPHRITIS

This is the prototypical postinfectious glomerulonephritis and a leading cause of acute nephritic syndrome. Most cases are sporadic, though the disease can occur as an epidemic. Glomerulonephritis develops, on average, 10 days after pharyngitis or 2 weeks after a skin infection (impetigo) with a nephritogenic strain of group Ab-hemolytic streptococcus. The known nephritic strains include M types 1, 2, 4, 12, 18, 25, 49, 55, 57, and 60. Immunity to these strains is type-specific and long-lasting, and repeated infection and nephritis are rare. Epidemic poststreptococcal glomerulonephritis is most commonly encountered in children of 2 to 6 years of age with pharyngitis during the winter months. This entity appears to be decreasing in frequency, possibly due to more widespread and prompt use of antibiotics. Poststreptococcal glomerulonephritis in association with cutaneous infections usually occurs in a setting of poor personal hygiene or streptococcal superinfection of another skin disease.

The classic clinical presentation of poststreptococcal glomerulonephritis is full-blown nephritic syndrome with oliguric acute renal failure; however, most patients have milder disease. Indeed, subclinical cases outnumber overt cases by four- to tenfold during

epidemics. Patients with overt disease present with gross hematuria (red or "smoky" urine), headache, and generalized symptoms such as anorexia, nausea, vomiting, and malaise. Swelling of the renal capsule can cause flank or back pain. Physical examination reveals hypervolemia, edema, and hypertension. The urinary sediment is nephritic, with dysmorphic red blood cells, red cell casts, leukocytes, occasionally leukocyte casts, and subnephrotic proteinuria. Fewer than 5% of patients develop nephrotic-range proteinuria. The latter may only manifest as acute nephritis resolves and renal blood flow andGFRrecover. Coexistent rheumatic fever is extremely rare.

The serum creatinine is often mildly elevated at presentation. Serum C3 levels and CH_{50} are depressed within 2 weeks in ~90% of cases. C4 levels are characteristically normal, indicating activation of the alternate pathway of complement. Complement levels usually return to normal within 6 to 8 weeks. Persistently depressed levels after this period should suggest another cause, such as the presence of a C3 nephritic factor (see "Membranoproliferative Glomerulonephritis"). The majority of patients (>75%) have transient hypergammaglobulinemia and mixed cryoglobulinemia. The antecedent streptococcal infection may still be evident or may have resolved either spontaneously or in response to antibiotic therapy. Most patients (>90%) have circulating antibodies against streptococcal exoenzymes such as antistreptolysin O (ASO), anti-deoxyribonuclease B (anti-DNAse B), antistreptokinase (ASKase), anti-nicotinyl adenine dinucleotidase (anti-NADase), and antihyaluronidase (AHase). ASO, anti-DNAse B, anti-NAD, and AHase are most useful after pharyngeal infection, whereas anti-DNAse B and AHase are more sensitive indices of streptococcal skin infection. Antibody titers tend to rise after 7 days, peak after 1 month, and return to normal levels after 3 to 4 months. These tests are relatively specific, with a false-positive rate of<5%. Early antibiotic therapy may prevent the development of an antibody response.

Acute poststreptococcal glomerulonephritis is usually diagnosed on clinical and serologic grounds, without resort to renal biopsy, especially in children with a typical antecedent history. The characteristic lesion on light microscopy is diffuse proliferative glomerulonephritis. Crescents are uncommon, and extraglomerular involvement is usually mild. Immunofluorescence microscopy reveals diffuse granular deposition of IgG and C3, giving rise to a "starry sky" appearance (Fig. 274-2). More extensive immunoglobulin deposition throughout the glomerular capillary wall ("garland pattern") is associated with a worse prognosis. The characteristic finding on electron microscopy is the presence of large electron-dense immune deposits in the subendothelial, subepithelial, and mesangial areas. The acute inflammatory reaction is initiated, in large part, by the subendothelial and mesangial deposits, which activate complement and trigger leukocyte recruitment and glomerular injury. Subepithelial deposits are often more prominent on electron microscopy, however, probably because the subendothelial and mesangial deposits are scavenged more efficiently by invading phagocytes. Extensive subepithelial immune deposits, or "humps," tend to be associated with worse proteinuria, being juxtaposed to the glomerular filtration barrier for protein.**The pathogenesis of immune-complex glomerulonephritis is discussed extensively in Chap. 273*.

In addition to poststreptococcal glomerulonephritis, the nephritic syndrome andRPGN can complicate acute immune-complex glomerulonephritis due to other viral, bacterial,

fungal, and parasitic infections. Several warrant specific mention. Diffuse proliferative immune-complex glomerulonephritis is a well-described complication of acute and subacute bacterial endocarditis and is usually associated with hypocomplementemia. The glomerular lesion typically resolves following eradication of the cardiac infection. *Shunt nephritis* is a syndrome characterized by immune-complex glomerulonephritis secondary to infection of ventriculoatrial shunts inserted for treatment of childhood hydrocephalus. The most common offending organism is coagulase-negative staphylococcus. Renal impairment is usually mild and associated with hypocomplementemia. Nephrotic syndrome complicates 30% of cases. Acute proliferative glomerulonephritis can also complicate *chronic suppurative infections* and *visceral abscesses*. Patients typically present with a fever of unknown origin and an active urine sediment. Although immune deposits containing IgG and C3 are detected on renal biopsy, serum complement levels are usually normal.

TREATMENT

Treatment of poststreptococcal glomerulonephritis focuses on eliminating the streptococcal infection with antibiotics and providing supportive therapy until spontaneous resolution of glomerular inflammation occurs. Patients are usually confined to bed during the acute inflammatory phase. Diuretics and antihypertensive agents are employed to control extracellular fluid volume and blood pressure. Dialysis is rarely needed to control hypervolemia or the uremic syndrome. Poststreptococcal glomerulonephritis carries an excellent prognosis and rarely causesESRD. Microscopic hematuria may persist for as long as 1 year after the acute episode but eventually resolves. Whereas complete recovery is the rule in children, adults may occasionally be left with residual renal impairment.

Antiglomerular Basement Membrane Disease Anti-GBMdisease is an autoimmune disease in which autoantibodies directed against type IV collagen induceRPGN and crescentic glomerulonephritis (Figs. 273-1,274-1, and274-2). Acute nephritic syndrome is rare. Between 50 and 70% of patients have lung hemorrhage; the clinical complex of anti-GBM nephritis and lung hemorrhage is referred to as *Goodpasture's syndrome*. Anti-GBM disease is a rare disorder of unknown etiology with an annual incidence of 0.5 per million. There is a bimodal peak in incidence. Patients with Goodpasture's syndrome are typically young males (5 to 40 years; male-female ratio of 6:1). In contrast, patients presenting during the second peak in the sixth decade rarely suffer lung hemorrhage and have an almost equal sex distribution. The target antigen is a component of the noncollagenous (NCI) domain of thea3 chain of type IV collagen, thea3 chain being preferentially expressed in glomerular and pulmonary alveolar basement membrane. The trigger(s) for loss of self-tolerance to this Goodpasture antigen has not been well defined. A genetic predisposition is suggested by an association with HLA-DRw2 and occasional occurrence in identical twins. Patients with lung hemorrhage are more likely to be cigarette smokers and to have suffered a recent upper respiratory tract infection or exposure to volatile hydrocarbon solvents. These observations suggest that diverse insults to the alveolar basement membrane may render previously sequestered Goodpasture antigens available for interaction with circulating autoantibodies. It is not clear whether environmental factors also trigger the onset of nephritis. Binding of anti-GBM antibodies to the GBM induces activation of complement, leukocyte recruitment, necrotizing proliferative glomerulonephritis, disruption of the glomerular

capillary wall, leakage of fibrin into Bowman's space, and crescent formation (Chap. 273). A similar sequence of events in the lung leads to disruption of the alveolar capillary wall and pulmonary hemorrhage.

Anti-GBMdisease commonly presents with hematuria, nephritic urinary sediment, subnephrotic proteinuria, and rapidly progressive renal failure over weeks, with or without pulmonary hemorrhage. When pulmonary hemorrhage occurs, it usually predates nephritis by weeks or months. Hemoptysis can vary from fluffy pulmonary infiltrates on chest x-ray and mild dyspnea on exertion to life-threatening pulmonary hemorrhage. Hypertension is unusual and occurs in fewer than 20% of cases.

The diagnostic serologic marker is circulating anti-GBMantibodies with a specificity for the NCI domain of thea3 chain of type IV collagen (Fig. 274-1). Anti-GBM antibodies are detected in the serum of >90% of patients with anti-GBM nephritis by specific immunoassay. If immunoassays are not available, circulating anti-GBM antibodies can be detected in 60 to 80% of patients by indirect immunofluorescence, i.e., by incubating the patient's serum with stored sections of normal human kidneys. Complement levels are normal. About 20% of patients have low titers ofANCA, usually a perinuclear ANCA (Chap. 275), the pathophysiologic significance of which is unclear. Occasional patients have a positive cytoplasmic ANCA, which may signal the presence of coexistent extraglomerular renal vasculitis. Patients with lung involvement frequently have microcytic, hypochromic, iron-deficiency anemia from alveolar hemorrhage, and abnormal bilateral hilar and basilar interstitial shadowing on chest x-ray that may be difficult to distinguish from pulmonary edema or infection. The diffusion capacity for carbon dioxide is a useful tool for distinguishing among the latter diagnoses, being increased in patients with lung hemorrhage due to uptake of carbon monoxide by alveolar blood, and reduced in patients with infection or pulmonary edema.

Renal biopsy is the gold standard for diagnosis of anti-GBMnephritis. The typical morphologic pattern on light microscopy is diffuse proliferative glomerulonephritis, with focal necrotizing lesions and crescents in >50% of glomeruli (crescentic glomerulonephritis). Immunofluorescence microscopy reveals linear ribbon-like deposition of IgG along the GBM (Fig. 274-2). C3 is present in the same distribution in 70% of patients. Prominent IgG deposition along the tubule basement membrane and tubulointerstitial inflammation is found occasionally. Electron microscopy reveals nonspecific inflammatory changes without immune deposits. Typical features on lung biopsy include alveolar hemorrhage, disruption of alveolar septa, hemosiderin-laden macrophages, and linear staining of IgG along the alveolar capillary basement membrane.

It should be noted that Goodpasture's syndrome is not the only cause of the pulmonary-renal syndrome (i.e., renal failure and lung hemorrhage). Other important causes of this clinical complex include severe cardiac failure complicated by pulmonary edema (often blood-tinged) and prerenal azotemia; renal failure from any cause complicated by hypervolemia and pulmonary edema; immune complex-mediated vasculitides such as systemic lupus erythematosus (SLE), Henoch-Schonlein purpura, and cryoglobulinemia; pauci-immune vasculitides such as Wegener's granulomatosis and polyarteritis nodosa; infections such as Legionnaire's disease; and renal vein thrombosis with pulmonary embolism. In general, these disorders can be differentiated

by astute analysis of the clinical, serologic, and histopathologic findings.

TREATMENT

Prior to the introduction of immunosuppressive therapy, greater than 80% of patients with anti-GBMnephritis developedESRDwithin 1 year, and many patients died from pulmonary hemorrhage or complications of uremia. With early and aggressive use of plasmapheresis, glucocorticoids, cyclophosphamide, and azathioprine, renal and patient survival have improved dramatically. In general, emergency plasmapheresis is performed daily or on alternate days until anti-GBM antibodies are not detected in the circulation (usually 1 to 2 weeks). Prednisone (1 mg/kg per day) is started simultaneously, in combination with either cyclophosphamide (2 to 3 mg/kg per day) or azathioprine (1 to 2 mg/kg per day) to suppress new synthesis of anti-GBM antibodies. The speed of initiation of therapy is a critical determinant of outcome. One-year renal survival approaches 90% if treatment is started before serum creatinine exceeds 442 umol/L (5 mg/dL) and falls to about 10% if renal failure is more advanced. Patients who require dialysis at presentation rarely recover renal function. Serial anti-GBM titers are monitored to gauge response to therapy. Relapses are not unusual and are often heralded by rising antibody titers. In patients with ESRD, renal transplantation is a viable treatment option. Recurrence of anti-GBM nephritis in the allograft is extremely unusual provided that anti-GBM antibody titers have been consistently negative for 2 to 3 months prior to transplantation. However, in occasional patients with Alport's syndrome, when the allograft presents normal GBM components to the immune system of the recipient for the first time, anti-GBM nephritis can occur de novo in renal allografts.

Pauci-Immune Glomerulonephritis The major pauci-immune glomerulonephritides are *idiopathic renal-limited crescentic glomerulonephritis*, *microscopic polyarteritis nodosa*, and *Wegener's granulomatosis* (Fig. 274-1).RPGN is a more common clinical presentation than acute nephritic syndrome, and the usual pathology is necrotizing glomerulonephritis with crescents affecting>50% of glomeruli (crescentic glomerulonephritis). The marked overlap of clinical features and glomerular histopathology, and the presence of circulatingANCA in most patients, suggest that these entities are a spectrum of a single disease. Here, we focus on idiopathic renal-limited crescentic glomerulonephritis.**The ANCA-associated glomerulopathies with extrarenal features, namely Wegener's granulomatosis, Churg-Strauss syndrome, and microscopic polyarteritis nodosa, are discussed in Chap. 275.*

Idiopathic Renal-Limited Crescentic Glomerulonephritis This is more common in middle-aged and older patients and shows a slight male preponderance. Patients typically present withRPGN, nephritic syndrome being rare.ANCA, usually a perinuclear ANCA IgG with specificity for myeloperoxidase (Chap. 275), are detected in 70 to 90% of patients (Fig. 274-1). The erythrocyte sedimentation rate and C-reactive protein levels may be elevated; however, C3 levels are typically normal, and circulating immune complexes, cryoglobulins, and anti-GBMantibodies are not detected. Most patients have crescents on light microscopy, often associated with necrotizing glomerulonephritis. Immune deposits are scanty or absent. Immunofluorescence microscopy reveals abundant fibrin deposits within crescents (Fig. 274-2). Most cases are treated aggressively with glucocorticoids, with or without cyclophosphamide or azathioprine (Chap. 275).

NEPHROTIC SYNDROME

GENERAL FEATURES AND COMPLICATIONS

The *nephrotic syndrome* is a clinical complex characterized by a number of renal and extrarenal features, the most prominent of which are proteinuria of>3.5 g per 1.73 m_2 per 24 h (in practice, >3.0 to 3.5 g per 24 h), hypoalbuminemia, edema, hyperlipidemia, lipiduria, and hypercoagulability. It should be stressed that the key component is *proteinuria*, which results from altered permeability of the glomerular filtration barrier for protein, namely theGBM and the podocytes and their slit diaphragms. The other components of the nephrotic syndrome and the ensuing metabolic complications are all secondary to urine protein loss and can occur with lesser degrees of proteinuria or may be absent even in patients with massive proteinuria.

In general, the greater the proteinuria, the lower the serum albumin level. *Hypoalbuminemia* is compounded further by increased renal catabolism and inadequate, albeit usually increased, hepatic synthesis of albumin. The pathophysiology of *edema* formation in nephrotic syndrome is poorly understood. The *underfilling hypothesis* postulates that hypoalbuminemia results in decreased intravascular oncotic pressure, leading to leakage of extracellular fluid from blood to the interstitium. Intravascular volume falls, thereby stimulating activation of the renin-angiotensin-aldosterone axis and the sympathetic nervous system and release of vasopressin (antidiuretic hormone), and suppressing atrial natriuretic peptide release. These neural and hormonal responses promote renal salt and water retention, thereby restoring intravascular volume and triggering further leakage of fluid to the interstitium. This hypothesis does not, however, explain the occurrence of edema in many patients in whom plasma volume is expanded and the renin-angiotensin-aldosterone axis is suppressed. The latter finding suggests that *primary renal salt and water retention* may also contribute to edema formation in some cases.

Hyperlipidemia is believed to be a consequence of increased hepatic lipoprotein synthesis that is triggered by reduced oncotic pressure and may be compounded by increased urinary loss of proteins that regulate lipid homeostasis. Low-density lipoproteins and cholesterol are increased in the majority of patients, whereas very low density lipoproteins and triglycerides tend to rise in patients with severe disease. Although not proven conclusively, hyperlipidemia may accelerate atherosclerosis and progression of renal disease.

Hypercoagulability is probably multifactorial in origin and is caused, at least in part, by increased urinary loss of antithrombin III, altered levels and/or activity of proteins C and S, hyperfibrinogenemia due to increased hepatic synthesis, impaired fibrinolysis, and increased platelet aggregability. As a consequence of these perturbations, patients can develop spontaneous *peripheral arterial or venous thrombosis*, *renal vein thrombosis*, and *pulmonary embolism.* Clinical features that suggest acute renal vein thrombosis include sudden onset of flank or abdominal pain, gross hematuria, a left-sided varicocele (the left testicular vein drains into the renal vein), increased proteinuria, and an acute decline inGFR. Chronic renal vein thrombosis is usually asymptomatic. Renal vein thrombosis is particularly common (up to 40%) in patients with nephrotic syndrome

due to membranous glomerulopathy, membranoproliferative glomerulonephritis, and amyloidosis.

Other metabolic complications of nephrotic syndrome include *protein malnutrition* and iron-resistant *microcytic hypochromic anemia* due to transferrin loss. *Hypocalcemia* and secondary hyperparathyroidism can occur as a consequence of vitamin D deficiency due to enhanced urinary excretion of cholecalciferol-binding protein, whereas loss of thyroxine-binding globulin can result in *depressed thyroxine levels*. An increased susceptibility to *infection* may reflect low levels of IgG that result from urinary loss and increased catabolism. In addition, patients are prone to unpredictable changes in the *pharmacokinetics* of therapeutic agents that are normally bound to plasma proteins.

ETIOLOGY AND DIFFERENTIAL DIAGNOSIS

Proteinuria>150 mg per 24 h is abnormal and can result from a number of mechanisms. *Glomerular proteinuria* results from leakage of plasma proteins through a perturbed glomerular filtration barrier; *tubular proteinuria* results from failure of tubular reabsorption of low-molecular-weight plasma proteins that are normally filtered and then reabsorbed and metabolized by tubular epithelium; *overflow proteinuria* results from filtration of proteins, usually immunoglobulin light chains, that are present in excess in the circulation. Tubular proteinuria virtually never exceeds 2 g per 24 h and thus, by definition, never causes nephrotic syndrome. Overflow proteinuria should be suspected in patients with clinical or laboratory evidence of multiple myeloma or other lymphoproliferative malignancy. Suspicion is heightened when there is a discrepancy between proteinuria detected by dipsticks, which are sensitive to albumin but not light chains, and the sulfosalicylic acid precipitation method, which detects both.

Nephrotic syndrome can complicate any disease that perturbs the negative electrostatic charge or architecture of theGBM and the podocytes and their slit diaphragms. Six entities account for greater than 90% of cases of nephrotic syndrome in adults: minimal change disease (MCD), focal and segmental glomerulosclerosis (FSGS), membranous glomerulopathy,MPGN, diabetic nephropathy, and amyloidosis. Diabetic nephropathy and amyloidosis, being manifestations of systemic diseases, are discussed inChap. 275. *Renal biopsy* is a valuable tool in adults with nephrotic syndrome for establishing a definitive diagnosis, guiding therapy, and estimating prognosis. Renal biopsy is not required in the majority of children with nephrotic syndrome as most cases are due to MCD and respond to empiric treatment with glucocorticoids.

MINIMAL CHANGE DISEASE

This glomerulopathy accounts for about 80% of nephrotic syndrome in children of younger than 16 years and 20% in adults (Table 274-1). The peak incidence is between 6 and 8 years. Patients typically present with nephrotic syndrome and benign urinary sediment. Microscopic hematuria is present in 20 to 30%. Hypertension and renal insufficiency are very rare.

MCD(also called nil disease, lipoid nephrosis, or foot process disease) is so named because glomerular size and architecture are normal by light microscopy. Immunofluorescence studies are typically negative for immunoglobulin and C3. Mild

mesangial hypercellularity and sparse deposits of C3 and IgM may be detected. Occasionally, mesangial proliferation is associated with scanty IgA deposits, similar to those found in IgA nephropathy. However, the natural history of this variant and response to therapy resemble classic MCD. Electron microscopy reveals characteristic *diffuse effacement of the foot processes of visceral epithelial cells* (Fig. 274-3). This morphologic finding is referred to as foot process fusion in the older literature.

The etiology ofMCD is unknown and the vast majority of cases are idiopathic (Table 274-1). MCD occasionally develops after upper respiratory tract infection, immunizations, and atopic attacks. Patients with atopy and MCD have an increased incidence of HLA-B12, suggesting a genetic predisposition. MCD, often in association with interstitial nephritis, is a rare side effect of nonsteroidal anti-inflammatory drugs (NSAIDs), rifampin, and interferon-a. The occasional association with lymphoproliferative malignancies (such as Hodgkin's lymphoma), the tendency for idiopathic MCD to remit during intercurrent viral infection such as measles, and the good response of idiopathic forms to immunosuppressive agents (see below) suggest an immune etiology. In children, the urine contains albumin principally and minimal amounts of higher molecular weight proteins such as IgG anda_2-macroglobulin. This *selective proteinuria* in conjunction with foot process effacement suggests injury to podocytes and loss of the fixed *negative charge* in the glomerular filtration barrier for protein. Proteinuria is typically nonselective in adults, suggesting more extensive perturbation of membrane permeability.

TREATMENT

MCDis highly steroid-responsive and carries an excellent prognosis. Spontaneous remission occurs in 30 to 40% of childhood cases but is less common in adults. Approximately 90% of children and 50% of adults enter remission following 8 weeks of high-dose oral glucocorticoids. In a typical regimen using prednisone, children receive 60 mg/m_2 of body surface area daily for 4 weeks, followed by 40 mg/m_2 on alternate days for an additional 4 weeks; adults receive 1 to 1.5 mg/kg body weight per day for 4 weeks, followed by 1 mg/kg per day on alternate days for 4 weeks. Up to 90% of adults enter remission if therapy is extended for 20 to 24 weeks. Nephrotic syndrome relapses in over 50% of cases following withdrawal of glucocorticoids. Alkylating agents are reserved for the small number of patients who fail to achieve lasting remission. These include patients who relapse during or shortly after withdrawal of steroids (steroid-dependent) and those who relapse more than three times per year (frequently relapsing). In these settings, cyclophosphamide (2 to 3 mg/kg per day) or chlorambucil (0.1 to 0.2 mg/kg per day) is started after steroid-induced remission and continued for 8 to 12 weeks. Cytotoxic agents may also induce remission in occasional steroid-resistant cases. These benefits must be balanced against the risk of infertility, cystitis, alopecia, infection, and secondary malignancies, particularly in children and young adults. Azathioprine has not been proven to be a useful adjunct to steroid therapy. Cyclosporine induces remission in 60 to 80% of patients; it is an alternative to cytotoxic agents and an option in patients who are resistant to cytotoxic agents. Unfortunately, relapse is usual when cyclosporine is withdrawn, and long-term therapy carries the risk of nephrotoxicity and other side effects. Long-term renal and patient survival is excellent in MCD.

FOCAL AND SEGMENTAL GLOMERULOSCLEROSIS WITH HYALINOSIS

The pathognomonic morphologic lesion inFSGS is sclerosis with hyalinosis involving portions (segmental) of fewer than 50% (focal) of glomeruli on a tissue section. The incidence of idiopathic (primary) FSGS has increased over the past two decades so that it now accounts for about one-third of cases of nephrotic syndrome in adults and as many as one-half of cases of nephrotic syndrome in blacks. FSGS can complicate a number of systemic diseases and sustained glomerular capillary hypertension following nephron loss from any cause (Table 274-2 andChap. 273).

IdiopathicFSGStypically presents as nephrotic syndrome (~66%) or subnephrotic proteinuria (~33%) in association with hypertension, mild renal insufficiency, and an abnormal urine sediment that contains red blood cells and leukocytes. Proteinuria is nonselective in most cases.

Light microscopy of renal biopsy tissue revealsFSGSwith entrapment of amorphous hyaline material, a process that shows a predilection for juxtamedullary glomeruli. The sclerotic scars contain areas of glomerular capillary collapse and hyaline material composed of collagen types I, III, and IV. Adhesions occur between areas of capillary collapse and Bowman's capsule. Immunofluorescence studies are usually negative. Electron microscopy reveals evidence of damage to visceral epithelial cells, including swelling and detachment of podocytes from theGBM, effacement of foot processes, transition to foam cells, and overt cell degeneration and necrosis.

The etiology of primaryFSGS is unclear (Table 274-2). There is evidence that a circulating nonimmunoglobulin permeability factor triggers FSGS in at least a subgroup of patients. The latter individuals tend to be young and prone to develop early recurrence of FSGS following renal transplantation. Plasmapharesis has been employed with variable success to control the nephrotic syndrome in this group. The overlap of clinical and morphologic features betweenMCD and FSGS has prompted some authorities to speculate that they are a spectrum of morphologic manifestations of a single pathogenetic process. FSGS is a potential long-term consequence of nephron loss from any cause. It can complicate congenital renal diseases such as congenital oligomeganephronia, in which both kidneys have a reduced complement of nephrons, and congenital unilateral agenesis. In addition, FSGS may develop following acquired loss of nephrons from extensive surgical ablation of renal mass; reflux nephropathy; glomerulonephritis; interstitial nephritis; sickle cell disease; and the combined effects of ischemia, cyclosporine nephrotoxicity, and rejection on renal allograft function (Table 274-2). It appears that>50% of nephrons must be lost for development of secondary FSGS.

TREATMENT

In contrast toMCD, spontaneous remission of primaryFSGS is rare and renal prognosis is relatively poor. Proteinuria remits in only 20 to 40% of patients treated with glucocorticoids for 8 weeks. Uncontrolled studies suggest that up to 70% respond when steroid therapy is prolonged for 16 to 24 weeks. Cyclophosphamide and cyclosporine, when used at doses described above for MCD, induce partial or complete remission in 50 to 60% of steroid-responsive patients but are generally ineffective in steroid-resistant

cases. Poor prognostic factors at presentation include hypertension, abnormal renal function, black race, and persistent heavy proteinuria. Renal transplantation is complicated by recurrence of FSGS in the allograft in about 50% of cases and graft loss in about 10%. Factors associated with an increased risk of recurrence include a short time interval between the onset of the FSGS andESRD, young age at onset, and possibly the presence of mesangial hypercellularity on renal biopsy.

MEMBRANOUS GLOMERULOPATHY

This lesion is a leading cause of idiopathic nephrotic syndrome in adults (30 to 40%) and a rare cause in children (<5%). It has a peak incidence between the ages of 30 to 50 years and a male-female ratio of 2:1 (Table 274-3). Membranous glomerulopathy derives its name from the characteristic light-microscopic appearance on renal biopsy, namely diffuse thickening of theGBM, which is most apparent upon staining with periodic acid-Schiff (PAS). Most patients (>80%) present with nephrotic syndrome, proteinuria usually being nonselective. Microscopic hematuria is present in up to 50% of cases, but red blood cells casts, macroscopic hematuria, and leukocytes are extremely rare. Hypertension is documented in only 10 to 30% of patients at the outset but is common later in patients with progressive renal failure. Serologic tests such as antinuclear antibody,ANCA, anti-GBM antibody, cryoglobulin titers, and complement levels are normal in the idiopathic form.

Light microscopy of renal biopsy sections reveals diffuse thickening of theGBMwithout evidence of inflammation or cellular proliferation. Silver staining demonstrates characteristic *spikes* along the GBM, which represent projections of new basement membrane engulfing subepithelial immune deposits. Immunofluorescence reveals granular deposition of IgG, C3, and the terminal components of complement (C5b-9) along the glomerular capillary wall. Electron-microscopic appearances vary depending on the stage of disease. The earliest finding is the presence of subepithelial immune deposits (Fig. 274-3). As these deposits enlarge, spikes of new basement membrane extend out between the immune deposits and begin to engulf them. With time, the deposits are completely surrounded and incorporated into the basement membrane.

The pathogenesis of idiopathic human membranous glomerulopathy is incompletely understood. The presence of electron-dense immune deposits that contain IgG and C3 suggest an immune process. About one-third of adult membranous nephropathy occurs in association with systemic diseases such asSLE, infections such as hepatitis B, malignancy, and drug therapy with gold and penicillamine (Table 274-3).

Nephrotic syndrome remits spontaneously and completely in up to 40% of patients with membranous glomerulopathy. The natural history of another 30 to 40% is characterized by repeated relapses and remissions. The final 10 to 20% suffer a slow progressive decline inGFR that typically culminates inESRDafter 10 to 15 years. Presenting features that predict a poor prognosis include male gender, older age, hypertension, severe proteinuria and hyperlipidemia, and impaired renal function. Controlled trials of glucocorticoids have failed to show consistent improvement in proteinuria or renal protection. Cyclophosphamide, chlorambucil, and cyclosporine have each been shown to reduce proteinuria and/or slow the decline in GFR in patients with progressive disease in small or uncontrolled studies. These observations need to be confirmed in

controlled prospective studies. Transplantation is a successful treatment option for patients who reach ESRD.

MEMBRANOPROLIFERATIVE GLOMERULONEPHRITIS

This morphologic entity, also known as mesangiocapillary glomerulonephritis, is characterized by thickening of theGBM and proliferative changes on light microscopy (Table 274-4). Two major types are identified; both are characterized by a diffuse increase in mesangial cellularity and matrix, and by thickening and reduplication of the GBM such that the lobular pattern of the glomerular tuft is exaggerated. The hallmark of type IMPGN is the presence of subendothelial and mesangial deposits on electron microscopy that contain C3 and IgG or IgM; rarely, IgA deposits are demonstrated by immunofluorescence microscopy (Fig. 274-3). The hallmark of type II MPGN (dense deposit disease) is the presence of electron-dense deposits within the GBM and other renal basement membranes (shown by electron microscopy) that stain for C3, but little or no immunoglobulin.

Most patients with type IMPGNpresent with heavy proteinuria or nephrotic syndrome, active urinary sediment, and normal or mildly impairedGFR. C3 levels are usually depressed, and C1q and C4 levels are borderline or low. Type I MPGN is an immune-complex glomerulonephritis and can be associated with a variety of chronic infections (e.g., bacterial endocarditis, HIV, hepatitis B and C), systemic immune-complex diseases (e.g.,SLE, cryoglobulinemia), and malignancies (e.g., leukemias, lymphomas). Type I MPGN is a relatively benign disease, and 70 to 85% of patients survive without clinically significant impairment of GFR. There is no proven therapy for patients with progressive disease beyond eradicating the underlying infection, malignancy, or systemic disease, when possible. The incidence of type I MPGN appears to be falling, possibly because the overall incidence of hepatitis C infection has fallen dramatically in western society over the past decade.

Type IIMPGN can also present with proteinuria and nephrotic syndrome; however, some patients present with nephritic syndrome,RPGN, or recurrent macroscopic hematuria. Type II MPGN is an autoimmune disease in which patients have an IgG autoantibody, termed *C3 nephritic factor*, that binds to C3 convertase, the enzyme that metabolizes C3, and renders it resistant to inactivation (Chap. 273). Type II MPGN runs a variable course; theGFRremains stable in some patients and declines gradually toESRDover 5 to 10 years in others. There is no effective therapy for this disease.

FIBRILLARY-IMMUNOTACTOID GLOMERULOPATHY

This emerging clinicopathologic entity accounts for 1% of diagnoses in most large renal biopsy series. Virtually all patients present with proteinuria, and>50% have nephrotic syndrome. The majority of patients also have hematuria, hypertension, and renal insufficiency. The light-microscopic appearances vary from mesangial expansion and basement membrane thickening withPAS-positive material to proliferative and crescentic glomerulonephritis. On electron microscopy, this PAS-positive material is observed to be composed of randomly arranged (fibrillary glomerulopathy) or organized bundles (immunotactoid glomerulopathy) of microfibrils and microtubules, the compositon of which has yet to be defined. The etiology of fibrillary-immunotactoid

glomerulopathy remains to be determined. Patients with the immunotactoid variant have an increased incidence of lymphoproliferative malignancy. There is no proven therapy for fibrillary-immunotactoid glomerulopathy, and many patients progress to ESRDover 1 to 10 years. Transplantation appears to be a viable option in the latter setting.

MESANGIAL PROLIFERATIVE GLOMERULONEPHRITIS

In 5 to 10% of patients with idiopathic nephrotic syndrome, renal biopsy reveals a diffuse increase in glomerular cellularity, predominantly due to proliferation of mesangial and endothelial cells, and infiltration by monocytes. Findings on immunofluorescence microscopy vary and include deposits of IgA, IgG, IgM, and/or complement, or absence of immune reactants. It is likely that this morphologic entity is, in fact, a heterogeneous group of diseases that includes atypical forms ofMCD andFSGS and milder or resolving forms of the immune-complex and pauci-immune glomerulopathies described above under nephritic syndrome andRPGN. In keeping with the heterogeneity of this diagnosis, the prognosis is variable. In general, persistent nephrotic-range proteinuria signals a poor prognosis, with many patients progressing toESRDover 10 to 20 years despite immunosuppressive therapy.

TREATMENT

Nephrotic Syndrome and Complications The treatment of nephrotic syndrome involves (1) specific treatment of the underlying morphologic entity and, when possible, causative disease (see above); (2) general measures to control proteinuria if remission is not achieved through immunosuppressive therapy and other specific measures; and (3) general measures to control nephrotic complications.

General measures may be warranted to control proteinuria in nephrotic syndrome if patients do not respond to immunosuppressive therapy and other specific measures and suffer progressive renal failure or severe nephrotic complications. Nonspecific measures that may reduce proteinuria include *angiotensin-converting enzyme (ACE) inhibitors*, and*NSAIDs*. The first of these measures aim to reduce proteinuria and slow the rate of progression of renal failure by lowering intraglomerular pressure and preventing the development of hemodynamically mediated focal segmental glomerulosclerosis. There is conclusive evidence that ACE inhibitors are renoprotective in human diabetic nephropathy (Chap. 275) and that ACE inhibitors slow the development of secondaryFSGS in experimental animals. Their role in the treatment of nephrotic syndrome in other settings is unproven. NSAIDs also reduce proteinuria in some patients with nephrotic syndrome, probably by altering glomerular hemodynamics andGBMpermeability characteristics. This potential benefit must be balanced against the risk of inducing acute renal failure, hyperkalemia, salt and water retention, and other side effects.

Complications of nephrotic syndrome that may require treatment include edema, hyperlipidemia, thromboembolism, malnutrition, and vitamin D deficiency. Edema should be managed cautiously by moderate *salt restriction*, usually 1 to 2 g/day, and the judicious use of *loop diuretics*. It is unwise to remove >1.0 kg of edema per day as more aggressive diuresis may precipitate intravascular volume depletion and prerenal azotemia. Administration of salt-poor albumin is not recommended as most is excreted

within 24 to 48 h. Whereas many nephrologists advocate lowering low-density lipoproteins and cholesterol levels with *lipid-lowering drugs* to prevent accelerated atherosclerosis and slow the rate of decline ofGFR, the value of such interventions in this setting has not been conclusively shown. *Anticoagulation* is indicated for patients with deep venous thrombosis, arterial thrombosis, and pulmonary embolism. Patients may be relatively resistant to heparin as a consequence of antithrombin III deficiency. Renal vein and vena caval angiography are probably indicated only when embolization occurs on anticoagulation and insertion of a caval filter is contemplated. There is no consensus regarding the optimal *diet* for patients with nephrotic syndrome. High-protein diets to prevent protein malnutrition are now in disfavor, since protein supplements have little, if any, effect on serum albumin levels and may hasten the progression of renal disease by increasing urinary protein excretion. The potential value of dietary protein restriction for reducing proteinuria must be balanced against the risk of contributing to malnutrition. *Vitamin D* supplementation is advisable in patients with clinical or biochemical evidence of vitamin D deficiency.

ASYMPTOMATIC ABNORMALITIES OF THE URINARY SEDIMENT

HEMATURIA

Most asymptomatic glomerular hematuria is due to *IgA nephropathy* (Berger's disease) or *thin basement membrane (TBM) disease* (benign hematuria). A rarer but more ominous cause of isolated hematuria is *Alport's syndrome*. The latter is the most common form of hereditary nephritis, is usually transmitted as an X-linked dominant trait, and is associated with sensorineural deafness, ophthalmologic abnormalities, and progressive renal insufficiency (Chap. 275). TBM disease is sometimes familial but, in contrast to Alport's syndrome, is usually a benign disorder. Asymptomatic hematuria may also be the presenting feature of indolent forms of most other primary and secondary proliferative glomerulopathies (Fig. 274-1). Glomerular hematuria must be distinguished from a variety of renal parenchymal and extrarenal causes of hematuria. It is particularly important to exclude malignancy of the kidney or urinary tract, particularly in older male patients (Chap. 94). Other potential diagnoses include vascular, cystic, and tubulointerstitial diseases; papillary necrosis; hypercalciuria and hyperuricosuria; benign prostatic hypertrophy; and renal calculi. Important clues to the presence of glomerular hematuria are the presence of urinary red blood cell casts, dysmorphic urinary red blood cells, proteinuria of greater than 2.0 g per 24 h, and clinical or serologic evidence of nephritic syndrome,RPGN, or a compatible systemic disease.

IgA Nephropathy (Berger's Disease) IgA nephropathy is the most common glomerulopathy worldwide and accounts for 10 to 40% of glomerulonephritis in most series (Table 274-5). The disease is particularly common in southern Europe and Asia and appears to be more common in blacks than whites. Familial clustering has been reported but is rare. No consistent HLA association has emerged, although HLA-B35 appears to be more common in French patients. Most cases are idiopathic. The renal and serologic abnormalities in IgA nephropathy and Henoch-Schonlein purpura (Chap. 275) are indistinguishable, and most authorities consider these to be a spectrum of a single disease. Less commonly, IgA nephropathy is found in association with systemic diseases, including chronic liver disease, Crohn's disease, gastrointestinal adenocarcinoma, chronic obstructive bronchiolitis, idiopathic interstitial pneumonia,

dermatitis herpetiformis, mycosis fungoides, leprosy, ankylosing spondylitis, relapsing polychondritis, and Sjogren's syndrome. In many of these conditions, IgA is deposited in the glomerulus without inducing inflammation, and this may be a clinically insignificant consequence of perturbed IgA homeostasis.

Patients with IgA nephropathy typically present with gross hematuria, often 24 to 48 h after a pharyngeal or gastrointestinal infection, vaccination, or strenuous exercise. Other cases are diagnosed upon detection of microscopic hematuria during routine physical examinations. Hypertension (20 to 30%) and nephrotic syndrome (~10%) are unusual at presentation. Light microscopy of renal biopsy specimens typically shows mesangial expansion by increased matrix and cells. Diffuse proliferation, cellular crescents, interstitial inflammation, and areas of glomerulosclerosis may be evident in severe cases. The diagnostic finding, for which the disease is named, is mesangial deposition of IgA, detected by immunofluorescence microscopy. C3 is usually detected in the area of immune deposits, and IgG is observed in 50% of cases. Electron microscopy reveals electron-dense deposits in the mesangium and, in severe cases, these extend into the paramesangial subendothelial space. The pathogenesis of IgA nephropathy is incompletely understood.

TREATMENT

There is no proven therapy for IgA nephropathy. A recent, relatively large randomized controlled trial suggested a benefit of fish oils in patients with progressive disease and heavy proteinuria; however, this experience has not been universal. Some authorities advocate a trial of high-dose glucocorticoids with or without cytotoxic agents in patients with severe nephrotic syndrome and those with nephritic syndrome orRPGN and evidence of active inflammation on renal biopsy.

IgA nephropathy typically smolders for decades, with patients often suffering exacerbations of hematuria and renal impairment during intercurrent infections. As many as 20 to 50% of patients developESRDwithin 20 years. Clinical predictors of a poor prognosis include older age, male sex, hypertension, nephrotic-range proteinuria, and renal insufficiency at presentation. Histologic features that predict an aggressive course include diffuse severe disease, extracapillary proliferation (crescents), extension of immune attack into the paramesangial subendothelial space, glomerulosclerosis, interstitial fibrosis, and arteriolar hyalinosis.

Thin Basement Membrane Disease (Benign Hematuria) This disorder can be heredofamilial or sporadic and is as common as IgA nephropathy in some series of asymptomatic hematuria. When familial, it is usually inherited as an autosomal dominant trait and is due to a defect in the gene encoding the a4 chain of type IV collagen.TBMdisease typically manifests in childhood as persistent hematuria. Intermittent hematuria and exacerbation of hematuria during upper respiratory tract infections have also been reported. The kidney is normal on light and immunofluorescence microscopy. TheGBM is thin (usually <275 nm in children and<300 nm in adults) by comparison with normal subjects. TBM disease is usually a benign condition, and progressive renal impairment or proteinuria should prompt a search for an alternative diagnosis. A small proportion of patients do, however, appear to develop hypertension and focal glomerulosclerosis upon long-term follow-up. The molecular

basis for the sporadic form of TBM disease has not been determined.

PROTEINURIA

Between 0.5 and 10% of the population have isolated proteinuria, defined as proteinuria in the presence of an otherwise normal urinary sediment, a radiologically normal urinary tract, and the absence of known renal disease. The majority of these patients excrete <2 g of protein per day, and more than 80% have an excellent prognosis (*benign isolated proteinuria*). A minority (10 to 25%) are found to have persistent proteinuria (*persistent isolated proteinuria*), some of whom develop progressive renal insufficiency over 10 to 20 years.

Benign Isolated Proteinuria The major categories of benign isolated proteinuria are idiopathic transient proteinuria, functional proteinuria, intermittent proteinuria, and postural proteinuria. *Idiopathic transient proteinuria* is usually observed in young adults and refers to dipstick-positive proteinuria in an otherwise healthy individual that disappears spontaneously by the next clinic visit. *Functional proteinuria* refers to transient proteinuria during fever, exposure to cold, emotional stress, congestive cardiac failure, or obstructive sleep apnea. This phenomenon is presumed to be mediated through changes in glomerular ultrafiltration pressure and/or membrane permeability. Patients with *intermittent proteinuria* have proteinuria in approximately half of their urine samples in the absence of other renal or systemic abnormalities. *Postural proteinuria* is proteinuria (usually<2.0 g per 24 h) that is evident only in the upright position. This disorder affects 2 to 5% of adolescents and may be transient (~80%) or fixed (~20%). Fixed postural proteinuria resolves within 10 to 20 years in most cases. In each of these conditions, renal biopsy reveals either normal renal parenchyma or mild and nonspecific changes involving podocytes or the mesangium. All carry an excellent prognosis.

Persistent Isolated Proteinuria Isolated proteinuria detected on multiple ambulatory clinic visits in both the recumbent and upright position usually signals a structural renal lesion. Virtually all glomerulopathies that induce nephrotic syndrome (see above) can cause persistent isolated proteinuria. The most common lesion on renal biopsy is mild mesangial proliferative glomerulonephritis with or without focal and segmental glomerulosclerosis (30 to 70%), followed by focal or diffuse proliferative glomerulonephritis (~15%) and interstitial nephritis (~5%). Although this clinical entity carries a worse prognosis than benign isolated proteinuria, the prognosis is still relatively good, with only 20 to 40% of patients developing renal insufficiency after 20 years. Furthermore, progression to ESRDis extremely rare. It is wise to exclude monoclonal gammopathy by urinary electrophoresis in older patients.

CHRONIC GLOMERULONEPHRITIS

This syndrome is characterized by persistent proteinuria and/or hematuria and renal insufficiency that progresses slowly over years. Chronic glomerulonephritis usually comes to light (1) upon routine urinalysis, (2) when routine blood tests reveal unexplained anemia or elevated blood urea nitrogen and creatinine, (3) following discovery of bilateral small kidneys on abdominal imaging, (4) during evaluation for secondary causes of hypertension, or (5) during a clinical exacerbation of glomerulonephritis triggered by pharyngitis (synpharyngitic) or other infections. Chronic

glomerulonephritis can be a manifestation of virtually all of the major glomerulopathies. Renal biopsy typically reveals a variable combination of proliferative, membranous, and sclerotic changes, depending on the causative glomerulopathy. Arteriosclerosis, induced by secondary hypertension, is a common finding in the renal vasculature. Tubulointerstitial inflammation and scarring are frequent additional findings and portend a poor prognosis. Glomerular hypertension and hyperfiltration through remnant functioning nephrons can hasten progression toESRD(Chap. 273). Treatment is directed at lowering systemic and glomerular hypertension, usually with anACEinhibitor, and controlling extracellular fluid volume, anemia, metabolic abnormalities, and the uremic syndrome through judicious use of diuretics, erythropoietin, and dietary modification (Chap. 270). Some patients develop ESRD and require renal replacement therapy with dialysis or transplantation.

275. GLOMERULOPATHIES ASSOCIATED WITH MULTISYSTEM DISEASES - *Yvonne M. O'Meara, Hugh R. Brady, Barry M. Brenner*

An array of multisystem diseases can cause glomerular injury, with glomerulopathy being either the dominant presenting feature or a relatively benign and clinically insignificant manifestation that is overshadowed by involvement of other organs. Glomerulopathies associated with multisystem diseases are often classified as *secondary* glomerulopathies to distinguish them from the *primary* glomerulopathies (Chap. 274) in which the pathology is limited to the kidneys. It should be emphasized, however, that most morphologic patterns of glomerular injury (see Table 273-1) can manifest as a renal-limited process (i.e., primary) or as part of a systemic disease (i.e., secondary). The diagnostic approach to glomerular disease involves identifying the presenting clinical syndrome (e.g., nephritic, nephrotic), defining the pathologic features (e.g., proliferative, crescentic, membranous), and attempting to establish the specific disease that provoked glomerular injury [e.g., systemic lupus erythematosus (SLE), Henoch-Schonlein purpura].

In this**chapter**, we focus on the epidemiology, clinicopathologic features, and management of the major glomerulopathies associated with systemic diseases.**The pathogenesis of glomerular injury is discussed in Chap. 273, and the overall place of the major glomerulopathies in the differential diagnosis of the major renal syndromes is described in Chap. 274.*

DIABETIC NEPHROPATHY (See also Chaps. 273 and 333)

Diabetic nephropathy is the leading cause of end-stage renal disease (ESRD) in western societies and accounts for 30 to 35% of patients on renal replacement therapy in North America. Type 1 diabetes mellitus (type 1 DM; formerly, insulin-dependent diabetes mellitus) and type 2 diabetes mellitus (type 2 DM; formerly, non-insulin-dependent diabetes mellitus) affect 0.5 and 4% of the population, respectively. Nephropathy complicates 30% of cases of type 1 DM and approximately 20% of cases of type 2 DM. However, most diabetic patients with ESRD have type 2 DM because of the greater prevalence of type 2 DM worldwide (90% of all individuals with diabetes). Risk factors for the development of diabetic nephropathy include hyperglycemia, systemic hypertension, glomerular hypertension and hyperfiltration, proteinuria, and possibly cigarette smoking, hyperlipidemia, and gene polymorphisms affecting the activity of the renin-angiotensin-aldosterone axis. For reasons that are unclear, ESRD from diabetic nephropathy is more common in blacks with type 2 DM than in whites (4:1 ratio), whereas the reverse is true for type 1 DM.

The pathophysiology, clinical features, and morphology of diabetic nephropathy are similar in type 1 and type 2DM, although the time course may be condensed in type 2 DM. Glomerular hypertension and hyperfiltration are the earliest renal abnormalities in experimental and human diabetes and are observed within days to weeks of diagnosis. Microalbuminuria, so named because the abnormal albumin excretion of 30 to 300 mg/24 h is below the limits of detection of standard dipsticks, develops after approximately 5 years of sustained glomerular hypertension and hyperfiltration in type 1 DM. Microalbuminuria is the first manifestation of injury to the glomerular filtration barrier and predicts the development of overt nephropathy. Dipstick-positive proteinuria,

ultimately reaching nephrotic levels, typically develops 5 to 10 years after the onset of microalbuminuria (i.e., 10 to 15 years after the onset of diabetes) and is associated with hypertension and progressive loss of renal function. In addition, patients can display features of tubulointerstitial disease such as hyperkalemia and type IV renal tubular acidosis.ESRDtypically develops 5 to 10 years after the development of overt nephropathy. As noted above, the course of diabetic nephropathy may be shorter in type 2 DM, and many patients present with established nephropathy and hypertension. Diabetic nephropathy is usually diagnosed on clinical grounds without a renal biopsy. Supportive clues are the presence of normal sized or enlarged kidneys, evidence of proliferative diabetic retinopathy, and a bland urinary sediment. Retinopathy is found in 90 and 60% of patients with type 1 and type 2 DM, respectively, who develop nephropathy.

The earliest morphologic abnormalities in diabetic nephropathy are thickening of the glomerular basement membrane (GBM) and expansion of the mesangium due to accumulation of extracellular matrix. With time, matrix accumulation becomes diffuse and is evident as eosinophilic, periodic acid Schiff-positive glomerulosclerosis on renal biopsy. Prominent areas of nodular matrix expansion (nodular glomerulosclerosis, the classic Kimmelsteil-Wilson lesion) are often superimposed on this background. The glomeruli and kidneys are typically normal or increased in size, distinguishing diabetic nephropathy from most other forms of chronic renal insufficiency (renal amyloidosis and polycystic kidney disease being other important exceptions). Immunofluorescence microscopy may reveal deposition of IgG along the GBM in a linear pattern, but this does not appear to be immunopathogenetic as in anti-GBM disease. Immune deposits are not seen. The renal vasculature typically displays evidence of atherosclerosis, as a consequence of hyperlipidemia, and hypertensive arteriosclerosis.

TREATMENT

Therapy is aimed at retarding the progression of nephropathy through control of blood sugar, systemic blood pressure, and glomerular capillary pressure. Glycemic control is achieved through regulation of diet and administration of oral hypoglycemic agents and insulin (Chap. 333). Angiotensin-converting enzyme (ACE) inhibitors are the drugs of choice as they control both systemic hypertension and intraglomerular hypertension by inhibiting the actions of angiotensin II on the systemic vasculature and renal efferent arterioles. ACE inhibitors also attenuate the stimulatory effect of angiotensin II on glomerular cell growth and matrix production. Because ACE inhibitors have been shown conclusively to delay the time toESRD by 50% in patients with type 1DM in a large randomized controlled trial and to delay progression significantly in type 2 DM, it is felt that all patients with diabetes should receive an ACE inhibitor on the development of microalbuminuria, even in the absence of systemic hypertension (Fig. 275-1). However, approximately 80% of patients with diabetes require more than one drug to control systemic hypertension, and aggressive lowering of blood pressure in these patients retards not only the rate of progression of nephropathy, but also the rate of progression of other complications of DM.

Diabetic nephropathy is the most common cause ofESRDrequiring renal replacement therapy, and patients with diabetes have the highest annual mortality rate (20 to 30%) of any group on dialysis, in large part as a result of accelerated atherosclerosis. The

survival rates of younger patients undergoing either peritoneal dialysis or hemodialysis are comparable; however, older patients with diabetes appear to have a higher mortality rate on peritoneal dialysis. Transplantation is the preferred mode of renal replacement therapy in patients who are otherwise medically suitable.

IMMUNOLOGICALLY MEDIATED MULTISYSTEM DISEASES

The glomerulus is a frequent target of injury in a variety of immunologically mediated multisystem diseases, particularly systemic vasculitis andSLE. Systemic vasculitis is usually classified according to the size of the inflamed vessel (Chap. 317). The major *large vessel* vasculitides are Takayasu's disease and giant cell arteritis. Glomerular injury is exceedingly rare in these diseases.

CLASSIC POLYARTERITIS NODOSA(See alsoChap. 317)

The typical glomerular lesion in classic polyarteritis nodosa (PAN) is ischemic collapse and obsolescence. Characteristic clinical and serologic features are hypertension, a bland urine sediment with subnephrotic proteinuria, slowly progressive renal insufficiency, normal serum complement levels, and absence of antineutrophil cytoplasmic antibodies (ANCA). Treatment with glucocorticoids and immunosupressive agents, such as cyclophosphamide, affords a 5-year patient survival of approximately 80%, as compared with 10% in untreated cases.

ANCA-ASSOCIATED SMALL-VESSEL VASCULITIS

The ANCA-associated small-vessel vasculitides are Wegener's granulomatosis, the microscopic and Churg-Strauss variants of polyarteritis nodosa, and pauci-immune renal-limited glomerulonephritis. These diseases share a number of clinocopathologic and serologic features and may represent a spectrum of manifestations of a single disease. They are more common in whites and older patients (mean age 57 years) and show a slight male preponderance. Their incidence peaks in the winter months, and many patients have a viral-like prodrome, suggesting a pathogenetic role for an infective agent. Patients typically present with nonspecific constitutional symptoms and signs such as lethargy, malaise, anorexia, weight loss, fever, arthralgias, and myalgias. Nonspecific laboratory abnormalities include a rapid sedimentation rate, elevated C-reactive protein, leukocytosis, thrombocytosis, and normochromic, normocytic anemia. Serum complement levels are typically normal.

The majority of patients with these conditions have circulatingANCA. It is not clear whether ANCA are involved in the pathogenesis of vasculitis or merely represent an epiphenomenon of the vasculitic process, and there is debate whether serial ANCA titers are useful for monitoring disease activity and predicting relapse. Some ANCA activate cytokine-primed neutrophils in vitro and provoke them to injure endothelial cells, suggesting a pathogenetic role (Chap. 273). ANCA are not entirely specific for vasculitis and are also found, albeit at low titers, in some patients (~20%) with anti-GBMdisease and in patients with inflammatory bowel disease, primary biliary cirrhosis, and other autoimmune disorders.

Patients withANCA-associated renal disease usually present with a nephritic urine

sediment and moderate proteinuria. Renal dysfunction can vary from a mild decrement in glomerular filtration rate (GFR) to rapidly progressive glomerulonephritis (RPGN). Renal biopsy typically reveals focal, segmental, necrotizing glomerulonephritis with crescent formation. Immunofluorescence and electron microscopy are remarkable for the paucity or absence of immunoglobulin, complement, and immune deposits: so-called pauci-immune glomerulonephritis. These findings are in stark contrast to the prominent granular deposition of IgG and C3 in immune-complex glomerulonephritides such as Henoch-Schonlein purpura and lupus nephritis. ANCA-associated vasculitis is usually responsive to combined therapy with glucocorticoids and cyclophosphamide, and the 5-year patient survival rate usually exceeds 75%. The distinguishing features of individual ANCA-associated renal diseases are summarized below.

Wegener's Granulomatosis (See also Chap. 317) Renal injury occurs in 80% of patients with Wegener's granulomatosis and varies from indolent smoldering inflammation to rapidly progressive renal failure. Cytoplasmic ANCA are detected at presentation in 80% of patients with renal disease and in 10% more on follow-up. Renal biopsy typically reveals focal, segmental, necrotizing pauci-immune glomerulonephritis with crescent formation. In contrast to the lung, granulomas are rarely seen in the kidney.

TREATMENT

Glucocorticoids and cyclophosphamide are the mainstays of treatment and dramatically ameliorate glomerular injury. Steroids are usually administered initially by pulse intravenous therapy on three consecutive days, followed by a daily oral dose of about 1 mg/kg body weight tapered to zero over 3 to 6 months. Cyclophosphamide is typically administered orally at a daily dose of 1 to 2 mg/kg or as monthly intravenous pulses of 1 g/m_2 of body surface area. Plasmapheresis may be a useful adjunct in patients with severe nephritis requiring dialysis. As many as 30% of patients relapse after treatment-induced remission. A persistently elevated or rising ANCA titer may predict relapse in individual patients; however, this relationship is not strong enough to justify treatment based on titers alone. Recent studies demonstrate that administration of trimethoprim-sulfamethoxazole reduces the relapse rate, possibly by eradicating nasal carriage of *Staphylococcus aureus*. Dialysis and renal transplantation afford excellent survival in patients with ESRD. Recurrence of Wegener's granulomatosis in the allograft is rare. ACE inhibitors may help to slow the progression to end-stage renal failure.

Microscopic Polyarteritis Nodosa (See also Chap. 317) Microscopic PAN is a systemic disease characterized by leukocytoclastic vasculitis involving multiple organ systems including the lungs, skin, joints, and kidneys. Clinical renal disease ranges from a nephritic urinary sediment with mild impairment of GFR to RPGN. The usual histopathologic lesion is pauci-immune focal segmental necrotizing and crescentic glomerulonephritis. Circulating ANCA are detected in 70 to 80% of patients at presentation, with cytoplasmic and perinuclear ANCA being equally prevalent. The treatment of microscopic PAN involves glucocorticoids and cyclophosphamide, as for Wegener's granulomatosis. Plasmapheresis may benefit patients with severe acute renal failure or massive pulmonary hemorrhage.

Churg-Strauss Syndrome (See also Chap. 317) Clinical renal involvement in

Churg-Strauss syndrome is relatively infrequent and usually limited to mild proteinuria and hematuria. Evolution to chronic renal failure is rare. Renal biopsy most frequently reveals extraglomerular pathology, with involvement of the renal vasculature and tubulointerstitium by granulomatous vasculitis. Focal segmental glomerulonephritis with crescents is also seen. A minority of patients have focal segmental necrotizing glomerulonephritis.

Henoch-Schonlein Purpura (See also Chap. 317) Extrarenal features of Henoch-Schonlein purpura include a petechial rash on the extremities, arthropathy, and abdominal pain. Nephritis is present in 80% of patients and manifests as a nephritic urine sediment and moderate proteinuria. Macroscopic hematuria and nephrotic-range proteinuria are uncommon. Light-microscopic appearances can vary from mild mesangial proliferation and expansion to diffuse proliferation with glomerular crescents. The glomerular lesion is identical to that found in IgA nephropathy (Berger's disease; seeChap. 274), suggesting that Henoch-Schonlein nephritis and IgA nephropathy are a spectrum of manifestations of a single disease. The *sine qua non* for diagnosis is the presence of mesangial IgA deposition on immunofluorescence microscopy. IgG and C3 are also detected. Electron microscopy reveals mesangial immune deposits. Immune complexes may also be present in the peripheral glomerular capillary wall and paramesangial areas. Biopsy of involved skin reveals dermal IgA deposition and leukocytoclastic vasculitis. IgA deposition is also seen in areas of uninvolved skin.

TREATMENT

Since there is no proven therapy for Henoch-Schonlein nephritis, treatment is supportive. Steroids and/or cytotoxic agents are often tried in patients with severe disease, but without compelling scientific evidence to support their use. The disease typically undergoes clinical exacerbations and remissions in the first year and then enters long-term remission. The prognosis is generally excellent; chronic renal failure and persistent hypertension occur in fewer than 10% of patients.

ESSENTIAL MIXED CRYOGLOBULINEMIA (See alsoChap. 317)

Renal involvement is most common with the mixed cryoglobulinemias (types II and III), which are more common in females and usually begin in the sixth decade. Most patients present with a variable combination of leukocytoclastic vasculitis, skin ulcerations, arthralgias, fatigue, and Raynaud's phenomenon. Renal disease is a complication in 50% of patients and usually develops after 12 to 24 months. The typical clinical renal manifestations are nephrotic-range proteinuria, microscopic hematuria, and hypertension. Acute nephritic syndrome occurs in 20 to 30%, and oliguric acute renal failure in about 5% of patients with renal disease. The characteristic morphologic lesions are diffuse mesangial proliferative or membranoproliferative glomerulonephritis. The glomerular capillaries frequently contain eosinophilic hyaline "pseudothrombi" composed of precipitated immunoglobulins. Granular deposition of IgG, IgM, and C3 is usually prominent on immunofluorescence microscopy. Electron microscopy typically reveals subendothelial deposits containing microfibrils and microtubules that display a characteristic "thumbprint" appearance.

Circulating levels of C3, C4, and CH50 are depressed in about 80% of patients with

renal involvement, and a transient antinuclear antibody (ANA) (speckled pattern) is sometimes detected. Abnormal liver function tests are found in about 15% of patients at presentation and in up to 50% subsequently. It now appears that most patients with essential mixed cryoglobulinemia (EMC) (i.e., idiopathic) are chronically infected with hepatitis C virus (HCV). In keeping with a pathogenetic role for this virus, HCV RNA has been isolated from the serum of patients with EMC, indicating active infection, and anti-HCV antibodies have been detected in both the serum and cryoprecipitates in association with viral antigens.

TREATMENT

Traditionally, glucocorticoids, with or without cyclophosphamide, and plasmapheresis were the standard treatment forEMC. Recent reports indicate that interferon a controls viral replication and stabilizes renal function in most patients infected with EMC andHCV. Unfortunately, most patients relapse when interferon ais discontinued, a major problem given the prohibitive cost of the drug. In general, patient and renal survival are good in EMC, with 75% of patients being alive at 10 years.

SYSTEMIC LUPUS ERYTHEMATOSUS (See also Chap. 311)

Renal involvement is clinically evident in 40 to 85% of patients withSLE; it varies from isolated abnormalities of the urinary sediment to full-blown nephritic or nephrotic syndrome or chronic renal failure. Most glomerular injury is triggered by the formation of immune complexes within the glomerular capillary wall; however, thrombotic microangiopathy may be the dominant reason for renal dysfunction in a small subset of patients with the antiphospholipid antibody syndrome.

Immune-Complex-Mediated Lupus Nephritis The renal biopsy has proven very useful for identifying the different patterns of immune-complex glomerulonephritis inSLE, which are diverse, portend different prognoses, and do not necessarily correlate with the clinical findings. Indeed, clinically silent lupus nephritis is well described in which the urinalysis is virtually normal but renal biopsy demonstrates varying degrees of injury.

The World Health Organization categorizes lupus nephritis into six histologic classes. *Class I* consists of a normal biopsy on light microscopy with occasional mesangial deposits on immunofluorescence microscopy. Patients in this category usually do not have clinical renal disease. Patients with *class II* or mesangial lupus nephritis have prominent mesangial deposits of IgG, IgM, and C3 on immunofluorescence and electron microscopy. Mesangial lupus nephritis is designated as class IIA when the glomeruli are normal by light microscopy and class IIB when there is mesangial hypercellularity. Microscopic hematuria is common with this lesion, and 25 to 50% of patients have moderate proteinuria. Nephrotic syndrome is not seen, and renal survival is excellent (>90% at 5 years). *Class III* describes focal segmental proliferative lupus nephritis with necrosis or sclerosis affecting fewer than 50% of glomeruli. Up to one-third of patients have nephrotic syndrome, and glomerular filtration is impaired in 15 to 25%. In *class IV* or diffuse proliferative lupus nephritis, most glomeruli show cell proliferation, often with crescent formation. Other features on light microscopy include fibrinoid necrosis and "wire loops," which are caused by basement membrane thickening and mesangial interposition between basement membrane and endothelial cells. Deposits of IgG, IgM,

IgA, and C3 are evident by immunofluorescence, and crescents stain positive for fibrin. Electron microscopy reveals numerous immune deposits in mesangial, subepithelial, and subendothelial locations. Tubuloreticular structures are frequently seen in endothelial cells. These are not specific for lupus nephritis and also occur in HIV-associated nephropathy. Electron microscopy may also reveal curvilinear parallel arrays of microfibrils, measuring approximately 10 to 15 nm in diameter, with "thumbprinting," similar to those seen in cryoglobulinemia. Nephrotic syndrome and renal insufficiency are present in at least 50% of patients with class IV disease. Diffuse proliferative lupus nephritis is the most aggressive renal lesion inSLE, and as many as 30% of these patients progress to terminal renal failure. *Class V* is termed membranous lupus nephritis because of its similarity to idiopathic membranous glomerulopathy. Thickening of theGBM is evident by light microscopy. Electron microscopy reveals predominant subepithelial deposits in addition to subendothelial and mesangial deposits. Proliferative changes may also be evident, but the predominant pattern is that of membranous glomerulopathy. Most patients present with nephrotic syndrome (90%), but significant impairment ofGFR is relatively unusual (10%). Tubulointerstitial changes such as active infiltration by inflammatory cells, tubular atrophy, and interstitial fibrosis are seen to varying degrees in lupus nephritis and are most severe in classes III and IV, especially in patients with long-standing disease. *Class VI* probably represents the end stages of proliferative lupus nephritis and is characterized by diffuse glomerulosclerosis and advanced tubulointerstitial disease. These patients are often hypertensive, may have nephrotic syndrome, and usually have impaired GFR.

Transformation from one class to another is relatively frequent. For example, class III often progresses to class IV spontaneously, and class IV can transform to class II or class V after treatment. Class II and class V lupus nephritis may predate other manifestations of lupus, whereas class III and class IV usually occur in patients who have systemic features ofSLE. A semiquantitative analysis can be performed by using a variety of features on renal biopsy, scored 0 to 3+, to derive indices of disease activity and chronicity. Features that suggest active inflammation include endocapillary proliferation, glomerular leukocyte infiltration, wire loop deposits, cellular crescents, and interstitial inflammation. In contrast, features that suggest chronicity include glomerulosclerosis, fibrous crescents, tubular atrophy, and interstitital fibrosis. In some, but not all, studies, these indices have been useful in predicting response to therapy and renal prognosis.

Patients with active lupus nephritis have a range of serologic abnormalities. Hypocomplementemia is present in 75 to 90% of patients and is most striking with diffuse proliferative glomerulonephritis.ANA are usually detected (95 to 99%), although not specific forSLE. ANA titers tend to fall with treatment, and ANA may not be detected during remissions. Anti-double-stranded DNA (dsDNA) antibodies are highly specific for SLE, and changes in their titers correlate with the activity of lupus nephritis. Almost 100% of patients taking procainamide and 65% of patients taking hydralazine develop ANA; however, overt lupus, including nephritis, occurs in fewer than 10% of these patients, and anti-DNA antibodies are not usually detected. Other antibodies found in patients with SLE include anti-Sm (17 to 30%; highly specific, but not sensitive); anti-RNP, which frequently accompanies anti-Sm in low titer; anti-Ro (35%); anti-La (15%); and anti-histone antibodies (70% of patients with SLE and 95% of patients with drug-induced lupus).

TREATMENT

The treatment of lupus nephritis is controversial and based largely on the class of injury and disease activity. Because there is relatively poor correlation between clinical features (urinalysis findings, serum creatinine) and histologic class, the renal biopsy findings are an important guide to therapy. Treatment is not indicated for class I and most cases of class II lupus nephritis, as these histologic patterns portend an excellent prognosis (100% and>90% 5-year survival rates, respectively). Extrarenal manifestations may warrant treatment with glucocorticoids, salicylates, or antimalarials. Glucocorticoids and cyclophosphamide are the mainstays of therapy for patients with proliferative nephritis (classes III and IV). High-dose steroids given as intravenous boluses (pulse therapy) are usually effective at rapidly controlling acute glomerular inflammation. Cyclophosphamide and azathioprine are important adjuncts to steroid therapy and appear to afford better long-term preservation of renal function than steroids alone. Intravenous pulse cyclophosphamide is as efficacious as oral therapy and appears to be less toxic. Most authorities advocate an initial regimen of monthly intravenous boluses of cyclophosphamide for 6 months. Subsequent therapy is tailored to disease activity and typically involves dosing every 3 to 6 months for a total treatment period of 18 to 24 months. The initial dose of cyclophosphamide is 0.5 g/m_2, and the dose is increased gradually to a maximum of 1 g/$m_2$unless patients develop leukopenia or other side effects. Steroids are usually started simultaneously at 1 mg/kg per day and are tapered over the first 6 months to a maintenance dose of 5 to 10 mg/d for the duration of cyclophosphamide therapy. Five-year renal survival rates of 60 to 90% have been obtained with this and similar regimens. A large randomized, prospective trial indicated that plasmapheresis does not offer additional benefit in patients with severe proliferative lupus nephritis. Mycophenolate mofetil has recently been used to treat patients with lupus nephritis that is resistant to steroids and cyclophosphamide.

The management of membranous lupus nephritis is less well defined. As with idiopathic membranous glomerulopathy, the incidence of spontaneous remission approaches 50% in membranous lupus nephritis, and the course of the disease is generally indolent, with a 70- to 90% renal survival rate at 5 years. Some authorities advocate steroids andACEinhibitors at the time of diagnosis, whereas others reserve them for patients with progressive renal insufficiency or severe nephrotic syndrome. Useful parameters for monitoring the response to therapy and predicting relapse include the activity of the urine sediment, proteinuria,GFR, serum complement levels, and anti-dsDNA titers. Despite maximal immunosuppressive therapy, about 20% of patients with aggressive lupus nephritis developESRDrequiring dialysis.SLEtends to become quiescent with advanced uremia, and patients rarely develop systemic flares once they commence dialysis. Recurrence of nephritis and systemic flares are also very uncommon after renal transplantation, and allograft survival rates are comparable to those in patients with other causes of ESRD.

ANTIPHOSPHOLIPID ANTIBODY SYNDROME AND THROMBOTIC MICROANGIOPATHY

Patients with this syndrome can develop a variable degree of renal impairment due to thrombotic microangiopathy. The latter typically affects the interlobular arteries,

arterioles, and glomerular capillaries and is characterized by intravascular microthrombi and swelling of endothelial cells. Decreased levels of tissue plasminogen activator and increased level of a_2-antiplasmin, both of which would tend to promote thrombosis, have been described in this syndrome. Anticoagulation to maintain the Internalized Normal Ratio (INR)>3.0 may be beneficial in reducing the incidence of recurrent thromboses. There are uncontrolled reports of a benefit of plasmapheresis in the setting of acute renal failure secondary to thrombotic microangiopathy.

RHEUMATOID ARTHRITIS (See also Chap. 312)

Although extra-articular manifestations are present in 35% of patients with rheumatoid arthritis, direct involvement of the kidney by rheumatoid disease is rare, and glomerular injury is usually secondary to amyloid A (AA) amyloidosis or a side effect of drug therapy. AA amyloidosis is a complication experienced by 10 to 20% of patients with rheumatoid arthritis, and renal involvement is evident clinically in 3 to 10% of these patients (nephrotic syndrome, renal insufficiency). Amyloidosis is more frequent in patients with rheumatoid arthritis of long duration (>10 years), with circulating rheumatoid factor, and with destructive arthropathy. Less frequent glomerular lesions include mesangial proliferative glomerulonephritis and basement membrane thickening by subepithelial immune deposits. Gold and penicillamine may cause nephrotic syndrome by inducing membranous glomerulopathy, whereas nonsteroidal anti-inflammatory drugs (NSAIDs) can trigger the nephrotic syndrome by inducing minimal change nephropathy, usually in association with acute interstitial nephritis (see below).

SJOGREN'S SYNDROME (See alsoChap. 314)

Tubulointerstitial injury is the most common form of renal involvement in Sjogren's syndrome and usually presents as either Fanconi's syndrome, distal renal tubular acidosis, or impairment of renal concentrating ability. Glomerulonephritis is relatively rare and should prompt a search for evidence of secondary causes. Membranous glomerulopathy and membranoproliferative glomerulonephritis (MPGN) are the most common lesions. Anecdotal reports describe successful therapy with glucocorticoids and cytotoxic agents.

POLYMYOSITIS AND DERMATOMYOSITIS (See also Chap. 382)

Occasional cases of focal mesangial proliferative glomerulonephritis with mesangial deposition of IgG and complement have been described in polymyositis/dermatomyositis. Membranous glomerulopathy has also been reported, particularly when polymyositis/dermatomyositis is associated with malignancy.

MIXED CONNECTIVE TISSUE DISEASE (See also Chap. 313)

Mixed connective tissue disease is a syndrome that includes features ofSLE, scleroderma, and polymyositis and is associated with high titers of antiribonucleoprotein antibodies and negative antismooth muscle antibodies. Renal involvement occurs in fewer than 15% of patients and manifests as hematuria and subnephrotic proteinuria. The usual pathologic lesion is membranous glomerulopathy orMPGN. The prognosis is

usually excellent, and steroid therapy may be useful in rare patients with progressive renal disease.

GLOMERULAR DEPOSITION DISEASES

The glomerular deposition diseases are characterized by deposition of abnormal proteins, usually immunoglobulins or fragments thereof, within the glomerulus. They include amyloidosis, light and heavy chain deposition disease, cryoglobulinemia, and fibrillary/immunotactoid glomerulonephritis. Here, we focus on amyloidosis and light chain deposition disease (LCDD). Cryoglobulinemic nephropathy is described above in the discussion on systemic vasculitis.**Fibrillary and immunotactoid glomerulopathy are discussed in Chap. 274.*

AMYLOIDOSIS (See alsoChap. 319)

Amyloidosis is classified according to the major component of its fibrils: for example, immunoglobulin light chains in amyloid L (AL) amyloidosis, serum amyloid A in AA amyloidosis,b_2-microglobulin in dialysis-associated amyloidosis, and amyloid bprotein in Alzheimer's disease and Down's syndrome. Amyloid deposits also contain a nonfibrillar component called the P component, a seruma$_1$glycoprotein with a high affinity for the fibrillar components of all forms of amyloid. AL and AA amyloidosis frequently involve the kidneys, whereas involvement by other forms of amyloidosis is very rare.

There is substantial overlap in the renal clinicopathologic presentations ofAL andAAamyloidosis. Glomeruli are involved in 75 to 90% of patients, usually in association with involvement of other organs. The clinical correlate of glomerular amyloid deposition is nephrotic-range proteinuria. In addition, over 50% of patients have impaired glomerular filtration at diagnosis. Hypertension is present in about 20 to 25%. Renal size is usually normal or slightly enlarged. A minority of patients present with renal failure due to amyloid deposition in the renal vasculature or with Fanconi's syndrome, nephrogenic diabetes insipidus, or renal tubular acidosis due to involvement of the tubulointerstitium. Rectal biopsy and abdominal fat pad biopsy reveal amyloid deposits in about 70% of patients and may obviate the need for renal biopsy.

Renal biopsy gives a very high yield if there is clinical evidence of renal involvement. The earliest pathologic changes are mesangial expansion by amorphous hyaline material and thickening of theGBM. Further amyloid deposition results in the development of large nodular eosinophilic masses. When stained with Congo red, these deposits show apple-green birefringence under polarized light. Immunofluorescence microscopy is usually only weakly positive for immunoglobulin light chains because amyloid fibrils are usually derived from the variable region of light chains. Electron microscopy reveals the characteristic nonbranching extracellular amyloid fibrils of 7.5 to 10 nm in diameter. Tubulointerstitial and vascular deposits of amyloid are also seen and may occasionally be more prominent than glomerular deposits.

TREATMENT

Most patients with renal involvement byALamyloidosis developESRDwithin 2 to 5 years. No treatment has been shown consistently to improve this prognosis; however, some

success has been reported with a combination of melphalan and prednisone. Preliminary studies have reported a benefit of high-dose melphelan with autologous stem cell transplantation. Colchicine delays the onset of nephropathy in patients with familial Mediterranean fever but has not proved useful in patients with established disease or with other forms of amyloid. Remissions may be achieved inAAamyloidosis by eradication of the underlying cause. Renal replacement therapy is offered to patients who reach ESRD; however, the 1-year survival rate on dialysis is low (~66%) by comparison with other causes of ESRD. Most patients die from extrarenal complications, particularly cardiovascular disease. Renal transplantation is a viable option in patients with AA amyloidosis whose primary disease has been eradicated. Transplantation is also an option for patients with AL amyloidosis, although a poor prognosis because of extrarenal organ involvement may preclude them as candidates. Here again, the survival rate is lower by comparison with other causes of ESRD; most of the excess mortality is due to infectious and cardiovascular complications. Recurrence of amyloidosis in the allograft is common but rarely leads to graft loss.

LIGHT CHAIN DEPOSITION DISEASE (See also Chap. 113)

Renal involvement is a complication in 90% of patients withLCDD and is often the dominant feature. Nephrotic syndrome and renal impairment are the usual presenting features. Microscopic hematuria occurs in about 20% of patients. Defective hydrogen ion and potassium excretion and urinary concentration may be evident if light chains are deposited predominantly in the tubules. The most common pathologic lesion on renal biopsy is ribbon-like thickening of the tubular basement membrane due to light chain deposition. Mesangial expansion and nodular glomerulosclerosis are found in about 33% of patients. This light-microscopic appearance resembles that of idiopathicMPGN and diabetic nephropathy. Superimposed crescentic change is occasionally seen. Immunofluorescence studies are strongly positive for monoclonal light chains, in contrast toALamyloid, because the constant region of the immunoglobulin is typically deposited. The tissue deposits in LCDD are granular rather than fibrillar on electron microscopy, appear more amorphous in character, do not stain with Congo red, and seem to have a greater affinity for basement membranes.

The prognosis ofLCDD is poor when it is associated with multiple myeloma, and most patients progess rapidly toESRD. Treatment with melphalan and prednisone has been reported to reduce proteinuria and stabilize renal function in uncontrolled studies. In the absence of myeloma, the prognosis is somewhat more variable, and several patients have undergone successful renal transplantation.

WALDENSTROM'S MACROGLOBULINEMIA (See alsoChap. 113)

This disorder is characterized by monoclonal proliferation of an IgM-secreting clone of plasma cells. The circulating IgM paraprotein frequently gives rise to the hyperviscosity syndrome, which may compromise renal blood flow andGFR. Direct renal involvement is rare and, when present, involves deposition of large amorphous deposits of eosinophilic material in the glomerular capillaries. Renal amyloidosis can also occur.

DRUG-INDUCED GLOMERULAR DISEASE

A variety of drugs damage the glomerular filtration barrier and induce proteinuria and nephrotic syndrome. In contrast, drug-induced proliferative glomerulonephritis is rare. The more common drug-induced glomerulopathies are discussed here. Additional associations are included in Table 275-1 andTable 71-1.

NSAIDshave a variety of renal side effects, including hemodynamically mediated acute renal failure, salt and water retention, hyponatremia, hyperkalemia, papillary necrosis, acute interstitial nephritis, nephrotic syndrome, andESRD. Nephrotic syndrome and acute renal failure frequently coexist due to a combination of acute interstitial nephritis and a glomerular lesion that is identical to that of minimal change disease. This entity occurs most commonly in patients on propionic acid derivatives such as fenoprofen, ibuprofen, and naproxen but can occur with other NSAIDs, ampicillin, rifampin, and interferona. Withdrawal of the drug usually results in resolution of renal disease. Membranous nephropathy is also described as an idiosyncratic reaction to NSAIDs.

Gold therapy, administered by injection or orally, induces proteinuria in 5 to 25% of patients with rheumatoid arthritis. Proteinuria develops after 4 to 6 months of therapy, and up to 33% of patients develop full-blown nephrotic syndrome. Renal biopsy typically reveals membranous glomerulopathy, though minimal change disease or mesangial proliferative lesions have also been described. Progressive renal impairment is rare. Nephrotic syndrome is more common in patients who are HLA-B8/DR3 positive, suggesting a genetic susceptibility. Withdrawal of the drug leads to gradual resolution of the proteinuria.

Penicillamine also induces proteinuria in 5 to 30% of patients. As with gold, the underlying glomerular lesion is usually membranous glomerulopathy, and proteinuria gradually resolves after withdrawal of the drug. Acute renal failure secondary to crescentic glomerulonephritis with immune deposits has also been described.

Intravenous heroin use is associated with an increased incidence of focal and segmental glomerulosclerosis (heroin-associated nephropathy). It is not clear whether the nephrotoxin in this setting is heroin itself or a contaminant. Heroin-associated nephropathy occurs predominantly in blacks and is characterized by nephrotic syndrome, hypertension, and a gradual progression toESRDover a period of 3 to 5 years. The pathologic features are similar to those of idiopathic focal segmental glomerulosclerosis, although mesangial deposition of IgM and C3 may be more prominent. The incidence of this disease appears to be declining steadily. Potential reasons for the decline include increased purity of street heroin and a bias to attribute focal segmental glomerulosclerosis to HIV infection when both risk factors coexist. Intravenous *amphetamine* abuse is a rare cause of systemic necrotizing vasculitis.

HEREDITARY DISEASES WITH GLOMERULAR INVOLVEMENT

ALPORT'S SYNDROME (See also Chap. 351)

Alport's syndrome is the most common hereditary nephritis and is usually transmitted as an X-linked dominant trait. The genetic defect resides in the gene for thea5 chain of type IV collagen located on the long arm of the X chromosome; type IV collagen is a major structural component of theGBM. Numerous genetic mutations have been

detected, ranging from major deletions to point mutations, and this genetic heterogeneity is reflected in the phenotypic variations of the disease. In the X-linked forms, males usually present with microscopic hematuria, proteinuria (nephrotic-range in 30%), and progressive renal insufficiency. Common extrarenal manifestations include sensorineural hearing loss (~60%), bilateral anterior lenticonus (~15 to 30%), and recurrent corneal erosions. Platelet defects are described but are rare. Female carriers usually have mild disease and do not develop renal insufficiency. Autosomal dominant and recessive forms also exist in which there are mutations in the gene for the a3 chain of type IV collagen, and males and females are equally affected. Genetic analysis to detect mutations in the genes encoding the a3 and a5 chains of type IV collagen may become the diagnostic method of choice.

Typical light-microscopic features on renal biopsy include mesangial hypercellularity, focal and segmental glomerulosclerosis, chronic tubulointerstitial fibrosis, atrophy, and accumulation of foam cells. Electron microscopy reveals thickening, fragmentation, and lamellation of the lamina densa of theGBM. Patchy thinning of the GBM may also be seen, especially early in the course of the disease and in female carriers.

Males with the disease tend to progress toESRD and are suitable candidates for dialysis and transplantation. About 5% of transplant recipients develop anti-GBMdisease in the renal allograft; their immune system recognizes normal GBM of the transplanted kidney as a foreign antigen. These patients can have antibodies against the a3 (Goodpasture antigen) ora5 chains of type IV collagen, probably because defective synthesis of the a5 chain results in defective incorporation or orientation of the a3 chain in the GBM.

SICKLE CELL DISEASE (See alsoChap. 106)

Glomerular disease is common (15 to 30%) in homozygotes for sickle cell disease. Glomerular hyperfiltration and hypertrophy occur within the first 5 years of life. Approximately 15 to 30% of patients develop proteinuria in the first three decades, and 5% developESRD. The glomerular pathology is usually focal segmental glomerulosclerosis, probably due to sustained glomerular capillary hypertension.MPGN is also seen on occasion. Predictors of chronic renal failure are worsening anemia, proteinuria, nephrotic syndrome, and hypertension.ACEinhibitors may slow the progression of renal disease by lowering systemic and glomerular capillary hypertension.

FABRY'S DISEASE (See also Chap. 349)

In patients with Fabry's disease, renal biopsy reveals accumulation of neutral glycosphingolipids with terminal a-galactosyl moieties in lysosomes of glomerular, tubular, vascular, and interstitial cells. Focal and global glomerulosclerosis are later features. Electron microscopy reveals stacked, concentric lamellar profiles known as "myeloid" bodies, which are characteristic. Renal disease manifests in the late teens to early twenties with lipiduria, proteinuria with minimal hematuria, nephrotic syndrome, hypertension, and progressive renal insufficiency. The most striking systemic manifestations are skin lesions (angiokeratomas), corneal and lens opacities, painful dysesthesias of the extremities, and arthropathy of the terminal interphalangeal joints. The diagnosis of Fabry's disease can often be made by careful physical examination,

especially if many of the typical clinical features are present. Measurement of urinary glycosphingolipids and estimation of peripheral leukocytea-galactosidase levels help confirm the diagnosis. The renal lesion is progressive, and these patients often tolerate hemodynamic changes during dialysis poorly because of progressive vascular disease. Successful renal transplantation has been reported despite recurrence in the allograft.

NAIL-PATELLA SYNDROME

The nail-patella syndrome is a rare hereditary disorder transmitted as an autosomal dominant trait. The abnormal gene is located on the long arm of chromosome 9, and candidate genes include the a1 chain of type V collagen and the LIM homeodomain protein Lmxlb. The phenotype is characterized by multiple osseous abnormalities, primarily affecting the elbows and knees, and nail dysplasia. About 50% of patients have clinically evident nephropathy. The light-microscopic features on renal biopsy include localGBMthickening, tubular atrophy, interstitial fibrosis, and varying degrees of glomerular sclerosis. Electron microscopy reveals irregular thickening of the GBM, with electrolucent areas giving it a "moth-eaten" appearance. Cross-striated fibrils with the periodicity of collagen can be identified in the mesangium and basement membrane. The disease usually manifests clinically as asymptomatic hematuria and proteinuria, occasionally in the nephrotic range, but it may be silent. The renal lesion is relatively benign, and progression toESRDoccurs in 10 to 30% of patients.

LIPODYSTROPHY

MPGNtype II (dense deposit disease) is the most frequent glomerular lesion in patients with lipodystrophy (80%), whereas MPGN type I affects the remainder (20%). The disease occurs mostly in females between the ages of 5 and 15 years, and the clinical presentation and course are similar to those of idiopathic MPGN, namely nephrotic-range proteinuria and progressive renal insufficiency. Low C3 levels are common in association with C3 nephritic factor (Chap. 274).

LECITHIN-CHOLESTEROL ACYLTRANSFERASE DEFICIENCY (See alsoChap. 344)

Renal manifestations of this disease include proteinuria, microscopic hematuria, and progressive renal insufficiency. Renal biopsy typically reveals focal and segmental glomerulosclerosis. Electron-microscopic findings include irregular rounded, lucent lacunae that contain solid or laminated dense structures in theGBM, mesangial matrix, and Bowman's capsular and renal tubular basement membranes. Endothelial cell detachment is also evident, and capillary lumens may be occluded by vacuolated foam cells. Recurrence of the disease has been documented in the renal allograft but without marked impairment of graft function.

GLOMERULAR LESIONS ASSOCIATED WITH INFECTIOUS DISEASES

VIRAL INFECTIONS

Hepatitis B, hepatitis C, and HIV are strongly associated with glomerular disease (Table 275-2). Glomerular lesions associated with *hepatitis B virus* (HBV) infection include membranous glomerulopathy,MPGN, IgA nephropathy, essential mixed

cryoglobulinemia, and polyarteritis nodosa. Membranous glomerulopathy is most common. In endemic areas, such as Asia and Africa, 80 to 100% of children and 30 to 45% of adults with membranous glomerulopathy have HBV surface antigenemia. HBV antigens have been identified in renal immune deposits, suggesting in situ immune-complex formation after planting of HBV antigens or trapping of circulating immune complexes containing HBV antigens. Patients typically present with nephrotic syndrome and microscopic hematuria. Hypertension and renal impairment are rare. The most common associated hepatic lesion is chronic persistent or chronic active hepatitis. In nonendemic areas there is a male preponderance, and many patients are intravenous drug users or have other risk factor for acquisition of HBV. The asymptomatic carrier state of HBV is frequently associated with MPGN in endemic areas. Hypertension and azotemia are more common with this morphologic pattern than with membranous glomerulopathy. Children with HBV-associated membranous glomerulonephritis have a good prognosis, and almost two-thirds enter spontaneous remission within 3 years.ESRD is rare. In contrast, 30% of adults develop progressive renal failure within 5 years, with 10% reaching ESRD. Steroids and cytotoxic agents are contraindicated as they may lead to increased viral replication and worsening of liver disease. Interferon a may reduce proteinuria and stabilize renal function in patients with progressive disease.

HCVinfection (Chap. 295) should be considered in all patients with cryoglobulinemic proliferative glomerulonephritis,MPGN, and membranous glomerulopathy. These three clinocopathologic entities may represent a spectrum of morphologic manifestations of the same pathogenetic process, namely HCV-induced immune-complex disease. Up to 30% of patients with chronic HCV infection have an abnormal urinary sediment. HCV infection accounts for 10 to 20% of type I MPGN and is a major cause of essential mixed cryoglobulinemia. Renal biopsy reveals typical features of type I MPGN and IgG, IgM, C3, and/or cryoglobulin deposits. Most patients present with nephrotic syndrome and microscopic hematuria and may have red blood cell casts. Liver function tests are usually abnormal, and C3 levels are typically depressed. Anti-HCV antibodies are detected in most patients, and viral RNA has been documented in blood and cryoglobulins. Various treatments have been reported to be useful in HCV-induced renal disease including steroids, cytotoxic agents, and plasmapheresis; however, controlled trials to support their use are lacking. Interferon a has been demonstrated to clear antigenemia, lower cryoglobulin levels, and stabilize renal disease. Unfortunately, relapse is usual once the drug is discontinued.

HIV infection (Chap. 309) has been associated with focal segmental glomerulosclerosis, acute diffuse proliferative glomerulonephritis, and mesangioproliferative glomerulonephritis, including IgA nephropathy,MPGN, and membranous glomerulopathy. The classic and most common HIV-associated glomerulopathy is an aggressive form of focal segmental glomerulosclerosis, an entity that is termed *HIV-associated nephropathy (HIVAN)*. This disease may be the first manifestation of infection in otherwise asymptomatic patients. HIVAN is more common in blacks than in other ethnic groups and is more frequent in intravenous drug abusers with HIV infection than in homosexuals. The disease has been described in all high-risk groups, however, including infants of HIV-positive mothers. Renal biopsy typically reveals visceral epithelial cell swelling, collapse of the glomerular capillary tuft, severe tubulointerstitial inflammation, and microcystic dilatation of renal tubules. Electron microscopy

characteristically reveals severe visceral epithelial cell injury and tubuloreticular inclusions in glomerular endothelial cells, tubular cells and infiltrating leukocytes. This constellation of findings has been termed collapsing glomerulopathy, but it should be emphasized that a similar picture can be seen in the absence of HIV infection. The presence of tubuloreticular inclusions and the aggressive clinical course distinguish HIVAN from idiopathic focal segmental glomerulosclerosis. The mechanisms of renal cell injury are still being defined. Viral DNA has been demonstrated in the renal epithelia of HIV-infected patients with and without nephropathy, suggesting that pathogenetic factors, other than infection of cells, are required for induction of disease. The typical clinical correlates of HIVAN are severe nephrotic syndrome and rapid progression toESRD, occurring in weeks to months. Despite early reports of poor survival of patients on dialysis, more recent studies indicate improved survival for both asymptomatic patients with HIV and patients with full-blown AIDS. There is no proven therapy for HIVAN. The initial experience with combined highly active antiretroviral therapy (triple therapy) suggests that these regimens have reduced the incidence of nephropathy in HIV-infected patients and improved prognosis in patients with established nephropathy.

BACTERIAL INFECTIONS (Table 275-2)

Immune-complex glomerulonephritis is a relatively frequent complication of inefective *endocarditis* (Chap. 126). Other mechanisms of renal injury in bacterial endocarditis include embolic renal infarction, septic abscesses, acute tubular necrosis secondary to septicemia and drug therapy, disseminated intravascular coagulation, and antibiotic-induced acute interstitial nephritis. Patients typically present with microscopic hematuria, urinary red blood cell casts, pyuria and modest proteinuria (nephrotic range in 25% of patients), and variable degrees of renal failure. Rheumatoid factor is present in 10 to 70%, and circulating immune complexes in 90%. Serum complement levels are usually depressed. Renal biopsy reveals mild focal proliferative glomerulonephritis with mesangial and capillary wall deposition of IgG and C3 by immunofluorescence microscopy and subendothelial, mesangial, and subepithelial electron-dense deposits by electron microscopy. Occasional patients develop diffuse necrotizing glomerulonephritis with crescent formation and present with nephritic syndrome or RPGN. Endocarditis-associated glomerulonephritis typically has a good prognosis and resolves with eradication of the underlying infection.

Immune-complex glomerulonephritis is a complication in 1 to 4% of patients with *infected ventriculoatrial shunts*. Nephritis can manifest weeks to years after shunt insertion and usually presents with microscopic hematuria. Nephrotic syndrome occurs in 30 to 50%. The usual renal pathology is a membranoproliferative pattern, although diffuse proliferation can also occur. Immunofluorescence reveals IgM and C3 in the capillary wall and mesangial area, while subendothelial deposits and mesangial interposition are seen by electron microscopy. Up to one-third of patients may have residual renal impairment despite removal of the infected shunt and resolution of the infection.

Suppurative infections such as intrathoracic and intraabdominal abscesses, osteomyelitis, and dental abscesses have been associated with glomerulonephritis. The usual presentation is hematuria, urinary red blood cell casts, proteinuria, and acute renal failure. Oliguria and hypertension are common. Pathologic renal lesions include

mesangial proliferative, membranoproliferative, and diffuse proliferative glomerulonephritis with crescents. Immunofluorescence reveals mesangial and capillary wall deposition predominantly of C3, although IgG and IgM may also be seen.

Nephrotic syndrome is a complication in 0.3% of patients with secondary *syphilis* and 8% of patients with congenital syphilis. The usual pathology is membranous glomerulopathy; however, mild mesangial and endocapillary proliferation can occur. IgG and IgM are evident in affected regions by immunofluorescence microscopy, and treponemal antigens have been identified in diseased glomeruli. C3 and C4 are typically depressed in congenital syphilis. The treatment consists of penicillin to eradicate the infection.

Leprosy most commonly causes AA amyloidosis; however, a syndrome resembling acute poststreptococcal glomerulonephritis has also been described.

PROTOZOAN AND PARASITIC INFECTIONS

Transient proteinuria (50% of patients) and nephrotic syndrome (<1% of patients) are complications of infection with *Plasmodium falciparum*. Membranoproliferative glomerulonephritis is the usual pathologic lesion and may respond to eradication of infection. *Plasmodium malariae* has been associated with diffuse or focal proliferative glomerulonephritis, membranous glomerulopathy, and minimal change disease. Eradication of the malarial infection does not consistently induce remission of the nephrotic syndrome. *Schistosoma mansoni* causes nephrotic syndrome in 5 to 10% of patients, and progression toESRD is common. The usual pathology isMPGN or mesangial proliferative glomerulonephritis, although membranous glomerulonephritis and amyloidosis are occasionally seen. *Filiariasis* can trigger membranous glomerulonephritis (*Loa loa*) and occasionally induces proliferative glomerulonephritis (*Onchocerca volvulus*). *Congenital toxoplasmosis* infection occasionally induces immune-complex glomerulonephritis characterized by mesangial and subendothelial immune deposits that contain *Toxoplasma* antigens. Membranous glomerulopathy and proliferative glomerulonephritis are occasional complications of *hydatid disease* and *trichinosis*, respectively.

GLOMERULAR LESIONS ASSOCIATED WITH NEOPLASIA

Glomerulopathies associated with neoplasia include membranous glomerulopathy, minimal change disease, focal segmental glomerulosclerosis, immune-complex glomerulonephritis, fibrillary/immunotactoid glomerulonephritis,LCDD, and amyloidosis. Mild proteinuria is common in patients with *solid tumors*, but overt glomerulonephritis is rare. Occasional patients with solid tumors of the lung, gastrointestinal tract, breast, kidney, and ovary develop full-blown nephrotic syndrome, usually due to a membranous glomerulopathy. Estimates of the incidence of occult malignancy in patients presenting with membranous glomerulopathy range from 0.1 to 10%. Most authorities agree that an extensive search for malignancy is not indicated, unless there are other suggestive clinical features. As many as 35% of patients with renal cell carcinoma have mesangial deposition of IgG and C3 visible on immunofluorescence; however, morphologic abnormalities are detected in only 50% of these patients, and clinically significant glomerulopathy is rare. Glomerular amyloidosis has also been described in association

with this tumor.

An array of glomerular disease has been reported in patients with lymphoproliferative malignancy. Nephrotic syndrome is a recognized complication of *Hodgkin's lymphoma*, with 70% of cases due to minimal change disease. The latter may occur concurrently with (40 to 45%), precede (10 to 15%), or follow (40 to 50%) diagnosis of the malignancy. It is postulated that a lymphokine or other mediator released by malignant T lymphocytes perturbs podocyte function and alters glomerular permeability in this setting. Nephrotic syndrome typically resolves with successful treatment and relapses with recurrence of disease. Less frequent associations with Hodgkin's lymphoma include focal segmental glomerulosclerosis, membranous glomerulopathy,MPGN, proliferative glomerulonephritis, and crescentic glomerulonephritis. Minimal change disease, membranous glomerulopathy, MPGN, and crescentic glomerulonephritis have also been reported in patients with *non-Hodgkin's lymphoma*. Glomerulopathy in the context of leukemia is rare. MPGN can complicate *chronic lymphatic leukemia* and related *B cell lymphomas*, particularly when associated with cryoglobulinemia. Other glomerular lesions associated with *paraproteinemia* include primary amyloid, LCDD, proliferative glomerulonephritis induced by cryoglobulinemia, and fibrillary/immunotactoid glomerulopathy. Here again, the renal lesion frequently improves or resolves with successful treatment of the underlying malignancy.

(Bibliography omitted in Palm version)

276. HEREDITARY TUBULAR DISORDERS - *John R. Asplin*, *Fredric L. Coe*

The hereditary renal tubular disorders and their morphologic and functional abnormalities, mode of inheritance, and associated abnormalities are summarized in Table 276-1. The individual disorders are discussed in detail below.

AUTOSOMAL DOMINANT POLYCYSTIC KIDNEY DISEASE

ETIOLOGY AND PATHOLOGY

Autosomal dominant polycystic kidney disease (ADPKD) has a prevalence of 1:300 to 1:1000 and accounts for approximately 10% of end-stage renal disease (ESRD) in the United States. Some 90% of cases are inherited as an autosomal dominant trait, and approximately 10% are spontaneous mutations.

GENETIC CONSIDERATIONS

Three forms ofADPKDhave been identified. ADPKD-1 accounts for 90% of cases, and the gene has been localized to the short arm of chromosome 16. The gene for ADPKD-2 has been mapped to the long arm of chromosome 4. The protein products of the two genes form the polycystin complex, which may regulate cell-cell or cell-matrix interactions. A defect in either of these proteins interrupts the normal function of the polycystin complex, resulting in the same phenotype for two distinct genetic abnormalities. ADPKD-2 appears to have a later age of onset of symptoms and renal failure than ADPKD-1. A third form has been documented but has not been mapped to a gene at this point.

The kidneys are grossly enlarged, with multiple cysts studding the surface of the kidney. The cysts contain straw-colored fluid that may become hemorrhagic. The cysts are spherical, vary in size from a few millimeters to centimeters, and are distributed evenly throughout the cortex and medulla. Only 1 to 5% of nephrons will develop cysts. Cysts form when a "second hit" causes a somatic mutation in the normal allele of a tubule cell, leading to monoclonal proliferation of the tubular epithelium. The remaining renal parenchyma reveals varying degrees of tubular atrophy, interstitial fibrosis, and nephrosclerosis.

CLINICAL FEATURES

The disease may present at any age but most frequently causes symptoms in the third or fourth decade. Patients may develop chronic flank pain from the mass effect of the enlarged kidneys. Acute pain indicates infection, urinary tract obstruction by clot or stone, or sudden hemorrhage into a cyst. Gross and microscopic hematuria are common, and impaired renal concentrating ability frequently leads to nocturia. Nephrolithiasis occurs in 15 to 20% of patients, calcium oxalate and uric acid stones being most common. Low urine pH, low urine citrate, and urinary stasis from distortion of the collecting system by cysts all play a role in stone formation. Hypertension is found in 20 to 30% of children and up to 75% of adults. It is secondary to intrarenal ischemia from distortion of the renal architecture, leading to activation of the renin-angiotensin system. Patients with hypertension have a much more rapid progression toESRD.

Urinary tract infection is common and may involve the bladder or renal interstitium (pyelonephritis) or infect a cyst (pyocyst). Pyocysts can be difficult to diagnose but are more likely to be present if the patient has positive blood cultures, new renal pain, or failed to improve clinically after a standard course of antibiotic therapy.

Progressive decline in renal function is common, with approximately 50% of patients developingESRD by age 60. However, there is considerable variation in age of onset of renal failure, even within the same family. Hypertension, recurrent infections, male sex, and early age of diagnosis are related to early onset renal failure. Renal failure usually progresses slowly; if a sudden decrement in kidney function occurs, ureteral obstruction from stone, clot, or compression by a cyst are likely causes. Patients usually have high hematocrits for their level of renal function, as erythropoietin production is high. Fluid overload is uncommon because of a tendency for renal salt wasting.

Extrarenal manifestations of this disease are frequent and underscore the systemic nature of the defect. Hepatic cysts occur in 50 to 70% of patients. Cysts are generally asymptomatic, and liver function is normal, though women may develop massive hepatic cystic disease on occasion. Cyst formation has also been observed in the spleen, pancreas, and ovaries. Intracranial aneurysms are present in 5 to 10% of asymptomatic patients, with potential for permanent neurologic injury or death from subarachnoid hemorrhage. Screening of allADPKDpatients for aneurysms is not recommended, but patients with a family history of subarachnoid hemorrhage should be studied noninvasively with magnetic resonance imaging angiography. Colonic diverticular disease is the most common extrarenal abnormality, and patients are more likely to develop perforation than the general population with colonic diverticula. Mitral valve prolapse is found in 25% of patients, and the prevalence of aortic and tricuspid valve insufficiency is increased.

DIAGNOSIS

Ultrasound is the preferred technique for diagnosis of symptomatic patients and for screening asymptomatic family members. The ability to detect cysts increases with the subject's age: 80 to 90% ofADPKDpatients over the age of 20 will have detectable cysts, and almost 100% over the age of 30 will have cysts. At least three to five cysts in each kidney is the standard diagnostic criteria for ADPKD. Computed tomography (CT) scan may be more sensitive than ultrasound in detection of small cysts. Genetic linkage analysis is now available for diagnosis of ADPKD but is reserved for cases where radiographic imaging is negative and the need for definitive diagnosis critical, such as screening family members for potential kidney donation.

TREATMENT

The goals of treatment are to slow the rate of progression of renal disease and minimize symptoms. Hypertension and renal infection should be treated aggressively to maintain renal function. Converting enzyme inhibitors are effective antihypertensive agents, though patients should be closely monitored as some develop renal insufficiency and hyperkalemia. Urinary infection is treated in a standard manner unless a pyocyst is suspected, in which case antibiotics that penetrate cysts should be used, such as trimethoprim-sulfamethoxazole, ciprofloxacin, and chloramphenicol. Chronic pain from

cysts can be managed by cyst puncture and sclerosis with ethanol.

AUTOSOMAL RECESSIVE POLYCYSTIC KIDNEY DISEASE

GENETIC CONSIDERATIONS

Autosomal recessive polycystic kidney disease (ARPKD) is a rare genetic disease that has an incidence between 1:10,000 and 1:40,000. The gene for ARPKD has been localized to chromosome 6. In the past, ARPKD was considered to be a family of disorders, categorized as neonatal, infantile, and childhood forms depending on the age of onset and the relative degree of involvement of the kidneys and liver. However, variable clinical presentations within siblings in the same family, as well as the localization of the disease to chromosome 6 in multiple families, support the premise that this is a single genetic disease with variable phenotypic presentation.

At birth the kidneys are enlarged with a smooth external surface. The distal tubules and collecting ducts are dilated into elongated cysts that are arranged in a radial fashion. As the patient ages, the cysts may become more spherical and the disease can be confused withADPKD. Interstitial fibrosis is also seen as renal function deteriorates. Liver involvement includes proliferation and dilation of small intrahepatic bile ducts as well as periportal fibrosis.

CLINICAL FEATURES

The majority of cases are diagnosed in the first year of life, presenting as bilateral abdominal masses. Death in the neonatal period is most commonly due to pulmonary hypoplasia. Hypertension and impaired urinary concentrating ability are common. The time course toESRD is variable, though many children maintain adequate kidney function for years. Older children present with complications secondary to congenital hepatic fibrosis and generally have less severe kidney disease. Hepatosplenomegaly, portal hypertension, and esophageal varices are frequent complications ofARPKD.

DIAGNOSIS

Ultrasound is the most common technique used to diagnoseARPKD, prenatally and in childhood. Ultrasound examination reveals enlarged kidneys with increased echogenicity. At times spherical cysts may be seen, potentially leading to an incorrect diagnosis ofADPKD. A thorough family history and imaging the kidneys of the parents aids in differentiation from other cystic diseases. The recent mapping of the gene should allow linkage studies to be used in diagnosis.

TREATMENT

Aggressive treatment of hypertension and urinary tract infection are the major goals of therapy in order to maintain native renal function as long as possible. Dialysis and transplant are appropriate when kidney failure occurs. Hepatic fibrosis may lead to life-threatening variceal hemorrhage, requiring sclerotherapy or portocaval shunting.

TUBEROUS SCLEROSIS

Patients with this multisystem disease most commonly present with skin lesions and benign tumors of the central nervous system (Chap. 370). Renal involvement is common; angiomyolipomas are the most frequent abnormality and are usually bilateral. Renal cysts may be present as well and can give an appearance similar to that ofADPKD. Histologically, the cysts are unique -- the cyst lining cells are large with an eosinophilic staining cytoplasm and may form hyperplastic nodules that can fill the cyst space.

GENETIC CONSIDERATIONS

One-third of cases are inherited as an autosomal dominant trait, the rest are due to sporadic mutations. Mutations of tumor-suppression genes have been identified on chromosomes 9 (*TSCI*) and 16 (*TSC2*). Mutations of *TSC2* account for the majority of cases and are more likely to be associated with mental retardation and polycystic kidneys. Tuberous sclerosis may be confused withADPKD if extrarenal manifestations are minimal.

VON HIPPEL-LINDAU DISEASE

This autosomal dominant disease is characterized by hemangioblastomas of the retina and the central nervous system (Chap. 370). Renal cysts occur in the majority of cases and are usually bilateral. The *VHL* gene is a tumor-suppressor gene and has been localized to chromosome 3. It is the same gene that is mutated in sporadic renal cell carcinoma, which may be found in up to 25% of patients with von Hippel-Lindau disease and is frequently multifocal. Yearly screening of adults using CT scans has been recommended in an attempt to diagnose renal cell cancers at an early stage.

MEDULLARY SPONGE KIDNEY

ETIOLOGY AND PATHOLOGY

Medullary sponge kidney (MSK) is a congenital disorder. Although some cases have apparent autosomal dominant inheritance, most are sporadic. It is found in 0.5 to 1% of all intravenous pyelograms. Males and females are affected equally. The pathologic lesion is cystic dilation of the inner medullary and papillary collecting ducts, with collecting diameters ranging from 1 to 5 mm. Bilateral renal involvement is present in 70% of cases, but not all papillae are equally affected. The dilated ducts are lined by cuboidal epithelium with areas of pseudostratified and stratified squamous epithelium. Calculi are frequently found in the dilated collecting ducts.

CLINICAL FEATURES

Patients generally present in the third or fourth decade with kidney stones, infection, or recurrent hematuria. The disease is most commonly diagnosed by intravenous pyelogram, which shows linear striations radiating into the renal papillae or small cystic collections of contrast in the dilated ducts (Fig. 276-1). Approximately 60% of patients withMSK have stones, and 12% of all stone formers will have MSK. Hypercalciuria occurs with the same frequency in MSK as it does in random stone formers. Papillary

nephrocalcinosis occurs more frequently in patients with MSK than in the random stone former. Proteinuria is minimal, if present at all, and renal function is normally preserved unless there is renal damage from recurrent infection or severe stone disease.

TREATMENT

Asymptomatic patients require no specific therapy except to maintain high fluid intake to reduce the risk of nephrolithiasis. If stones are present, standard laboratory evaluation should be done and metabolic abnormalities treated as in any stone former (Chap. 279). Infection should be treated aggressively, and instrumentation of the urinary tract should be minimized to avoid introducing infection.

JUVENILE NEPHRONOPHTHISIS/MEDULLARY CYSTIC DISEASE

ETIOLOGY AND PATHOLOGY

Juvenile nephronophthisis (JN) and medullary cystic disease (MCD) have similar pathologic findings but differ in inheritance pattern and age of onset.

GENETIC CONSIDERATIONS

JNis inherited as an autosomal recessive disease; linkage studies have shown 70% of the cases to map to a gene (*NPH1*) on the short arm of chromosome 2.MCD is an autosomal dominant disease. Linkage analysis has identified genes on chromosomes 1 and 16 as being associated with MCD. In both conditions, the kidneys tend to be small, with cysts throughout the medulla; the cortex and papilla rarely have cysts. The cysts originate in the collecting ducts, distal convoluted tubules, and loops of Henle and range in size from 1 to 10 mm. Sclerotic glomeruli, tubule atrophy, and interstitial fibrosis are frequent findings on biopsy.

CLINICAL FEATURES

Patients withJNpresent during childhood with symptoms of polyuria, growth retardation, anemia, and progressive renal insufficiency. Most patients developESRDprior to the age of 20; JN accounts for 2 to 10% of renal failure in children. Hepatic fibrosis and cerebellar ataxia has been reported in association with JN. JN with retinal degeneration is termed the *Senior-Loken syndrome*; it does not link to the *NPH1* gene at chromosome 2.MCDpresents in the third or fourth decade, though some cases may be diagnosed in the elderly population. Presenting symptoms in MCD are the same as in JN except for growth retardation. In addition, MCD does not have extrarenal abnormalities. Severe salt wasting can be seen, though this is usually a transient phase that resolves as the disease progresses to ESRD. Other features of tubule damage are often found, including hyperkalemia and hyperchloremic metabolic acidosis. Proteinuria is mild, and hematuria is rare.

DIAGNOSIS

The diagnosis is suggested by a family history of renal disease. The pattern of inheritance and age of onset aid in distinguishingJN/MCDfrom other inherited diseases.

Radiographic studies show small kidneys, loss of the corticomedullary junction, and multiple cysts in the medulla.CT scan is more sensitive than ultrasound in making the diagnosis. Open renal biopsy, including medullary tissue, may be required for diagnosis in some cases.

TREATMENT

Treatment is mainly supportive, as there is no specific therapy to prevent loss of renal function. Patients with salt wasting require a large oral intake of salt and water to maintain adequate extracellular volume. Alkali replacement and erythropoietin are required for acidosis and anemia, respectively. Renal transplantation has been performed in numerous patients, and the disease does not recur.

LIDDLE'S SYNDROME

Liddle's syndrome is a rare familial disease with a clinical presentation of hyperaldosteronism, consisting of hypertension, hypokalemia, and metabolic alkalosis. However, aldosterone levels are undetectable in these patients, and a nonaldosterone mineralocorticoid has not been isolated. Increased distal tubule sodium reabsorption, due to activating mutations in the amiloride-sensitive sodium channel, has been described in multiple families. Pharmacologic agents that block distal tubule sodium uptake, such as amiloride and triamterene, are effective in treating the hypertension and electrolyte abnormalities. As expected, spironolactone is ineffective, since the disease is not mediated via the aldosterone receptor.

BARTTER'S SYNDROME

CLINICAL FEATURES

Hypokalemia secondary to renal potassium wasting, metabolic alkalosis, and normal to low blood pressure are the clinical features of Bartter's syndrome. Three phenotypes of Bartter's syndrome have now been recognized. *Antenatal Bartter's syndrome* is characterized by polyhydramnios and premature delivery. During infancy, episodes of fever and dehydration are common and can lead to growth retardation. Nephrocalcinosis secondary to hypercalciuria is frequent. The infants also have a characteristic facies consisting of a triangular face with prominent eyes and ears. Prostaglandin E production is very high. Most cases of *classic Bartter's syndrome* present during childhood. Symptoms such as weakness and cramps are secondary to the hypokalemia. Polyuria and nocturia are common due to the hypokalemia-induced nephrogenic diabetes insipidus. Growth retardation may be seen. The *Gitelman's variant of Bartter's syndrome* presents during adolescence or adulthood and generally has a milder course than Bartter's syndrome. The dominant features are fatigue and weakness. It is distinguished from Bartter's syndrome by hypocalciuria, hypomagnesemia with hypermagnesuria, and normal prostaglandin production. All three forms are inherited as autosomal recessive traits. Although rarely required for diagnosis, renal biopsy reveals hyperplasia of the juxtaglomerular apparatus and prominence of medullary interstitial cells, with variable degrees of interstitial fibrosis, though these are not pathognomonic for the syndrome.

PATHOGENESIS

The pathogenesis of Bartter's syndrome has long been a matter of debate as the distinction of the primary disorder from the secondary phenomena induced by volume depletion and hypokalemia is difficult.

GENETIC CONSIDERATIONS

Recently, mutations in several renal tubule transport proteins have been shown to be responsible for the syndrome. In antenatal and classic Bartter's syndrome, impaired Cl^- reabsorption in the thick ascending limb of the loop of Henle is the underlying defect. Inadequate Cl^-reabsorption causes volume depletion and activates the renin-angiotensin system. Distal delivery of NaCl and water are high in the presence of high aldosterone, promoting secretion of K^+ and H^+ ions. Prostaglandin overproduction is mediated by volume depletion, hypokalemia, and high angiotensin II and kallikrein levels. Increased prostaglandin production contributes to the severity of disease by inducing resistance to the pressor effects of angiotensin II and reducing reabsorption in the thick ascending limb of the loop of Henle. Mutations in the bumetanide-sensitive Na:K:2Cl channel, the apical ATP-regulated K^+channel, and the basolateral Cl^- channel have been described in classic and antenatal Bartter's. All of these mutations would lead to a loss of Cl^-reabsorption in the loop of Henle. In Gitelman's syndrome, mutations have been found in the thiazide-sensitive NaCl transporter. The reduced Na^+reabsorption in the distal convoluted tubule leads to volume depletion and hypokalemia, though not as severe as would result from a lesion in the loop of Henle. Loss of activity of the thiazide-sensitive transporter increases tubule calcium reabsorption, leading to the classic finding of hypocalciuria in Gitelman's syndrome.

DIAGNOSIS

Hypokalemia, metabolic alkalosis, and normal to low blood pressure are the clinical findings characteristic of Bartter's syndrome. The differential diagnosis includes vomiting, surreptitious diuretic abuse, and magnesium deficiency. Chronic vomiting can be diagnosed by a low urine Cl^- concentration. Magnesium deficiency causes kaluresis and alkalosis, simulating Bartter's syndrome. Serum and urine magnesium will be low in such cases. Diuretic abuse produces metabolic abnormalities indistinguishable from Bartter's syndrome. Urine should be screened for diuretics multiple times before the diagnosis of Bartter's is made in a patient without a family history of the disorder.

TREATMENT

Dietary intake of sodium and potassium should be liberal. Potassium supplements are usually required. Magnesium supplements are needed in patients with Gitelman's syndrome. Spironolactone will reduce potassium wasting. Prostaglandin synthetase inhibitors are useful in patients with antenatal and classic Bartter's syndrome but are of no benefit in Gitelman's syndrome. Angiotensin-converting enzyme inhibitors may be beneficial in some patients.

CONGENITAL NEPHROGENIC DIABETES INSIPIDUS

GENETIC CONSIDERATIONS

This rare genetic disorder is most commonly inherited as an X-linked disease, with full expression in males and variable penetrance in females. Vasopressin acts through two receptors; type 1 receptors are located in the vasculature, while type 2 receptors are found in the collecting ducts of the kidney. In nephrogenic diabetes insipidus (NDI), only the actions requiring type 2 receptors are abnormal. Inactivating mutations of the type 2 vasopressin receptor, located on the long arm of the X chromosome, are responsible for the renal resistance to vasopressin. Less frequently, NDI may be inherited as an autosomal recessive trait, in which mutations in the gene for the water channels in collecting duct cells (aquaporin 2) lead to abnormal cell routing of aquaporin 2.

CLINICAL FEATURES

The clinical presentation is that of persistent polyuria, dehydration, and hypotonic urine in the presence of hypernatremia. Vasopressin levels are appropriately elevated in the hypertonic state, but renal response is lacking. The onset of the disorder is in infancy. The recurrent hypernatremia may lead to seizures or mental retardation. Once old enough to satisfy their thirst, children will be clinically stable though in a chronic state of polyuria and polydypsia. Renal function is normal, and radiographic studies of the urinary system reveal dilated ureters and bladder secondary to the chronically high urine flow. Since the most common form of the disease is X-linked, most patients are male. Heterozygous females generally have mild concentrating defects, though a few have phenotypic expression similar to males due to skewed X-chromosome inactivation. In the autosomal recessive form, males and females are affected equally.

TREATMENT

Treatment is aimed at maintaining adequate hydration. In the infant, low-solute feedings and high water intake are generally adequate. Addition of a thiazide diuretic reduces urine flow by inhibiting sodium reabsorption in the distal convoluted tubule. This lowers free water production and, by causing extracellular volume contraction, increases proximal salt and water reabsorption, reducing delivery to the distal nephron. Administration of vasopressin and its analogues has no role in the management of this disorder.

RENAL TUBULAR ACIDOSIS

Renal tubular acidosis (RTA) is a disorder of renal acidification out of proportion to the reduction in glomerular filtration rate. RTA is characterized by hyperchloremic metabolic acidosis with a normal serum anion gap [$Na^+ - (Cl^- + HCO_3^-)$]. There are multiple forms of RTA, depending on which aspects of renal acid handling have been affected. Defective bicarbonate reabsorption in the proximal tubule, suppressed renal ammoniagenesis, and inadequate distal tublule proton secretion are the abnormalities that produce RTA. Three types of RTA exist (Table 276-2). Types 1 and 2 may be inherited or acquired. Type 4 is acquired and is associated with either hypoaldosteronism or tubular hyporesponsiveness to mineralocorticoids. Type 3 was formerly used to define distal RTA with bicarbonate wasting in children; however, the bicarbonaturia resolves with age and is not truly part of a pathologic process. The term *type 3 RTA* is no longer used.

TYPE 1 (DISTAL)RTA

In this disorder the distal nephron does not lower urine pH normally, either because the collecting ducts permit excessive back-diffusion of hydrogen ions from lumen to blood or because there is inadequate transport of hydrogen ions. Excretion of titratable acid is low, as inadequate proton secretion prevents titration of urinary buffers such as phosphate. Urine ammonium excretion is inappropriately low for the level of acidosis, as the defect in acidification reduces the ion trapping required for ammonium excretion. Urinary concentration and potassium conservation also tend to be impaired.

Chronic acidosis lowers tubule reabsorption of calcium, causing renal hypercalciuria and mild secondary hyperparathyroidism. Buffering of bone by the daily metabolic acid load contributes to hypercalciuria. Urine citrate excretion is low, as acidosis and hypokalemia stimulate proximal tubule reabsorption of citrate. The hypercalciuria, alkaline urine, and low levels of urine citrate, which normally complexes about 40% of urine calcium, cause calcium phosphate stones and nephrocalcinosis. Growth in children is stunted because of rickets; this growth defect responds to amelioration of the acidosis with alkali. In the adult, osteomalacia occurs. In both children and adults, bone diseases may result, in part, from acidosis-induced loss of bone material and inadequate production of 1,25-dihydroxyvitamin D_3[1,25$(OH)_2D_3$]. Since the kidney does not conserve potassium or concentrate the urine normally, polyuria and hypokalemia occur. With the stress of an intercurrent illness, acidosis and hypokalemia can be life-threatening.

GENETIC CONSIDERATIONS

Type 1RTA can be familial, with autosomal dominant as the most common form of inheritance. X-linked, autosomal recessive, and sporadic cases have been reported. Mutations in the chloride-bicarbonate exchange gene (*AE1*) have been found in the autosomal dominant form. The cause of the autosomal recessive form is not known at this time. Other hereditary diseases that cause type 1 RTA include galactosemia, Ehler-Danlos syndrome, Fabry's disease,MSK, Wilson's disease, and hereditary elliptocytosis. The majority of cases of type 1 RTA are secondary to a systemic disorder such as Sjogren's syndrome, hypergammaglobulinemia, chronic active hepatitis, or lupus.

Diagnosis The diagnosis of type 1 RTA is suggested by a normal anion gap metabolic acidosis with a simultaneous urine pH greater than 5.5. Osteomalacia or rickets and calcium phosphate stones or nephrocalcinosis support the diagnosis, though they are not present in all cases. Bicarbonaturia is not present, which distinguishes this disorder from type 2 RTA. If acidosis is not severe and urine pH is equivocal, the oral ammonium chloride (NH_4Cl) loading test should be carried out: 0.1 g (1.9 mmol) NH_4Cl per kilogram of body weight is administered, and blood and urine pH are measured repeatedly over the next 6 h. Although systemic acidosis worsens, urine pH does not fall below 5.5. Urinary tract infection must not be present during this test because bacteria may possess urease, which hydrolyzes urea to ammonia and produces an alkaline urine.

Chronic diarrheal states cause normal anion gap acidosis and hypokalemia; urine pH may be>5.5 if ammonium production is very high. The urine anion gap ($Na^+ + K^+ - Cl^-$)

can be used to estimate renal ammonium production and distinguishRTA from gastrointestinal bicarbonate loss. Normally the urine anion gap is positive, as unmeasured anions exceed unmeasured cations. If urine ammonium levels are high, urine chloride concentration increases to balance the charge. Unmeasured cation (predominantly ammonium) now exceeds unmeasured anion, and the urine anion gap is negative. During metabolic acidosis, a negative urine anion gap suggests an extrarenal cause of acidosis, whereas a positive urine anion gap suggests RTA. The urine anion gap cannot be used if there are large amounts of unmeasured anions, such as bicarbonate or ketones, in the urine.

TREATMENT

Alkali supplements are the standard therapy. Enough alkali is prescribed to titrate the daily metabolic acid production, usually in the range of 0.5 to 2.0 mmol/kg body weight in four to six divided doses per day. Sodium bicarbonate and Shohl's solution (1 mmol sodium citrate and 1 mmol citric acid per mL) are common treatments. Potassium alkali salts can be used if hypokalemia is a persistent problem. Citrate requires less frequent dosing than bicarbonate salts as it is metabolized to bicarbonate after absorption. The dose of alkali should be raised until acidosis and hypercalciuria are both eliminated, and the patients should be followed by measurements of serum potassium, chloride, and CO_2content approximately twice yearly. Requirements for alkali usually rise during intercurrent illnesses but are usually below 4 mmol/kg body weight per day. The relatives of patients with idiopathic type 1RTAshould be screened for this disorder, as timely treatment can prevent growth retardation in children. Incomplete RTA secondary to idiopathic hypercalciuria is best treated using thiazide diuretics in conjunction with potassium citrate (Chap. 279).

TYPE 2 (PROXIMAL) RTA

Type 2 RTA usually occurs as part of a generalized disorder of proximal tubule function, presenting as hyperchloremic acidosis with other features of Fanconi syndrome. Bicarbonate reabsorption in the proximal tubule is defective. At normal concentrations of plasma bicarbonate, large amounts of bicarbonate are delivered to the distal tubule, overwhelming the absorptive capacity of the distal tubule and resulting in bicarbonaturia. As plasma bicarbonate levels fall, the lower filtered load of bicarbonate can be reabsorbed by the proximal tubule, resulting in normal distal delivery of bicarbonate. At this point the distal nephron can acidify the urine normally, resulting in normal excretion of daily metabolic acid production, albeit at a low serum bicarbonate level. Hypophosphatemia and low calcitriol levels are common and may lead to rickets or osteomalacia. Hypercalciuria occurs, but stone formation is unusual since urine citrate levels are normal or high because of reduced proximal tubule citrate reabsorption. Type 2 RTA may be inherited as autosomal dominant, autosomal recessive, or X-linked disorder. It may be acquired in association with other diseases (see "Fanconi Syndrome") or be secondary to drugs that inhibit carbonic anhydrase activity, such as acetazolamide.

Type 2RTA may be distinguished from type 1 RTA by the ability to normally acidify urine during spontaneous or ammonium chloride-induced acidosis. Correction of acidosis with bicarbonate will result in bicarbonaturia in type 2 RTA but not type 1 RTA. Fractional

excretion of bicarbonate is >15% at normal or near-normal serum bicarbonate levels. In distal RTA it is<10%. It is unusual for serum bicarbonate levels to fall below 15 mmol/L in proximal RTA. The urine anion gap will be positive, as ammonium excretion is normal to handle daily acid production but is not elevated as in nonrenal causes of acidosis.

TREATMENT

Children should be treated to prevent growth retardation. Alkali must be given in large amounts daily, 5 to 15 mmol/kg body weight per day, because bicarbonate is rapidly excreted in the urine. A thiazide diuretic can be used in conjunction with a low-salt diet to reduce the amount of bicarbonate required. Potassium supplementation is often required.

TYPE 4RTA

In type 4 RTA, also called *hyperkalemic distal RTA*, distal tubule secretion of both potassium and hydrogen ions is abnormal, resulting in hyperchloremic acidosis with hyperkalemia. Type 4 RTA is an acquired disorder; a moderate degree of renal insufficiency is present in the majority of patients. Patients with type 4 RTA can be differentiated from patients with type 1 since they have an acid urine (pH < 5.5) during periods of acidosis (Table 276-2) and hyperkalemia. They differ from type 2 patients by having a fractional excretion of bicarbonate<10% and a daily bicarbonate requirement of 1 to 3 mmol/kg body weight per day. Because potassium and hydrogen ion excretion are abnormal, such patients are considered to have generalized distal nephron dysfunction due to either insufficient aldosterone production or intrinsic renal disease causing aldosterone resistance. The resulting hyperkalemia reduces proximal tubule ammonia production, in addition to the inadequate proton secretion, leading to inadequate excretion of the daily metabolic proton load. These patients have an acid urine despite reduced proton secretion because there is inadequate ammonia to buffer protons in the distal tubule. If buffer delivery to the distal nephron is increased, urine pH will rise despite persistent acidosis.

Type 4RTA due to inadequate aldosterone production has multiple etiologies. Hyporeninemic hypoaldosteronism is the most common cause of type 4 RTA. Plasma levels of renin and aldosterone are subnormal, even during extracellular volume depletion, and the most common causes of this are diabetic nephropathy and chronic tubulointerstitial nephropathies. Nonsteroidal anti-inflammatory drugs, angiotensin-converting enzyme inhibitors, trimethoprim, and heparin can reduce aldosterone production and produce a type 4 RTA. Drug-induced type 4 RTA is usually seen in patients with preexisting renal insufficiency. Reduced aldosterone production may be due to adrenal disease, either occurring as an isolated defect or as part of a more generalized adrenal disorder (Chap. 331). Renin levels are normal to high in adrenal disorders.

Patients with tubular resistance to aldosterone present with the same clinical features as those with hyporeninemic hypoaldosteronism. A tubulointerstitial process damages the distal tubule, restricting potassium and hydrogen ion excretion, despite adequate aldosterone levels. Obstructive uropathy and sickle cell disease are the most common causes of acquired tubular resistance to aldosterone. Hyporeninemic

hypoaldosteronism can be found in addition to tubular aldosterone resistance in many patients. Spironolactone, a competitive inhibitor of the aldosterone receptor, produces an aldosterone-resistant state. Amiloride and triamterene are diuretics that block sodium transport in the distal nephron, blunting the effect of aldosterone on the distal tubule.

TREATMENT

This is aimed mainly at reducing serum potassium, as acidosis will usually improve once the hyperkalemic block of ammonium production is removed. All patients should be placed on a low-potassium diet. Any drug that suppresses aldosterone production or blocks aldosterone effect should be discontinued. Mineralocorticoid supplementation with fludrocortisone, 0.1 to 0.2 mg/d, will improve hyperkalemia and acidosis; however, the patients who also have a partial tubule resistance to mineralocorticoid will require a higher dose. Mineralocorticoid replacement may not be appropriate for patients with hypertension or a history of heart failure. In such situations, a loop diuretic with a liberal sodium intake can usually promote adequate potassium excretion. Exchange resins will reduce potassium levels but are usually not tolerated well enough to be used for long-term treatment.

PSEUDOHYPOALDOSTERONISM

GENETIC CONSIDERATIONS

This rare inherited disorder is transmitted as either an autosomal dominant or recessive trait. The autosomal dominant form is caused by mutations in the mineralocorticoid receptor gene; the autosomal recessive disease is caused by inactivating mutations in the amiloride-sensitive epithelial sodium channel. The inability to respond to aldosterone leads to hyperkalemia, metabolic acidosis, salt wasting, and volume depletion, which present during childhood. Plasma renin and aldosterone levels are elevated. Treatment includes salt supplements, alkali, and potassium restriction.

VITAMIN D DISORDERS

X-LINKED HYPOPHOSPHATEMIC RICKETS (See also Chap. 342)

This disorder, also called *vitamin D-resistant rickets*, is an X-linked dominant disorder characterized by hypophosphatemia with renal phosphate wasting, rickets, and short stature. Hypophosphatemia is present soon after birth; rachitic bowing of the legs develops when the child begins to walk. Children have growth retardation, which is limited almost entirely to the lower extremities. Dentition is delayed, and skull abnormalities are common. Females generally have less severe disease than males. Presentation in adults ranges from disabling bone pain to no active symptoms, but generally some physical sign of childhood disease, such as short stature or bowed legs, is present. Overgrowth of bone at joints or sites of muscle attachment may reduce the mobility of the joint or cause nerve entrapment.

Hypophosphatemia secondary to reduced renal phosphate reabsorption is the hallmark of the disease. Intestinal phosphate absorption is low, worsening hypophosphatemia. Serum calcium levels are usually normal, with low intestinal absorption and renal

excretion of calcium. Serum alkaline phosphatase and osteocalcin levels are elevated. Parathyroid hormone levels are normal, as would be expected with normal serum calcium. $1,25(OH)_2D_3$ levels are usually normal, though in the setting of hypophosphatemia $1,25(OH)_2D_3$ levels should be elevated. Inadequate 1a-hydroxylase activity appears to play some role in the disease. Linkage analysis has localized the gene to the Xp22.1 region of the X chromosome. The gene has been identified and appears to be related to a family of endopeptidase genes.

TREATMENT

The goal of therapy is to raise serum phosphorous to normal or near-normal levels to improve bone mineralization. Oral neutral phosphate, 1 to 4 g/d in four to six doses, combined with calcitriol is an effective therapy that improves growth rate, reduces bone pain, and leads to radiographically evident improvement of the bone disease. Patients should be closely monitored during therapy as they may develop nephrocalcinosis and renal insufficiency.

VITAMIN D-DEPENDENT RICKETS TYPE I

GENETIC CONSIDERATIONS

This is an autosomal recessive disorder in which $1,25(OH)_2D_3$ levels are very low but 25-hydroxyvitamin D levels are normal. The disease is caused by inactivating mutations in the gene encoding the 1a-hydroxylase enzyme, leading to a clinical syndrome of vitamin D deficiency.

Symptoms usually appear before the age of 2, including rickets and growth retardation. Levels of serum calcium and phosphorous are low, but that of alkaline phosphatase is elevated. Intestinal calcium absorption and urinary calcium excretion are low. Parathyroid hormone is elevated in response to the hypocalcemia, resulting in increased urinary phosphate losses.

TREATMENT

Calcitriol (0.5 to 1 ug/d) leads to rapid correction of the biochemical abnormalities and resolution of the bone disease. Calcium and phosphorous supplementation are usually not required.

VITAMIN D-DEPENDENT RICKETS TYPE II (See also Chap. 342)

End-organ resistance to $1,25(OH)_2D_3$ is the pathogenesis of this disorder. Serum calcium and phosphate levels are low, secondary hyperparathyroidism is present, and $1,25(OH)_2D_3$ levels are elevated. Inheritance is usually autosomal recessive, though sporadic cases have been reported. Most patients present during childhood with rickets, though some have a milder form of disease not recognized until adulthood. Alopecia is common and tends to be associated with the more severe childhood form of the disease. Multiple defects have been detected in $1,25(OH)_2D_3$ receptor interaction, including absent hormone binding to the receptor, decreased receptor affinity, abnormal hormone-receptor localization, and abnormalities of the DNA-binding domain of the

receptor. Pharmacologic doses of calcitriol (5 to 30 ug/d) along with mineral supplementation will improve the biochemical disorders and bone disease, though some patients have no response to massive doses of calcitriol.

ONCOGENIC OSTEOMALACIA

This syndrome generally occurs in adults with highly vascular mesenchymal tumors. Patients present with bone pain and muscle weakness. Symptoms may be present for years before the correct diagnosis is made. Over 90% of the tumors are benign, and most are found in the extremities or maxillofacial region. Hypophosphatemia secondary to renal phosphate wasting and low levels of $1,25(OH)_2D_3$are the major biochemical abnormalities. Serum calcium and parathyroid hormone levels are normal. It appears the tumor produces a humoral agent that reduces proximal tubule phosphate reabsorption and 1a-hydroxylase activity. Removal of the tumor leads to rapid resolution of the disease.

X-LINKED RECESSIVE NEPHROLITHIASIS

This disorder presents as calcium nephrolithiasis in male children and progresses to nephrocalcinosis and renal failure. Low-molecular-weight proteinuria and hypercalciuria are also prominent features of the disease. Kidney biopsy reveals tubular atrophy, interstitial fibrosis, and medullary calcifications. The gene has been mapped to the short arm of the X chromosome and encodes a voltage-gated chloride channel (CLC-5). Dent's disease has been mapped to the same gene and has a similar presentation, except for an increased incidence of rickets.

ISOLATED HYPOURICEMIA (See also Chap. 353)

This disorder is generally inherited as an autosomal recessive trait. Most commonly there is deficient urate reabsorption in the proximal tubule, though some patients have been demonstrated to oversecrete urate. Serum uric acid is usually<120 umol/L (2 mg/dL) and hyperuricosuria is common, possibly due to decreased intestinal urate excretion. Hypouricemia is usually an incidental finding, as patients with this disorder are asymptomatic except for an increased risk of nephrolithiasis. Other disorders associated with hypouricemia include Fanconi syndrome, Wilson's disease, Hodgkin's disease, and Hartnup disease. No treatment is required except for high fluid intake to prevent kidney stones. Alkali and allopurinol may be used to prevent stones if fluids alone are not sufficient. Hypercalciuria has been associated with isolated hypouricemia in some families.

SELECTED DISORDERS OF AMINO ACID TRANSPORT

HARTNUP DISEASE

This disorder is characterized by reduced intestinal absorption and renal reabsorption of neutral amino acids. The defect involves an amino acid transporter on the brush border of the jejunum and the proximal tubule. Intestinal absorption of free amino acids is reduced, though the neutral amino acids can be absorbed when present in di- and tripeptides. Degradation of unabsorbed tryptophan by intestinal bacteria produces

indolic acids that are absorbed and subsequently excreted at high levels in the urine of these patients. The disorder is inherited as an autosomal recessive trait, affecting males and females equally. Widespread screening of newborns has estimated an incidence of 1 in 24,000 live births.

The majority of individuals with this disorder are asymptomatic. Approximately 10 to 20% present with clinical symptoms similar to those seen in pellagra, including a photosensitive erythematous scaly rash, intermittent cerebral ataxia, delirium, and diarrhea. Short stature is noted in some patients. The symptoms are thought to be due to deficiency in the essential amino acid tryptophan and resultant inadequate synthesis of nicotinamide. Though the inheritance of the disorder is Mendelian autosomal recessive, the development of symptomatic disease appears to be multifactorial. Diet, environment, and polygenic traits controlling plasma amino acid levels all contribute to development of symptoms.

Clinically affected patients can be differentiated from patients with pellagra by dietary history and the presence of aminoaciduria. Diagnosis is made by the characteristic finding of large amounts of neutral amino acids in the urine. It can easily be distinguished from generalized aminoaciduria by the normal excretion of proline. There are no other renal tubule defects as in Fanconi syndrome. Heterozygotes have normal urinary amino acid excretion.

TREATMENT

Symptomatic individuals should receive oral nicotinamide, 40 to 200 mg/d, and a high-protein diet to compensate for the poor amino acid absorption. Some patients who do not respond to nicotinamide may improve with tryptophan ethyl ester, which is lipid soluble and can be absorbed without an active transport system.

FANCONI SYNDROME

GENETIC CONSIDERATIONS

Fanconi syndrome is a generalized defect in proximal tubule transport involving amino acids, glucose, phosphate, uric acid, sodium, potassium, bicarbonate, and proteins. Idiopathic Fanconi syndrome may be inherited as an autosomal dominant, autosomal recessive, or X-linked trait. Sporadic cases are also seen. A variety of inherited systemic disorders are also associated with Fanconi syndrome including Wilson's disease, galactosemia, tyrosinemia, cystinosis, fructose intolerance, and Lowe's oculocerebral syndrome. The syndrome may be acquired in multiple myeloma, amyloid, and heavy metal toxicity.

The patients may present with a wide array of laboratory abnormalities including proximal renal tubular acidosis, glucosuria with a normal serum glucose, hypophosphatemia, hypouricemia, hypokalemia, generalized aminoaciduria, and low-molecular-weight proteinuria. Some patients do not have abnormalities in all proximal tubule transporters and may present with only a few of the laboratory findings. Rickets and osteomalacia are common findings secondary to the hypophosphatemia; production of calcitriol may also be abnormal. Metabolic acidosis also contributes to the

bone disease. Polyuria, salt wasting, and hypokalemia may be quite severe.

TREATMENT

Treatment includes phosphate supplements and calcitriol to heal the bone lesions, alkali for the acidosis, and liberal intake of salt and water. Alkali in the form of potassium salts may be particularly useful in the patient withRTA and hypokalemia. Aminoaciduria, glucosuria, hypouricemia, and low-molecular-weight proteinuria do not require treatment.

277. TUBULOINTERSTITIAL DISEASES OF THE KIDNEY - *Alan S. L. Yu, Barry M. Brenner*

Primary tubulointerstitial diseases of the kidney, as distinct from the disorders considered in Chaps. 274 and275, are characterized by histologic and functional abnormalities that involve the tubules and interstitium to a greater degree than the glomeruli and renal vasculature (Table 277-1). Secondary tubulointerstitial disease occurs as a consequence of progressive glomerular or vascular injury. These disorders can be further divided into acute and chronic forms. The chronic group may be due to sustained insults by a factor or factors that initially cause acute disease or to a slower, progressive, cumulative insult without an identifiable acute episode. Morphologically, acute forms of these disorders are characterized by interstitial edema, often associated with cortical and medullary infiltration by both mononuclear cells and polymorphonuclear leukocytes, and patchy areas of tubule cell necrosis. In more chronic forms, interstitial fibrosis predominates, inflammatory cells are typically mononuclear, and abnormalities of the tubules tend to be more widespread, as evidenced by atrophy, luminal dilatation, and thickening of tubule basement membranes. Because of the nonspecific nature of the histology, particularly in chronic tubulointerstitial diseases, biopsy specimens rarely provide a specific diagnosis. The urine sediment is also unlikely to be diagnostic, except in allergic forms of acute tubulointerstitial disease, in which eosinophils may predominate in the urinary sediment.

Defects in renal function often accompany these alterations of tubule and interstitial structure (Table 277-2). Proximal tubule dysfunction may be manifested as selective reabsorptive defects leading to hypokalemia, aminoaciduria, glycosuria, phosphaturia, uricosuria, or bicarbonaturia (proximal or type II renal tubular acidosis;Chap. 276). In combination, these defects constitute the *Fanconi syndrome*. Proteinuria, predominantly of low-molecular-weight proteins, is usually modest, rarely exceeding 2 g/d.

Defects in urinary acidification and concentrating ability often represent the most troublesome of the tubule dysfunctions encountered in patients with tubulointerstitial disease. Hyperchloremic metabolic acidosis often develops at a relatively early stage in the course. Patients with this finding generally elaborate urine of maximal acidity (pH £ 5.3). In such patients the defect in acid excretion is usually caused by a reduced capacity to generate and excrete ammonia due to the reduction in renal mass. Preferential damage to the collecting ducts, as in amyloidosis or chronic obstructive uropathy, may also predispose to distal or type I renal tubular acidosis (RTA), characterized by high urine pH (³5.5) during spontaneous or NH_4Cl-induced metabolic acidosis. Patients with tubulointerstitial diseases affecting predominantly medullary and papillary structures may also exhibit concentrating defects, with resultant nocturia and polyuria. Analgesic nephropathy and sickle cell disease are prototypes of this form of injury.

TOXINS

Although the kidneys constitute less than 1% of total body mass, they receive approximately 20% of the cardiac output, and 90% or more of renal blood flow is distributed to the renal cortex. Exposure of tubules and interstitium of the renal cortex to circulating toxins is therefore greater than for most other tissues. Transport processes in

renal tubules contribute further to the intrarenal accumulation of toxins, enhancing local concentrations of noxious agents. The urinary concentrating mechanism can also establish high levels of toxins within medullary and papillary portions of the kidney, predisposing these regions to chemical injury. Finally, the relatively acid pH of the fluid within most nephron segments may affect the ionization characteristics of potentially toxic compounds and thereby influence local concentration and solubility. Although these processes render the kidney vulnerable to toxic injury, the role of nephrotoxins in renal damage often goes unrecognized because the manifestations of such injury are usually nonspecific in nature and insidious in onset. Diagnosis largely depends on a history of exposure to a certain toxin. Particular attention should be paid to the occupational history, as well as to an assessment of exposure -- current and remote -- to drugs, especially antibiotics and analgesics, and to dietary supplements or herbal remedies. The recognition of a potential association between a patient's renal disease and exposure to a nephrotoxin is crucial, because, unlike many other forms of renal disease, progression of the functional and morphologic abnormalities associated with toxin-induced nephropathies may be prevented, and even reversed, by eliminating additional exposure.

EXOGENOUS TOXINS

Analgesic Nephropathy A distinct clinicopathologic syndrome has been described in heavy users of analgesic mixtures containing phenacetin in combination with aspirin, acetaminophen, or caffeine. These individuals have an approximately 20-fold increased risk of end-stage renal disease (ESRD). Analgesic nephropathy has been an important cause of chronic renal failure in Australia, Switzerland, Sweden, Belgium, and the southeastern United States.

Morphologically, analgesic nephropathy is characterized by papillary necrosis and tubulointerstitial inflammation. At an early stage, damage to the vascular supply of the inner medulla (vasa recta) leads to a local interstitial inflammatory reaction and, eventually, to papillary ischemia, necrosis, fibrosis, and calcification. The susceptibility of the renal papillae to damage by phenacetin is believed to be related to the establishment of a renal gradient for its acetaminophen metabolite, resulting in papillary tip concentrations tenfold higher than those in renal cortex. Hydration dissipates this gradient and may explain the protective effect of this maneuver in preventing phenacetin-induced papillary necrosis in animals. Aspirin in these analgesic compounds contributes to renal injury by uncoupling oxidative phosphorylation in renal mitochondria and by inhibiting the synthesis of renal prostaglandins, which are potent endogenous renal vasodilator hormones.

Analgesic nephropathy occurs some three to five times more commonly in women than in men. A direct relationship exists between the total amount of analgesic compounds ingested and the degree of renal impairment. The intake of 1.0 g phenacetin per day for 1 to 3 years or the total ingestion of 2 kg phenacetin in combination with other analgesics appears to represent minimum requirements for the development of analgesic nephropathy.

Whether single-ingredient analgesics other than phenacetin, when used alone, cause renal disease is controversial. Recent reports have suggested a two- to threefold

increase in the risk ofESRDamong regular users of acetaminophen, and perhaps nonsteroidal anti-inflammatory drugs (NSAIDs), but not among regular users of aspirin. Until conclusive evidence is available, physicians should consider screening regular users of acetaminophen and NSAIDs for evidence of renal disease.

In analgesic nephropathy, renal function usually declines gradually, in association with chronic necrosis of papillae and diffuse tubulointerstitial damage to the renal cortex. Occasionally, papillary necrosis may be associated with hematuria and even renal colic owing to obstruction of a ureter by necrotic tissue. More than half of patients with analgesic nephropathy have pyuria, which, if persistently associated with sterile urine, provides an important clue to the diagnosis. Nonetheless, active pyelonephritis may coexist in patients with analgesic nephropathy. Proteinuria, if present, is typically mild (< 1 g/d). Patients with analgesic nephropathy are usually unable to generate maximally concentrated urine, reflecting the underlying medullary and papillary damage. An acquired form of distalRTA may contribute to the development of *nephrocalcinosis*. The occurrence of anemia out of proportion to the degree of azotemia also may provide a clue to the diagnosis of analgesic nephropathy. When analgesic nephropathy has progressed to renal insufficiency, the kidneys usually appear bilaterally shrunken on intravenous pyelography, and the calyces are deformed. A "ring sign" on the pyelogram is pathognomonic of papillary necrosis and represents the radiolucent sloughed papilla surrounded by the radiodense contrast material in the calyx. Renal sonography may reveal papillary calcifications surrounding the central sinus complex in a "garland" pattern. Transitional cell carcinoma may develop in the urinary pelvis or ureters as a late complication of analgesic abuse.

TREATMENT

Every effort must be made to convince the patient who ingests excessive amounts of analgesic combinations to discontinue this hazardous practice. When renal damage is at an early stage, cessation of abuse usually arrests the progression of the nephrotoxic process; not infrequently, overall renal function improves with time. With continued abuse, however, progressive renal damage leads invariably to chronic renal failure.

Lead Nephropathy (See also Chap. 395) Lead intoxication may produce a chronic tubulointerstitial renal disease. Children who repeatedly ingest lead-based paints may develop kidney disease as adults. Significant occupational exposure may occur in a diverse variety of workplaces where lead-containing metals or paints are heated to high temperatures, such as battery factories, smelters, salvage yards, and firing ranges. Alcohol, illegally distilled in an apparatus constructed from automobile radiators (so-called moonshine), is another cause of lead poisoning. Environmental lead exposure, particularly in industrial regions, may be great enough to produce changes in renal function.

Tubule transport processes enhance the accumulation of lead within renal cells, particularly in the proximal convoluted tubule, leading to cell degeneration, mitochondrial swelling, and eosinophilic intranuclear inclusion bodies rich in lead. In addition to tubule degeneration and atrophy, lead nephropathy is associated with ischemic changes in the glomeruli, fibrosis of the adventitia of small renal arterioles, and focal areas of cortical scarring. Eventually, the kidneys become atrophic. Urinary excretion of lead, porphyrin

precursors such asd-aminolevulinic acid and coproporphyrin, and urobilinogen, may be increased. Patients with chronic lead nephropathy are characteristically *hyperuricemic*, a consequence of enhanced reabsorption of filtered urate. Acute gouty arthritis (so-called saturnine gout) develops in about 50% of patients with lead nephropathy, in striking contrast to other forms of chronic renal failure in which de novo gout is rare (Chap. 347). Hypertension is also a complication. Therefore, in any patient with slowly progressive renal failure, atrophic kidneys, gout, and hypertension, the diagnosis of lead intoxication should be considered. Features of acute lead intoxication (abdominal colic, anemia, peripheral neuropathy, and encephalopathy) are usually absent.

The diagnosis may be suspected by finding elevated serum levels of lead. However, because blood levels may not be elevated even in the presence of a toxic total-body burden of lead, the quantitation of lead excretion following infusion of the chelating agent calcium disodium edetate is a more reliable indicator of serious lead exposure. While urinary excretion of more than 0.6 mg/d of lead is generally considered to be indicative of overt or potential toxicity, recent evidence suggests that even lead burdens of 0.15 to 0.6 mg/d may cause progressive loss of renal function.

TREATMENT

Treatment includes removing the patient from the source of exposure and augmenting lead excretion with a chelating agent such as calcium disodium edetate.

Miscellaneous Nephrotoxins Use of *lithium salts* for bipolar disorder has been associated with polyuria and polydipsia caused by tubulointerstitial disease. There are only rare reports of chronic renal insufficiency attributable to this agent. Renal function should be followed in patients taking this drug, and caution should be exercised if lithium is employed in patients with underlying renal disease.

The immunosuppressant *cyclosporine* causes both acute and chronic renal injury. The acute injury and the use of cyclosporine in transplantation are discussed inChap. 272. The chronic injury results in an irreversible reduction in glomerular filtration rate (GFR), with mild proteinuria and arterial hypertension. Hyperkalemia is a relatively common complication and results in part from tubule resistance to aldosterone. Hypomagnesemia due to urinary magnesium wasting is less common but can cause hypocalcemia. The histologic changes in renal tissue include patchy interstitial fibrosis and tubular atrophy. In addition, the intrarenal vasculature often demonstrates hyalinosis, and focal segmental glomerular sclerosis can be present as well. Fibrosis may be the result of a cyclosporine-induced increase in renal collagen production. Vasoconstrictive mediators, such as angiotensin II, or vasoconstriction itself may also play a role in chronic cyclosporine toxicity. In patients receiving this drug for renal transplantation (Chap. 272), chronic rejection and recurrence of the primary disease may coincide with chronic cyclosporine injury, and on clinical grounds, distinction among these may be difficult. Although most patients experience stable, albeit reduced, renal function, progressive renal injury can occur without a progressive reduction in GFR. Dose reduction appears to mitigate cyclosporine-associated renal fibrosis but may increase the risk of rejection and graft loss. The optimal dosage of cyclosporine in renal transplantation remains controversial. Treatment of any associated arterial hypertension may lessen renal injury.

Many agents that commonly lead to acute renal failure are also capable of producing tubulointerstitial injury (Chap. 269). These include antibiotics (e.g., aminoglycosides, amphotericin B), radiographic contrast agents, various hydrocarbons (e.g., carbon tetrachloride), and heavy metals (e.g., mercury, cadmium, and bismuth).

METABOLIC TOXINS

Acute Uric Acid Nephropathy (See also Chap. 322) Acute overproduction of uric acid and extreme hyperuricemia often lead to a rapidly progressive renal insufficiency, so-called acute uric acid nephropathy. This tubulointerstitial disease is usually seen as part of the tumor lysis syndrome in patients given cytotoxic drugs for the treatment of lymphoproliferative or myeloproliferative disorders but may also occur in these patients before such treatment is begun. The pathologic changes are largely the result of deposition of uric acid crystals in the kidneys and their collecting systems, leading to partial or complete obstruction of collecting ducts, renal pelvis, or ureter. Since obstruction is often bilateral, patients typically show the clinical course of acute renal failure, characterized by oliguria and rapidly rising serum creatinine concentration. In the early phase uric acid crystals can be found in urine, usually in association with microscopic or gross hematuria. Hyperuricemia can also be a consequence of renal failure of any etiology. The finding of a urine uric acid-creatinine ratio greater than 1 mg/mg (0.7 mol/mol) distinguishes acute uric acid nephropathy from other causes of renal failure.

Prevention of hyperuricemia in patients at risk by treatment with allopurinol in doses of 200 to 800 mg/d prior to cytotoxic therapy reduces the danger of acute uric acid nephropathy. Once hyperuricemia develops, however, efforts should be directed to preventing deposition of uric acid within the urinary tract. Increasing urine volume with potent diuretics (furosemide or mannitol) effectively lowers intratubular uric acid concentrations, and alkalinization of the urine to pH 7 or greater with sodium bicarbonate and/or a carbonic anhydrase inhibitor (acetazolamide) enhances uric acid solubility. If these efforts, together with allopurinol therapy, are ineffective in preventing acute renal failure, dialysis should be instituted to lower the serum uric acid concentration as well as to treat the acute manifestations of uremia.

Gouty Nephropathy (See also Chap. 322) Patients with less severe but prolonged forms of hyperuricemia are predisposed to a more chronic tubulointerstitial disorder, often referred to as *gouty nephropathy*. The severity of renal involvement correlates with the duration and magnitude of the elevation of the serum uric acid concentration. Histologically, the distinctive feature of gouty nephropathy is the presence of crystalline deposits of uric acid and monosodium urate salts in kidney parenchyma. These deposits not only cause intrarenal obstruction but also incite an inflammatory response, leading to lymphocytic infiltration, foreign-body giant cell reaction, and eventual fibrosis, especially of medullary and papillary regions of the kidney. Bacteriuria and pyelonephritis occur in about one-fourth of cases, presumably as complications of intrarenal urinary stasis. Since patients with gout frequently suffer from hypertension and hyperlipidemia, degenerative changes of the renal arterioles may constitute a striking feature of the histologic abnormality, often out of proportion to other morphologic defects. Clinically, gouty nephropathy is an insidious cause of renal insufficiency. Early

in its course,GFR may be near normal, often despite focal morphologic changes in medullary and cortical interstitium, proteinuria, and diminished urinary concentrating ability. Whether reducing serum uric acid levels with allopurinol exerts a beneficial effect on the kidney remains to be demonstrated. Although such undesirable consequences of hyperuricemia as gout and uric acid stones respond well to allopurinol, use of this drug in asymptomatic hyperuricemia has not been shown to improve renal function consistently. On the other hand, uricosuric agents such as probenecid, which may increase uric acid stone production, clearly have no role in the treatment of renal disease associated with hyperuricemia.

Hypercalcemic Nephropathy (See also Chap. 341) Chronic hypercalcemia, as occurs in primary hyperparathyroidism, sarcoidosis, multiple myeloma, vitamin D intoxication, or metastatic bone disease, can cause tubulointerstitial damage and progressive renal insufficiency. The earliest lesion is a focal degenerative change in renal epithelia, primarily in collecting ducts, distal convoluted tubules, and loops of Henle. Tubule cell necrosis leads to nephron obstruction and stasis of intrarenal urine, favoring local precipitation of calcium salts and infection. Dilatation and atrophy of tubules eventually occur, as do interstitial fibrosis, mononuclear leukocyte infiltration, and interstitial calcium deposition (nephrocalcinosis). Calcium deposition also may occur in glomeruli and the walls of renal arterioles.

Clinically, the most striking defect is an inability to concentrate the urine maximally, resulting in polyuria and nocturia. Defective transport of NaCl in the ascending limb of Henle's loop is responsible, at least in part, for this concentrating defect. Additionally, reduced collecting duct responsiveness to vasopressin may contribute. Reductions in GFRand renal blood flow also occur, both in acute severe hypercalcemia and with prolonged hypercalcemia of lesser severity. DistalRTA and sodium and potassium wasting also have been described in these chronic states. Eventually, uncontrolled hypercalcemia leads to severe tubulointerstitial damage and overt renal failure. Abdominal x-rays may demonstrate nephrocalcinosis as well as nephrolithiasis, the latter due to the hypercalciuria that often accompanies hypercalcemia.

TREATMENT

This consists of reducing the serum calcium concentration toward normal and correcting the primary abnormality of calcium metabolism. The management of hypercalcemia is discussed in Chap. 341. Prognosis for recovery of renal function depends on the severity of the renal lesion at the time hypercalcemia is corrected. Renal dysfunction of acute hypercalcemia may be completely reversible. Gradual, progressive renal insufficiency related to chronic hypercalcemia, however, may not improve with correction of the calcium disorder. Nonetheless, every effort should be made to return serum calcium concentration to normal to minimize further loss of renal function.

Hypokalemic Nephropathy (See alsoChap. 49) Disturbances of renal structure and function occur commonly in patients with moderate to severe potassium depletion of at least several weeks' duration. Histologically, renal epithelial cells are often seen to contain numerous vacuoles, most marked in proximal tubules. Glomeruli are reduced in size and may become sclerotic. Whether prolonged or recurrent potassium deficiency results in irreversible tubulointerstitial fibrosis, scarring, and atrophy is unresolved. Loss

of urinary concentrating ability is the most commonly encountered functional defect and may be due to defective operation of the countercurrent multiplier system and elevated intrarenal prostaglandins. Nocturia, polyuria, and polydipsia are frequent symptoms. Urinalysis often reveals no abnormalities except for mild proteinuria. Serum creatinine and urea nitrogen concentrations usually remain within normal limits.

Miscellaneous Metabolic Toxins Urinary oxalate, derived from the metabolism of glycine and, to a variable extent, from ingested oxalate, may deposit as insoluble intratubular calcium oxalate crystals and result in chronic tubulointerstitial damage in patients with hereditary or acquired forms of *hyperoxaluria*. *Cystinosis* and *Fabry's disease* are other hereditary depositional disorders affecting the renal tubules and interstitium (Chap. 276).

RENAL PARENCHYMAL DISEASE ASSOCIATED WITH EXTRARENAL NEOPLASM

Except for the glomerulopathies associated with lymphomas and several solid tumors (Chap. 275), the renal manifestations of primary extrarenal neoplastic processes are confined mainly to the interstitium and tubules. Although metastatic renal involvement by solid tumors is unusual, the kidneys are often invaded by neoplastic cells in various lymphomas and leukemias and in multiple myeloma. In postmortem studies of patients with *lymphoma*, renal involvement is found in approximately half. The involvement may be focal, in the form of multiple discrete nodules, or diffuse, with lymphomatous infiltration throughout the renal parenchyma. Diffuse infiltration is seen most commonly in lymphomas other than Hodgkin's disease. There may be flank pain related to massive renal infiltration, and x-rays may show enlargement of one or both kidneys. Renal insufficiency occurs in a minority of cases, and overt uremia is rare. Treatment of the primary disease may improve renal function in these cases.

The kidneys are also commonly involved in various forms of *leukemia*. At postmortem examination, bilateral renal involvement is present in approximately 50% of cases. As with lymphoma, uremia is rarely, if ever, a consequence of leukemic infiltration of the kidneys. The kidneys can also be involved in leukemias because of the associated high incidence of hyperuricemia, hypercalcemia, and lysozymuria. The myelogenous leukemias, particularly of the monocytic type, may be complicated by tubule defects involving potassium and magnesium wasting.

PLASMA CELL DYSCRASIAS

Several glomerular and tubulointerstitial disorders may occur in association with plasma cell dyscrasias (Table 277-3;Chap. 113). Infiltration of the kidneys with myeloma cells is infrequent. When it occurs, the process is usually focal, so renal insufficiency from this cause is also uncommon. The more usual lesion is *myeloma kidney*, characterized histologically by atrophic tubules, many with eosinophilic intraluminal casts, and numerous multinucleated giant cells within tubule walls and in the interstitium. The frequent occurrence of myeloma kidney in patients with Bence Jones proteinuria has suggested a causal relation. Bence Jones proteins are thought to cause myeloma kidney through direct toxicity to renal tubule cells. In addition, Bence Jones proteins may precipitate within the distal nephron where the high concentrations of these proteins and the acid composition of the tubule fluid favor intraluminal cast formation and intrarenal

obstruction. Occasionally, acute renal failure occurs after intravenous pyelography in patients with multiple myeloma and is believed to result from the further precipitation of Bence Jones proteins induced by dehydration prior to radiographic study. Dehydration of the patient with myeloma in preparation for intravenous pyelography should therefore be avoided. Multiple myeloma may also affect the kidneys indirectly. Hypercalcemia or hyperuricemia may lead to the nephropathies described above. Proximal tubule disorders are also seen occasionally, including type II proximalRTA and the Fanconi syndrome.

AMYLOIDOSIS (See alsoChaps. 275 and319)

Glomerular pathology usually predominates and leads to heavy proteinuria and azotemia. However, tubule function may also be deranged, giving rise to a nephrogenic diabetes insipidus and to distal (type I)RTA. In several cases these functional abnormalities correlated with peritubular deposition of amyloid, particularly in areas surrounding vasa rectae, loops of Henle, and collecting ducts. Bilateral enlargement of the kidneys, especially in a patient with massive proteinuria and tubule dysfunction, should raise the possibility of amyloid renal disease.

IMMUNE DISORDERS

ALLERGIC INTERSTITIAL NEPHRITIS

An acute diffuse tubulointerstitial reaction may result from hypersensitivity to a number of drugs, including sulfonamides, many penicillins and cephalosporins, the fluoroquinolone antibiotics ciprofloxacin and norfloxacin, and the antituberculous drugs isoniazid and rifampin. Acute tubulointerstitial damage has also occurred after use of thiazide and loop diuretics, antiulcer medications (cimetidine, ranitidine, and omeprazole), andNSAIDs. Of note, the tubulointerstitial nephropathy that develops in some patients taking NSAIDs may be associated with nephrotic-range proteinuria and histologic evidence of either minimal change or membranous glomerulopathy. Grossly, the kidneys are usually enlarged. Histologically, the glomeruli appear normal. The principal pathologic abnormalities are in the interstitium of the kidney, which reveals pronounced edema and infiltration with polymorphonuclear leukocytes, lymphocytes, plasma cells, and, in some cases, large numbers of eosinophils. If the process is severe, tubule cell necrosis and regeneration may also be apparent. Immunofluorescence studies have either been unrevealing or demonstrated a linear pattern of immunoglobulin and complement deposition along tubule basement membranes. In a few cases of methicillin-induced acute tubulointerstitial disease, circulating anti-tubule basement membrane antibodies have also been found, suggesting that autoantibody formation may have been induced by the penicilloyl hapten of methicillin (by conjugation of hapten with tubule basement membrane proteins, thereby altering the native antigenicity of the basement membrane).

Most patients require several weeks of drug exposure before developing evidence of renal injury. Rare cases have occurred after only a few doses or after a year of more of use. Azotemia is usually present; a diagnostic triad of fever, skin rash, and peripheral blood eosinophilia is highly suggestive of acute tubulointerstitial nephritis but is often absent. Examination of the urine sediment reveals hematuria and often pyuria;

occasionally, eosinophils may be present. Proteinuria is usually mild to moderate, except in cases ofNSAID-induced tubulointerstitial nephritis with minimal change glomerulopathy. The clinical picture may be confused with acute glomerulonephritis, but when acute azotemia and hematuria are accompanied by eosinophilia, skin rash, and a history of drug exposure, a hypersensitivity reaction leading to acute tubulointerstitial nephritis should be regarded as the leading diagnostic possibility. Discontinuation of the drug usually results in complete reversal of the renal injury; rarely, renal damage may be irreversible. Glucocorticoids may accelerate renal recovery, but their value has not been definitively established.

SJOGREN'S SYNDROME (See alsoChap. 314)

When the kidneys are involved in this disorder, the predominant histologic findings are those of chronic tubulointerstitial disease. Interstitial infiltrates are composed primarily of lymphocytes, causing the histology of the renal parenchyma in these patients to resemble that of the salivary and lacrimal glands. Renal functional defects include diminished urinary concentrating ability and distal (type I)RTA. Urinalysis may show pyuria (predominantly lymphocyturia) and mild proteinuria.

TUBULOINTERSTITIAL ABNORMALITIES ASSOCIATED WITH GLOMERULONEPHRITIS

Primary glomerulopathies are often associated with damage to tubules and the interstitium. Occasionally, the primary disorder may affect glomeruli and tubules directly. For example, in more than half of patients with the nephropathy of systemic lupus erythematosus, deposits of immune complexes can be identified in tubule basement membranes, usually accompanied by an interstitial mononuclear inflammatory reaction. Similarly, in many patients with glomerulonephritis associated with anti-glomerular basement membrane antibody, the same antibody is reactive against tubule basement membranes as well. More frequently, tubulointerstitial damage is a secondary consequence of glomerular dysfunction. The extent of tubulointerstitial fibrosis correlates closely with the degree of renal impairment. Potential mechanisms by which glomerular disease might cause tublointerstitial injury include glomerular leak of plasma proteins toxic to epithelial cells, activation of tubule epithelial cells by glomerulus-derived cytokines, reduced peritubular blood flow leading to downstream tubulointerstitial ischemia, and hyperfunction of remnant tubules.

MISCELLANEOUS DISORDERS

VESICOURETERAL REFLUX (See also Chap. 281)

When the function of the ureterovesical junction is impaired, urine may reflux into the ureters due to the high intravesical pressure that develops during voiding. Clinically, reflux is often detected on the voiding and postvoiding films obtained during intravenous pyelography, although voiding cystourethrography may be required for definitive diagnosis. Bladder infection may ascend the urinary tract to the kidneys through incompetent ureterovesical sphincters. Not surprisingly, therefore, reflux is often discovered in patients with acute and/or chronic urinary tract infections. With more severe degrees of reflux, characterized by dilatation of ureters and renal pelves,

progressive renal damage often appears, and although active infection may also be present, uncertainty exists as to the necessity of infection in producing the scarred kidney of reflux nephropathy. Substantial proteinuria is often present, and glomerular lesions similar to those of idiopathic focal glomerulosclerosis (Chap. 274) are often found in addition to the changes of chronic tubulointerstitial disease. Surgical correction of reflux is usually necessary only with the more severe degrees of reflux since renal damage correlates with the extent of reflux. Obviously, if extensive glomerulosclerosis already exists, urologic repair may no longer be warranted.

RADIATION NEPHRITIS

Renal dysfunction can be expected to occur if 23 Gy (2300 rad) or more of x-ray irradiation is administered to both kidneys during a period of 5 weeks or less. Histologic examination of the kidneys reveals hyalinized glomeruli, atrophic tubules, extensive interstitial fibrosis, and hyalinization of the media of renal arterioles. Radiation-induced renal ischemia is believed to be the main pathogenic factor responsible for the tubulointerstitial damage, which may not become evident clinically for months after completion of radiation. The presentation of acute radiation nephritis includes rapidly progressive azotemia, moderate to malignant hypertension, anemia, and proteinuria that may reach the nephrotic range. More than 50% progress to chronic renal failure. A more insidious form is characterized by slower development of azotemia, anemia, and nephrotic syndrome. Malignant hypertension may follow unilateral renal irradiation and resolve with ipsilateral nephrectomy. Radiation nephritis has all but vanished because of heightened awareness of its pathogenesis by radiotherapists.

278. VASCULAR INJURY TO THE KIDNEY - *Kamal F. Badr*, *Barry M. Brenner*

Adequate delivery of blood to the glomerular capillary network is crucial for glomerular filtration and overall salt and water balance. Thus, in addition to the threat to the viability of renal tissue, vascular injury to the kidney may compromise the maintenance of body fluid volume and composition. Involvement of the renal vessels by atherosclerotic, hypertensive, embolic, inflammatory, and hematologic disorders is usually a manifestation of generalized vascular pathology. The morphologic and clinical responses to these insults and the unique renal vasculopathy associated with the toxemias of pregnancy are considered in this**chapter**.

THROMBOEMBOLIC DISEASES OF THE RENAL ARTERIES

Thrombosis of the major renal arteries or their branches is an important cause of deterioration of renal function, especially in the elderly. It is often difficult to diagnose and therefore requires a high index of suspicion. Thrombosis may occur as a result of intrinsic pathology in the renal vessels (posttraumatic, atherosclerotic, or inflammatory) or as a result of emboli originating in distant vessels, most commonly fat emboli, emboli originating in the left heart (mural thrombi following myocardial infarction, bacterial endocarditis, or aseptic vegetations), or "paradoxical" emboli passing from the right side of the circulation via a patent foramen ovale or atrial septal defect. Renal emboli are bilateral in 15 to 30% of cases.

The clinical presentation is variable, depending on the time course and the extent of the occlusive event. Acute thrombosis and infarction, such as follows embolization, may result in sudden onset of flank pain and tenderness, fever, hematuria, leukocytosis, nausea, and vomiting. If infarction occurs, renal enzymes may be elevated, namely aspartate aminotransferase (AST), lactic dehydrogenase (LDH; most reliable), and alkaline phosphatase, which rise and fall in the order listed. Urinary lactic dehydrogenase and alkaline phosphatase also may increase after infarction. Renal function deteriorates acutely, leading in bilateral thrombosis to acute oliguric renal failure. More gradual (i.e., atherosclerotic) occlusion of a single renal artery may go undetected. A spectrum of clinical presentations lies between these two extremes (Table 278-1). Hypertension usually follows renal infarction and results from renin release in the peri-infarction zone. Hypertension is usually transient but may be persistent. Diagnosis is established by renal arteriography.

TREATMENT

Management of *acute* renal arterial thrombosis includes surgical intervention, anticoagulant therapy, conservative and supportive therapy, and control of hypertension. The choice of treatment depends mainly on (1) the condition of the patient, in particular the patient's ability to withstand major surgery, and (2) the extent of renovascular occlusion and amount of renal mass at risk of infarction. In general, supportive care and anticoagulant therapy are indicated in unilateral disease. In bilateral thrombosis, medical and surgical therapies yield comparable results. Twenty-five percent of patients die during the acute episode, usually from extrarenal complications. In *chronic* ischemic renal disease, surgical revascularization is more likely to preserve and improve renal function and to control the hypertension (see below).

ATHEROEMBOLIC DISEASE OF THE RENAL ARTERIES

Atheroembolic disease typically results from multiple showers of cholesterol-containing microemboli dislodged from atheromatous plaques in large arteries. Such emboli occlude small (150- to 200-um diameter) vessels in the kidneys and in other organs (retina, brain, pancreas, muscles, skin, and extremities). Atheroembolic disease usually occurs in an elderly individual with atherosclerotic disease elsewhere and usually follows aortic surgery or renal or coronary arteriography. Spontaneous atheroembolic disease has also been reported. Manifestations include deterioration of renal function (sudden or gradual), mild proteinuria, microscopic hematuria, and leukocyturia. Urine volume may remain normal or fall to oliguric levels depending on severity. Renal ischemia can induce or exacerbate preexisting hypertension. In elderly patients with mild to moderate cholesterol embolization, the remaining nephrons may subsequently undergo injury, likely a result of hyperfiltration, which may lead to nephrotic-range proteinuria. Renal biopsy reveals "focal segmental sclerosis" (FGS). Renal function deteriorates at a slower rate in these individuals than in patients with more substantial embolic burdens, and they would be expected to benefit from angiotensin-converting enzyme (ACE) inhibitor therapy aimed at lowering intraglomerular pressures in remnant nephrons, even if their systemic blood pressure is in the "normal" range.

Antemortem diagnosis of atherosclerotic renal emboli is difficult. The demonstration of cholesterol emboli in the retina is helpful, but a firm diagnosis is established only by demonstration of cholesterol crystals in the smaller arteries and arterioles in renal biopsy or autopsy specimens. These also may be seen in asymptomatic skeletal muscle or skin. No specific treatment is available.

RENAL VEIN THROMBOSIS (RVT)

Thrombosis of one or both main renal veins occurs in a variety of settings (Table 278-2). The pathogenesis is not always clear, particularly when it occurs in so-called hypercoagulable states such as may develop in pregnant women, users of oral contraceptives, subjects with nephrotic syndrome, or dehydrated infants. Nephrotic syndrome accompanying membranous glomerulopathy and certain carcinomas seems to predispose to the development of RVT, which occurs in 10 to 50% of patients with these disorders. RVT may exacerbate preexisting proteinuria but is infrequently the cause of the nephrotic syndrome.

The clinical manifestations depend on the severity and abruptness of its occurrence. Acute cases occur typically in children and are characterized by sudden loss of renal function, often accompanied by fever, chills, lumbar tenderness (with kidney enlargement), leukocytosis, and hematuria. Hemorrhagic infarction and renal rupture may lead to hypovolemic shock. In young adultsRVT is usually suspected from an unexpected and relatively acute or subacute deterioration of renal function and/or exacerbation of proteinuria and hematuria in the appropriate clinical setting (underlying nephrotic syndrome, trauma, pregnancy, oral contraceptive use). In cases of gradual thrombosis, usually occurring in the elderly, the only manifestation may be recurrent pulmonary emboli or development of hypertension. A Fanconi-like syndrome and proximal renal tubular acidosis have been described.

The definitive diagnosis can only be established through selective renal venography with visualization of the occluding thrombus. Short of angiography, magnetic resonance imaging (MRI) often provides definitive evidence of thrombus.

TREATMENT

Treatment consists of anticoagulation, the main purpose of which is prevention of pulmonary embolization, although some authors have also claimed improvement in renal function and proteinuria. Encouraging reports have appeared concerning the use of streptokinase. Spontaneous recanalization with clinical improvement also has been observed. Anticoagulant therapy is more rewarding in the acute thrombosis seen in younger individuals. Nephrectomy is advocated in infants with life-threatening renal infarction. Thrombectomy is effective in some cases.

RENAL ARTERY STENOSIS/ISCHEMIC RENAL DISEASE

Stenosis of the main renal artery and/or its major branches accounts for 2 to 5% of hypertension (seeChap. 246). The common cause in the middle-aged and elderly is an atheromatous plaque at the origin of the renal artery. In a large unselected autopsy series, stenosis producing > 50% renal artery diameter reduction was found in 18% of those between 65 and 74 years of age and in 42% of those older than 75 years. Bilateral involvement was found in half of the affected cases in both age groups. Ischemic renal disease has emerged as an important cause of end-stage renal disease. It should be considered seriously in elderly individuals, particularly in those with evidence of atherosclerotic arterial disease elsewhere. In elderly patients with myocardial infarction or symptomatic peripheral vascular disease, the incidence of renal arterial stenosis can be up to 40%. In younger women, stenosis is due to intrinsic structural abnormalities of the arterial wall caused by a heterogeneous group of lesions termed *fibromuscular dysplasia*.

Renal artery stenosis should be suspected when hypertension develops in a previously normotensive individual over 50 years of age or in the young (under 30 years) with suggestive features: symptoms of vascular insufficiency to other organs, high-pitched epigastric bruit on physical examination, symptoms of hypokalemia secondary to hyperaldosteronism (muscle weakness, tetany, polyuria), and metabolic alkalosis. If renal arterial stenosis is suspected, the best initial screening test is a renal ultrasound, which may reveal unilateral renal hypotrophy (but normal cortical echogenicity). Absence of compensatory hypertrophy in the contralateral kidney should raise the suspicion of bilateral stensosis or superimposed intrinsic (structural) renal disease, most commonly hypertensive or diabetic nephropathy. A positive captopril test, which has a sensitivity and specificity of greater than 95%, constitutes an excellent follow-up procedure to assess the need for more invasive radiographic evaluation. The test relies on the exaggerated increase in plasma renin activity (PRA) after administration of captopril to patients with renovascular hypertension as compared with those with essential hypertension. It is considered positive when all the following criteria are satisfied: stimulated PRA of 12 (ug/L)/h, absolute increase in PRA of 10 (ug/L)/h or more, and increase in PRA of>150% [or 400% if baseline PRA is<3 (ug/L)/h]. BecauseACEinhibitors magnify the impairment in renal blood flow and glomerular

filtration rate (GFR) caused by functionally significant renal artery stenosis, use of these drugs in association with ^{99m}Tc-DTPA or ^{99m}MAG$_3$renography greatly enhances the predictive value of radionuclide renography (>90% sensitivity and specificity). Magnetic resonance angiography (MRA) has replaced previous modalities as the most sensitive (100%) and specific (95%) test for the diagnosis of renal arterial stenosis. The most definitive diagnostic procedure is bilateral arteriography with repeated bilateral renal vein and systemic renin determinations. If renal vein renin measurements from the two kidneys differ by a factor of 1.5:1 or more (higher value from the affected kidney) in a patient with radiographic unilateral renal artery stenosis, the chance of cure of hypertension by surgical reconstruction or angioplasty is almost 90%, particularly if the renal vein renin level from the unaffected kidney is equal to or less than systemic levels (suppressible). A ratio of less than 1.5:1, however, does not exclude the diagnosis of renovascular hypertension, particularly in the presence of bilateral disease.

TREATMENT

The aims of treatment are control of the blood pressure and restoration of perfusion to the ischemic kidney. In general, it is now firmly established that interventional therapy (i.e., surgery or angioplasty) is superior to medical therapy, which, while controlling blood pressure, does little to salvage renal mass lost to ischemic injury. Success rates with percutaneous transluminal angioplasty in young patients with fibromuscular dysplasia are 50% cure and improvement in blood pressure control in another 30%. Angioplasty is best suited for noncalcified, segmental short lesions and is also useful in some elderly patients who are poor surgical risks. About half of elderly individuals with reduced renal function as a result of renal arterial stenosis improve following angioplasty or surgery, even when preintervention arteriography shows little evidence of cortical perfusion. Despite the risks associated with surgery, long-term follow-up studies demonstrate an advantage of surgery over angioplasty both with regard to the incidence of restenosis and to the preservation or improvement inGFR. As with coronary angioplasty, stenting of renal arteries following balloon angioplasty is being used increasingly. Initial results are highly encouraging, with restenosis rates less than 15% at 6 months. Renal functional recovery or stabilization of renal function is seen in approximately 70% of patients. An illustrative example of renal artery stenting is shown inFig. 278-1.

Renal artery stenosis, particularly if atherosclerotic, is a progressive disease that may lead to gradual and silent loss of renal functional tissue (ischemic renal disease). Progression of ipsilateral atherosclerotic narrowing can be expected in nearly 50% of individuals, resulting in complete occlusion in about 10%. Thus, these patients need careful follow-up of initially nonclinically significant narrowing (<70%) for the possibility of further occlusion or the development of contralateral disease (30%). Compensatory contralateral hypertrophy may maintain renal function until affected by superimposed pathologic processes, at which time azotemia supervenes. Ischemic renal disease is now recognized as a significant cause of end-stage renal disease in patients over 50 years of age (approximately 15%). Even if angioplasty or surgery fail to return blood pressure to normal, these procedures usually render medical therapy easier.

HEMOLYTIC UREMIC SYNDROME (HUS) AND THROMBOTIC THROMBOCYTOPENIC PURPURA (TTP) (See alsoChap. 116)

HUS and TTP, consumptive coagulopathies characterized by microangiopathic hemolytic anemia and thrombocytopenia, have a particular predilection for the kidney and the central nervous system, the latter especially in TTP. The kidneys of patients with HUS or TTP often exhibit a "flea-bitten" appearance, the result of multiple cortical hemorrhagic infarcts. The major sites of pathology are the small renal arteries and afferent arterioles, which are nearly occluded as a result of marked intimal hyperplasia (particularly in TTP) and fibrin deposits in the subintimal regions. When the vasoocclusive process is extensive, bilateral cortical necrosis may occur. In addition, arteriolar microaneurysms, glomerular infarction, or nonspecific focal changes may be seen. In keeping with the focal nature of the vascular lesions, patchy areas of interstitial edema, tubular necrosis, and, eventually, fibrosis occur. By immunofluorescence staining, complement components and immunoglobulins may be demonstrated in the arterioles, and fibrinogen deposits are present in arteries, arterioles, and glomerular capillary loops.

Several mechanisms have been implicated in the etiology of the intravascular coagulopathy seen inHUS andTTP, including induction of a generalized Shwartzman phenomenon by microorganisms or endotoxin, genetic predisposition, and deficiency of platelet antiaggregatory substance(s) (e.g., prostacyclin). Some patients improve after exchange transfusion or plasmapheresis, suggesting accumulation of an as yet unidentified toxin.

Renal failure is common in bothHUS andTTP, usually manifested by azotemia, mild proteinuria, microscopic and/or gross hematuria, and cylindruria. Patients with HUS have more severe renal failure, often marked by oligoanuria and hypertension and commonly progressing to chronic renal failure. The prognosis in HUS is better in children than in adults. In TTP, the course of which may span days to months, renal failure is usually less severe.

TREATMENT

In the management ofTTP, high-dose glucocorticoids and plasma exchange often provide complete remission or cure. Plasma exchange should be initiated as early as possible, and the treatment cycles can be repeated if thrombocytopenia recurs. Splenectomy and antiplatelet therapy also have been used with varying degrees of success in patients with TTP. The success of plasma exchange in adultHUS is less well established than in TTP.

ARTERIOLAR NEPHROSCLEROSIS (See alsoChaps. 241 and246)

Whether hypertension is "essential" or of known etiology, persistent exposure of the renal circulation to elevated intraluminal pressures results in development of intrinsic lesions of the renal arterioles (hyaline arteriolosclerosis) that eventually lead to loss of function (nephrosclerosis). Nephrosclerosis is divided into two distinct entities: "benign" and "malignant" (or accelerated).

Benign Arteriolar Nephrosclerosis Benign arteriolar nephrosclerosis is seen in patients who are hypertensive for an extended period of time (blood pressure more than

150/90 mmHg) but whose hypertension has not progressed to a malignant form (described below). Such patients, usually in the older age group, are often discovered to be hypertensive on routine physical examination or as a result of nonspecific symptomatology (e.g., headaches, weakness, palpitations).

Kidney size is normal to reduced, with loss of cortical mass leading to a fine granularity. Although the larger arteries may show atherosclerotic changes, the characteristic pathology is in the afferent arterioles, which have thickened walls due to deposition of homogeneous eosinophilic material (hyaline arteriolosclerosis). This material is composed of plasma proteins and fats that have been deposited in the arteriolar wall due to injury to the endothelium, probably secondary to the elevated intraluminal hydraulic pressure. Narrowing of vascular lumina results, with consequent ischemic injury to glomeruli and tubules.

Nephrosclerosis accompanying long-standing systemic arterial hypertension is only one manifestation of a generalized process affecting the cardiovascular system. Physical examination, therefore, may reveal changes in retinal vessels (arteriolar narrowing and/or flame-shaped hemorrhages), cardiac hypertrophy, and possibly signs of congestive heart failure. Renal disease may manifest as a mild to moderate elevation of serum creatinine concentration, microscopic hematuria, and/or mild proteinuria. In general, clinical evaluation does not reveal significant renal abnormalities. More specialized examination may disclose elevated urinary albumin excretion, tapering and loss of caliber of intrarenal vessels on arteriography, and an exaggerated natriuresis in response to a fluid challenge. Patients with benign nephrosclerosis maintain a near-normalGFRdespite a reduction in renal blood flow.

Malignant Arteriolar Nephrosclerosis Patients with long-standing benign hypertension or patients not known to be hypertensive previously may develop malignant hypertension characterized by a sudden (accelerated) elevation of blood pressure (diastolic often above 130 mmHg) accompanied by papilledema, central nervous system manifestations, cardiac decompensation, and acute progressive deterioration of renal function. The absence of papilledema does not rule out the diagnosis in a patient with markedly elevated blood pressure and rapidly declining renal function. The kidneys are characterized by a flea-bitten appearance resulting from hemorrhages in surface capillaries. Histologically, two distinct vascular lesions can be seen. The first, affecting arterioles, is fibrinoid necrosis, i.e., infiltration of arteriolar walls with eosinophilic material including fibrin. There is thickening of vessel walls and, occasionally, an inflammatory infiltrate (necrotizing arteriolitis). The second lesion, involving the interlobular arteries, is a concentric hyperplastic proliferation of the cellular elements of the vascular wall with deposition of collagen to form a hyperplastic arteriolitis (onion-skin lesion). Fibrinoid necrosis occasionally extends into the glomeruli, which also may undergo proliferative changes or total necrosis. Most glomerular and tubular changes are secondary to ischemia and infarction. The sequence of events leading to the development of malignant hypertension is poorly defined. Two pathophysiologic alterations appear central in its initiation and/or perpetuation: (1) increased permeability of vessel walls to invasion by plasma components, particularly fibrin, which activates clotting mechanisms leading to a microangiopathic hemolytic anemia, thus perpetuating the vascular pathology; and (2) activation of the renin-angiotensin-aldosterone system at some point in the disease process, which

contributes to the acceleration and maintenance of blood pressure elevation and, in turn, to vascular injury.

Malignant hypertension is most likely to develop in a previously hypertensive individual, usually in the third or fourth decade of life. There is a higher incidence among men, particularly black men. The presenting symptoms are usually neurologic (dizziness, headache, blurring of vision, altered states of consciousness, and focal or generalized seizures). Cardiac decompensation and renal failure appear thereafter. Renal abnormalities include a rapid rise in serum creatinine, hematuria (at times macroscopic), proteinuria, and red and white blood cell casts in the sediment. Nephrotic syndrome may be present. Elevated plasma aldosterone levels cause hypokalemic metabolic alkalosis in the early phase. Uremic acidosis and hyperkalemia eventually obscure these early findings. Hematologic indices of microangiopathic hemolytic anemia (i.e., schistocytes) are often seen.

TREATMENT

Control of hypertension is the principal goal of therapy for both benign and malignant forms. The time of initiation of therapy, its effectiveness, and patient compliance are crucial factors in arresting the progression of benign nephrosclerosis. Untreated, most of these patients succumb to the extrarenal complications of hypertension. In contrast, malignant hypertension is a medical emergency; its natural course includes a death rate of 80 to 90% within 1 year of onset, almost always due to uremia. Supportive measures should be instituted to control the neurologic, cardiac, and other complications of acute renal failure, but the mainstay of therapy is prompt and aggressive reduction of blood pressure, which, if successful, can reverse all complications in the majority of patients. Presently, 5-year survival is 50%, and some patients have evidence of partial reversal of the vascular lesions and a return of renal function to near-normal levels.

SCLERODERMA (PROGRESSIVE SYSTEMIC SCLEROSIS) (See alsoChap. 313)

Renal vascular involvement in scleroderma is characterized by a distinctive lesion of the small arteries (diameters of 150 to 500 um) consisting of intimal proliferation, medial thinning, and increased collagen deposition in the adventitial layer. Fibrinoid changes in the walls of afferent arterioles and microinfarcts may occur. Glomerular changes are generally nonspecific and secondary to ischemic damage. Tubules are often atrophic. As part of a generalized increase in vasomotor tone, a vasospastic (Raynaud-like) phenomenon at the level of the renal vasculature contributes to the renal insufficiency. Reduction in renal blood flow is the major mechanism underlying the deterioration in kidney function, being present in 80% of patients, even in the absence of other clinical abnormalities. As vascular narrowing progresses, hypertension, azotemia, and proteinuria eventually develop. Plasma renin rises in response to sustained renal ischemia. The resulting hypertension causes further renal injury and may play a role in the ultimate destruction of nephrons. As more and more nephrons are lost to the combined insults of ischemia and hypertension, development of azotemia heralds a particularly grim prognosis. Proteinuria, usually mild, is a consequence of ischemic and hypertensive glomerular injury.

Although most patients with scleroderma present with extrarenal manifestations, renal

involvement is eventually manifested in half of patients followed for up to 20 years. Renal involvement can present in one of two ways, depending on whether malignant hypertension is superimposed on the renal pathology: (1) *Persistent urinary abnormalities* with or without hypertension tend to follow an indolent course with mild proteinuria, occasional casts, cellular elements in the urinary sediment, and a propensity for development of hypertension. Azotemia is absent initially, but when it develops, dialysis is required within 1 year. (2) *Scleroderma renal crisis* is a rapid deterioration in renal function, usually accompanied by malignant hypertension, oliguria, fluid retention, microangiopathic hemolytic anemia, and central nervous system involvement. It may occur in patients with previously undemonstrable or slowly progressive renal disease. Untreated, it leads to chronic renal failure within days to months.

The prognosis of scleroderma renal disease is generally poor, particularly following the onset of azotemia. Aggressive antihypertensive therapy may be effective in delaying the progression of renal failure. In scleroderma renal crisis, prompt treatment with beta blockers, minoxidil, and particularlyACEinhibitors may reverse acute renal failure. The effect of these interventions on renal function over the long term is uncertain.

SICKLE CELL NEPHROPATHY (See alsoChaps. 106 and275)

Sickle cell disease causes renal complications that arise mainly as a result of sickling of red blood cells in the microvasculature. The hypertonic and relatively hypoxic environment of the renal medulla, coupled with the slow blood flow in the vasa recta, favors the sickling of red blood cells, with resultant local infarction (papillary necrosis). Functional tubule defects in patients with sickle cell disease are likely the result of partial ischemic injury to the renal tubules.

In addition to the intrarenal microvascular pathology described above, young patients with sickle cell disease are characterized by renal hyperperfusion, glomerular hypertrophy, and hyperfiltration. Many of these individuals eventually develop a glomerulopathy leading to glomerular proteinuria (present in as many as 30%) and, in some, the nephrotic syndrome. In recent studies, the mechanisms underlying proteinuria in sickle cell nephropathy have been characterized as an early increase in pore radius, followed, as renal failure supervenes, with a reduction in pore number, but the onset of a dramatic loss of size-selectivity. Mild azotemia and hyperuricemia also can develop, but advanced renal failure and uremia are rare. Pathologic examination reveals the typical lesion of "hyperfiltration nephropathy," namely, focal segmental glomerular sclerosis. This finding has led to the suggestion that anemia-induced hyperfiltration in childhood is the principal cause of the adult glomerulopathy. Nephron loss secondary to ischemic injury also contributes to the development of azotemia in these patients.

In addition to the glomerulopathy described above, renal complications of sickle cell disease include the following: *Cortical infarcts* can cause loss of function, persistent hematuria, and perinephric hematomas. *Papillary infarcts*, demonstrated radiographically in 50% of patients with sickle trait, lead to an increased risk of bacterial infection in the scarred renal tissues and functional tubule abnormalities. Painless gross hematuria occurs with a higher frequency in sickle trait than in sickle cell disease and likely results from infarctive episodes in the renal medulla. *Functional tubule*

abnormalities such as nephrogenic diabetes insipidus result from marked reduction in vasa recta blood flow, combined with ischemic tubule injury. This concentrating defect places these patients at increased risk of dehydration and, hence, sickling crises. The concentrating defect also occurs in individuals with sickle trait. Other tubule defects involve potassium and hydrogen ion excretion, occasionally leading to hyperkalemic metabolic acidosis and a defect in uric acid excretion which, combined with increased purine synthesis in the bone marrow, results in hyperuricemia.

Management of sickle nephropathy is not separate from that of overall patient management (Chap. 106). In addition, however, the use ofACEinhibitors has been associated with improvement of the hyperfiltration glomerulopathy.

TOXEMIAS OF PREGNANCY (See also Chap. 7)

Renal function is "reset" at a higher level during normal pregnancy. Renal plasma flow and GFRboth increase by 30 to 50%. Therefore, serum creatinine levels above 70 umol/L (0.8 mg/dL) or blood urea nitrogen (BUN) levels above 4.6 mmol/L (13 mg/dL) are abnormal in pregnant women and should be investigated. Systolic and diastolic blood pressures decrease by an average of 10 to 15 mmHg below pregravid values. A diastolic pressure above 75 mmHg during the second trimester or above 85 mmHg during the third trimester is therefore abnormal. Vasodilation in the uterine, renal, and cutaneous beds, vasodilator prostaglandin release from the uteroplacental unit, and a decrease in arteriolar sensitivity to angiotensin II all play a role in the decline of blood pressure during pregnancy.

Preeclampsia-Eclampsia The toxemia syndrome, usually occurring in the third trimester of primigravidas, includes hypertension, proteinuria, edema, consumptive coagulopathy, sodium retention, hyperreflexia (preeclampsia), and, if uncontrolled, convulsions (eclampsia). In pure preeclampsia (i.e., not superimposed on previously existing hypertensive or renal disease), the primary sites of pathology are the glomerular endothelial cells. These cells show marked swelling due to an increase in cytoplasmic volume with vacuolization (endotheliosis) and encroach on the vascular lumen, rendering the enlarged glomeruli ischemic. The glomerular basement membrane and the extraglomerular blood vessels are intact. The pathogenesis is unknown. Coagulation abnormalities, hormonal factors, uteroplacental ischemia, and immune mechanisms have all been implicated. Increased microvascular reactivity may be a result of endothelial cell damage, which, in turn, alters the balance of endothelium-derived vasodilator/vasoconstrictor autacoids. Recent evidence suggests that preeclampsia may be characterized by selective dysregulation of vascular cell adhesion molecule-1 (VCAM-1) (but not other leukocyte adhesion molecules). This abnormality is not present in non-proteinuric gestational hypertension, and subsides post-partum. Induction of VCAM-1 expression in preeclampsia may contribute to leukocyte-mediated tissue injury in this condition or may reflect perturbation of other, previously unrecognized functions of this molecule in pregnancy. Despite sodium retention, intravascular volume is contracted as compared with pregravid values. An increased sensitivity to angiotensin II is the basis for the "roll-over test" (an increase in diastolic blood pressure of 20 mmHg or more on changing the patient's position from lateral recumbent to supine, presumably due to alterations in circulating angiotensin levels). In the supine position, the reduction in venous return due to compression by the

gravid uterus increases circulating levels of angiotensin II. This increase results in a hypertensive response in preeclamptic patients, who are hyperresponsive to angiotensin II, but not in normal women, in whom pregnancy leads to a relative resistance to the pressor effects of this hormone.

A diagnosis of preeclampsia-related hypertension can be made when repeated measurements over a 4- to 6-h period show a blood pressure of 140/85 mmHg or more. The rise in blood pressure tends to be more severe at night. When preeclampsia occurs in a previously hypertensive patient, a rapid acceleration of the blood pressure elevation is accompanied by an increase in proteinuria, oliguria, edema, and coagulopathy. This is a life-threatening syndrome and tends to recur with future pregnancies. In addition to proteinuria, which correlates with the severity of the renal lesion,GFR and renal plasma flow are depressed. In view of the preexisting high levels, however, GFR in preeclamptic women often remains above nonpregnant levels. Uric acid clearance also falls, resulting in hyperuricemia. In the postpartum period, these patients are particularly susceptible to the development of "postpartum renal failure," which is thought to be a form of adultHUS.

TREATMENT

Treatment consists of bed rest in a quiet environment and control of neurologic manifestations and blood pressure, the former with magnesium sulfate and the latter usually with vasodilators such as hydralazine and methyldopa. Diuretics are avoided. The ultimate "treatment" is delivery, which should be induced if fetal maturity is adequate or if life-threatening coagulopathy or renal failure occur. The long-term prognosis is generally favorable.

Development of acute renal failure/preeclampsia in a pregnant woman should alert the physician to potential preexisting renal disease and/or hypertension. The latter is particularly likely if systolic blood pressure is greater than 200 mmHg. Hypertension and preexisting proteinuria tend to worsen in 50% of women during pregnancy. In addition, these abnormalities may be unmasked during pregnancy as the first manifestations of an underlying glomerulopathy. Conversely, patients with established underlying renal disease should be followed closely during pregnancy, with monthly measurements of 24-h urinary protein excretion andGFR. Sudden deterioration should raise suspicion of superimposed preeclampsia. There is no convincing evidence that pregnancy has an adverse effect on the long-term outcome of immunologic glomerular diseases or diabetic nephropathy. In all situations, control of blood pressure should be the primary therapeutic goal in view of its established beneficial effects on the progression of renal injury.

Bilateral Cortical Necrosis Acute bilateral cortical necrosis is associated with septic abortions, abruptio placentae, and preeclampsia. Coagulation in cortical vessels and arterioles leads to renal tissue necrosis. Anuria and renal failure ensue and may be irreversible. In other cases, renal function returns partially, but on long-term follow-up most patients slowly progress to uremia.

279. NEPHROLITHIASIS - *John R. Asplin*, *Fredric L. Coe*, *Murray J. Favus*

TYPES OF STONES

Calcium salts, uric acid, cystine, and struvite ($MgNH_4PO_4$) are the basic constituents of most kidney stones in the western hemisphere. Calcium oxalate and calcium phosphate stones make up 75 to 85% of the total (Table 279-1) and may be admixed in the same stone. Calcium phosphate in stones is usually hydroxyapatite [$Ca_5(PO_4)_3OH$] or, less commonly, brushite ($CaHPO_4 \times H_2O$).

Calcium stones are more common in men; the average age of onset is the third decade. Approximately 60% of people who form a single calcium stone eventually form another within the next 10 years. The average rate of new stone formation in patients who have had a previous stone is about one stone every 2 or 3 years. Calcium stone disease is frequently familial.

In the urine, calcium oxalate monohydrate crystals (whewellite) usually grow as biconcave ovals that resemble red blood cells in shape and size but may occur in a larger, "dumbbell" form. In polarized light the crystals appear bright against a dark background, with an intensity that is dependent on orientation, a property known as *birefringence.* Calcium oxalate dihydrate crystals (weddellite) are bipyramidal. Apatite crystals do not exhibit birefringence and appear amorphous because the actual crystals are too small to be resolved by light microscopy.

Uric acid stones (Table 279-1) are radiolucent and are also more common in men. Half of patients with uric acid stones have gout; uric acid lithiasis is usually familial whether or not gout is present. In urine, uric acid crystals are red-orange in color because they absorb the pigment uricine. Anhydrous uric acid produces small crystals that appear amorphous by light microscopy. They are indistinguishable from apatite crystals, except for their birefringence. Uric acid dihydrate tends to form teardrop-shaped crystals as well as flat, rhomboid plates; both are strongly birefringent. Uric acid gravel appears like red dust, and the stones are also orange or red on some occasions. *Cystine stones* are uncommon (Table 279-1), lemon yellow, and sparkle; radiopacity is due to the sulfur content. Cystine crystals appear in the urine as flat, hexagonal plates.

Struvite stones are common (Table 279-1) and potentially dangerous. These stones occur mainly in women or patients who require chronic bladder catheterization and result from urinary tract infection with urease-producing bacteria, usually *Proteus* species. The stones can grow to a large size and fill the renal pelvis and calyces to produce a "staghorn" appearance. They are radiopaque and have a variable internal density. In urine, struvite crystals are rectangular prisms said to resemble coffin lids.

MANIFESTATIONS OF STONES

As stones grow on the surfaces of the renal papillae or within the collecting system, they need not produce symptoms. Asymptomatic stones may be discovered during the course of radiographic studies undertaken for unrelated reasons. Stones rank, along with benign and malignant neoplasms, renal cysts, and genitourinary tuberculosis, among the common causes of isolated hematuria. Much of the time, however, stones

break loose and enter the ureter or occlude the ureteropelvic junction, causing pain and obstruction.

STONE PASSAGE

A stone can traverse the ureter without symptoms, but passage usually produces pain and bleeding. The pain begins gradually, usually in the flank, but increases over the next 20 to 60 min to become so severe that narcotic drugs may be needed for its control. The pain may remain in the flank or spread downward and anteriorly toward the ipsilateral loin, testis, or vulva. Pain that migrates downward indicates that the stone has passed to the lower third of the ureter, but if the pain does not migrate, the position of the stone cannot be predicted. A stone in the portion of the ureter within the bladder wall causes frequency, urgency, and dysuria that may be confused with urinary tract infection. The vast majority of ureteral stones less than 0.5 cm in diameter will pass spontaneously.

It has been standard practice to diagnose acute renal colic by intravenous pyelography; however, helical computed tomography (CT) scan without radiocontrast enhancement is now the preferred procedure. CT has the advantage of detecting uric acid stones in addition to the traditional radioopaque stones, and CT does not expose the patient to the risk of radio-contrast agents.

OTHER SYNDROMES

Staghorn Calculi Struvite, cystine, and uric acid stones often grow too large to enter the ureter. They gradually fill the renal pelvis and may extend outward through the infundibula to the calyces themselves.

Nephrocalcinosis Calcium stones grow on the papillae. Most break loose and cause colic, but they may remain in place so that multiple papillary calcifications are found by x-ray, a condition termed *nephrocalcinosis*. Papillary nephrocalcinosis is common in hereditary distal renal tubular acidosis (RTA) and in other types of severe hypercalciuria. In medullary sponge kidney disease (Chap. 276) calcification may occur in dilated distal collecting ducts.

Sludge Sufficient uric acid or cystine in the urine may plug both ureters with precipitate. Calcium oxalate crystals do not do this because less than 100 mg oxalate usually is excreted daily in the urine even in severe hyperoxaluric states, compared with 1000 mg uric acid in patients with hyperuricosuria and 400 to 800 mg cystine in patients with cystinuria. Calcium phosphate crystals can render the urine milky but do not plug the urinary tract.

INFECTION

Although urinary tract infection is not a direct consequence of stone disease, it can occur after instrumentation and surgery of the urinary tract, which are frequent in the treatment of stone disease. Stone disease and urinary tract infection can enhance their respective seriousness and interfere with treatment. Obstruction of an infected kidney by a stone may lead to sepsis and extensive damage of renal tissue, since it converts

the urinary tract proximal to the obstruction into a closed, or partially closed, space that can become an abscess. Stones may harbor bacteria in the stone matrix, leading to recurrent urinary tract infection. On the other hand, infection due to bacteria that possess the enzyme urease can cause stones composed of struvite.

ACTIVITY OF STONE DISEASE

Active disease means that new stones are forming or that preformed stones are growing. Sequential radiographs of the renal areas are needed to document the growth or appearance of new stones and to ensure that passed stones are actually newly formed, not preexistent ones.

PATHOGENESIS OF STONES

Urinary stones usually arise because of the breakdown of a delicate balance. The kidneys must conserve water, but they must excrete materials that have a low solubility. These two opposing requirements must be balanced during adaptation to diet, climate, and activity. The problem is mitigated to some extent by the fact that urine contains substances that inhibit crystallization of calcium salts and others that bind calcium in soluble complexes. These protective mechanisms are less than perfect. When the urine becomes supersaturated with insoluble materials, because excretion rates are excessive and/or because water conservation is extreme, crystals form and may grow and aggregate to form a stone.

SUPERSATURATION

In a solution in equilibrium with crystals of calcium oxalate, the product of the chemical activities of the calcium and oxalate ions in the solution is termed the *equilibrium solubility product*. If crystals are removed, and if either calcium or oxalate ions are added to the solution, the activity product increases, but the solution may remain clear; no new crystals form. Such a solution is *metastably supersaturated.* If new calcium oxalate seed crystals are now added, they will grow in size. Ultimately, the activity product reaches a critical value at which a solid phase begins to develop spontaneously. This value is called the *upper limit of metastability*, or the *formation product*. Stone growth in the urinary tract requires a urine that, on average, is above the equilibrium solubility product. Excessive supersaturation is common in stone formation.

Calcium, oxalate, and phosphate form many stable soluble complexes among themselves and with other substances in urine, such as citrate. As a result, their free ion activities are below their chemical concentrations and can be measured only by indirect techniques. Reduction in ligands such as citrate can increase ion activity without changing total urinary calcium. Urine supersaturation can be increased by dehydration or by overexcretion of calcium, oxalate, phosphate, cystine, or uric acid. Urine pH is also important; phosphate and uric acid are weak acids that dissociate readily over the physiologic range of urine pH. Alkaline urine contains more dibasic phosphate, favoring deposits of brushite, and apatite. Below a urine pH of 5.5, uric acid crystals (p*K* 5.47) predominate, whereas phosphate crystals are rare. The solubility of calcium oxalate, on the other hand, is not influenced by changes in urine pH. Measurements of supersaturation in a pooled 24-h urine sample probably underestimate the risk of

precipitation. Transient dehydration, variation of urine pH, and postprandial bursts of overexcretion may cause values considerably above average.

NUCLEATION

Homogeneous Nucleation In urine that is supersaturated with respect to calcium oxalate, these two ions form clusters. Most small clusters eventually disperse because the internal forces that hold them together are too weak to overcome the random tendency of ions to move away. Clusters of over 100 ions can remain stable because attractive forces balance surface losses. Once they are stable, nuclei can grow at levels of supersaturation below that needed for their creation. The formation product marks the point at which stable nuclei become frequent enough to create a permanent solid phase.

Heterogeneous Nucleation If a supersaturated urine is seeded with preformed nuclei of a crystal that is similar in structure to calcium oxalate, calcium and oxalate ions in solution will bind to the crystal's surface as they would on a seed crystal of calcium oxalate itself. The seeding of a supersaturated solution by foreign nuclei is called *heterogeneous nucleation*. Cell debris, calcifications on the renal papillae, as well as other urinary crystals, can serve as heterogeneous nuclei that permit calcium oxalate stones to form, even though urine calcium oxalate supersaturation never exceeds the metastable limit for homogenous nucleation.

INHIBITORS OF CRYSTAL FORMATION

Stable nuclei must grow and aggregate to produce a stone of clinical significance. Urine contains potent inhibitors of nucleation, growth, and aggregation for calcium oxalate and calcium phosphate but not for uric acid, cystine, or struvite. Inorganic pyrophosphate is a potent inhibitor that appears to affect calcium phosphate more than calcium oxalate crystals. Citrate inhibits crystal growth and nucleation, though most of the stone inhibitory activity of citrate is due to lowering urine supersaturation via complexation of calcium. Other urine components such as glycoproteins inhibit all three processes of calcium oxalate stone formation. Slowing of crystal growth increases the apparent upper limit of metastability because the critical growth of ion clusters into stable nuclei is hindered. As a consequence of the presence of these inhibitors, crystal growth in urine is slow compared with growth in simple salt solutions, and the upper limit of metastability is higher.

EVALUATION AND TREATMENT OF PATIENTS WITH NEPHROLITHIASIS

Most patients with nephrolithiasis have remediable metabolic disorders that cause stones and can be detected by chemical analyses of serum and urine. Adults with recurrent kidney stones and children with even a single kidney stone should be evaluated. A practical outpatient evaluation consists of two or three 24-h urine collections, each with a corresponding blood sample; measurements of serum and urine calcium, uric acid, electrolytes and creatinine, urine pH, volume, oxalate, and citrate should be made. Since stone risks vary with diet, activity, and environment, at least one urine collection should be made on a weekend when the patient is at home and another on a work day. When possible, the composition of kidney stones should be determined because treatment depends on stone type (Table 279-1). No matter what disorders are

found, every patient should be counseled to avoid dehydration and to drink sufficient water so that they excrete at least 2 L of urine every day. Since treatment is prolonged, the use of medications must be justified by the activity and severity of stone disease and the importance of protection against new stones.

TREATMENT

The management of stones already present in the kidneys or urinary tract requires a combined medical and surgical approach. The specific treatment depends on the location of the stone, the extent of obstruction, the function of the affected and unaffected kidney, the presence or absence of urinary tract infection, the progress of stone passage, and the risks of operation or anesthesia given the clinical state of the patient. In general, severe obstruction, infection, intractable pain, and serious bleeding are indications for removal of a stone.

In the past, stones were removed by operation or by passing a flexible basket retrograde up the ureter from the bladder during cystoscopy. There are now three alternatives. *Extracorporeal lithotripsy* causes the in situ fragmentation of stones in the kidney, renal pelvis, or ureter by exposing them to shock waves. The kidney stone is centered at a focal point of parabolic reflectors, and high-intensity shock waves are created by high-voltage discharge. The waves are transmitted to the patient using water as a conduction medium, either by placing the patient in a water tank or by placing water-filled cushions between the patient and the shock wave generators. After multiple discharges, most stones are reduced to powder that moves through the ureter into the bladder. *Percutaneous ultrasonic lithotripsy* requires the passage of a rigid cystoscope-like instrument into the renal pelvis through a small incision in the flank. Stones can be disrupted by a small ultrasound transducer, and fragments can be removed directly. The last method is *laser lithotripsy via a ureteroscope* for removal of ureteral stones. These various forms of lithotripsy have largely replaced pyelolithotomy and ureterolithotomy.

CALCIUM STONES

Idiopathic Hypercalciuria (See also Chap. 341) This condition appears to be hereditary, and its diagnosis is straightforward (Table 279-1). In some patients, primary intestinal hyperabsorption of calcium causes transient postprandial hypercalcemia that suppresses secretion of parathyroid hormone. The renal tubules are deprived of the normal stimulus to reabsorb calcium at the same time that the filtered load of calcium is increased. In other patients, reabsorption of calcium by the renal tubules appears to be defective, and secondary hyperparathyroidism is evoked by urinary losses of calcium. Renal synthesis of 1,25-dihydroxyvitamin D is increased, enhancing intestinal absorption of calcium. In the past, the separation of "absorptive" and "renal" forms of hypercalciuria was used to guide treatment. However, these may not be distinct entities but the extremes of a continuum of behavior. Vitamin D overactivity, either through high vitamin D levels or excess vitamin D receptor, is a likely explanation for the hypercalciuria in many of these patients. Hypercalciuria contributes to stone formation by raising urine saturation with respect to calcium oxalate and calcium phosphate.

TREATMENT

Thiazide diuretics lower urine calcium in idiopathic hypercalciuria and are effective in preventing the formation of stones. Three 3-year randomized trials have shown a 50% decrease in stone formation in the thiazide-treated group as compared to the placebo-treated controls. The drug effect requires slight contraction of the extracellular fluid volume, and massive use of NaCl reduces its therapeutic effect. Thiazide-induced hypokalemia should be aggressively treated since hypokalemia will reduce urine citrate, increasing urine calcium ion levels.

Hyperuricosuria About 20% of calcium oxalate stone formers are hyperuricosuric, primarily because of an excessive intake of purine from meat, fish, and poultry. The mechanism of stone formation is probably due to salting out calcium oxalate by urate. A low-purine diet is desirable but difficult for many patients to achieve. The alternative is allopurinol, which has been shown to be effective in a randomized controlled trial. A dose of 100 mg bid is usually sufficient.

Primary Hyperparathyroidism (See also Chap. 341) The diagnosis of this condition is established by documenting that hypercalcemia that cannot be otherwise explained is accompanied by inappropriately elevated serum concentrations of parathyroid hormone. Hypercalciuria, usually present, raises the urine supersaturation of calcium phosphate and/or calcium oxalate (Table 279-1). Prompt diagnosis is important because parathyroidectomy should be carried out before renal damage or bone disease occurs.

Distal Renal Tubular Acidosis (See also Chap. 276) The defect in this condition seems to reside in the distal nephron, which cannot establish a normal pH gradient between urine and blood, leading to hyperchloremic acidosis. The diagnosis is suggested by a minimum urine pH in the presence of systemic acidosis above 5.5. If the diagnosis is in doubt because metabolic abnormalities are mild, oral challenge with NH_4Cl, 1.9 mmol/kg of body weight, will not lower urine pH below 5.5 in patients with distalRTA. Hypercalciuria, an alkaline urine, and a low urine citrate level cause supersaturation with respect to calcium phosphate. Calcium phosphate stones form, nephrocalcinosis is common, and osteomalacia or rickets may occur. Renal damage is frequent, and glomerular filtration rate falls gradually. Treatment with supplemental alkali reverses hypercalciuria and limits the production of new stones. The usual dose of sodium bicarbonate is 0.5 to 2.0 mmol/kg of body weight per day in four to six divided doses. An alternative is potassium citrate supplementation, given at the same dose per day but needing to be given only three to four times per day. In incomplete distal RTA, systemic acidosis is absent, but urine pH cannot be lowered below 5.5 after an exogenous acid load such as ammonium chloride. Incomplete RTA may develop in some patients who form calcium oxalate stones because of idiopathic hypercalciuria; the importance of RTA in producing stones in this situation is uncertain, and thiazide treatment is a reasonable alternative. Some patients with incomplete RTA form calcium phosphate stones because of low urine citrate and an alkaline urine and are best treated with alkali as if RTA were complete.

Hyperoxaluria Overabsorption of dietary oxalate and consequent oxaluria, i.e., so-called intestinal oxaluria, is one consequence of fat malabsorption (Chap. 286). The latter can be caused by a variety of conditions, including bacterial overgrowth syndromes, chronic disease of the pancreas and biliary tract, jejunoileal bypass in

treatment of obesity, or ileal resection for inflammatory bowel disease. With fat malabsorption, calcium in the bowel lumen is bound by fatty acids instead of oxalate, which is left free for absorption in the colon. Delivery of unabsorbed fatty acids and bile salts to the colon may injure the colonic mucosa and enhance oxalate absorption. Dietary excess of oxalate in patients with normal intestinal function is a common cause of mild elevation of urine oxalate, but seldom to the level seen in patients with enteric hyperoxaluria. Hereditary hyperoxaluria states are rare causes of severe hyperoxaluria; patients usually present with recurrent calcium oxalate stones during childhood. Type I hereditary hyperoxaluria is inherited as an autosomal recessive trait and is due to a deficiency in the peroxisomal enzyme alanine:glyoxylate aminotransferase. Type II is due to a deficiency of D-glyceric dehydrogenase. Ethylene glycol intoxication and methoxyflurane also can cause oxalate overproduction and hyperoxaluria. Hyperoxaluria from any cause can produce tubulointerstitial nephropathy (Chap. 277) and lead to stone formation.

TREATMENT

The oxalate-binding resin cholestyramine at a dose of 8 to 16 g/d, correction of fat malabsorption, and a low-fat, low oxalate diet are effective treatments for oxaluria secondary to intestinal overabsorption. Calcium supplements, given with meals, precipitate oxalate in the gut lumen providing an alternative form of therapy. Treatment for hereditary hyperoxaluria includes a high fluid intake, neutral phosphate, and pyridoxine (25 to 200 mg/d). Citrate supplementation may also have some benefit. Even with aggressive therapy, irreversible renal failure secondary to recurrent stone formation often occurs. Segmental liver transplant, to correct the enzyme defect, combined with a kidney transplant have been successfully utilized in patients with hereditary hyperoxaluria.

Hypocitraturia Urine citrate prevents calcium stone formation by creating a soluble complex with calcium, effectively reducing free urine calcium. Hypocitraturia is found in 15 to 60% of stone formers, either as a single disorder or in combination with other metabolic abnormalities. It can be secondary to systemic disorders, such as RTA, chronic diarrheal illness, or hypokalemia, or it may be a primary disorder, in which case it is called *idiopathic hypocitraturia*.

TREATMENT

Treatment is with alkali, which increases urine citrate excretion; generally bicarbonate or citrate salts are used. Potassium salts are preferred as sodium loading increases urinary excretion of calcium, reducing the effectiveness of treatment. A recent randomized, placebo-controlled trial has demonstrated the effectiveness of potassium citrate in idiopathic hypocitraturia.

Idiopathic Calcium Lithiasis Some patients have no metabolic cause for stones despite a thorough metabolic evaluation (Table 279-1). The best treatment appears to be high fluid intake so that the urine specific gravity remains at 1.005 or below throughout the day and night. Oral phosphate at a dose of 2 g phosphorus daily may lower urine calcium and increase urine pyrophosphate and thereby reduce the rate of recurrence. Orthophosphate causes mild nausea and diarrhea initially, but tolerance

may improve with continued intake. Thiazide treatment to reduce calcium excretion and allopurinol to diminish uric acid output also may be helpful.

URIC ACID STONES

These stones form because the urine becomes supersaturated with undissociated uric acid that is protonated at its N-9 position. In gout, idiopathic uric acid lithiasis, and dehydration, the average pH is usually below 5.4 and often below 5.0. Undissociated uric acid therefore predominates and is soluble in urine only in concentrations of 100 mg/L. Concentrations above this level represent supersaturation that causes crystals and stones to form. Hyperuricosuria, when present, increases supersaturation, but urine of low pH can be supersaturated with undissociated uric acid even though the daily excretion rate is normal. Myeloproliferative syndromes, chemotherapy of malignant tumors, and the Lesch-Nyhan syndrome cause such massive production of uric acid and consequent hyperuricosuria that stones and uric acid sludge form even at a normal urine pH. Plugging of the renal collecting tubules by uric acid crystals can cause acute renal failure.

TREATMENT

The two goals of treatment are to raise urine pH and to lower excessive urine uric acid excretion to less than 1 g/d. Supplemental alkali, 1 to 3 mmol/kg of body weight per day, should be given in three or four evenly spaced, divided doses, one of which should be given at bedtime. The form of the alkali may be important. Potassium citrate may reduce the risk of calcium salts crystallizing when urine pH is increased, whereas sodium citrate or sodium bicarbonate may increase the risk. If the overnight urine pH is below 5.5, the evening dose of alkali may be raised or 250 mg acetazolamide added at bedtime. A low-purine diet should be instituted in those uric acid stone formers with hyperuricosuria. Patients who continue to form uric acid stones despite treatment with fluids, alkali, and a low-purine diet should have allopurinol added to their regimen. If hypercalciuria is also present, it should be specifically treated, as alkali alone could lead to calcium phosphate stone formation.

CYSTINURIA AND CYSTINE STONES (See also Chap. 352)

In this disorder, proximal tubular and jejunal transport of the dibasic amino acids cystine, lysine, arginine, and ornithine are defective, and excessive amounts are lost in the urine. Clinical disease is due solely to the insolubility of cystine, which forms stones.

Pathogenesis Cystinuria occurs because of defective transport of amino acids by the brush borders of renal tubule and intestinal epithelial cells. Cystine, lysine, arginine, and ornithine appear to share a common renal transport pathway, since infusion of lysine decreases tubular reabsorption of the other three. However, cystine is also transported by a separate transport mechanism, because cystinuria and dibasic aminoaciduria can occur independently. The intestinal defects are not similar in all patients who are homozygous for cystinuria, and the extent of aminoaciduria in individuals who are heterozygous carriers of the defect varies from family to family. Three types of inheritance have been described (Chap. 352). A gene located on chromosome 2 and designated SLC3A1, codes for a dibasic amino acid transporter and has been found to

be abnormal in Type I cystinuria. Linkage analysis has mapped Type III cystinuria to chromosome 19.

Diagnosis Cystine stones are formed only by patients with cystinuria, but 10% of stones in cystinuric patients do not contain cystine; therefore, every stone former should be screened for the disease. The sediment from a first morning urine specimen in many patients with homozygous cystinuria reveals typical flat, hexagonal, platelike cystine crystals. Cystinuria also can be detected using the urine sodium nitroprusside test. The test is positive with 75 to 125 mg cystine per gram of creatinine, a concentration lower than that in the urine of patients with cystinuria but above the levels in normal urine. Because the test is sensitive, it is positive in many asymptomatic heterozygotes for cystinuria. A positive nitroprusside test or the finding of cystine crystals in the urine sediment should be evaluated by measurement of daily cystine excretion. Normal adults excrete 40 to 60 mg cystine per gram of creatinine, heterozygotes usually excrete less than 300 mg/g, and homozygotes almost always excrete above 250 mg/g.

TREATMENT

This consists of a high fluid intake, even at night. Daily urine volume should exceed 3 L. Raising urine pH with alkali is helpful, provided the urine pH exceeds 7.5. A low-salt diet (100 mmol/d) can reduce cystine excretion up to 40%. Because side effects are frequent, drugs such as penicillamine and tiopronin, which form the soluble disulfide cysteine-drug complexes, should be used only when fluid loading, salt reduction, and alkali therapy are ineffective. Captopril, which has a free sulfhydryl group to bind cysteine, has been used in a limited number of patients with some success. Low-methionine diets have not proved to be practical for clinical use, but patients should avoid protein gluttony.

STRUVITE STONES

These stones are a result of urinary infection with bacteria, usually *Proteus* species, which possess urease, an enzyme that degrades urea to NH_3 and CO_2. The NH_3hydrolyzes to $NH_4^+$and raises urine pH to 8 or 9. The CO_2hydrates to $H_2CO_3$and then dissociates to CO_3^{2-}which precipitates with calcium as $CaCO_3$. The NH_4^+precipitates $PO_4^{3-}$and $Mg^{2+}$to form $MgNH_4PO_4$(struvite). The result is a stone of calcium carbonate admixed with struvite. Struvite does not form in urine in the absence of infection, because NH_4^+concentration is low in urine that is alkaline in response to physiologic stimuli. Chronic *Proteus* infection can occur because of impaired urinary drainage, urologic instrumentation or surgery, and especially with chronic antibiotic treatment, which can favor the dominance of *Proteus* in the urinary tract.

TREATMENT

Complete removal of the stone with subsequent sterilization of the urinary tract is the treatment of choice for patients who can tolerate the procedures. Open surgery is successful in debulking the stone and improving renal function if obstruction is present; however, there is recurrence of stone in 25% of the patients. Irrigation of the renal pelvis and calyces with hemiacidrin, a solution that dissolves struvite, can reduce recurrence after surgery. Newer procedures such as lithotripsy and percutaneous nephrolithotomy,

alone or in combination, have largely replaced open surgery. Stone-free rates of 50 to 90% have been reported after these procedures. Antimicrobial treatment is best reserved for dealing with acute infection and for maintenance of a sterile urine after surgery, in the hope of preventing recurrence or minimizing stone growth. Urine cultures and culture of stone fragments removed at surgery should guide the choice of antibiotic. Methenamine mandelate, which lowers urine pH and liberates formaldehyde, can be used for chronic suppression of infection when a stone is present. For patients who are not candidates for surgical removal of stone, acetohydroxamic acid, an inhibitor of urease, can be used. Though effective in treating the stones, acetohydroxamic acid has many side effects, such as headache, tremor, and thrombophlebitis, which limits its use. Lowering urine pH with chronic administration of NH_4Cl may retard stone growth but also may raise urine calcium level and promote the formation of calcium oxalate stones.

280. URINARY TRACT INFECTIONS AND PYELONEPHRITIS - *Walter E. Stamm*

DEFINITIONS

Acute infections of the urinary tract can be subdivided into two general anatomic categories: lower tract infection (urethritis and cystitis) and upper tract infection (acute pyelonephritis, prostatitis, and intrarenal and perinephric abscesses). Infections at these various sites may occur together or independently and may either be asymptomatic or present as one of the clinical syndromes described below. Infections of the urethra and bladder are often considered superficial (or mucosal) infections, while prostatitis, pyelonephritis, and renal suppuration signify tissue invasion.

From a microbiologic perspective, urinary tract infection (UTI) exists when pathogenic microorganisms are detected in the urine, urethra, bladder, kidney, or prostate. In most instances, growth of more than 10^5 organisms per milliliter from a properly collected midstream "clean-catch" urine sample indicates infection. However, significant bacteriuria is lacking in some cases of true UTI. Especially in symptomatic patients, a smaller number of bacteria (10^2 to 10^4/mL) may signify infection. In urine specimens obtained by suprapubic aspiration or "in-and-out" catheterization and in samples from a patient with an indwelling catheter, colony counts of 10^2 to 10^4/mL generally indicate infection. Conversely, colony counts of $>10^5$/mL of midstream urine are occasionally due to specimen contamination, which is especially likely when multiple species are found.

Infections that recur after antibiotic therapy can be due to the persistence of the originally infecting strain (as judged by species, antibiogram, serotype, and molecular type) or to reinfection with a new strain. "Same-strain" recurrent infections that become evident within 2 weeks of cessation of therapy can be the result of unresolved renal or prostatic infection (termed *relapse*) or of persistent vaginal or intestinal colonization leading to rapid reinfection of the bladder.

Symptoms of dysuria, urgency, and frequency that are unaccompanied by significant bacteriuria have been termed the *acute urethral syndrome*. Although widely used, this term lacks anatomic precision because many cases so designated are actually bladder infections. Moreover, since the causative agent can usually be identified in these patients, the term *syndrome* -- implying unknown causation -- is inappropriate.

Chronic pyelonephritis refers to chronic interstitial nephritis believed to result from bacterial infection of the kidney (Chap. 277). Many noninfectious diseases also cause an interstitial nephritis that is indistinguishable pathologically from chronic pyelonephritis.

ACUTE UTIS: URETHRITIS, CYSTITIS, AND PYELONEPHRITIS

EPIDEMIOLOGY

Epidemiologically, UTIs are subdivided into catheter-associated (or nosocomial) infections and non-catheter-associated (or community-acquired) infections. Infections in either category may be symptomatic or asymptomatic. Acute community-acquired infections are very common and account for more than 7 million office visits annually in

the United States. These infections occur in 1 to 3% of schoolgirls and then increase markedly in incidence with the onset of sexual activity in adolescence. The vast majority of acute symptomatic infections involve young women; a prospective study demonstrated an annual incidence of 0.5 to 0.7 infections per patient-year in this group. Acute symptomatic UTIs are unusual in men under the age of 50. The development of asymptomatic bacteriuria parallels that of symptomatic infection and is rare among men under 50 but common among women between 20 and 50. Asymptomatic bacteriuria is more common among elderly men and women, with rates as high as 40 to 50% in some studies.

ETIOLOGY

Many different microorganisms can infect the urinary tract, but by far the most common agents are the gram-negative bacilli. *Escherichia coli* causes approximately 80% of acute infections in patients without catheters, urologic abnormalities, or calculi. Other gram-negative rods, especially *Proteus* and *Klebsiella* and occasionally *Enterobacter*, account for a smaller proportion of uncomplicated infections. These organisms, plus *Serratia* and *Pseudomonas*, assume increasing importance in recurrent infections and in infections associated with urologic manipulation, calculi, or obstruction. They play a major role in nosocomial, catheter-associated infections (see below). *Proteus* spp., by virtue of urease production, and *Klebsiella* spp., through the production of extracellular slime and polysaccharides, predispose to stone formation and are isolated more frequently from patients with calculi.

Gram-positive cocci play a lesser role in UTIs. However, *Staphylococcus saprophyticus* -- a novobiocin-resistant, coagulase-negative species -- accounts for 10 to 15% of acute symptomatic UTIs in young females. Enterococci occasionally cause acute uncomplicated cystitis in women. More commonly, enterococci and *Staphylococcus aureus* cause infections in patients with renal stones or previous instrumentation or surgery. Isolation of *S. aureus* from the urine should arouse suspicion of bacteremic infection of the kidney.

About one-third of women with dysuria and frequency have either an insignificant number of bacteria in midstream urine cultures or completely sterile cultures and have been previously defined as having the urethral syndrome. About three-quarters of these women have pyuria, while one-quarter have no pyuria and little objective evidence of infection. In the women with pyuria, two groups of pathogens account for most infections. Low quantities (10^2 to 10^4 bacteria per milliliter) of typical bacterial uropathogens such as *E. coli*, *S. saprophyticus*, *Klebsiella*, or *Proteus* are found in midstream urine specimens from most of these women. These bacteria are probably the causative agents in these infections because they can usually be isolated from a suprapubic aspirate, are associated with pyuria, and respond to appropriate antimicrobial therapy. In other women with acute urinary symptoms, pyuria, and urine that is sterile (even when obtained by suprapubic aspiration), sexually transmitted urethritis-producing agents such as *Chlamydia trachomatis*, *Neisseria gonorrhoeae*, and herpes simplex virus are etiologically important. These agents are found most frequently in young, sexually active women with new sexual partners.

The causative role of nonbacterial pathogens in UTIs remains poorly defined.

Ureaplasma urealyticum has frequently been isolated from the urethra and urine of patients with acute dysuria and frequency but is also found in specimens from many patients without urinary symptoms. Ureaplasmas probably account for some cases of urethritis and cystitis. *U. urealyticum* and *Mycoplasma hominis* have been isolated from prostatic and renal tissues of patients with acute prostatitis and pyelonephritis, respectively, and are probably responsible for some of these infections as well. Adenoviruses cause acute hemorrhagic cystitis in children and in some young adults, often in epidemics. Although other viruses can be isolated from urine (e.g., cytomegalovirus), they are thought not to cause UTI. Colonization of the urine of catheterized or diabetic patients by *Candida* and other fungal species is common and sometimes progresses to symptomatic invasive infection (Chap. 205).**Mycobacterial infection of the genitourinary tract is discussed in Chap. 169.*

PATHOGENESIS AND SOURCES OF INFECTION

The urinary tract should be viewed as a single anatomic unit that is united by a continuous column of urine extending from the urethra to the kidney. In the vast majority ofUTIs, bacteria gain access to the bladder via the urethra. Ascent of bacteria from the bladder may follow and is probably the pathway for most renal parenchymal infections.

The vaginal introitus and distal urethra are normally colonized by diphtheroids, streptococcal species, lactobacilli, and staphylococcal species but not by the enteric gram-negative bacilli that commonly causeUTIs. In females prone to the development of cystitis, however, enteric gram-negative organisms residing in the bowel colonize the introitus, the periurethral skin, and the distal urethra before and during episodes of bacteriuria. The factors that predispose to periurethral colonization with gram-negative bacilli remain poorly understood, but alteration of the normal vaginal flora by antibiotics, other genital infections, or contraceptives (especially spermicide) appears to play an important role. Loss of the normally dominant H_2O_2-producing lactobacilli in the vaginal flora appears to facilitate colonization by *E. coli.* Small numbers of periurethral bacteria probably gain entry to the bladder frequently, a process that is facilitated in some cases by urethral massage during intercourse. Whether bladder infection ensues depends on interacting effects of the pathogenicity of the strain, the inoculum size, and the local and systemic host defense mechanisms.

Under normal circumstances, bacteria placed in the bladder are rapidly cleared, partly through the flushing and dilutional effects of voiding but also as a result of the antibacterial properties of urine and the bladder mucosa. Owing mostly to a high urea concentration and high osmolarity, the bladder urine of many normal persons inhibits or kills bacteria. Prostatic secretions possess antibacterial properties as well. Polymorphonuclear leukocytes enter the bladder epithelium and the urine soon after infection arises and play a role in clearing bacteriuria. The role of locally produced antibody remains unclear.

Hematogenous pyelonephritis occurs most often in debilitated patients who are either chronically ill or receiving immunosuppressive therapy. Metastatic staphylococcal or candidal infections of the kidney may follow bacteremia or fungemia, spreading from distant foci of infection in the bone, skin, vasculature, or elsewhere.

CONDITIONS AFFECTING PATHOGENESIS

Gender and Sexual Activity The female urethra appears to be particularly prone to colonization with colonic gram-negative bacilli because of its proximity to the anus, its short length (about 4 cm), and its termination beneath the labia. Sexual intercourse causes the introduction of bacteria into the bladder and is temporally associated with the onset of cystitis; it thus appears to be important in the pathogenesis ofUTIs in younger women. Voiding after intercourse reduces the risk of cystitis, probably because it promotes the clearance of bacteria introduced during intercourse. In addition, use of spermicidal compounds with a diaphragm or cervical cap or of spermicide-coated condoms dramatically alters the normal introital bacterial flora and has been associated with marked increases in vaginal colonization with *E. coli* and in the risk of UTI.

In males who are <50 years old and who have no history of heterosexual or homosexual rectal intercourse,UTI is exceedingly uncommon, and this diagnosis should be questioned in the absence of clear documentation. An important factor predisposing to bacteriuria in men is urethral obstruction due to prostatic hypertrophy. Homosexuality is also associated with an increased risk of cystitis in men, probably related to rectal intercourse. Men (and women) who are infected with HIV and who have CD4+ T cell counts of <200/uL are at increased risk of both bacteriuria and symptomatic UTI. Finally, lack of circumcision has been identified as a risk factor for UTI in both neonates and young men.

Pregnancy UTIs are detected in 2 to 8% of pregnant women. Symptomatic upper tract infections, in particular, are unusually common during pregnancy; fully 20 to 30% of pregnant women with asymptomatic bacteriuria subsequently develop pyelonephritis. This predisposition to upper tract infection during pregnancy results from decreased ureteral tone, decreased ureteral peristalsis, and temporary incompetence of the vesicoureteral valves. Bladder catheterization during or after delivery causes additional infections. Increased incidences of low-birth-weight infants, premature delivery, and newborn mortality result from UTIs during pregnancy, particularly those infections involving the upper tract.

Obstruction Any impediment to the free flow of urine -- tumor, stricture, stone, or prostatic hypertrophy -- results in hydronephrosis and a greatly increased frequency ofUTI. Infection superimposed on urinary tract obstruction may lead to rapid destruction of renal tissue. It is of utmost importance, therefore, when infection is present, to identify and repair obstructive lesions. On the other hand, when an obstruction is minor and is not progressive or associated with infection, great caution should be exercised in attempting surgical correction. The introduction of infection in such cases may be more damaging than an uncorrected minor obstruction that does not significantly impair renal function.

Neurogenic Bladder Dysfunction Interference with the nerve supply to the bladder, as in spinal cord injury, tabes dorsalis, multiple sclerosis, diabetes, and other diseases, may be associated withUTI. The infection may be initiated by the use of catheters for bladder drainage and is favored by the prolonged stasis of urine in the bladder. An additional factor often operative in these cases is bone demineralization due to immobilization, which causes hypercalciuria, calculus formation, and obstructive

uropathy.

Vesicoureteral Reflux Defined as reflux of urine from the bladder cavity up into the ureters and sometimes into the renal pelvis, vesicoureteral reflux occurs during voiding or with elevation of pressure in the bladder. In practice, this condition is demonstrated by the finding of retrograde movement of radiopaque or radioactive material during a voiding cystourethrogram. An anatomically impaired vesicoureteral junction facilitates reflux of bacteria and thus upper tract infection. However, since a fluid connection between the bladder and the kidney always exists, even in the normal urinary system, some retrograde movement of bacteria probably takes place during infection but is not detected by radiologic techniques.

Vesicoureteral reflux is common among children with anatomic abnormalities of the urinary tract as well as among children with anatomically normal but infected urinary tracts. In the latter group, reflux disappears with advancing age and is probably attributable to factors other thanUTI. Long-term follow-up of children with UTI who have reflux has established that renal damage correlates with marked reflux, not with infection.

The routine search for reflux would be aided by the development of noninvasive tests applicable to young children, in whom the need for an effective technique is greatest. In the meantime, it appears reasonable to search for reflux in anyone with unexplained failure of renal growth or with renal scarring, becauseUTI per se is an insufficient explanation for these abnormalities. On the other hand, it is doubtful that all children who have recurrent UTIs but whose urinary tract appears normal on pyelography should be subjected to voiding cystoureterography merely for the detection of the rare patient with marked reflux not revealed by the intravenous pyelogram.

Bacterial Virulence Factors Not all strains of *E. coli* are equally capable of infecting the intact urinary tract. Bacterial virulence factors markedly influence the likelihood that a given strain, once introduced into the bladder, will causeUTI. Most *E. coli* strains that cause symptomatic UTIs in noncatheterized patients belong to a small number of specific O, K, and H serogroups. These uropathogenic clones have accumulated a number of virulence genes that are often closely linked on the bacterial chromosome in "virulence islands." Adherence of bacteria to uroepithelial cells is a critical first step in the initiation of infection. For both *E. coli* and *Proteus*, fimbriae (hairlike proteinaceous surface appendages) mediate the attachment of bacteria to specific receptors on epithelial cells. The attachment of bacteria to uroepithelial cells initiates a number of important events in the mucosal epithelial cell, including secretion of interleukin (IL) 6 and IL-8 and induction of both apoptosis and epithelial cell desquamation. Besides fimbriae, uropathogenic *E. coli* strains usually produce hemolysin and aerobactin (a siderophore for scavenging iron) and are resistant to the bactericidal action of human serum. Nearly all *E. coli* strains causing acute pyelonephritis and most of those causing acute cystitis are uropathogenic. In contrast, infections in patients with structural or functional abnormalities of the urinary tract are generally caused by bacterial strains that lack these uropathogenic properties; the implication is that these properties are not needed for infection of the compromised urinary tract.

Genetic Factors Increasing evidence suggests that host genetic factors influence

susceptibility toUTI. A maternal history of UTI is more often found among women who have experienced recurrent UTIs than among controls. The number and type of receptors on uroepithelial cells to which bacteria may attach are at least in part genetically determined. Many of these structures are components of blood group antigens and are present on both erythrocytes and uroepithelial cells. For example, P fimbriae mediate attachment of *E. coli* to P-positive erythrocytes and are found on nearly all strains causing acute uncomplicated pyelonephritis. Conversely, P blood group-negative individuals, who lack these receptors, have a decreased likelihood of pyelonephritis. It has also been demonstrated that nonsecretors of blood group antigens are at increased risk of recurrent UTI; this predisposition may relate to a different profile of genetically determined glycolipids on uroepithelial cells.

LOCALIZATION OF INFECTION

Unfortunately, currently available methods of distinguishing renal parenchymal infection from cystitis are neither reliable nor convenient enough for routine clinical use. Fever or an elevated level of C-reactive protein often accompanies acute pyelonephritis and is found in rare cases of cystitis but may also occur in infections other than pyelonephritis.

CLINICAL PRESENTATION

Cystitis Patients with cystitis usually report dysuria, frequency, urgency, and suprapubic pain. The urine often becomes grossly cloudy and malodorous, and it is bloody in about 30% of cases. White cells and bacteria can be detected by examination of unspun urine in most cases. However, some women with cystitis have only 10^2 to 10^4bacteria per milliliter of urine, and in these instances bacteria cannot be seen in a Gram-stained preparation of unspun urine. Physical examination generally reveals only tenderness of the urethra or the suprapubic area. If a genital lesion or a vaginal discharge is evident, especially in conjunction with fewer than 10^5bacteria per milliliter on urine culture, then pathogens that may cause urethritis, vaginitis, or cervicitis, such as *C. trachomatis*, *N. gonorrhoeae*, *Trichomonas*, *Candida*, and herpes simplex virus, should be considered. Prominent systemic manifestations such as a temperature of>38.3°C (>101°F), nausea, and vomiting usually indicate concomitant renal infection, as does costovertebral angle tenderness. However, the absence of these findings does not ensure that infection is limited to the bladder and urethra.

Acute Pyelonephritis Symptoms of acute pyelonephritis generally develop rapidly over a few hours or a day and include a fever, shaking chills, nausea, vomiting, and diarrhea. Symptoms of cystitis may or may not be present. Besides fever, tachycardia, and generalized muscle tenderness, physical examination reveals marked tenderness on deep pressure in one or both costovertebral angles or on deep abdominal palpation. In some patients, signs and symptoms of gram-negative sepsis predominate. Most patients have significant leukocytosis and bacteria detectable in Gram-stained unspun urine. Leukocyte casts are present in the urine of some patients, and the detection of these casts is pathognomonic. Hematuria may be demonstrated during the acute phase of the disease; if it persists after acute manifestations of infection have subsided, a stone, a tumor, or tuberculosis should be considered.

Except in individuals with papillary necrosis, abscess formation, or urinary obstruction,

the manifestations of acute pyelonephritis usually respond to therapy within 48 to 72 h. However, despite the absence of symptoms, bacteriuria or pyuria may persist. In severe pyelonephritis, fever subsides more slowly and may not disappear for several days, even after appropriate antibiotic treatment has been instituted.

Urethritis Approximately 30% of women with acute dysuria, frequency, and pyuria have midstream urine cultures that show either no growth or insignificant bacterial growth. Clinically, these women cannot always be readily distinguished from those with cystitis. In this situation, a distinction should be made between women infected with sexually transmitted pathogens, such as *C. trachomatis*, *N. gonorrhoeae*, or herpes simplex virus, and those with low-count *E. coli* or staphylococcal infection of the urethra and bladder. Chlamydial or gonococcal infection should be suspected in women with a gradual onset of illness, no hematuria, no suprapubic pain, and >7 days of symptoms. The additional history of a recent sex-partner change, especially if the patient's partner has recently had chlamydial or gonococcal urethritis, should heighten the suspicion of a sexually transmitted infection, as should the finding of mucopurulent cervicitis (Chaps. 132 and133). Gross hematuria, suprapubic pain, an abrupt onset of illness, a duration of illness of <3 days, and a history ofUTIsfavor the diagnosis of *E. coli* UTI.

Catheter-Associated UTIs (See alsoChap. 135) Bacteriuria develops in at least 10 to 15% of hospitalized patients with indwelling urethral catheters. The risk of infection is about 3 to 5% per day of catheterization. *E. coli*, *Proteus*, *Pseudomonas*, *Klebsiella*, *Serratia*, staphylococci, enterococci, and *Candida* usually cause these infections. Many infecting strains display markedly greater antimicrobial resistance than organisms that cause community-acquiredUTIs. Factors associated with an increased risk of catheter-associated UTI include female sex, prolonged catheterization, severe underlying illness, disconnection of the catheter and drainage tube, other types of faulty catheter care, and lack of systemic antimicrobial therapy.

Infection occurs when bacteria reach the bladder by one of two routes: by migrating through the column of urine in the catheter lumen (intraluminal route) or by moving up the mucous sheath outside the catheter (periurethral route). Hospital-acquired pathogens reach the patient's catheter or urine-collecting system on the hands of hospital personnel, in contaminated solutions or irrigants, and via contaminated instruments or disinfectants. Bacteria usually enter the catheter system at the catheter-collecting tube junction or at the drainage bag portal. The organisms then ascend intraluminally into the bladder within 24 to 72 h. Alternatively, the patient's own bowel flora may colonize the perineal skin and periurethral area and reach the bladder via the external surface of the catheter. This route is particularly common in women. Studies have demonstrated the importance of the attachment and growth of bacteria on the surfaces of the catheter in the pathogenesis of catheter-associatedUTI. Such bacteria growing in biofilms on the catheter eventually produce encrustations consisting of bacteria, bacterial glycocalyces, host urinary proteins, and urinary salts. These encrustations provide a refuge for bacteria and may protect them from antimicrobial agents and phagocytes.

Clinically, most catheter-associated infections cause minimal symptoms and no fever and often resolve after withdrawal of the catheter. The frequency of upper tract infection associated with catheter-induced bacteriuria is unknown. Gram-negative bacteremia,

which follows catheter-associated bacteriuria in 1 to 2% of cases, is the most significant recognized complication of catheter-inducedUTIs. The catheterized urinary tract has repeatedly been demonstrated to be the most common source of gram-negative bacteremia in hospitalized patients, generally accounting for about 30% of cases.

Catheter-associatedUTIs can sometimes be prevented in patients catheterized for<2 weeks by use of a sterile closed collecting system, by attention to aseptic technique during insertion and care of the catheter, and by measures to minimize cross-infection. Other preventive approaches, including short courses of systemic antimicrobial therapy, topical application of periurethral antimicrobial ointments, use of preconnected catheter-drainage tube units, use of catheters impregnated with antimicrobial agents, and addition of antimicrobial drugs to the drainage bag, have all been protective in at least one controlled trial but are not recommended for general use. Despite precautions, the majority of patients catheterized for>2 weeks eventually develop bacteriuria. The need for treatment as well as the optimal type and duration of treatment for such patients with asymptomatic bacteriuria have not been established. Removal of the catheter in conjunction with a short course of antibiotics to which the organism is susceptible probably constitutes the best course of action and nearly always eradicates bacteriuria. Treatment of asymptomatic catheter-associated bacteriuria may be of greatest benefit to elderly women, who most often develop symptoms if left untreated. If the catheter cannot be removed, antibiotic therapy usually proves to be unsuccessful and may in fact result in infection with a more resistant strain. In this situation, the bacteriuria should be ignored unless the patient develops symptoms or is at high risk of developing bacteremia. In these cases, use of systemic antibiotics or urinary bladder antiseptics may reduce the degree of bacteriuria and the likelihood of bacteremia. Because of spinal cord injury, incontinence, or other factors, some patients in hospitals or nursing homes require long-term or semipermanent bladder catheterization. Measures intended to prevent infection have been largely unsuccessful, and essentially all such chronically catheterized patients develop bacteriuria. If feasible, intermittent catheterization by a nurse or by the patient appears to reduce the incidence of bacteriuria and associated complications in such patients. Treatment should be provided when symptomatic infections arise, but treatment of asymptomatic bacteriuria in such patients has no apparent benefit.

DIAGNOSTIC TESTING

Determination of the number and type of bacteria in the urine is an extremely important diagnostic procedure. In symptomatic patients, bacteria are usually present in the urine in large numbers ($\geq 10^5$/mL). In asymptomatic patients, two consecutive urine specimens should be examined bacteriologically before therapy is instituted, and$\geq 10^5$bacteria of a single species per milliliter should be demonstrable in both specimens. Since the large number of bacteria in the bladder urine is due in part to bacterial multiplication during residence in the bladder cavity, samples of urine from the ureters or renal pelvis may contain$<10^5$bacteria per milliliter and yet indicate infection. Similarly, the presence of bacteriuria of any degree in suprapubic aspirates or of$\geq 10^2$bacteria per milliliter of urine obtained by catheterization usually indicates infection. In some circumstances (antibiotic treatment, high urea concentration, high osmolarity, low pH), urine inhibits bacterial multiplication, resulting in relatively low bacterial colony counts despite infection. For this reason, antiseptic solutions should not be used in washing the periurethral area before

collection of the urine specimen. Water diuresis or recent voiding also reduces bacterial counts in urine.

Rapid methods of detection of bacteriuria have been developed as alternatives to standard culture methods. These methods detect bacterial growth by photometry, bioluminescence, or other means and provide results rapidly, usually in 1 to 2 h. Compared with urine cultures, these techniques generally exhibit a sensitivity of 95 to 98% and a negative predictive value of >99% when bacteriuria is defined as 10^5colony-forming units per milliliter. However, the sensitivity of these tests falls to 60 to 80% when 10^2 to 10^4colony-forming units per milliliter is the standard of comparison.

Microscopy of urine from symptomatic patients can be of great diagnostic value. Microscopic bacteriuria, which is best assessed with Gram-stained uncentrifuged urine, is found in more than 90% of specimens from patients whose infections are associated with colony counts of at least 10^5/mL, and this finding is very specific. However, bacteria cannot usually be detected microscopically in infections with lower colony counts (10^2 to 10^4/mL). The detection of bacteria by urinary microscopy thus constitutes firm evidence of infection, but the absence of microscopically detectable bacteria does not exclude the diagnosis. When carefully sought by means of chamber-count microscopy, pyuria is a highly sensitive indicator ofUTI in symptomatic patients. Pyuria is demonstrated in nearly all acute bacterial UTIs, and its absence calls the diagnosis into question. The leukocyte esterase "dipstick" method is less sensitive than microscopy in identifying pyuria but is a useful alternative where microscopy is not feasible. Pyuria in the absence of bacteriuria (sterile pyuria) may indicate infection with unusual bacterial agents such as *C. trachomatis*, *U. urealyticum*, and *Mycobacterium tuberculosis* or with fungi. Alternatively, sterile pyuria may be demonstrated in noninfectious urologic conditions such as calculi, anatomic abnormality, nephrocalcinosis, vesicoureteral reflux, interstitial nephritis, or polycystic disease.

Although many authorities have recommended that urine culture and antimicrobial susceptibility testing be performed for any patient with a suspectedUTI, it may be more practical and cost-effective to manage women who have symptoms characteristic of acute uncomplicated cystitis without an initial urine culture. Two approaches to presumptive therapy have generally been used. In the first, treatment is initiated solely on the basis of a typical history and/or typical findings on physical examination. In the second, women with symptoms and signs of acute cystitis and without complicating factors are managed with urinary microscopy (or, alternatively, with a leukocyte esterase test). A positive result for pyuria and/or bacteriuria provides enough evidence of infection to indicate that urine culture and susceptibility testing can be omitted and the patient treated empirically. Urine should be cultured, however, when a woman's symptoms and urine-examination findings leave the diagnosis of cystitis in question. Pretherapy cultures and susceptibility testing are also essential in the management of all patients with suspected upper tract infections and of those with complicating factors, as in these situations any of a variety of pathogens may be involved and antibiotic therapy is best tailored to the individual organism.

TREATMENT

The following principles underlie the treatment ofUTIs:

1. Except in acute uncomplicated cystitis in women, a quantitative urine culture, a Gram stain, or an alternative rapid diagnostic test should be performed to confirm infection before treatment is begun. When culture results become available, antimicrobial sensitivity testing should be used to direct therapy.

2. Factors predisposing to infection, such as obstruction and calculi, should be identified and corrected if possible.

3. Relief of clinical symptoms does not always indicate bacteriologic cure.

4. Each course of treatment should be classified after its completion as a failure (symptoms and/or bacteriuria not eradicated during therapy or in the immediate posttreatment culture) or a cure (resolution of symptoms and elimination of bacteriuria). Recurrent infections should be classified as same-strain or different-strain and as early (occurring within 2 weeks of the end of therapy) or late.

5. In general, uncomplicated infections confined to the lower urinary tract respond to short courses of therapy, while upper tract infections require longer treatment. After therapy, early recurrences due to the same strain may result from an unresolved upper tract focus of infection but often (especially after short-course therapy for cystitis) result from persistent vaginal colonization. Recurrences>2 weeks after the cessation of therapy nearly always represent reinfection with a new strain or with the previously infecting strain that has persisted in the vaginal and rectal flora.

6. Despite increasing resistance, community-acquired infections, especially initial infections, are usually due to more antibiotic-sensitive strains.

7. In patients with repeated infections, instrumentation, or recent hospitalization, the presence of antibiotic-resistant strains should be suspected.

The anatomic location of a UTI greatly influences the success or failure of a therapeutic regimen. Bladder bacteriuria (cystitis) can usually be eliminated with nearly any antimicrobial agent to which the infecting strain is sensitive; in the past, it was demonstrated that as little as a single dose of 500 mg of intramuscular kanamycin eliminated bladder bacteriuria in most cases. With upper tract infections, however, single-dose therapy fails in the majority of cases, and even a 7-day course is unsuccessful in many instances. Longer periods of treatment (2 to 6 weeks) aimed at eradicating a persistent focus of infection may be necessary in some cases.

In *acute uncomplicated cystitis*, more than 90 to 95% of infections are due to one of two organisms: *E. coli* or *S. saprophyticus*. Although resistance patterns vary geographically and resistance has increased in many areas, most strains are sensitive to many antibiotics. In most parts of the United States, more than one-quarter of *E. coli* strains causing acute cystitis are resistant to amoxicillin, sulfa drugs, and cephalexin, and resistance to trimethoprim (TMP) and trimethoprim-sulfamethoxazole (TMP-SMZ) is now approaching these levels as well.

Many have advocated single-dose treatment for acute cystitis. The advantages of

single-dose therapy include less expense, ensured compliance, fewer side effects, and perhaps less intense pressure favoring the selection of resistant organisms in the intestinal, vaginal, or perineal flora. However, more frequent recurrences develop shortly after single-dose therapy than after 3-day treatment, and single-dose therapy does not eradicate vaginal colonization with *E. coli* as effectively as do longer regimens. A 3-day course of therapy withTMP-SMZ,TMP, norfloxacin, ciprofloxacin, or ofloxacin appears to preserve the low rate of side effects of single-dose therapy while improving efficacy (Table 280-1); thus 3-day regimens are currently preferred for acute cystitis. Neither single-dose nor 3-day therapy should be used for women with symptoms or signs of pyelonephritis, urologic abnormalities or stones, or previous infections due to antibiotic-resistant organisms. Males with UTIoften have urologic abnormalities or prostatic involvement and hence are not candidates for single-dose or 3-day therapy. For empirical therapy, they should generally receive a 7- to 14-day course of a fluoroquinolone (Table 280-1).

The choice of treatment for women with acute urethritis depends on the etiologic agent involved. In chlamydial infection, azithromycin (1 g in a single oral dose) or doxycycline (100 mg orally bid for 7 days) should be used. Women with acute dysuria and frequency, negative urine cultures, and no pyuria usually do not respond to antimicrobial agents.

In women, *acute uncomplicated pyelonephritis* without accompanying clinical evidence of calculi or urologic disease is due to *E. coli* in most cases. Although the optimal route and duration of therapy have not been established, a 7- to 14-day course of a fluoroquinolone, an aminoglycoside, or a third-generation cephalosporin is usually adequate. Neither ampicillin norTMP-SMZshould be used as initial therapy because >25% of strains of *E. coli* causing pyelonephritis are now resistant to these drugs in vitro. For at least the first few days of treatment, antibiotics should probably be given intravenously to most patients, but patients with mild symptoms can be treated for 7 to 14 days with an oral antibiotic (usually ciprofloxacin or ofloxacin), with or without an initial single parenteral dose (Table 280-1). Patients who fail to respond to treatment within 72 h or who relapse after therapy should be evaluated for unrecognized suppurative foci, calculi, or urologic disease.

ComplicatedUTIs(those arising in a setting of catheterization, instrumentation, urologic anatomic or functional abnormalities, stones, obstruction, immunosuppression, renal disease, or diabetes) are typically due to hospital-acquired bacteria, including *E. coli*, *Klebsiella*, *Proteus*, *Serratia*, *Pseudomonas*, enterococci, and staphylococci. Many of the infecting strains are antibiotic-resistant. Empirical antibiotic therapy ideally provides broad-spectrum coverage against these pathogens. In patients with minimal or mild symptoms, oral therapy with a fluoroquinolone, such as ciprofloxacin or ofloxacin, can be administered until culture results and antibiotic sensitivities are known. In patients with more severe illness, including acute pyelonephritis or suspected urosepsis, hospitalization and parenteral therapy should be undertaken. Commonly used empirical regimens include imipenem alone, a penicillin or cephalosporin plus an aminoglycoside, and (when the involvement of enterococci is unlikely) ceftriaxone or ceftazidime. When information on the antimicrobial sensitivity pattern of the infecting strain becomes available, a more specific antimicrobial regimen can be selected. Therapy should generally be administered for 10 to 21 days, with the exact duration depending on the

severity of the infection and the susceptibility of the infecting strain. Follow-up cultures 2 to 4 weeks after cessation of therapy should be performed to demonstrate cure.

In *pregnancy*, acute cystitis can be managed with 7 days of treatment with amoxicillin, nitrofurantoin, or a cephalosporin. All pregnant women should be screened for asymptomatic bacteriuria during the first trimester and, if bacteriuric, should be treated with one of the regimens listed inTable 280-1. After treatment, a culture should be performed to ensure cure, and cultures should be repeated monthly thereafter until delivery. Acute pyelonephritis in pregnancy should be managed with hospitalization and parenteral antibiotic therapy, generally with a cephalosporin or an extended-spectrum penicillin. Continuous low-dose prophylaxis with nitrofurantoin should be given to women who have recurrent infections during pregnancy.

Asymptomatic bacteriuria is common, especially among elderly patients, but has not been linked to adverse outcomes in most circumstances other than pregnancy (see above). Thus antimicrobial therapy is unnecessary and may in fact promote the emergence of resistant strains in most patients with asymptomatic bacteriuria. High-risk patients with neutropenia, renal transplants, obstruction, or other complicating conditions may require treatment when asymptomatic bacteriuria occurs. Seven days of therapy with an oral agent to which the organism is sensitive should be given initially. If bacteriuria persists, it can be monitored without further treatment in most patients. Longer-term therapy (4 to 6 weeks) may be necessary in high-risk patients with persistent asymptomatic bacteriuria.

UROLOGIC EVALUATION

Very few women with recurrentUTIshave correctable lesions discovered at cystoscopy or upon intravenous pyelography, and these procedures should not be undertaken routinely in such cases. Urologic evaluation should be performed in selected instances -- namely, in women with relapsing infection, a history of childhood infections, stones or painless hematuria, or recurrent pyelonephritis. Most males with UTI should be considered to have complicated infection and thus should be evaluated urologically. Possible exceptions include young men who have cystitis associated with sexual activity, who are uncircumcised, or who have AIDS. Men or women presenting with acute infection and signs or symptoms suggestive of an obstruction or stones should undergo prompt urologic evaluation, generally by means of ultrasound.

PROGNOSIS

In patients with uncomplicated cystitis or pyelonephritis, treatment ordinarily results in complete resolution of symptoms. Lower tract infections in women are of concern mainly because they cause discomfort, morbidity, loss of time from work, and substantial health-care costs. Cystitis may also result in upper tract infection or in bacteremia (especially during instrumentation), but little evidence suggests that renal impairment follows. When repeated episodes of cystitis occur, they are nearly always reinfections, not relapses.

Acute uncomplicated pyelonephritis in adults rarely progresses to renal functional impairment and chronic renal disease. Repeated upper tract infections often represent

relapse rather than reinfection, and a vigorous search for renal calculi or an underlying urologic abnormality should be undertaken. If neither is found, 6 weeks of chemotherapy may be useful in eradicating an unresolved focus of infection.

Repeated symptomaticUTIs in children and in adults with obstructive uropathy, neurogenic bladder, structural renal disease, or diabetes progress to chronic renal disease with unusual frequency. Asymptomatic bacteriuria in these groups as well as in adults without urologic disease or obstruction predisposes to increased numbers of episodes of symptomatic infection but does not result in renal impairment in most instances.

PREVENTION

Women who experience frequent symptomaticUTIs(³3 per year on average) are candidates for long-term administration of low-dose antibiotics directed at preventing recurrences. Such women should be advised to avoid spermicide use and to void soon after intercourse. Daily or thrice-weekly administration of a single dose ofTMP-SMZ(80/400 mg),TMPalone (100 mg), or nitrofurantoin (50 mg) has been particularly effective. Norfloxacin and other fluoroquinolones have also been used for prophylaxis. Prophylaxis should be initiated only after bacteriuria has been eradicated with a full-dose treatment regimen. The same prophylactic regimens can be used after sexual intercourse to prevent episodes of symptomatic infection in women in whom UTIs are temporally related to intercourse. Other patients for whom prophylaxis appears to have some merit include men with chronic prostatitis; patients undergoing prostatectomy, both during the operation and in the postoperative period; and pregnant women with asymptomatic bacteriuria. All pregnant women should be screened for bacteriuria in the first trimester and should be treated if bacteriuria is demonstrated.

PAPILLARY NECROSIS

When infection of the renal pyramids develops in association with vascular diseases of the kidney or with urinary tract obstruction, renal papillary necrosis is likely to result. Patients with diabetes, sickle cell disease, chronic alcoholism, and vascular disease seem peculiarly susceptible to this complication. Hematuria, pain in the flank or abdomen, and chills and fever are the most common presenting symptoms. Acute renal failure with oliguria or anuria sometimes develops. Rarely, sloughing of a pyramid may take place without symptoms in a patient with chronicUTI, and the diagnosis is made when the necrotic tissue is passed in the urine or identified as a "ring shadow" on pyelography. If renal function deteriorates suddenly in a diabetic individual or a patient with chronic obstruction, the diagnosis of renal papillary necrosis should be entertained, even in the absence of fever or pain. Renal papillary necrosis is often bilateral; when it is unilateral, however, nephrectomy may be a life-saving approach to the management of overwhelming infection.

EMPHYSEMATOUS PYELONEPHRITIS AND CYSTITIS

These unusual clinical entities almost always occur in diabetic patients, often in concert with urinary obstruction and chronic infection. Emphysematous pyelonephritis is usually characterized by a rapidly progressive clinical course, with high fever, leukocytosis,

renal parenchymal necrosis, and accumulation of fermentative gases in the kidney and perinephric tissues. Most patients also have pyuria and glucosuria. *E. coli* causes most cases, but occasionally other Enterobacteriaceae are isolated. Gas in tissues can often be seen on plain films and can best be confirmed and localized by computed tomography. Surgical resection of the involved tissue in addition to systemic antimicrobial therapy is usually needed to prevent mortality in emphysematous pyelonephritis.

Emphysematous cystitis also occurs primarily in diabetic patients, usually in association with *E. coli* or other facultative gram-negative rods and often in relation to bladder outlet obstruction. Patients with this condition are generally less severely ill and have less rapidly progressive disease than those with emphysematous pyelonephritis. The patient typically reports abdominal pain, dysuria, frequency, and (in some cases) pneumaturia. Computed tomography shows gas within both the bladder lumen and the bladder wall. Generally, conservative therapy with systemic antimicrobial agents and relief of outlet obstruction are effective, but some patients do not respond to these measures and require cystectomy.

RENAL AND PERINEPHRIC ABSCESS

SeeChap. 130.

PROSTATITIS

The term *prostatitis* has been used for various inflammatory conditions affecting the prostate, including acute and chronic infections with specific bacteria and, more commonly, instances in which signs and symptoms of prostatic inflammation are present but no specific organisms can be detected. Patients with acute bacterial prostatitis can usually be identified on the basis of typical symptoms and signs, pyuria, and bacteriuria. To classify a patient with suspected chronic prostatitis correctly, first-void and midstream urine specimens, a prostatic expressate, and a postmassage urine specimen should be quantitatively cultured and evaluated for numbers of leukocytes. On the basis of the results of these studies, patients can be classified as having chronic bacterial prostatitis, chronic nonbacterial prostatitis, or prostatodynia. Patients with suspected chronic prostatitis usually have low back pain, perineal or testicular discomfort, mild dysuria, and lower urinary obstructive symptoms. Microscopic pyuria may be the only objective manifestation of prostatic disease.

ACUTE BACTERIAL PROSTATITIS

When it occurs spontaneously, this disease generally affects young men; however, it may also be associated with an indwelling urethral catheter. It is characterized by fever, chills, dysuria, and a tense or boggy, extremely tender prostate. Although prostatic massage usually produces purulent secretions with a large number of bacteria on culture, bacteremia may result from manipulation of the inflamed gland. For this reason and because the etiologic agent can usually be identified by Gram's staining and culture of urine, vigorous prostatic massage should be avoided. In non-catheter-associated cases, the infection is generally due to common gram-negative urinary tract pathogens (*E. coli* or *Klebsiella*). Initially, an intravenous fluoroquinolone, third-generation

cephalosporin, or aminoglycoside can be administered if gram-negative rods are visible in urine, and a cephalosporin or nafcillin can be given if gram-positive cocci are detected. Although many of these drugs do not readily diffuse into the noninflamed prostate gland, the response to antibiotics in acute bacterial prostatitis is usually prompt, perhaps because drugs penetrate more readily into the acutely inflamed prostate. In catheter-associated cases, the spectrum of etiologic agents is broader, including hospital-acquired gram-negative rods and enterococci. The urinary Gram stain may be particularly helpful in such cases. Imipenem, an aminoglycoside, a fluoroquinolone, or a third-generation cephalosporin should be used for initial therapy until the organism has been isolated and its susceptibilities have been determined. The long-term prognosis is good, although in some instances acute infection may result in abscess formation, epididymoorchitis, seminal vesiculitis, septicemia, and residual chronic bacterial prostatitis. Since the advent of antibiotics, the frequency of acute bacterial prostatitis has diminished markedly. In many instances, infections diagnosed as acute prostatitis are probably cases of posterior urethritis.

CHRONIC BACTERIAL PROSTATITIS

This entity is now infrequent but should be considered in men with a history of recurrent bacteriuria. Symptoms are often lacking between episodes, and the prostate usually feels normal on palpation. Obstructive symptoms or perineal pain develops in some patients. Intermittently, infection spreads to the bladder, producing frequency, urgency, and dysuria. A pattern of relapsing infection in a middle-aged man strongly suggests chronic bacterial prostatitis. Classically, the diagnosis is established by culture of *E. coli*, *Klebsiella*, *Proteus*, or other uropathogenic bacteria from the expressed prostatic secretion or postmassage urine in higher quantities than are found in first-void or midstream urine. Antibiotics promptly relieve the symptoms associated with acute exacerbations but have been less effective in eradicating the focus of chronic infection in the prostate. The relative ineffectiveness of antimicrobial agents for long-term cure results in part from the poor penetration of the prostate by most of these drugs; the low pH that prevails in this organ precludes the passage of most agents. Fluoroquinolones, including ciprofloxacin and ofloxacin, have been considerably more successful than other antimicrobials, but they must generally be given for at least 12 weeks to be effective. Patients with frequent episodes of acute cystitis in whom attempts at curative therapy fail can be managed with prolonged courses of antimicrobials (usually a sulfonamide,TMP, or nitrofurantoin), with a view toward suppressing symptoms and keeping the bladder urine sterile. Total prostatectomy obviously results in the cure of chronic prostatitis but is associated with considerable morbidity. Transurethral prostatectomy is safer but cures only one-third of patients.

NONBACTERIAL PROSTATITIS

Patients who present with symptoms and signs of prostatitis, increased numbers of leukocytes in expressed prostatic secretion and postmassage urine, no bacterial growth in cultures, and no history of recurrent episodes of bacterial prostatitis are classified as having nonbacterial prostatitis. Prostatic inflammation can be considered present when the expressed prostatic secretion and postmassage urine contain at least tenfold more leukocytes than the first-void and midstream urine specimens or when the expressed prostatic secretion contains^{3}1000 leukocytes per microliter.

The presumably infectious etiology of this condition remains unidentified. Evidence for a causative role of both *U. urealyticum* and *C. trachomatis* has been presented but is not conclusive. Since most cases of nonbacterial prostatitis occur in young, sexually active men and since many cases follow an episode of nonspecific urethritis, the causative agent may well be sexually transmitted. The effectiveness of antimicrobial agents in this condition remains uncertain. Some patients benefit from a 4- to 6-week course of treatment with erythromycin, doxycycline,TMP-SMZ, or a fluoroquinolone, but controlled trials are lacking.

PROSTATODYNIA

Patients who have symptoms and signs of prostatitis but who have no evidence of prostatic inflammation (normal leukocyte counts) and negative urine cultures are classified as having prostatodynia. Despite their symptoms, these patients most likely do not have prostatic infection and should not be given antimicrobial agents.

281. URINARY TRACT OBSTRUCTION - *Julian L. Seifter*, *Barry M. Brenner*

Obstruction to the flow of urine, with attendant stasis and elevation in urinary tract pressure, impairs renal and urinary conduit functions and is a common cause of acute and chronic renal failure. With early relief of obstruction, the defects in function usually disappear completely. However, chronic obstruction may produce permanent loss of renal mass (renal atrophy) and excretory capability, as well as enhanced susceptibility to local infection and stone formation. Early diagnosis and prompt therapy are therefore essential to minimize the otherwise devastating effects of obstruction on kidney structure and function.

ETIOLOGY

Obstruction to urine flow can result from *intrinsic* or *extrinsic mechanical blockade* as well as from *functional defects* not associated with fixed occlusion of the urinary drainage system. Mechanical obstruction can occur at any level of the urinary tract, from the renal calyces to the external urethral meatus. Normal points of narrowing, such as the ureteropelvic and ureterovesical junctions, bladder neck, and urethral meatus, are common sites of obstruction. When blockage is above the level of the bladder, unilateral dilatation of the ureter (*hydroureter*) and renal pyelocalyceal system (*hydronephrosis*) occur; lesions at or below the level of the bladder cause bilateral involvement.

Common forms of obstruction are listed in Table 281-1. In childhood, *congenital malformations*, including marked narrowing of the ureteropelvic junction, anomalous (retrocaval) location of the ureter, and posterior urethral valves, predominate. The latter defect is the most common cause of bilateral hydronephrosis in boys. Children may also have bladder dysfunction secondary to congenital urethral stricture, urethral meatal stenosis, or bladder neck obstruction. In adults, urinary tract obstruction is due mainly to *acquired defects*. Pelvic tumors, calculi, and urethral stricture predominate. Ligation of, or injury to, the ureter during pelvic or colonic surgery can lead to hydronephrosis which, if unilateral, may remain relatively silent and undetected. *Schistosoma haematobium* and genitourinary tuberculosis are infectious causes of ureteral obstruction. Obstructive uropathy may also result from extrinsic neoplastic (carcinoma of cervix or colon, retroperitoneal lymphoma) or inflammatory disorders. One such inflammatory disorder is retroperitoneal fibrosis, a process of unknown cause seen most commonly in middle-aged men, which occasionally leads to bilateral ureteral obstruction. Retroperitoneal fibrosis must be distinguished from other retroperitoneal causes of ureteral obstruction, particularly lymphomas and pelvic neoplasms.

Functional impairment of urine flow usually results from disorders that involve both the ureter and bladder. Common functional lesions include neurogenic bladder, often with adynamic ureter, and vesicoureteral reflux. Reflux of urine from bladder to ureter(s) is more common in children than in adults and may result in severe unilateral or bilateral hydroureter and hydronephrosis. Abnormal insertion of the ureter into the bladder is the most common cause of vesicoureteral reflux in children. Reflux in the absence of urinary tract infection or bladder neck obstruction usually does not lead to renal parenchymal damage and often resolves spontaneously as the child matures. Surgical reinsertion of the ureter into the bladder is indicated if reflux is severe and unlikely to improve spontaneously, if renal function deteriorates, or if urinary tract infections recur despite

chronic antimicrobial therapy. Hydronephrosis, usually more marked on the right than on the left, is common in pregnancy, due both to ureteral compression by the enlarged uterus and to functional effects of progesterone.

CLINICAL FEATURES

The pathophysiology and clinical features of urinary tract obstruction are summarized inTable 281-2. *Pain* is the symptom that most commonly provokes the need for medical attention. The pain of urinary tract obstruction is due to distention of the collecting system or renal capsule. The severity of the pain is influenced more by the rate at which distention develops than by the degree of distention. Acute supravesical obstruction, as from a stone lodged in a ureter (Chap. 279), is associated with excruciatingly severe pain, usually called *renal colic*. This pain is relatively steady and continuous, with little fluctuation in intensity, and often radiates to the lower abdomen, testes, or labia. By contrast, more insidious causes of obstruction, such as chronic narrowing of the ureteropelvic junction, may produce little or no pain yet result in total destruction of the affected kidney. Flank pain that occurs only with micturition is pathognomonic of vesicoureteral reflux.

Azotemia develops in urinary tract obstruction when overall excretory function is impaired. This may occur in the setting of bladder outlet obstruction, bilateral renal pelvic or ureteric obstruction, or unilateral disease in a patient with a solitary functioning kidney. Complete bilateral obstruction should be suspected when acute renal failure is accompanied by anuria. Any patient with renal failure otherwise unexplained or with a history of nephrolithiasis, hematuria, diabetes mellitus, prostatic enlargement, pelvic surgery, trauma, or tumor should be evaluated for urinary tract obstruction.

In the acute setting, bilateral obstruction may result in sodium and water retention that may mimic prerenal azotemia. However, with more prolonged obstruction, symptoms of *polyuria* and *nocturia* commonly accompany partial urinary tract obstruction and result from impaired renal concentrating ability. This defect usually does not improve with administration of vasopressin and is therefore a form of acquired nephrogenic diabetes insipidus. Disturbances in sodium chloride transport in the ascending limb of Henle and, in azotemic patients, the osmotic (urea) diuresis per nephron lead to decreased medullary hypertonicity and hence a concentrating defect. Partial obstruction, therefore, may be associated with increased rather than decreased urine output. Indeed, wide fluctuations in urine output in a patient with azotemia should always raise the possibility of intermittent or partial urinary tract obstruction. If fluid intake is inadequate, severe dehydration and hypernatremia may develop. Hesitancy and straining to initiate the urinary stream, postvoid dribbling, urinary frequency, and (overflow) incontinence are common with obstruction at or below the level of the bladder.

In addition to loss of urinary concentrating ability and azotemia, partial bilateral urinary tract obstruction often results in other derangements of renal function, including *acquired distal renal tubular acidosis*, *hyperkalemia*, and *renal salt wasting*. These defects in tubule function are often accompanied by renal tubulointerstitial damage. Morphologic abnormalities appear early in the course of obstruction; initially the interstitium becomes edematous and infiltrated with mononuclear inflammatory cells. With continued obstruction, the interstitium becomes fibrotic; scarring and atrophy of the

papillae and medulla occur and precede these processes in the cortex.

The possibility of urinary tract obstruction must always be considered in patients with urinary tract infections or urolithiasis. Urinary stasis encourages the growth of organisms as well as the formation of crystals, especially magnesium ammonium phosphate (struvite). *Hypertension* is frequent in acute and subacute unilateral obstruction and is usually a consequence of increased release of renin by the involved kidney. Chronic unilateral or bilateral hydronephrosis, in the presence of extracellular volume expansion or other renal disease, may result in significant hypertension. *Erythrocytosis*, an infrequent complication of obstructive uropathy, is probably secondary to increased erythropoietin production by the obstructed kidney.

DIAGNOSIS

A history of difficulty in voiding, pain, infection, or changes in urinary volume is common. Evidence for distention of the kidney or urinary bladder can often be obtained by palpation and percussion of the abdomen. A careful rectal examination may reveal enlargement or nodularity of the prostate, abnormal rectal sphincter tone, or a rectal or pelvic mass. The penis should be inspected for evidence of meatal stenosis or phimosis. In the female, vaginal, uterine, and rectal lesions responsible for urinary tract obstruction are usually revealed by inspection and palpation.

Urinalysis and examination of the urine sediment may reveal hematuria, pyuria, and bacteriuria. Often, however, the urine sediment is normal, even when obstruction leads to marked azotemia and extensive structural damage. An abdominal scout film should be obtained to evaluate the possibility of nephrocalcinosis or a radiopaque stone at any level of the urinary collecting system. As indicated inFig. 281-1, if urinary tract obstruction is suspected, a bladder catheter should be inserted. If diuresis does not follow, then abdominal ultrasonography should be performed to evaluate renal and bladder size, as well as pyelocalyceal contour. Ultrasonography is approximately 90% specific and sensitive for detection of hydronephrosis. False-positive results are associated with diuresis, renal cysts, or presence of an extrarenal pelvis, a normal congenital variant. Hydronephrosis may be absent on ultrasound when obstruction is associated with volume contraction, staghorn calculi, retroperitoneal fibrosis, or infiltrative renal disease.

In some cases, the intravenous urogram may define the site of obstruction. In the presence of obstruction, the appearance time of the nephrogram is often delayed. Eventually, however, the renal image becomes more dense than normal because of slow tubular fluid flow rate, which results in enhanced water reabsorption by the nephrons and greater concentration of contrast medium within tubules. The kidney involved by an acute obstructive process is usually slightly enlarged, and there is dilatation of the calyces, renal pelvis, and ureter above the obstruction. The ureter, however, is not tortuous, as is the case when the obstruction is chronic. In comparison with the nephrogram, the urogram may be extremely faint, especially if the dilated renal pelvis is voluminous, causing dilution of the contrast medium. The radiographic study should be continued until the site of obstruction is determined or the contrast medium is excreted. Radionuclide scans define less anatomic detail than intravenous urography and, like the urogram, are of limited value when renal function is poor. Nonetheless,

such scans are sensitive for the detection of obstruction and provide a substitute test in some patients at high risk for reaction to intravenous contrast.

To facilitate visualization of a suspected lesion in a ureter or renal pelvis, *retrograde* or *antegrade urography* should be attempted. These diagnostic studies may be preferable to the intravenous urogram in the azotemic patient, in whom poor excretory function precludes adequate visualization of the collecting system. Furthermore, intravenous urography carries the risk of contrast-induced acute renal failure in patients with proteinuria, renal insufficiency, diabetes mellitus, or multiple myeloma, particularly when performed under conditions of dehydration. The retrograde approach involves catheterization of the involved ureter under cystoscopic control, while the antegrade technique necessitates placement of a catheter into the renal pelvis via a needle inserted percutaneously under ultrasonic or fluoroscopic guidance. While the antegrade approach carries the added advantage of providing immediate decompression of a unilateral obstructing lesion, many urologists initially attempt the retrograde approach and resort to the antegrade method only when attempts at retrograde catheterization are unsuccessful or when cystoscopy or general anesthesia is contraindicated.

Patients suspected of having intermittent ureteropelvic obstruction (whether functional or mechanical) should have radiologic evaluation while they are in pain, since a normal urogram is commonly seen during asymptomatic periods. Hydration often helps to provoke a symptomatic attack. Voiding cystourethrography is of great value in the diagnosis of vesicoureteral reflux and bladder neck and urethral obstructions. Patients with obstruction at or below the level of the bladder exhibit thickening, trabeculation, and diverticula of the bladder wall. Postvoiding films reveal residual urine. If these radiographic studies fail to provide adequate information for diagnosis, endoscopic visualization by the urologist often permits precise identification of lesions involving the urethra, prostate, bladder, and ureteral orifices.

Computed tomography is useful in the diagnosis of specific intraabdominal and retroperitoneal causes of obstruction but is less practical as an initial test to establish the presence of obstruction. Magnetic resonance imaging may also be useful in the identification of specific obstructive causes.

TREATMENT

An individual with any form of urinary tract obstruction complicated by infection requires relief of obstruction as soon as possible to prevent development of generalized sepsis and progressive renal damage. On a temporary basis, depending on the site of obstruction, drainage is often satisfactorily achieved by nephrostomy; ureterostomy; or ureteral, urethral, or suprapubic catheterization. The patient with acute urinary tract infection and obstruction should be given appropriate antibiotics based on in vitro bacterial sensitivity and ability of the drug to concentrate in the kidney and urine. Treatment may be required for 3 to 4 weeks. Chronic or recurrent infections in an obstructed kidney with poor intrinsic function may necessitate nephrectomy. When infection is not present, immediate surgery often is not required, even in the presence of complete obstruction and anuria (because of the availability of dialysis), at least until acid-base, fluid and electrolyte, and cardiovascular status are restored to normal. Nevertheless, the site of obstruction should be ascertained as soon as feasible, in part

because of the possibility that sepsis may occur and necessitate prompt urologic intervention. Elective relief of obstruction is usually recommended in patients with urinary retention, recurrent urinary tract infections, persistent pain, or progressive loss of renal function. Infrequently, mechanical obstruction can be alleviated by nonsurgical means, as with radiation therapy for retroperitoneal lymphoma. Likewise, functional obstruction secondary to neurogenic bladder may be decreased with the combination of frequent voiding and cholinergic drugs.*The approach to obstruction secondary to renal stones is discussed in Chap. 279.*

PROGNOSIS

With relief of obstruction, the prognosis regarding return of renal function depends largely on whether irreversible renal damage has occurred. When obstruction is not relieved, the course will depend mainly on whether the obstruction is complete or incomplete, bilateral or unilateral, and whether urinary tract infection is also present. Complete obstruction with infection can lead to total destruction of the kidney within days. In dogs, relief of complete obstruction of 1 and 2 weeks' duration restores glomerular filtration rate to 60 and 30% of normal, respectively; after 8 weeks of obstruction, recovery does not occur. Nevertheless, in the absence of definitive evidence of irreversibility, every effort should be made to decompress in the hope of restoring renal function at least partially. A renal radionuclide scan, performed after a prolonged period of decompression, may be used to predict reversible renal function.

POSTOBSTRUCTIVE DIURESIS

Relief of bilateral, but not unilateral, complete urinary tract obstruction commonly leads to a postobstructive diuresis, characterized by polyuria, which may be massive. The urine is usually hypotonic and may contain large amounts of sodium chloride, potassium, and magnesium. The natriuresis is due, at least in part, to the excretion of retained urea, which acts as a poorly reabsorbable solute and diminishes salt and water reabsorption in the tubules (osmotic diuresis). The increase in intratubular pressure very likely also contributes to the impairment in net sodium chloride reabsorption, especially in the terminal nephron segments. Natriuretic factors (other than urea) may also accumulate during uremia induced by obstruction and depress salt and water reabsorption when urine flow is reestablished. In the majority of patients this diuresis is physiologic, resulting in the *appropriate* excretion of the excesses of salt and water retained during the period of obstruction. When extracellular volume and composition return to normal, the diuresis usually abates spontaneously. Therefore, replacement of urinary losses should serve only to prevent hypovolemia, hypotension, or disturbances in serum electrolyte concentrations. Occasionally, iatrogenic expansion of extracellular volume, secondary to administration of excessive quantities of intravenous fluids, is responsible for, or sustains, the diuresis observed in the postobstructive period. Replacement of no more than two-thirds of urinary volume losses per day is usually effective in avoiding this complication. The loss of electrolyte-free water with urea may result in hypernatremia. Serum and urine sodium and osmolal concentrations should guide the use of appropriate intravenous replacement. Often replacement with 0.45% saline is required. In a rare patient, relief of obstruction may be followed by urinary salt and water losses severe enough to provoke profound dehydration and vascular collapse. In these patients, an intrinsic defect in tubule reabsorptive function is probably

responsible for the marked diuresis. Appropriate therapy in such patients includes intravenous administration of salt-containing solutions to replace sodium and volume deficits.

PART ELEVEN -DISORDERS OF THE GASTROINTESTINAL SYSTEM

SECTION 1 -DISORDERS OF THE ALIMENTARY TRACT

282. APPROACH TO THE PATIENT WITH GASTROINTESTINAL DISEASE - *Daniel K. Podolsky*, *Kurt J. Isselbacher*

BIOLOGIC CONSIDERATIONS

The mucosal surface of the gastrointestinal (GI) tract is composed of a highly dynamic population of epithelial cells that are specialized for transmembrane absorption and secretion. These secretory and absorptive abilities facilitate digestion and nutrient uptake, which must be accomplished while keeping out potentially harmful pathogens and mutagens in the lumen. The barrier function is accomplished through both the physical integrity of the mucosal surface and the extensive population of resident immune cells.

The intestinal lymphoid system reflects a balance between dampening immune reactivity at the mucosal surface to prevent the constant and unrestrained activation of immune and inflammatory processes and immune response amplification in the underlying lamina propria and submucosa ready to respond when surface defenses have been breached. Derangements in the balance of suppression and stimulation predispose theGI tract to numerous inflammatory conditions.

The epithelial cells of the mucosal surface turn over very rapidly; the entire surface is regenerated every 24 to 72 h. This rapid turnover may permit rapid recovery of function following an acute insult and protect the cells against many mutagens in the lumen. Indeed, the small intestine rarely develops epithelial cancers. The slower turnover of colonic epithelium, the slower movement of the luminal contents, and differences in the mutagens in the luminal contents appear to foster colon cancers. Another fundamental feature of theGImucosa is the spatial segregation of the proliferative compartment from the terminally differentiated cells, especially in the small intestine, where a gradient of differentiation exists from the depths of the crypts of Lieberkuhn to the villus tip. This organization has a strong effect on the histology and pathophysiology of many mucosal disorders, such as celiac sprue.

Diseases of theGI tract produce clinical consequences through physical disruption of the mucosal layer (e.g., blood loss, fluid loss, pathogenic invasion) or nutritional derangements caused by impaired digestion and nutrient absorption. Focal or localized disease processes are more likely to disrupt mucosa; diffuse processes are more likely to alter absorption.

While the essential roles of theGItract -- the absorption of nutrients and the excretion of the products -- are accomplished in large part at the luminal surface, GI function also depends on the coordinated propulsion of food through the lumen by smooth-muscle contraction. The local and distant neural and endocrine factors that contribute to the regulation of intestinal motility are complex. Disruption of normal motility is common, with alterations in frequency of bowel movements, abdominal distention, abdominal pain, and nausea, individually or in varying combinations (so-called functional bowel

complaints), affecting as many as 15% of adults. Such symptoms may result from dysmotility related to the *direct* effects of an obstructing lesion or to the *indirect* actions of substances released by a primary mucosal disorder (e.g., inflammatory mediators such as arachidonic acid metabolites that also affect smooth-muscle activity).

The spectrum of diseases affecting theGI tract and their clinical manifestations are related to the component organ(s) involved (Table 282-1). Thus, esophageal disorders manifest themselves mainly through their effects on swallowing; gastric disorders are dominated by features relating to acid secretion; and diseases of the small and large intestine demonstrate disruption of nutrition and alterations of bowel movements. The GI tract may also be affected by systemic disorders, including vascular, inflammatory, infectious, and neoplastic conditions leading to focal or diffuse structural lesions. Metabolic and endocrine abnormalities as well as some drugs can disrupt normal bowel motility. When no structural lesion can be identified to explain GI symptoms, the disorder is termed *functional*.Table 282-2 summarizes criteria that may be used to distinguish functional from organic or structural diseases of the GI tract.

CLINICAL CONSIDERATIONS

History A thorough clinical history is essential in directing the clinician's attention to appropriate diagnostic considerations in the patient withGIsymptoms (Table 282-1). The most common complaints include pain and alterations in bowel habit, especially diarrhea or constipation. *Abdominal pain* is the most frequent and variable complaint and may reflect a broad spectrum of problems, from self-limited to urgent (Chap. 14). The intensity should be assessed and an initial distinction should be made between pain of acute onset and more chronic discomfort. Pain of abrupt onset more often reflects serious illness requiring urgent intervention, while a history of chronic discomfort is most often related to an indolent disorder. Dyspepsia, an ill-defined upper abdominal discomfort, is especially common and is often accompanied by varying degrees of nausea, bloating, and distention. Dyspepsia may be associated with peptic ulceration, but non-ulcer dyspepsia (NUD) is more common. A change in the pattern or character of pain may signify disease progression. Ascertaining the location of the pain (upper or lower, localized or diffuse), its character (sharp, burning, cramping), and its relationship to meals will often provide clues into the most important diagnostic considerations. Discomfort while the patient is eating suggests an esophageal disorder. Pain occurring shortly after the meal may signify biliary tract disease or abdominal angina; pain 30 to 90 min later is typical of peptic disease. Pain that is not affected by eating suggests a process outside of the bowel lumen, such as abscess, peritonitis, pancreatitis, and some malignancies. Conversely, factors that relieve the symptom are also helpful. For example, eating or antacid use typically relieves pain in peptic ulcer disease or gastritis. A relationship to bowel movement, especially together with an altered bowel habit, should focus attention on a disorder of the small or large bowel, such as inflammatory bowel disease.

Alterations in bowel habit can result from either disruption of normal intestinal motility or significant structural pathology. The temporal evolution of the change, the nature of the alteration, and the presence of other constitutional symptoms such as weight loss, fever, or anorexia are important. Temporary variation in bowel habit in association with some life stress and in the absence of signs of systemic illness suggests the common "irritable

bowel syndrome," especially when the alteration varies between diarrhea and constipation. Small, pellet-like stools associated with symptoms of dyspepsia (bloating, nausea, and "gas") are common. This diagnosis can essentially be made on the basis of a thorough history and physical examination and very limited laboratory testing, to exclude structural disease.

Constipation is a common complaint and may reflect an obstructing process but is more often due to impaired motility; though often functional in nature, drugs (e.g., anticholinergics), neurologic processes (e.g., Hirschsprung's disease), or smooth-muscle diseases (e.g., scleroderma) may cause decreased motility. The history and physical examination may provide evidence of a more generalized disorder such as hypothyroidism or depression. Pain associated with constipation may suggest an anal or perianal process with stool retention. The history may clarify that "constipation" actually reflects more an unrealized expectation of regularity than significant pathology. In contrast, progressively worsening constipation and weight loss in an adult with previously regular habits suggests the possible presence of an underlying obstructing process, particularly malignancy.

Although *diarrhea* refers to an increased frequency of movements, patients often use the term to describe loose or watery stools. If diarrhea is described, the daily average number of stools, their consistency, their pattern, and the presence of blood should be defined. The occurrence of nocturnal or true bloody diarrhea almost always reflects structural rather than functional bowel disease. A pungent stool odor or the presence of undigested meat in the movement is suggestive of pancreatic insufficiency. An alteration in color can be seen in cholestasis or steatorrhea (light-colored) or hemorrhage (melenic to maroon or bright red). Mucus in the movement is usually a sign of a functional bowel syndrome, while pus suggests infectious or inflammatory disease. Less common but more dramatic are the symptoms of acute GI bleeding, including hematemesis, melena, and hematochezia, which usually lead to prompt seeking of medical attention but should always be enquired after by the clinician.

In the evaluation of male patients, especially those with diarrhea or dysphagia, a tactful inquiry into sexual activity is essential. Homosexual males are at increased risk for a large variety of GI disorders as well as AIDS, which may first manifest itself with GI symptoms. AIDS patients are susceptible to a wide range of infections and neoplastic disorders of the GI tract, liver, and biliary tract (Chap. 308).

Finally, careful attention must be given to a general medical history with an emphasis on present or past use of medications or nonprescription drugs. Thyroid and other metabolic disorders, especially those affecting calcium metabolism, can cause a variety of GI symptoms. Unless asked, patients may forget to mention that they take aspirin almost daily for headache, and this may account for occult blood found in the stool. The use of daily laxatives may explain chronic diarrhea.

Physical Examination, Endoscopy, and Radiology All of the cardinal methods of examination are helpful in evaluating the patient with GI symptoms (Table 282-1). *Inspection* may disclose signs of cholestasis or nutritional deficiencies. Examination of the abdomen for an abnormal contour or inspection of the perianal region may reveal signs of a mass or a draining fistula. *Auscultation* may elicit a succussion splash in

patients with symptoms of gastric outlet obstruction. The absence of bowel sounds or an alteration in pitch can lead to recognition of an evolving ileus or an obstructing process. A bruit may be noted when symptoms of ischemic bowel disease are present. Careful *palpation* of the abdomen is especially important in detecting tenderness and masses, which can lead to the recognition of cholecystitis, Crohn's disease, periappendiceal abscess, and many other disorders. Findings on abdominal palpation will often be complemented by *percussion*, which is essential to assessing liver and spleen size.

Elicitation of *rebound tenderness*, either direct or referred, after abrupt removal of the examining hand provides an important clue to localized or more generalized peritonitis, which may suggest abdominal emergencies, such as a perforated viscus, intraabdominal abscess, or bowel infarction. Typically, the patient will remain immobile to avoid the accentuation of pain that may follow even slight movement or jarring of the abdomen. By contrast, patients with severe pain deriving from visceral disease, such as intestinal ischemia, are sometimes frantic to find a comfortable position. In these disorders, the absence of findings on palpation may be in striking contrast to the evident distress of the patient. Only when the process progresses to tissue destruction (e.g., intestinal infarction) and secondary peritonitis will the abdominal examination prove remarkable, often in concert with striking signs of systemic illness, including hemodynamic instability.

In addition to the examination of the abdomen, a digital rectal examination is also essential. In the patient with complaints of stool incontinence, the integrity of the sphincter can be assessed. Masses intrinsic to the rectum as well as abnormalities in the pelvis or the pouch of Douglas may only be detected by this examination. The presence of frank or occult blood in the stool is always important diagnostic information. Sigmoidoscopy should be viewed as a routine part of the physical examination in the patient with diarrhea, constipation, or frank or occult fecal blood. Sigmoidoscopy performed with either a rigid or a flexible fiberoptic instrument allows for direct inspection of the rectosigmoid mucosa, permitting the detection of cancers and polyps in this lower bowel segment that could be missed by barium x-rays. Inflammatory changes of the mucosa can help identify patients with infectious dysentery or other forms of colitis. Edema, granularity, diffuse friability (easily induced mucosal bleeding), and superficial ulcerations are characteristic of ulcerative colitis. Fresh stool samples for microbiologic studies and superficial mucosal biopsies obtained at the time of sigmoidoscopy can also yield crucial diagnostic information. The presence of polyps is an indication for colonoscopy (Chap. 283).

Many upper and lowerGI tract disorders are accessible to inspection via fiberoptic instruments. As a result, endoscopy has supplanted conventional contrast x-ray studies for many clinical problems, both because of its heightened precision for diagnosis and the opportunity in many instances to accomplish meaningful therapeutic intervention. However, it should be emphasized that *no procedure should be considered routine* and used indiscriminately; there must be a rational basis for its use in the individual patient. These techniques are discussed in detail inChap. 283. Upper GI endoscopy permits evaluation of the esophagus, stomach, duodenum, and, with specially designed instruments, proximal jejunum. Side-viewing scopes permit inspection and cannulation of the ampulla of Vater, facilitating retrograde cholangiopancreatography. Evaluation of some patients will be further benefited by endoscopic ultrasound (US), which can

delineate submucosal mass lesions and abnormalities in the pancreas. The colonoscope can be used to visualize the entire colon and often the terminal ileum, resulting in more accurate diagnosis of inflammatory bowel disease and mass lesions. Colonic polyps can almost always be removed at the time of their initial identification.

Endoscopic techniques are relatively precise in defining many problems, but the limitations of these tools, as well as the continued advantages of x-ray studies in some situations, should be recognized. Endoscopic tools are not useful in assessingGImotility, which may be assessed more accurately by barium studies. In addition, the small intestine remains largely inaccessible to fiberoptic instruments. In hospitals where endoscopy is not feasible, the upper GI series and barium enema remain good diagnostic modalities to evaluate the upper and lower GI tract, especially when air-contrast techniques are employed. However, they should generally be avoided in patients with GI bleeding or suspected bowel obstruction. In addition, the cathartics used to prepare the bowel may markedly worsen the condition of a patient with obstructing lesions or colitis.

Although endoscopy has obviated the need for many conventionalGIx-rays, other radiologic imaging modalities, includingUS, computed tomography (CT), and magnetic resonance imaging (MRI), have assumed a larger role in patients with GI symptoms. Both US and CT are useful in the delineation of abdominal masses. CT, though more expensive, is often more effective in the evaluation of the lower abdomen, where inflammatory masses in patients with Crohn's disease or complications of diverticular disease may be accurately imaged. However, US is an effective and less expensive tool for the evaluation of the right upper quadrant, including the gall bladder and biliary tract. MRI may give exquisitely accurate information on the anatomic extent of invasive rectal cancers and blood flow in patients with vascular disorders, but the full range of its uses in GI disorders remains to be delineated. More sophisticated CT and MRI equipment can actually permit the performance of digital angiography without the invasive catheterization necessary in conventional visceral angiography. CT "virtual colonoscopy," a nonendoscopic method of visualizing the colon, is developing rapidly.

Radionuclide scans can be used to localize a site of bleeding in theGItract. Radiolabeled technetium can detect a Meckel's diverticulum, which is an occasional source of bleeding.

DIAGNOSTIC APPROACHES (Table 282-1)

Abdominal Pain Determining the cause of abdominal pain is frequently a clinical challenge (Chap. 14). Differential diagnostic considerations may encompass diseases extrinsic to theGItract, such as disorders of the genitourinary tract (e.g., pelvic inflammatory disease) and the peritoneum. The initial goal is to distinguish between an urgent problem and a nonacute disorder. Initial clinical impressions based on the history and physical examination can be further refined through routine laboratory tests such as a complete blood count and differential as well as plain films of the abdomen. Specific features will dictate the appropriateness of urgentUS orCTexamination or the need to proceed promptly with surgery. In the patient with a long-standing and relatively stable problem, diagnostic evaluation can be more deliberate. A functional basis for the complaint may be established on the strength of the history and physical examination

alone. Radiologic contrast studies, other imaging modalities (e.g., US, CT), or endoscopic examination may be appropriate. If these approaches do not determine the cause of the patient's symptoms, more unusual causes of abdominal pain such as acute intermittent porphyria may have to be excluded through specific urine or blood tests (Chap. 346).

Problems of Swallowing Dysphagia nearly always signifies the presence of structural pathology. The approach should be as follows:

1. *Thorough determination of the nature of dysphagia*. Is the difficulty primarily in swallowing liquids, solids, or both? The location of the difficulty from the patient's perspective and presence or absence of accompanying *odynophagia* (pain on swallowing) are important to ascertain. These historic clues are complemented by careful visual and neurologic examination of the oropharynx.

2. *Routine esophageal x-rays* in the upright and lateral or Trendelenburg position. The horizontal views are essential for demonstration of the swallowing mechanism, unaided by gravity, and of the esophagogastric junction. For details of the pharyngoesophageal area, cineradiography is necessary because of the rapidity with which the contrast medium passes through. Hiatus hernia is extremely common (in 15 to 35% of persons over 50) and is often asymptomatic. Careful attention is usually needed to detect lower esophageal rings or webs, which may be visible as indentations in the barium column only from a limited angle.

3. *Esophagoscopy*. This procedure is desirable to biopsy masses or abnormal mucosa and to obtain washings for exfoliative cytologic study. The diagnoses of peptic esophagitis and Barrett's esophagus are made endoscopically. Endoscopy is the most sensitive technique for identifying esophageal or gastric varices, although they are seldom important in the absence of hemorrhage. Endoscopic instruments with aUS probe at the tip (endoscopic ultrasound) are useful diagnostic and staging tools for certain problems of the esophagus (and other sites of theGItract).

4. *Manometric studies* of the upper esophagus, particularly in conjunction with cineradiography. This procedure offers the best means of differentiating among disorders originating in the central nervous system, primary pharyngeal muscular disease, and cricopharyngeal dystonia. Manometry of the lower esophagus is useful in the diagnosis of diffuse esophageal spasm, achalasia, and infiltrative diseases that alter esophageal motility.

5. *24-Hour monitoring of esophageal pH* may be used to document esophageal reflux.

Peptic or Digestive Disorders The approaches to these disorders include the following:

1. *Insertion of a nasogastric tube.* This approach is used to establish whether significant gastric retention (more than 75 mL of gastric contents in the fasting state) exists and whether acid, bile, blood, or other materials are present. If pyloric obstruction or gastric atony is present, the tube is used to maintain suction while the patient's electrolyte and fluid balance is restored to normal; the stomach is kept as clean as possible so that

diagnostic investigation may be carried out.

2. *Upper gastrointestinal endoscopy* (Chap. 283). This procedure is most helpful in assessing the mucosa in gastritis or, together with biopsy and brushings for cytology, in differentiating between peptic and neoplastic ulcerating lesions. It may identify a specific bleeding site in clinical situations where several potential bleeding sites could exist, as in the patient with portal hypertension. In addition, it may be possible to cauterize or otherwise intervene to control hemorrhage via the endoscope (e.g., by injections of vasoconstricting agents such as epinephrine). *Helicobacter pylori* is a frequent cause of gastritis in patients with peptic ulceration and non-ulcer dyspepsia. Although *H. pylori* infection can be confirmed by endoscopy and biopsy, the diagnosis is more commonly made by breath and serologic tests (Chap. 285). Endoscopy is the diagnostic method of choice in the setting of upperGIbleeding (Chap. 44). Endoscopy can detect a number of potential sources of upper GI bleeding that are often missed by x-ray studies (e.g., erosive gastritis, Mallory-Weiss tear). Gastroscopy is particularly helpful in inspecting the postoperative stomach, especially in detecting stomal ulceration or so-called alkaline reflux gastritis. The first and second portions of the duodenum can also be routinely examined, and important information about ulcers and other lesions can be obtained. Radiologic studies may be useful when endoscopy is not readily available or in the assessment of suspected motility disorders (e.g., gastroparesis). In addition, radiologic examination may be preferred when there are contraindications to safe endoscopy.

3. *Gastric acid secretory studies.* Although not routinely necessary, these studies are useful in the diagnosis of the Zollinger-Ellison syndrome or atrophic gastritis and for determination of completeness of vagotomy. They should not be performed for the routine diagnosis of uncomplicated duodenal ulcer or to influence the choice of surgery for peptic ulcer.

Obstructive and Vascular Disorders of the Small Intestine (See alsoChaps. 289 and290) The plain x-ray film of the abdomen is the most important diagnostic adjunct to careful physical examination in patients with symptoms of obstruction. Patterns of dilation of individual loops of intestine may be characteristic, as in volvulus or acute pancreatitis; erect and decubitus views will often show fluid levels in the affected segments. Motility disorders of the small intestine (temporary ileus or chronic intestinal pseudoobstruction) may also present with obstructive symptoms and similar x-ray findings but must be managed medically without surgical intervention. Air under the diaphragm is diagnostic of a perforated viscus; air in the portal vein usually results from intestinal necrosis from mesenteric vascular occlusion. The diagnostic accuracy of the plain x-ray film in all types of intestinal obstruction is about 75%. In patients with symptoms of incomplete obstruction, the radiographic small-bowel series will often be diagnostic in defining the site and degree of obstruction. Infrequently, in this setting, all conventional x-ray studies are unremarkable. In such cases, the radiologist may perform a small-bowel enteroclysis study by passing a special tube into the proximal jejunum; the rapid instillation of barium through the tube will distend the intestine and often reveal subtle lesions missed by other tests.

Vascular diseases of the small intestine are among the most difficult diseases to diagnose. In chronic mesenteric ischemia, radiographic, endoscopic, and laboratory tests are usually normal. Early in the course of acute mesenteric ischemia, the plain film

of the abdomen may be unremarkable despite complaints of severe abdominal pain. In these settings, prompt mesenteric angiography is essential to confirm the diagnosis of vascular disease.

Inflammatory and Neoplastic Diseases of Small and Large Intestine Patients with these conditions are usually identified by history, physical examination, and careful examination of the stools for exudate and blood. Examination of fresh stool samples for common bacterial pathogens and parasites by laboratories skilled in these techniques is important in identifying or excluding infectious causes of diarrhea, particularly in the patient with colitis. Sigmoidoscopy is valuable in identifying mucosal and neoplastic lesions of the rectum and distal colon. The mucosal surface of the entire colon and terminal ileum can be examined directly and biopsied through the fiberoptic sigmoidoscope or colonoscope. The radiologic examination of the small intestine is highly reliable in identifying the prestenotic and stenotic lesions of Crohn's disease. In the colon, a single barium enema examination in a well-prepared patient has a diagnostic accuracy of 80 to 85%; the addition of air-contrast technique brings the accuracy up over 90%. Accuracy is greatly limited if the patient is poorly prepared for the examination. Colonoscopy may be preferable because of its greater accuracy and the fact that it enables the operator to remove any polyps that are encountered and to obtain preoperative tissue confirmation in the patient who probably has cancer.

Peroral biopsy of the small intestine (now most often accomplished during endoscopy) and forceps biopsy of the rectosigmoid are of considerable importance in revealing mucosal disease. Rectal biopsy is an excellent means of demonstrating amyloidosis, schistosomiasis, and amebiasis. Submucosal disease is not seen in these superficial biopsies. Hirschsprung's disease is diagnosed histologically by a deep surgical biopsy of the lower part of the rectum.

Malabsorption Syndromes Malabsorption may be suspected on the basis of history and physical examination and confirmed by examination of the stool. Radiologic examination is helpful to rule out local lesions and to suggest motor and secretory dysfunction, but it is rarely diagnostic unless an abnormal small-bowel mucosa or fistulas between the intestine and stomach are demonstrated.

Microscopic examination of a stool specimen stained with Sudan is a simple screening test for steatorrhea. Chemical analysis of 3-day stool collection for fat, with the patient on a standard diet, is used to establish the diagnosis of steatorrhea. The D-xylose absorption test is about 90% accurate in distinguishing mucosal disease from pancreatic insufficiency. Peroral biopsy of the small intestine via the endoscope or a specialized biopsy device is of value in the diagnosis of celiac disease, and it may show the less common infiltrations of the mucosa by amyloid or bacterial mucoproteins (Whipple's disease). Leakage of protein into the intestinal lumen may cause hypoproteinemia and can be demonstrated by the recovery in stools of the serum protein a_1-antitrypsin or intravenously administrated markers such as iodine- or chromium-labeled isotopes.***The tests useful in the diagnosis of malabsorption are discussed in Chap. 286.*

GIBleeding (See also Chap. 44) Acute bleeding in the GI tract is a common clinical problem. The history usually provides a reliable distinction between lower and upper tract sources. Once the patient with upper tract bleeding is hemodynamically stable, a

nasogastric tube is placed to confirm the site of blood loss and to empty the stomach. Endoscopy is then performed to define the cause and often to treat it. In patients with acute lower tract bleeding, sigmoidosopy may permit detection of distal sites of bleeding. Colonoscopy may also be of value, but visualization may be limited by active bleeding and poor bowel preparation. Barium studies should be avoided in the acute setting. They are usually nondiagnostic and the persistent contrast may interfere with interpretation of angiographic studies, which can often define a site of bleeding that is otherwise obscure. Radionuclide bleeding scan can locate the bleeding site. A Meckel's scan can be diagnostic when active bleeding arises distal to the duodenum in the absence of an identifiable source in the colon.

283. GASTROINTESTINAL ENDOSCOPY - *Mark Topazian*

Gastrointestinal endoscopy has been attempted for over 200 years, but the introduction of semi-rigid gastroscopes in the middle of the twentieth century marked the dawn of the modern endoscopic era. Since then, rapid advances in endoscopic technology have led to dramatic changes in the diagnosis and treatment of many digestive diseases. Innovative endoscopic devices and new endoscopic treatment modalities continue to expand the use of endoscopy in patient care.

Flexible endoscopes provide either an optical image (transmitted over fiberoptic bundles) or an electronic video image (generated by a charge-coupled device in the tip of the endoscope; see Color Atlas, Section III). Operator controls permit deflection of the endoscope tip; fiberoptic bundles bring light to the tip of the endoscope; and working channels allow washing, suctioning, and the passage of instruments. Progressive changes in the diameter and stiffness of endoscopes have improved the ease and patient tolerance of endoscopy.

ENDOSCOPIC PROCEDURES

Upper Endoscopy Upper endoscopy, also referred to as esophagogastroduodenoscopy (EGD), is performed by passing a flexible endoscope through the mouth into the esophagus, stomach, bulb, and second duodenum. The procedure is the best method of examining the upper gastrointestinal mucosa. While the upper gastrointestinal radiographic series has similar accuracy for diagnosis of duodenal ulcer, EGD is superior for detection of gastric ulcers and permits directed biopsy and endoscopic therapy, if needed. Topical pharyngeal anesthesia is used, and intravenous conscious sedation is given to most patients in the United States to ease the anxiety and discomfort of the procedure, although in many countries EGD is routinely performed without sedation. The recent development of ultrathin, 5-mm diameter endoscopes for transnasal, unsedated EGD may decrease the use of sedation for EGD in the United States, also decreasing the costs and risks of the procedure.

Colonoscopy Colonoscopy is performed by passing a flexible colonoscope through the anal canal into the rectum and colon. The cecum is reached in over 95% of cases, and the terminal ileum can often be examined. Colonoscopy is the "gold standard" for diagnosis of colonic mucosal disease. Barium enema is more accurate for evaluation of diverticula and for accurate measurement of colonic strictures, but colonoscopy has greater sensitivity for polyps and cancers. Colonoscopy is more uncomfortable thanEGD for most patients, and conscious sedation is usually given before colonoscopy in the United States, although a willing patient and a skilled examiner can complete the procedure without sedation in many cases.

Flexible Sigmoidoscopy Flexible sigmoidoscopy is similar to colonoscopy but visualizes only the rectum and a variable portion of the left colon, typically to 60 cm from the anal verge. This procedure causes abdominal cramping, but it is brief and is almost always performed without sedation. Flexible sigmoidoscopy is primarily used to screen asymptomatic, average-risk patients for colonic polyps and may also be used for evaluation of diarrhea and hematochezia.

Enteroscopy Enteroscopy is the relatively new field of small-bowel endoscopy. Two techniques are currently used. "Push" enteroscopy is performed with a long endoscope similar in design to an upper endoscope. The enteroscope is pushed down the small bowel with the help of a stiffening overtube that extends from the mouth to the duodenum. The mid-jejunum can often be reached; an instrument channel is present for biopsies or endoscopic therapy. "Sonde" enteroscopy uses a very thin, long, flexible endoscope with a weighted tip and no biopsy capability. The sonde enteroscope is passed through the nose, dragged to the duodenum by a standard endoscope, then slowly propelled forward by intestinal peristalsis for several hours. The cecum or distal ileum is reached in most cases. The small-bowel mucosa is examined during sonde enteroscope withdrawal, although parts of the mucosa may be missed when the endoscope is pulled back around turns. The major indication for these procedures is unexplained small-bowel bleeding.

Endoscopic Retrograde Cholangiopancreatography (ERCP) During ERCP, a side-viewing endoscope is passed through the mouth to the duodenum, the ampulla of Vater is identified and cannulated with a thin plastic catheter, and radiographic contrast material is injected into the bile duct and pancreatic duct under fluoroscopic guidance (Fig. 283-1). When indicated, the sphincter of Oddi can be opened using the technique of endoscopic sphincterotomy (Fig. 283-2). Stones can be retrieved from the ducts, and strictures of the ducts can be biopsied, dilated, and stented. ERCP is often performed for therapy but remains an important diagnostic tool, especially for bile duct stones.

Endoscopic Ultrasound (EUS) EUS utilizes high-frequency ultrasound transducers incorporated into the tip of a flexible endoscope. Ultrasound images are obtained of the gut wall and adjacent organs, vessels, and lymph nodes. By sacrificing depth of ultrasound penetration and bringing the ultrasound transducer close to the area of interest via endoscopy, very high resolution images are obtained. EUS provides the most accurate preoperative local staging of esophageal, pancreatic, and rectal malignancies, although it does not detect most distant metastases. Examples of EUS tumor staging are shown inFig. 283-3. EUS is also highly sensitive for diagnosis of bile duct stones, gallbladder disease, submucosal gastrointestinal lesions, and chronic pancreatitis. Fine-needle aspiration of masses and lymph nodes in the posterior mediastinum, abdomen, and pelvis can be performed under EUS guidance.

RISKS OF ENDOSCOPY

All endoscopic procedures carry some risk of bleeding and gastrointestinal perforation. These risks are quite low with diagnostic upper endoscopy and colonoscopy (<1:1000 procedures), although the risk is as high as 1:100 when therapeutic procedures such as polypectomy, control of hemorrhage, or stricture dilation are performed. Bleeding and perforation are rare with flexible sigmoidoscopy. The risks for diagnosticEUS are similar to the risks for diagnostic upper endoscopy.

Infectious complications are unusual with most endoscopic procedures. Stricture dilation, variceal sclerotherapy, andERCP for biliary obstruction all carry a higher incidence of postprocedure bacteremia, and prophylactic antibiotics may be indicated for these procedures in some patients (Table 283-1).

ERCPcarries additional risks. Pancreatitis occurs in about 5% of patients undergoing ERCP and is seen in up to 25% of patients with sphincter of Oddi dysfunction. Post-ERCP pancreatitis is usually mild and self-limited but may infrequently result in prolonged hospitalization, surgery, diabetes, or death. Bleeding occurs after 1% of endoscopic sphincterotomies. Ascending cholangitis, pseudocyst infection, and retroperitoneal perforation and abscess may all occur as a result of ERCP.

The conscious sedation administered during endoscopy may cause respiratory depression or allergic reactions. Percutaneous gastrostomy tube placement duringEGD is associated with a 10 to 15% incidence of complications, most often wound infections. Fasciitis, pneumonia, bleeding, and colonic injury may result from gastrostomy placement.

URGENT ENDOSCOPY

ACUTE GASTROINTESTINAL HEMORRHAGE

Endoscopy is an important diagnostic and therapeutic technique for patients with acute gastrointestinal hemorrhage. Although most gastrointestinal bleeding stops spontaneously, a minority of patients will have persistent or recurrent hemorrhage that may be life-threatening. Clinical predictors of rebleeding help identify patients most likely to benefit from urgent endoscopy and endoscopic, angiographic, or surgical hemostasis.

Initial Evaluation The initial evaluation of the bleeding patient focuses on the magnitude of hemorrhage as reflected by the postural vital signs, the frequency of hematemesis or melena, and (in some cases) findings on nasogastric lavage. The measured values of hematocrit and hemoglobin lag the clinical course and are not reliable gauges of the magnitude of acute bleeding. This initial evaluation, completed well before the bleeding source is confidently identified, guides immediate supportive care of the patient and helps determine the timing of endoscopy. The magnitude of the initial hemorrhage is probably the most important indication for urgent endoscopy, since a large initial bleed increases the likelihood of ongoing or recurrent bleeding. Patients with resting hypotension, repeated hematemesis, nasogastric aspirate that does not clear with repeated lavage, or those requiring blood transfusions should be considered for urgent endoscopy. In addition, patients with cirrhosis, coagulopathy, or respiratory or renal failure and those over 70 years of age are more likely to have significant rebleeding.

Bedside evaluation also suggests an upper or lower gastrointestinal source of bleeding in most patients. About 90% of patients with melena are bleeding proximal to the ligament of Treitz, and about 90% of patients with hematochezia are bleeding from the colon. It is important to note, however, that melena can result from bleeding in the small bowel or right colon, especially in older patients with slow colonic transit, so colonoscopy should be performed in patients with melena when upper endoscopy is unrevealing. Similarly, a minority of patients with massive hematochezia are bleeding from a duodenal ulcer, with rapid intestinal transit. Hence early upper endoscopy should be considered in patients with massive hematochezia.

Endoscopy should be performed after the patient has been resuscitated with

intravenous fluids and transfusions as necessary. Marked coagulopathy or thrombocytopenia is usually treated before endoscopy, since correction of these abnormalities may lead to resolution of bleeding, and techniques for endoscopic hemostasis are limited in such patients. Metabolic derangements should also be addressed. Tracheal intubation for airway protection should be considered before upper endoscopy in patients with repeated hematemesis and suspected variceal hemorrhage.

Most patients with impressive hematochezia can undergo colonoscopy after a rapid colonic purge with a polyethylene glycol solution; the preparation fluid is often administered via a nasogastric tube. In a minority of cases, persistent bleeding and recurrent hemodynamic instability prevent endoscopic visualization of the colonic mucosa, and other techniques (such as bleeding scans, angiography, or emergency subtotal colectomy) must be employed. Even in these cases, however, the anal and rectal mucosa should be visualized endoscopically early in the course, since bleeding lesions in or close to the anal canal are generally amenable to surgical transanal hemostatic techniques; and upper endoscopy should be performed to exclude duodenal ulcer.

Peptic Ulcer The endoscopic appearance of peptic ulcers provides useful prognostic information in patients with acute hemorrhage. When a platelet plug is seen protruding from a vessel wall in the base of an ulcer (a so-called sentinel clot or visible vessel), there is a 40% chance of major rebleeding from the ulcer. This finding often leads to local endoscopic therapy to decrease the rebleeding rate. A clean-based ulcer, on the other hand, is associated with low (3 to 5%) risk of rebleeding; patients with melena and a clean-based duodenal ulcer are often discharged to home from the emergency department or endoscopy suite if they are young, reliable, and otherwise healthy. Other findings have an intermediate risk of rebleeding: flat red or purple spots in the ulcer base have a 10% risk, and large adherent clots covering the ulcer base have a 20% risk. Occasionally, active spurting from an ulcer is seen (with>90% risk of ongoing bleeding). Examples of endoscopic stigmata of recent hemorrhage are shown inFig. 283-4.

Patients with a visible vessel or active bleeding are usually treated endoscopically, decreasing rebleeding rates by about half. Hemostatic techniques include "coaptive coagulation" of the vessel in the base of the ulcer, using a thermal probe that is pressed against the site of bleeding, or injection of epinephrine or sclerosant into and around the vessel.

Varices Two complementary strategies guide therapy of bleeding varices: local treatment of the bleeding vessel and treatment of underlying portal hypertension. Local therapies (including endoscopic sclerotherapy, endoscopic band ligation, and balloon tamponade with a Sengstaken-Blakemore tube) effectively control acute hemorrhage in most patients and are the mainstay of acute treatment, although therapies that decrease portal pressures (pharmacologic treatment, surgical shunts, or radiologically placed intrahepatic shunts) also play an important role.

Endoscopic band ligation is the preferred local therapy for bleeding esophageal varices. In this technique a varix is suctioned into a cap fitted on the end of the endoscope, and a rubber band is then released from the cap, ligating the varix. Acute hemorrhage can

be controlled in up to 90% of patients, and complications (such as sepsis, symptomatic esophageal ulceration, or esophageal stenosis) are uncommon. Endoscopic sclerotherapy is an older technique in which a sclerosing, thrombogenic solution is injected into or next to esophageal varices. Sclerotherapy also controls acute hemorrhage in most patients but has higher complication rates. These techniques are used when varices are actively bleeding during endoscopy or (more commonly) when varices are the only identifiable cause of acute hemorrhage.

After treatment of the acute hemorrhage, an elective course of endoscopic therapy can be undertaken with the goal of eradicating esophageal varices and preventing rebleeding months to years later. This chronic therapy is less successful, preventing long term rebleeding in about 50% of patients. Pharmacologic therapies that decrease portal pressure have similar efficacy, and the two modalities may be combined.

Gastric varices are less amenable to endoscopic therapy and are usually treated with a portal decompressive procedure (surgical portosystemic shunt or radiologic transjugular portosystemic shunt). Endoscopic therapy of gastric varices is usually reserved for actively bleeding varices or for patients with thrombosis of the portal venous system.

Dieulafoy's Lesion This lesion, also called *persistent caliber artery*, is a large-caliber arteriole that runs immediately beneath the gastrointestinal mucosa and bleeds through a pinpoint mucosal erosion. Dieulafoy's lesion is seen most commonly on the lesser curvature of the proximal stomach, causes impressive arterial hemorrhage, and is difficult to diagnose; it is often recognized only after repeated endoscopy for recurrent bleeding. Endoscopic therapy with a thermal probe usually controls acute bleeding and successfully ablates the underlying vessel once the bleeding site has been identified. Embolization or surgical oversewing are sometimes required.

Mallory-Weiss Tear A Mallory-Weiss tear is a linear mucosal rent near or across the gastroesophageal junction that is often associated with retching or vomiting. When the tear disrupts a submucosal arteriole, brisk hemorrhage may result. Endoscopy is the best method of diagnosis, and an actively bleeding tear can be treated endoscopically with coaptive coagulation using a thermal probe or by injection of dilute epinephrine. Since Mallory-Weiss tears only rarely rebleed, a sentinel clot in the base of the tear is usually not treated endoscopically.

Vascular Ectasias Vascular ectasias are flat mucosal vascular anomalies best diagnosed by endoscopy. They usually cause slow intestinal blood loss and have several characteristic distributions in the gastrointestinal tract. When limited to the cecum, where they occur as senile lesions, or the gastric antrum (gastric antral vascular ectasias, or "watermelon stomach"), ectasias are often responsive to local endoscopic ablative therapy. Patients with diffuse small-bowel vascular ectasias (associated with chronic renal failure and with hereditary hemorrhagic telangiectasia) often continue to bleed despite endoscopic treatment of accessible lesions and require systemic therapy.

Colonic Diverticula Diverticula form where nutrient arteries penetrate the muscular wall of the colon en route to the colonic mucosa. The artery found in the base of a diverticulum may bleed, causing painless and impressive hematochezia. Colonoscopy is indicated in patients with hematochezia and suspected diverticular hemorrhage, since

other causes of bleeding (such as vascular ectasias, colitis, and colonic malignancy) must be excluded. In addition, an actively bleeding diverticulum is occasionally seen and treated during colonoscopy.

GASTROINTESTINAL OBSTRUCTION AND PSEUDOOBSTRUCTION

Endoscopy is useful for evaluation and treatment of some forms of gastrointestinal obstruction. An important exception is small-bowel obstruction, which is generally not diagnosed by endoscopy or amenable to endoscopic therapy. Esophageal, gastroduodenal, and colonic obstruction or pseudoobstruction can all be diagnosed endoscopically and are often managed endoscopically as well.

Acute Esophageal Obstruction Esophageal obstruction by impacted food or an ingested foreign body is a potentially life-threatening event. Left untreated, the patient may develop esophageal ulceration, ischemia, and perforation. Patients with persistent esophageal obstruction often have hypersalivation and are usually unable to swallow water; endoscopy is generally the best initial test in such patients, since endoscopic removal of the obstructing material is usually possible, and the presence of an underlying esophageal stricture can often be determined. Radiographs of the chest and neck should be considered before endoscopy in patients with fever, obstruction for $^{3}24$ h, or ingestion of a sharp object such as a fishbone. Radiographic contrast studies interfere with subsequent endoscopy and are not advisable in patients with a clinical picture of persistent obstruction, unless an esophageal perforation is suspected. Occasionally, sublingual nifedipine or nitrates, or intravenous glucagon, may resolve an esophageal food impaction, but in most patients there is an underlying web, ring, or stricture and endoscopic removal of the obstructing food bolus is necessary.

Gastric Outlet Obstruction Obstruction of the gastric outlet is commonly caused by malignancy of the prepyloric gastric antrum or chronic peptic ulceration with stenosis of the pylorus. Patients vomit partially digested food many hours after eating. Gastric decompression with a nasogastric tube and subsequent lavage for removal of retained material is the first step in treatment. The diagnosis can then be confirmed with a saline load test, if desired. Endoscopy is useful for diagnosis and treatment. Patients with pyloric stenosis may be treated with endoscopic balloon dilation of the pylorus, and a course of endoscopic dilation results in long-term relief of symptoms in about 50% of patients. Malignant pyloric obstruction can be treated with endoscopically placed expandable stents if the patient is deemed a poor surgical candidate.

Colonic Obstruction and Pseudoobstruction These both present with abdominal distention and discomfort; tympany; and a dilated, air-filled colon on plain abdominal radiography. Both conditions may lead to colonic perforation if untreated. Acute colonic pseudoobstruction is a form of colonic ileus that is usually attributable to electrolyte disorders, narcotic and anticholinergic medications, immobility (as after surgery), and retroperitoneal hemorrhage or mass. Multiple causative factors are often present. Either colonoscopy or a water-soluble contrast enema may be used to look for an obstructing lesion and differentiate obstruction from pseudoobstruction. One of these diagnostic studies should be strongly considered if the patient does not have clear risk factors for pseudoobstruction, if radiographs do not show air in the rectum and sigmoid, or if the patient fails to improve when the underlying causes of pseudoobstruction have been

addressed. The risk of cecal perforation in pseudoobstruction rises when the cecal diameter exceeds 12 cm, and in such patients decompression of the colon may be achieved using intravenous neostigmine, colonoscopic decompression, or placement of a cecostomy tube. Most patients should receive a trial of conservative therapy (with correction of electrolyte disorders, removal of offending medications, and increased mobilization) before undergoing an invasive decompressive procedure.

Colonic obstruction is an indication for urgent surgery. In poor operative candidates or those with symptomatic partial obstruction from malignancy, a colonoscopically placed expandable stent can relieve obstruction and permit preparation of the bowel for elective surgery.

ACUTE BILIARY OBSTRUCTION

The steady, severe pain that occurs when a gallstone acutely obstructs the common bile duct often brings patients to a hospital. The diagnosis of a ductal stone is suspected when the patient is jaundiced or when serum liver tests or pancreatic enzyme levels are elevated, and it is confirmed by direct cholangiography (performed endoscopically, percutaneously, or during surgery).ERCP is currently the primary means of diagnosing and treating common bile duct stones in most hospitals in the United States.

Bile Duct Imaging While traditional noninvasive imaging tests such as ultrasound and biliary scintigraphy are not sufficiently accurate for reliable diagnosis of bile duct stones, newer imaging modalities such as spiral computed tomography (CT), magnetic resonance cholangiopancreatography (MRCP), andEUS are more accurate and have an emerging role in diagnosis. Examples of these modalities are shown in Fig. 283-5. During MRCP, images are obtained that demonstrate stagnant or slowly flowing fluid and subtract all other tissue. The resulting images of the right upper quadrant are strikingly similar to a direct cholangiogram, although with less resolution. MRCP can be performed rapidly without sedation and does not require any radiographic contrast. When an echo-endoscope is passed into the duodenum, detailed EUS views of the adjacent bile duct are readily obtained. While this procedure requires intravenous sedation, it has a very low incidence of complications, in contradistinction toERCP. Spiral CT has a sensitivity of 85% for diagnosis of bile duct stones, MRCP has a sensitivity of 85 to 95%, and EUS has a sensitivity of 88 to 98%. EUS is more accurate than ERCP in some hands.

The clinical role of these new imaging techniques is evolving. When a bile duct stone is highly likely and urgent treatment is required (as in a patient with jaundice and biliary sepsis),ERCP is the procedure of choice, since it remains the gold standard for diagnosis and provides immediate treatment. When a persistent bile duct stone is relatively unlikely (as in a patient with gallstone pancreatitis), less-invasive imaging techniques may supplant ERCP or intraoperative cholangiography.

Ascending Cholangitis Charcot's triad of jaundice, abdominal pain, and fever is present in about 70% of patients with ascending cholangitis and biliary sepsis. Initially, such patients are managed with fluid resuscitation and intravenous antibiotics. Abdominal ultrasound is often done early in the course, to look for gallbladder stones and bile duct dilation. The bile duct may not be dilated early in the course of acute biliary

obstruction, however. Medical management usually improves the patient's clinical status, providing a window of approximately 24 h during which biliary drainage should be established, typically byERCP. Undue delay can result in recrudesence of overt sepsis and increased morbidity. If, in addition to Charcot's triad, shock and confusion are present (Reynolds's pentad), urgent attempts to restore biliary drainage are usually indicated.

Gallstone Pancreatitis Gallstones may cause acute pancreatitis as they pass through the ampulla of Vater, where they obstruct the pancreatic duct (and sometimes cause reflux of bile into the pancreas). The occurrence of gallstone pancreatitis usually implies passage of a stone into the duodenum, and only about 20% of patients harbor a persistent stone in the ampulla or the common bile duct. Retained stones are more common in the subset of patients with jaundice, severe pancreatitis, or superimposed ascending cholangitis.

UrgentERCPdecreases the morbidity of gallstone pancreatitis in some subsets of patients, but it remains unclear whether the benefit of ERCP is mainly attributable to treatment and prevention of ascending cholangitis or to relief of pancreatic duct obstruction. ERCP is warranted early in the course of gallstone pancreatitis if ascending cholangitis is also suspected, especially in a jaundiced patient. Urgent ERCP may also be indicated in the minority of patients predicted to have severe pancreatitis using a multifactorial index of severity such as the Glasgow, Ranson's, or Apache II score.

ELECTIVE ENDOSCOPY

Dyspepsia and Reflux Dyspepsia is a burning discomfort in the upper abdomen that may be caused by diverse processes such as gastroesophageal reflux, peptic ulcer disease, and "nonulcer dyspepsia," a heterogeneous category that includes disorders of motility, sensation, and somatization. Gastric and esophageal malignancies are less common causes of dyspepsia. Careful history taking allows accurate differential diagnosis of dyspepsia in only about half of patients. In the remainder, endoscopy can be a useful diagnostic tool, especially in those patients whose symptoms are not resolved by an empirical trial of symptomatic treatment.

Gastroesophageal Reflux Disease (GERD) When classic symptoms of gastroesophageal reflux are present, such as water brash and substernal heartburn, presumptive diagnosis and empirical treatment are often sufficient. Although endoscopy is sensitive for diagnosis of esophagitis, it misses some cases of reflux, since some patients have symptomatic reflux without esophagitis. The most sensitive test for diagnosis of GERD is 24-h ambulatory pH monitoring. Endoscopy is nevertheless indicated in patients with resistant reflux symptoms and in those with recurrent dyspepsia after treatment that is not clearly due to reflux on clinical grounds alone, to assess the esophagus and exclude other diseases. Endoscopy is also advised in a patient with reflux and dysphagia, to look for a stricture or malignancy. Endoscopy is probably also indicated in patients with long-standing (³10 years) frequent heartburn, who are at sixfold increased risk of Barrett's esophagus compared to a patient with<1 year of reflux symptoms. Patients with Barrett's esophagus usually enter a program of periodic endoscopy with biopsies, to detect dysplasia or early carcinoma.

Peptic Ulcer Peptic ulcer classically causes epigastric gnawing or burning, often occurring nocturnally and promptly relieved by food or antacids. Although endoscopy is the most sensitive diagnostic test for peptic ulcer, immediate endoscopy is not a cost-effective strategy in young patients with ulcer-like dyspeptic symptoms unless endoscopy is available at low cost. Patients with suspected peptic ulcer should be evaluated for *Helicobacter pylori* infection. Serology (which documents past or present infection) and urea breath testing (which demonstrates current infection) are less invasive and costly than endoscopy with biopsy. Patients with ulcer-like symptoms despite treatment should undergo endoscopy to exclude gastric malignancy, and patients with "alarm symptoms" (early satiety or anorexia, early recurrence of symptoms, anemia) should also undergo endoscopy.

Nonulcer Dyspepsia This may be associated with bloating and, unlike peptic ulcer, tends not to remit and recur. Most patients do not respond to acid-reducing, prokinetic, or anti-*Helicobacter* therapy and are referred for endoscopy to exclude a refractory ulcer. While endoscopy usefully excludes other diagnoses, it generally does little to improve the treatment of patients with nonulcer dyspepsia.

Dysphagia About 50% of patients with difficulty swallowing have a mechanical obstruction; the remainder have a motor disorder. Careful history taking often suggests a diagnosis and leads to the appropriate use of diagnostic tests. Esophageal strictures typically cause progressive dysphagia, first for solids, then liquids; esophageal motor disorders often cause intermittent dysphagia for both solids and liquids. Some underlying disorders have characteristic historical features: Schatzki's ring causes episodic dysphagia for solids, typically at the beginning of a meal; pharyngeal motor disorders are associated with difficulty initiating deglutition ("transfer dysphagia") and nasal reflux with swallowing; and achalasia may cause nocturnal regurgitation of undigested food particles.

When mechanical obstruction is suspected, endoscopy is a useful initial diagnostic test, since it permits immediate biopsy and dilation of strictures, masses, or rings. Blind or forceful passage of an endoscope may lead to perforation in a patient with stenosis of the cervical esophagus or a Zencker's diverticulum, but gentle passage of an endoscope under direct visual guidance is reasonably safe even in these patients. Endoscopy can miss a subtle stricture or ring in some patients.

When a motor disorder is suspected, esophageal radiography is the best initial diagnostic test. The pharyngeal swallowing mechanism, esophageal peristalsis, and the lower esophageal sphincter can all be assessed. In some disorders, subsequent esophageal manometry may also be important for diagnosis.

Anemia and Occult Blood in the Stool Iron-deficiency anemia may be attributed to poor iron absorption (as in celiac sprue) or, more commonly, chronic blood loss. Intestinal bleeding should be strongly suspected in men and postmenopausal women with iron-deficiency anemia, and colonoscopy is indicated in such patients, even in the absence of detectable occult blood in the stool. About 30% will have large colonic polyps, 10% will have colorectal cancer, and additional patients will have colonic vascular lesions. When a convincing source of blood loss is not found in the colon, upper gastrointestinal endoscopy should also be performed; if no lesion is found,

duodenal biopsies should be obtained to exclude sprue. Evaluation of the small bowel may be appropriate if bothEGD and colonoscopy are unrevealing.

Tests for occult blood in the stool detect hemoglobin or the heme moiety and are most sensitive for colonic blood loss, although they will also detect larger amounts of upper gastrointestinal bleeding. Patients with occult blood in normal-appearing stool should undergo colonoscopy to diagnose or exclude colorectal neoplasia. The diagnostic yield is lower than in iron-deficiency anemia. Whether upper endoscopy is also indicated largely depends on the patient's symptoms.

The small intestine may be the source of chronic intestinal bleeding, especially if colonoscopy and upper endoscopy are not diagnostic. The utility of small-bowel evaluation varies with the clinical setting and is most important in patients whose bleeding causes chronic or recurrent anemia. While small-bowel radiography is usually normal, partial or total small-bowel enteroscopy yields a specific diagnosis in about 50% of such patients. The commonest finding is mucosal vascular ectasias or telangiectasias.

Colorectal Cancer Screening Most colon cancers develop from preexisting colonic adenomas, and colorectal cancer can be largely prevented by the detection and removal of colonic adenomatous polyps. Screening for polyps and early, asymptomatic cancers can be accomplished both by testing stool specimens for occult blood and by directly examining the colonic mucosa. Since tests for occult blood are insensitive, detecting only about one-fourth of colon cancers and large polyps, visualization of at least a part of the colon is an important component of colorectal cancer screening.

The choice of screening strategy for an asymptomatic patient depends in part on their personal and family history. A past history of inflammatory bowel disease or colorectal polyps, a family history of two or more first-degree family members with adenomatous polyps or cancer, certain familial cancer syndromes, or the finding of occult blood in the stool all place an individual at increased risk and alter screening recommendations. An individual without these factors is generally considered at average risk, and screening flexible sigmoidoscopy every 5 years beginning at age 50 is recommended. Screening strategies for higher risk patients are in Table 283-2. Screening strategies for the patient with one family member with colorectal cancer are debated. When the index case occurred at a young age (<60 years), screening colonoscopy should be offered when the patient is 10 years younger than the affected relative was when diagnosed.

Flexible sigmoidoscopy is an effective screening tool for two reasons: (1) the majority of colorectal cancers have traditionally occurred in the rectum and left colon, and (2) many right-sided colon cancers are associated with synchronous left-sided adenomas. The detection of an adenoma during sigmoidoscopy generally leads to full colonoscopy and detection of right-sided cancers, if present. Over the past several decades, however, there has been a gradual change in the distribution of colon cancers, with proportionally fewer rectal and left-sided cancers than in the past. This has spurred interest in evaluating the entire colon during a single screening examination. Barium enema has been advocated but requires flexible sigmoidoscopy also, to exclude missed rectal lesions. Large studies of colonoscopy for screening of average-risk individuals are currently underway. In addition, the new imaging technique of "virtual colonoscopy"

holds considerable promise. This modality uses data from helicalCT to generate a graphical display of a "flight" down the colonic lumen. While this technique is not yet sufficiently sensitive for routine clinical use, further refinement may result in a useful noninvasive screening method.

Diarrhea Most cases of diarrhea are acute, self-limited, and due to infections or medication. Chronic diarrhea (lasting >6 weeks) is more often due to a primary inflammatory or malabsorptive disorder, is less likely to resolve spontaneously, and generally requires diagnostic evaluation. Patients with chronic diarrhea or severe, unexplained acute diarrhea often undergo endoscopy if stool tests for pathogens are unrevealing. The choice of endoscopic test depends on the clinical setting.

Patients with colonic symptoms and findings such as bloody diarrhea, tenesmus, fever, or leukocytes in stool generally undergo sigmoidoscopy or colonoscopy to look for colitis. Sigmoidoscopy is often adequate and is the best initial test in most such patients. On the other hand, patients with symptoms and findings suggesting small-bowel disease such as large-volume watery stools; substantial weight loss; and malabsorption of iron, calcium, or fat may undergo upper endoscopy with duodenal biopsies.

Many patients with chronic diarrhea do not fit either of these patterns. When there is a long-standing history of alternating constipation and diarrhea dating to early adulthood, without findings such as blood in the stool or anemia, a diagnosis of irritable bowel syndrome may be made without direct visualization of the bowel. Steatorrhea and upper abdominal pain may prompt evaluation of the pancreas rather than the gut. Patients whose chronic diarrhea is not easily categorized often undergo initial colonoscopy to examine the entire colon (and terminal ileum) for inflammatory or neoplastic disease.

Minor Hematochezia Bright red blood passed with or on formed brown stool usually has a rectal, anal, or distal sigmoid source. Patients with even trivial amounts of hematochezia should be investigated with flexible sigmoidoscopy to exclude large polyps or cancers in the distal bowel. Patients who report red blood on the toilet tissue only, without blood in the toilet or on the stool, are bleeding from a lesion in the anal canal, and careful external and digital examinations and anoscopy are sufficient for diagnosis in most cases.

Unexplained Pancreatitis About 20% of patients with pancreatitis have no identified cause after routine clinical investigation (including a review of medication and alcohol use, measurement of serum triglyceride and calcium levels, abdominal ultrasonography, and CT). Endoscopic techniques lead to a specific diagnosis in the majority of such patients, often altering clinical management. Endoscopic investigation is particularly appropriate if the patient has had more than one episode of pancreatitis.

Microlithiasis, or the presence of microscopic crystals in bile, is a leading cause of previously unexplained acute pancreatitis and is sometimes seen during abdominal ultrasonography as layering sludge or flecks of floating, echogenic material in the gallbladder. Gallbladder bile can be obtained for microscopic analysis by administering a cholecystokinin analogue during endoscopy, causing contraction of the gallbladder. Bile is suctioned from the duodenum as it drains from the papilla, and the darkest fraction is examined for cholesterol crystals or bilirubinate granules. Alternatively, bile

can be aspirated from the bile duct duringERCP or the gallbladder can be examined for sludge or crystals byEUSbefore administering cholecystokinin. The latter strategy is probably the most sensitive means of diagnosing microlithiasis.

Previously undetected chronic pancreatitis, pancreatic malignancy, or pancreas divisum may be diagnosed by eitherERCP orEUS. Although ERCP remains the gold standard imaging test for chronic pancreatitis, EUS has good sensitivity and less risk than ERCP. Sphincter of Oddi dysfunction probably causes some cases of pancreatitis and can be diagnosed by manometric studies performed during ERCP.

OPEN-ACCESS ENDOSCOPY

While gastroenterologists have traditionally seen patients in consultation before arranging an endoscopic procedure, direct scheduling of endoscopic procedures by primary care physicians, or *open-access endoscopy*, is an increasingly common practice. When the indications for endoscopy are clear cut and appropriate, the procedural risks are low, and the patient understands what to expect, open-access endoscopy streamlines patient care and decreases costs.

Patients referred for open-access endoscopy should have a recent history, physical examination, and medication review. A copy of such an evaluation should be available when the patient comes to the endoscopy suite. Patients with unstable cardiovascular or respiratory conditions should not be referred directly for open-access endoscopy. Patients with selected cardiac conditions undergoing certain procedures should be prescribed prophylactic antibiotics prior to endoscopy, as described inTable 283-1. In addition, patients taking anticoagulants may need changes in treatment before endoscopy, as detailed inTable 283-3. While many endoscopists recommend discontinuing aspirin for 5 days before elective endoscopic procedures, most evidence suggests that in the absence of a preexisting bleeding disorder it is safe to perform endoscopic procedures in patients taking aspirin and nonsteroidal anti-inflammatory drugs.

Common indications for open-accessEGDinclude dyspepsia resistant to a trial of appropriate therapy; dysphagia or odynophagia; gastrointestinal bleeding; and persistent vomiting, anorexia, or early satiety. Open-access colonoscopy is often requested in men or postmenopausal women with iron-deficiency anemia, patients with occult blood in the stool, patients with a previous history of colorectal adenomatous polyps or cancer, and for screening in patients with above-average risk for colon cancer, as described in Table 283-2. Flexible sigmoidoscopy is commonly performed as an open-access procedure for cancer screening in asymptomatic persons over 50 and for patients with hematochezia.

When patients are referred for open-access colonoscopy, the primary care provider may need to choose a colonic preparation. Commonly used oral preparations include polyethelene glycol lavage solution and sodium phosphate. Sodium phosphate may cause fluid and electrolyte abnormalities, especially in patients with renal failure, congestive heart failure, and patients over 70 years of age.

284. DISEASES OF THE ESOPHAGUS - *Raj K. Goyal*

The two major functions of the esophagus are the transport of the food bolus from the mouth to the stomach and the prevention of retrograde flow of gastrointestinal contents. The transport function is achieved by peristaltic contractions in the pharynx and esophagus associated with relaxation of upper and lower esophageal sphincters (Chap. 40). Retrograde flow is prevented by the two esophageal sphincters, which remain closed between swallows. The upper esophageal sphincter (UES) consists of the cricopharyngeus and inferior pharyngeal constrictor muscles, striated muscles innervated by excitatory somatic lower motor neurons. These muscles exhibit no myogenic tone and receive no inhibitory innervation. The UES remains closed owing to the elastic properties of its wall and to neurogenic tonic contraction of the sphincter muscles. It is opened by central inhibition of the sphincter muscles in concert with forward displacement of the larynx by the suprahyoid muscles. In contrast, the lower esophageal sphincter (LES) is composed of smooth muscle and is innervated by parallel sets of parasympathetic excitatory and inhibitory pathways. It remains closed because of its intrinsic myogenic tone, which is modulated by the excitatory and inhibitory nerves. It opens in response to the activity of the inhibitory nerves. The neurotransmitters of the excitatory nerves are acetylcholine and substance P, and those of the inhibitory nerves are vasoactive intestinal peptide (VIP) and nitric oxide. The function of the LES is supplemented by the striated muscle of the diaphragmatic crura, which surrounds the LES and acts as an external LES. Relaxation of the LES without esophageal contraction occurs during belching and gastric distention. Gastric distention-evoked transient lower esophageal sphincter relaxation (tLESR) is a vasovagal reflex. Fatty meals, smoking, and beverages with a high xanthine content (tea, coffee, cola) also cause a reduction in sphincter pressure. Many hormones and neurotransmitters can modify LES pressure. Muscarinic M_2 and M_3receptor agonists, a-adrenergic agonists, gastrin, substance P, and prostaglandin F_{2a}cause contraction. Nicotine, b-adrenergic agonists, dopamine, cholecystokinin, secretin, VIP, calcitonin gene-related peptide (CGRP), adenosine, prostaglandin E, and nitric oxide donors such as nitrates reduce sphincter pressure.

SYMPTOMS

DYSPHAGIA See Chap. 40.

ESOPHAGEAL PAIN

Heartburn, or pyrosis, is characterized by burning retrosternal discomfort that may move up and down the chest like a wave. When severe, it may radiate to the sides of the chest, the neck, and the angles of the jaw. Heartburn is a characteristic symptom of reflux esophagitis and may be associated with regurgitation or a feeling of warm fluid climbing up the throat. It is aggravated by bending forward, straining, or lying recumbent and is worse after meals. It is relieved by an upright posture, by the swallowing of saliva or water, and, more reliably, by antacids. Heartburn is produced by heightened mucosal sensitivity and can be reproduced by infusion of dilute (0.1 *N*) hydrochloric acid (Bernstein test) or neutral hyperosmolar solutions into the esophagus.

Odynophagia, or painful swallowing, is characteristic of nonreflux esophagitis,

particularly monilial and herpes esophagitis. Odynophagia may occur with peptic ulcer of the esophagus (Barrett's ulcer), carcinoma with periesophageal involvement, caustic damage of the esophagus, and esophageal perforation. Odynophagia is unusual in uncomplicated reflux esophagitis. Crampy chest pain associated with impaction of a food bolus should be distinguished from odynophagia.

Atypical chest pain other than heartburn and odynophagia occurs in reflux esophagitis or esophageal motility disorders such as diffuse esophageal spasm. Spasm may occur spontaneously or during a meal. Chest pain due to periesophageal involvement with carcinoma or peptic ulcer may be constant and agonizing. Sometimes different types of esophageal pains exist together in the same patient, and frequently patients are not able to describe the pain accurately enough to allow its classification. Coronary artery disease should always be excluded before the esophagus is considered as the cause of atypical chest pain. The most frequent esophageal cause of chest pain is reflux esophagitis. Some patients with atypical chest pain have nonspecific esophageal motor abnormalities of uncertain significance. Many of these patients have behavioral abnormalities, psychosomatic disorders, depression, anxiety, panic reactions, and other psychological disorders.

REGURGITATION

Regurgitation is the effortless appearance of gastric or esophageal contents in the mouth. In distal esophageal obstruction and stasis, as in achalasia or the presence of a large diverticulum, the regurgitated material consists of tasteless mucoid fluid or undigested food. Regurgitation of sour or bitter-tasting material occurs in severe gastroesophageal reflux and is associated with incompetence of both theUES and the LES. Regurgitation may result in laryngeal aspiration, with spells of coughing and choking that awaken the patient from sleep, and in aspiration pneumonia. Water brash is reflex salivary hypersecretion that occurs in response to peptic esophagitis and should not be confused with regurgitation.

DIAGNOSTIC TESTS

RADIOLOGIC STUDIES

Barium swallow with fluoroscopy and an esophagogram is a widely used test for the diagnosis of esophageal disease and can be used to evaluate both structural and motor disorders. Spontaneous reflux of barium from the stomach into the esophagus suggests gastroesophageal reflux. Esophageal peristalsis is best studied in the recumbent position, because in the upright position barium passage occurs largely by gravity alone. A double-contrast esophagogram, obtained by coating the esophageal mucosa with barium and distending the esophageal lumen with air using effervescent granules, is particularly useful in demonstrating mucosal ulcers and early cancers. A barium-soaked piece of bread or a 13-mm barium tablet is sometimes used to demonstrate an obstructive lesion.Figures 284-1 and284-2illustrate the radiographic appearance of some esophageal disorders. Since the oropharyngeal phase of swallowing lasts no more than a second, videofluoroscopy is necessary to permit detection and analysis of abnormalities of oral and pharyngeal function. The pharynx is examined to detect stasis of barium in the valleculae and piriform sinuses and regurgitation of barium into the

nose and tracheobronchial tree.

ESOPHAGOSCOPY

Esophagoscopy is the direct method of establishing the cause of mechanical dysphagia and of identifying mucosal lesions that may not be identified by the usual barium swallow. If the lumen is markedly narrowed, use of a smaller-caliber endoscope may be needed; on occasion a stricture must be dilated before the examination can be completed. Endoscopic biopsies are useful in diagnosing carcinoma, reflux esophagitis, and other mucosal diseases. Cells obtained by a cytology balloon or brushing the mucosa can be evaluated for carcinoma. Endoscopic ultrasonography permits evaluation of intramural masses and staging of esophageal cancer.

ESOPHAGEAL MOTILITY

The study of esophageal motility entails simultaneous recording of pressures from different sites in the esophageal lumen with an assembly of pressure sensors positioned 5 cm apart. TheUES andLESappear as zones of high pressure that relax on swallowing. The pharynx and esophagus normally show peristaltic waves with each swallow.

Esophageal motility studies are helpful in the diagnosis of esophageal motor disorders (achalasia, spasm, scleroderma) (Fig. 284-3) but are of little value in the diagnosis of mechanical dysphagia. In patients with reflux esophagitis, esophageal manometry is useful in quantitating lower esophageal competence and providing information on the status of the esophageal body motor activity. Manometry provides quantitative data that cannot be obtained by barium swallow or endoscopy. Tests for reflux esophagitis are described later.

MOTOR DISORDERS

STRIATED MUSCLE

Oropharyngeal Paralysis Paralysis of oral muscle leads to difficulty initiating swallowing and drooling of food out of the mouth. Pharyngeal paralysis, characterized by dysphagia, nasal regurgitation, and aspiration during swallowing, occurs in a variety of neuromuscular disorders (see Table 40-1). Some of these disorders also involve laryngeal muscles, causing hoarseness. When the suprahyoid muscles are paralyzed, theUES does not open with swallowing, leading to paralytic achalasia of the UES and severe dysphagia.

Videofluoroscopy with barium of various consistencies may reveal difficulties in the oral phase of swallowing. The test may show barium in the valleculae and piriform sinuses, nasal and tracheal aspiration, failure of the upper sphincter to open, and/or abnormal movement of the hyoid bone and the larynx with a swallow (Fig. 284-1). Motility studies demonstrate a reduced amplitude of pharyngeal and upper esophageal contractions and reduced basal upper esophageal sphincter pressure without further relaxation on swallowing (Fig. 284-3). Patients with myasthenia gravis (Chap. 380) and polymyositis (Chap. 382) respond to treatment. Dysphagia resulting from a cerebrovascular accident improves with time, although often not completely. Treatment consists of maneuvers to

reduce pharyngeal stasis and enhance airway protection under the direction of a trained swallow therapist. Feeding by a nasogastric tube or an endoscopically placed gastrostomy tube may be necessary for nutritional support; however, these maneuvers do not provide protection against aspiration of salivary secretions. Cricopharyngeal myotomy is sometimes performed, but its usefulness is unproven. Extensive operative procedures to prevent aspiration are rarely needed. Death is often due to pulmonary complications.

Cricopharyngeal Bar Failure of the cricopharyngeus to relax on swallowing appears as a prominent bar on the posterior wall of the pharynx on barium swallow (Fig. 284-1). A transient cricopharyngeal bar is seen in up to 5% of individuals without dysphagia undergoing upper gastrointestinal studies; it can be produced in normal individuals during a Valsalva maneuver. A persistent cricopharyngeal bar may be caused by fibrosis in the cricopharyngeus. Some of these patients complain of food sticking in their throats. Cricopharyngeal myotomy may be helpful but is contraindicated in the presence of gastroesophageal reflux because it may lead to pharyngeal and pulmonary aspiration.

Globus Pharyngeus A sensation of a constant lump in the throat, but no difficulty in swallowing, occurs especially in individuals with emotional disorders, particularly women. Results of barium studies and manometry are normal. Treatment consists primarily of reassurance. Some patients with globus pharyngeus have associated reflux esophagitis, and they may respond to treatment of the esophagitis.

SMOOTH MUSCLE

Achalasia Achalasia is a motor disorder of the esophageal smooth muscle in which theLES does not relax normally with swallowing, and the esophageal body undergoes nonperistaltic contractions.

Pathophysiology The underlying abnormality is the loss of intramural neurons. Inhibitory neurons containingVIP and nitric oxide synthase are predominantly involved, but in advanced disease cholinergic neurons are also affected. Primary idiopathic achalasia accounts for most of the patients seen in the United States. Secondary achalasia may be caused by gastric carcinoma that infiltrates the esophagus, lymphoma, Chagas' disease, certain viral infections, eosinophilic gastroenteritis, and neurodegenerative disorders.

Clinical features Achalasia affects patients of all ages and both sexes. Dysphagia, chest pain, and regurgitation are the main symptoms. Dysphagia appears early, occurs with both liquids and solids, and is worsened by emotional stress and hurried eating. Various maneuvers designed to increase intraesophageal pressure, including the Valsalva maneuver, may aid the passage of the bolus into the stomach. Regurgitation and pulmonary aspiration occur because of retention of large volumes of saliva and ingested food in the esophagus. Patients may complain of difficulty belching. The presence of gastroesophageal reflux argues against achalasia; and in patients with long-standing heartburn, cessation of heartburn and appearance of dysphagia suggest development of achalasia on top of reflux esophagitis. The course is usually chronic, with progressive dysphagia and weight loss over months to years. Achalasia associated with carcinoma

is characterized by severe weight loss and a rapid downhill course if untreated.

Diagnosis A chest x-ray shows absence of the gastric air bubble and sometimes a tubular mediastinal mass beside the aorta. An air-fluid level in the mediastinum in the upright position represents retained food in the esophagus. Barium swallow shows esophageal dilation, and in advanced cases the esophagus may become sigmoid. On fluoroscopy, normal peristalsis is lost in the lower two-thirds of the esophagus. The terminal part of the esophagus shows a persistent beaklike narrowing representing the nonrelaxingLES(Fig. 284-1).

Manometry shows the basalLESpressure to be normal or elevated, and swallow-induced relaxation either does not occur or is reduced in degree, duration, and consistency. The esophageal body shows an elevated resting pressure. In response to swallows, primary peristaltic waves are replaced by simultaneous-onset contractions (Fig. 284-3). These contractions may be of poor amplitude (classic achalasia) or of large amplitude and long duration (vigorous achalasia). Cholecystokinin (CCK), which normally causes a fall in the sphincter pressure, paradoxically causes contraction of the LES (the CCK test). This paradoxical response occurs because, in achalasia, the neurally transmitted inhibitory effect of CCK is absent owing to the loss of inhibitory neurons. Endoscopy is helpful in excluding the secondary causes of achalasia, particularly gastric carcinoma.

TREATMENT

Treatment with soft foods, sedatives, and anticholinergic drugs is usually unsatisfactory. Nitrates and calcium channel blockers provide short-term benefit, but their use may be limited by side effects. Nitroglycerin, 0.3 to 0.6 mg, is used sublingually before meals and as needed for chest pain. Isosorbide dinitrate, 2.5 to 5 mg sublingually or 10 to 20 mg orally, is used before meals. Nitrates are associated with headache and postural hypotension. The calcium channel blocker nifedipine, 10 to 20 mg orally or sublingually before meals, is also effective. Endoscopic intrasphincteric injection of botulinum toxin is effective over a short period in some patients. Repeated injections may lead to fibrosis, complicating further operative therapy. Botulinum toxin acts by blocking cholinergic excitatory nerves in the sphincter. Balloon dilatation reduces the basalLESpressure by tearing muscle fibers. In experienced hands, this technique is effective in ~85% of patients. Perforation and bleeding are potential complications. Heller's extramucosal myotomy of the LES, in which the circular muscle layer is incised, is equally effective. Laparoscopic myotomy is the procedure of choice. Reflux esophagitis and peptic stricture may follow successful treatment (more often with myotomy than with balloon dilatation).

Diffuse Esophageal Spasm and Related Motor Disorders These disorders present with clinical symptoms of chest pain and dysphagia and are recognized by their manometric features. In pure form, they all show normal relaxation to swallows. Diffuse esophageal spasm is characterized by nonperistaltic contractions, usually of large amplitude and long duration. An esophageal motility pattern showing hypertensive but peristaltic contractions has been called "nutcracker esophagus."

Pathophysiology Nonperistaltic contractions are due to dysfunction of inhibitory nerves.

Histopathologic studies show patchy neural degeneration localized to nerve processes, rather than the prominent degeneration of nerve cell bodies seen in achalasia. Diffuse esophageal spasm may progress to achlasia. Hypertensive peristaltic contractions and hypertensive or hypercontractingLES may represent cholinergic or myogenic hyperactivity.

Clinical features Diffuse spasm and related motor disorders cannot be distinguished clinically. They all present with chest pain, dysphagia, or both. Chest pain is particularly marked in patients with esophageal contractions of large amplitude and long duration. Chest pain usually occurs at rest but may be brought on by swallowing or by emotional stress. The pain is retrosternal; it may radiate to the back, the sides of the chest, both arms, or the sides of the jaw and may last from a few seconds to several minutes. It may be acute and severe, mimicking the pain of myocardial ischemia. Dysphagia for solids and liquids may occur with or without chest pain and is correlated particularly with simultaneous-onset contractions.

Diffuse esophageal spasm and related esophageal motor disorders must be differentiated from other causes of chest pain, particularly ischemic heart disease with atypical angina. A complete cardiac workup should be done before a noncardiac etiology is considered seriously. The presence of dysphagia in association with pain should point to the esophagus as the site of disease. Esophageal motility disorders are an uncommon cause of noncardiac chest pain, which is more commonly due to reflux esophagitis or visceral hypersensitivity.

Diagnosis In diffuse esophageal spasm, barium swallow shows that normal sequential peristalsis below the aortic arch is replaced by uncoordinated simultaneous contractions that produce the appearance of curling or multiple ripples in the wall, sacculations, and pseudodiverticula -- the "corkscrew" esophagus (Fig. 284-1). Sometimes an esophageal contraction obliterates the lumen, and barium is pushed away in both directions. The barium swallow is frequently normal in diffuse esophageal spasm and mostly normal in the related disorders.

Diffuse esophageal spasm (Fig. 284-3) and related motor disorders (hypertensive peristaltic contraction, hypertensiveLES and hypercontracting LES) are manometric diagnoses. Because these abnormalities may be episodic, the results of manometry may be normal at the time of the study. Several techniques are used to provoke esophageal spasm. Cold swallows produce the chest pain but do not produce spasm on manometric studies. Solid boluses and pharmacologic agents, particularly edrophonium, induce both chest pain and motor abnormalities. However, correlation between induction of pain and motility changes is poor. The usefulness of pharmacologic provocative tests is limited.

TREATMENT

Anticholinergics are usually of limited value. Agents that relax smooth muscle, such as sublingual nitroglycerin (0.3 to 0.6 mg) or longer-acting agents such as isosorbide dinitrate (10 to 30 mg orally before meals) and nifedipine (10 to 20 mg orally before meals) are helpful. Sublingual forms of these agents can also be used. Reassurance and tranquilizers are helpful in allaying apprehension.

Scleroderma Esophagus The esophageal lesions in systemic sclerosis consist of atrophy of smooth muscle, manifested by weakness in the lower two-thirds of the esophageal body and incompetence of theLES. The esophageal wall is thin and atrophic and may exhibit areas of patchy fibrosis. Patients usually present with dysphagia to solids. Liquids may cause dysphagia when the patient is recumbent. These patients usually also complain of heartburn, regurgitation, and other symptoms of gastroesophageal reflux disease (GERD). Barium swallow shows dilation and loss of peristaltic contractions in the middle and distal portions of the esophagus. The LES is patulous, and gastroesophageal reflux may occur freely (Fig. 284-1). Mucosal changes due to esophageal ulceration and esophageal stricture may be present. Motility studies show a marked reduction in the amplitude of smooth-muscle contractions, which may be peristaltic or nonperistaltic. The resting pressure of the LES is subnormal, but sphincter relaxation is normal (Fig. 284-3). Similar esophageal motor abnormalities are found in other collagen vascular diseases and in Raynaud's syndrome alone. Dietary adjustments with the use of soft foods are helpful in management. GERD and its complications should be treated aggressively.

GASTROESOPHAGEAL REFLUX DISEASE

GERDis one of the most prevalent gastrointestinal disorders. Population-based studies show that up to 15% of individuals have heartburn at least once a week and about 7% have heartburn daily. Symptoms are caused by back flow of gastric acid and other gastric contents into the esophagus due to incompetent barriers at the gastroesophageal junction.

Pathophysiology The normal antireflux mechanisms consist of theLES, the crural diaphragm, and the anatomic location of the gastroesophageal junction below the diaphragmatic hiatus. Reflux occurs only when the gradient of pressure between the LES and the stomach is lost. It can be caused by a sustained or transient decrease in LES tone. A sustained hypotension of the LES may be due to muscle weakness that is often without apparent cause. Secondary causes of LES incompetence include scleroderma-like diseases, myopathy associated with chronic intestinal pseudo-obstruction, pregnancy, smoking, anticholinergic drugs, smooth-muscle relaxants [b-adrenergic agents, aminophylline, nitrates, calcium channel blockers, phosphodiesterase inhibitors that increase cyclic AMP or cyclic GMP (including sildenofil)], surgical destruction of the LES, and esophagitis.tLESRwithout associated esophageal contraction is due to a vagal reflex in which LES relaxation is elicited by gastric distention. Increased tLESR is associated withGERD. A similar reflex operates during belching. Apart from incompetent barriers, gastric contents are most likely to reflux (1) when gastric volume is increased (after meals, in pyloric obstruction, in gastric stasis, during acid hypersecretion states), (2) when gastric contents are near the gastroesophageal junction (in recumbency, bending down, hiatus hernia), and (3) when gastric pressure is increased (obesity, pregnancy, ascites, tight clothes). Incompetence of the diaphragmatic crural muscle, which surrounds the esophageal hiatus in the diaphragm and functions as an external LES, also predisposes to GERD.

The total exposure of the esophagus to refluxed acid correlates with potential for mucosal damage. Exposure depends on the amount of refluxed material per episode,

frequency of episodes, and rate of clearing the esophagus by gravity and peristaltic contractions. When peristaltic contractions are impaired, esophageal clearance is impaired. Acid refluxed into the esophagus is neutralized by saliva. Thus, impaired salivary secretion also increases esophageal exposure time. If the refluxed material extends to the cervical esophagus and breaches the upper sphincter, it can enter the pharynx, larynx, and trachea, causing chronic cough, bronchoconstriction, pharyngitis, laryngitis, or bronchitis.

Reflux esophagitis is a complication of reflux and develops when mucosal defenses are unable to counteract the damage done by acid, pepsin, and bile. *Mild esophagitis* involves microscopic changes of mucosal infiltration with granulocytes or eosinophils, hyperplasia of basal cells, and elongation of dermal pegs. Endoscopic appearance may be normal. *Erosive esophagitis* involves endoscopically apparent mucosal damage, redness, friability, bleeding, superficial, linear ulcers, and exudates. *Peptic stricture* results from fibrosis that causes lumenal constriction. These strictures occur in ~10% of patients with untreatedGERD. Short strictures caused by spontaneous reflux are usually 1 to 3 cm long and are present in the distal esophagus near the squamocolumnar junction (Fig. 284-2). Long, tubular peptic strictures can result from persistent vomiting or prolonged nasogastric intubation. Erosive esophagitis may cause bleeding and heal by intestinal metaplasia (*Barrett's esophagus*) that is a risk factor for adenocarcinoma.

Clinical Features Regurgitation of sour material in the mouth and heartburn are the characteristic symptoms ofGERD. Heartburn is produced by the contact of refluxed material with the inflamed or sensitized esophageal mucosa. Angina-like or atypical chest pain occurs in some patients, while others experience no heartburn or chest pain. Persistent dysphagia suggests development of a peptic stricture. Most patients with peptic stricture have a history of several years of heartburn preceding dysphagia. However, in one-third of patients, dysphagia is the presenting symptom. Rapidly progressive dysphagia and weight loss may indicate the development of adenocarcinoma in Barrett's esophagus. Bleeding occurs due to mucosal erosions or Barrett's ulcer. Severe reflux may reach the pharynx and mouth and result in laryngitis, morning hoarseness, and pulmonary aspiration. Recurrent pulmonary aspiration can cause aspiration pneumonia, pulmonary fibrosis, or chronic asthma. By contrast, many patients with GERD remain asymptomatic or self-treated and do not seek attention until severe complications occur.

Diagnosis The diagnostic approach toGERD can be divided into three categories:

1. documentation of mucosal injury,

2. documentation and quantitation of reflux, and

3. definition of the pathophysiology.

Reflux esophagitis and its complications are documented by the use of barium swallow, esophagoscopy, and mucosal biopsy. The results of barium swallow are usually normal in uncomplicated esophagitis but may reveal a stricture or ulcer. A high esophageal peptic stricture, a deep ulcer, or adenocarcinoma suggest Barrett's esophagus. Uncomplicated Barrett's esophagus is not diagnosed reliably by barium studies.

Esophagoscopy may reveal the presence of erosive esophagitis, distal peptic stricture, or a columnar-cell-lined lower esophagus with or without a proximally located peptic stricture, ulcer, or adenocarcinoma. Results of esophagoscopy may be normal in many patients with esophagitis; in such patients, mucosal biopsies and the Bernstein test are helpful. The mucosal biopsies should be performed at least 5 cm above theLES, because the esophageal mucosal changes of chronic esophagitis are quite frequent in the most distal esophagus in otherwise normal individuals. About 10% of biopsies yield a false-positive or false-negative result. The Bernstein test involves the infusion of solutions of 0.1 *N* HCl and normal saline into the esophagus. It is useful in diagnosing reflux esophagitis that is not endoscopically obvious. In patients with reflux esophagitis, infusion of acid, but not of saline, reproduces the symptoms of heartburn. Infusion of acid in normal individuals usually produces no symptoms. Supraesophageal manifestations are diagnosed by careful otolaryngological exam.

A therapeutic trial with a proton pump inhibitor (such as omeprazole, 40 mg bid) for 1 week provides strong support for the diagnosis ofGERD.

Documentation and quantitation of reflux when necessary can be done by ambulatory long-term (24-h) esophageal pH recording. For evaluation of pharyngeal reflux, a system of recording simultaneously from pharyngeal and esophageal sites may be useful. The pH recordings are helpful only in the evaluation of acid reflux. The presence of bile or intestinal alkaline secretions is suggested by the occurrence of reflux symptoms in the absence of gastric acid and demonstration of bile in an aspirate of esophageal reflux fluid. Documentation of reflux is necessary only when the role of reflux in the symptom complex is unclear, particularly in evaluation of supraesophageal symptoms and chest pain without endoscopic evidence of esophagitis.

Definition of pathophysiologic factors inGERD is sometimes indicated for management decisions such as antireflex surgery. Esophageal motility studies may provide useful quantitative information on the competence of theLES and on esophageal motor function.

TREATMENT

The goals of treatment are to decrease gastroesophageal reflux, render the refluxate harmless, improve esophageal clearance, and protect the esophageal mucosa. The management of uncomplicated cases generally includes weight reduction, sleeping with the head of the bed elevated by about 4 to 6 in. with blocks, and elimination of factors that increase abdominal pressure. Patients should not smoke and should avoid consuming fatty foods, coffee, chocolate, alcohol, mint, orange juice, and certain medications (such as anticholinergic drugs, calcium channel blockers, and other smooth-muscle relaxants). They should also avoid ingesting large quantities of fluids with meals. In mild cases, life-style changes and over-the-counter antisecretory agents may be adequate. In moderate cases, H_2receptor blocking agents (cimetidine, 300 mg; ranitidine, 150 mg bid; famotidine, 20 mg bid; nizatidine 150 mg bid) for 6 to 12 weeks are effective in symptom relief. Higher doses are necessary for healing erosive esophagitis, but proton pump inhibitors (PPIs) are more effective in this setting.

In cases resistant to H_2receptor blockers and severe cases, rigorous acid suppression

with aPPI is recommended. The PPIs are comparably effective: omeprazole (40 mg/d), lansoprazole (30 mg/d), pantoprazole (40 mg/d), and rabeprazole (20 mg/d) for 8 weeks can heal erosive esophagitis in up to 90% of patients. Reflux esophagitis requires prolonged therapy, for 3 to 6 months or longer if the disease recurs quickly. After initial therapy, a lower maintenance dose of PPI is used. Side effects are minimal. Aggressive acid suppression causes hypergastrinemia but does not increase the risk for carcinoid tumors or gastrinomas. Vitamin B_{12}absorption is compromised by the treatment. Patients with reflux esophagitis who have complications, such as Barrett's esophagus with concomitant esophagitis, should be treated vigorously. Patients who have an associated peptic stricture are treated with dilators to relieve dysphagia as well as provided with vigorous treatment for reflux.

Antireflux surgery, in which the gastric fundus is wrapped around the esophagus (fundoplication), increases theLESpressure and should be considered for patients with resistant and complicated reflux esophagitis that does not respond fully to medical therapy or for patients for whom long-term medical therapy is not desirable. Laparoscopic fundoplication is the surgery of choice. Ideal candidates for fundoplication are those in whom motility studies show persistently inadequate LES pressure but normal peristaltic contractions in the esophageal body.

Patients with alkaline esophagitis are treated with general antireflux measures and neutralization of bile salts with cholestyramine, aluminum hydroxide, or sucralfate. Sucralfate is particularly useful in these cases, as it also serves as a mucosal protector.

BARRETT'S ESOPHAGUS

The metaplasia of esophageal squamous epithelium to columnar epithelium (Barrett's esophagus) is a complication of severe reflux esophagitis, and it is a risk factor for esophageal adenocarcinoma (Chap. 90). Metaplastic columnar epithelium develops during healing of erosive esophagitis with continued acid reflux because columnar epithelium is more resistant to acid-pepsin damage than squamous epithelium. The metaplastic epithelium is a mosaic of different epithelial types including goblet cells and columnar cells that have features of both secretory and absorptive cells (incomplete or type III metaplasia). Barrett's epithelium progresses through a dysplastic stage before developing into adenocarcinoma. The rate of cancer development is 1 in 200 patient years; those with longer than 2 to 3 cm of intestinal metaplasia have a risk of developing esophageal cancer that is 30 to 125 times the risk of the general population.

Given the natural history, reflux esophagitis should be aggressively treated with drugs, and erosive esophagitis should be treated with drugs and surgery, if necessary, to prevent Barrett's esophagus. The prevalence of intestinal metaplasia is estimated at 4 to 10% of patients with significant heartburn. Barrett's esophagus is more common in men, particularly white men, and prevalence increases with age. A one-time esophagoscopy is recommended in patients with persistentGERDsymptoms at age 50. Established metaplasia does not regress with treatment; thus, acid suppression and fundoplication are indicated only when active esophagitis is also present.

The need and frequency of surveillance endoscopies in patients with established Barrett's esophagus are debated. The risk of developing esophageal adenocarcinoma is

related to the length of involved esophageal mucosa. People with short segments of Barrett's esophagus (distal 2 to 3 cm) account for up to 25% of unselected patients undergoing endoscopy with or withoutGERDsymptoms and appear to be at low risk. They are not routinely surveyed. However, those with long-segment Barrett's esophagus (>3 cm) are advised to have endoscopic surveillance at 1-year intervals for 2 years and then every 2 to 3 years. The frequency is increased if dysplasia is detected independent of the length of the metaplasia. Optical methods of recognizing dysplasia during the endoscopy (laser-induced fluorescence spectroscopy, optical coherence tomography) are being developed. Once high-grade dysplasia is detected, treatment of choice is esophagectomy of the Barrett's segment. Photodynamic laser or thermocoagulative mucosal ablation and endoscopic mucosal resection are being evaluated as alternatives.

Barrett's esophagus can also lead to chronic peptic ulcer of the esophagus with high (midesophageal) and long strictures.

INFLAMMATORY DISORDERS

INFECTIOUS ESOPHAGITIS

Infectious esophagitis can be due to viral, bacterial, fungal, or parasitic organisms. In severely immunocompromised patients, multiple organisms may coexist.

Viral Esophagitis *Herpes simplex virus* (HSV) type 1 occasionally causes esophagitis in immunocompetent individuals, but either HSV type 1 or HSV type 2 may afflict patients who are immunosuppressed (Chap. 182). Patients complain of an acute onset of chest pain, odynophagia, and dysphagia. Bleeding may occur in severe cases; and systemic manifestations such as nausea, vomiting, fever, chills, and mild leukocytosis may be present. Herpetic vesicles on the nose and lips may provide a clue to the diagnosis. Barium swallow is inadequate to detect early lesions and cannot reliably distinguish HSV infection from other types of infections. Endoscopy shows vesicles and small, discrete, punched-out superficial ulcerations with or without a fibrinous exudate. In later stages, a diffuse erosive esophagitis develops from enlargement and coalescence of the ulcers. Mucosal cells from a biopsy sample taken at the edge of an ulcer or from a cytologic smear show ballooning degeneration, ground-glass changes in the nuclei with eosinophilic intranuclear inclusions (Cowdry type A), and giant cell formation on routine stains. Culture for HSV becomes positive within days and is helpful in diagnosis. In patients with severe odynophagia, intravenous acyclovir, 400 mg five times a day, is usually initiated. Symptoms usually resolve in 1 week, but large ulcerations may take longer to heal. Foscarnet (90 mg/kg intravenously every 8 h) is used if resistance to acyclovir occurs.

Varicella-zoster virus (VZV) (Chap. 183) sometimes produces esophagitis in children with chickenpox and adults with herpes zoster. Esophageal VZV also can be the source of disseminated VZV infection without skin involvement. In an immunocompromised host, VZV esophagitis causes vesicles and confluent ulcers and usually resolves spontaneously, but it may cause necrotizing esophagitis in a severely compromised host. On routine histologic examination of mucosal biopsy samples or cytology specimens, VZV is difficult to distinguish fromHSV, but the distinction can be made

immunohistologically or by culture. Acyclovir reduces the duration of symptoms in VZV esophagitis.

Cytomegalovirus (CMV) infections (Chap. 185) occur only in immunocompromised patients. CMV is usually activated from a latent stage or may be acquired from blood product transfusions. CMV lesions initially appear as serpiginous ulcers in an otherwise normal mucosa. These may coalesce to form giant ulcers, particularly in the distal esophagus.

Patients present with odynophagia, chest pain, hematemesis, nausea, and vomiting. Diagnosis requires endoscopy and biopsies of the ulcer. Mucosal brushings are not useful. Routine histologic examination shows intranuclear and small intracytoplasmic inclusions in large fibroblasts and endothelial cells. Immunohistology with monoclonal antibodies toCMV and in situ hybridization of CMV DNA on centrifugation culture and are useful for early diagnosis. Ganciclovir, 5 mg/kg every 12 h intravenously, is the treatment of choice. Foscarnet (90 mg/kg every 12 h intravenously) is used in resistant cases. Therapy is continued until healing occurs, which may take 2 to 4 weeks.

HIV (Chap. 309) may be associated with a self-limited syndrome of acute esophageal ulceration associated with oral ulcers and a maculopapular skin rash, which occurs at the time of HIV seroconversion. Some patients with advanced disease have deep, persistent esophageal ulcers requiring treatment with oral glucocorticoids or thalidomide. Some ulcers respond to local steroid injection.

Bacterial Esophagitis *Bacterial esophagitis* is unusual, but esophagitis caused by *Lactobacillus* and b-hemolytic streptococci can occur in the immunocompromised host. In patients with profound granulocytopenia and patients with cancer, bacterial esophagitis is often missed because it is commonly present with other organisms, including viruses and fungi. In patients with AIDS, infection with *Cryptosporidium* or *Pneumocystis carinii* may cause nonspecific inflammation, and *Mycobacterium tuberculosis* infection may cause deep ulcerations of the distal esophagus.

***Candida* Esophagitis** *Candida* species are normal commensals in the throat but become pathogenic and produce esophagitis in immunodeficiency states. *Candida* esophagitis can occur without any predisposing factors. Patients may be asymptomatic or complain of odynophagia and dysphagia. Oral thrush or other evidence of mucocutaneous candidiasis may be absent. Rarely, *Candida* esophagitis is complicated by esophageal bleeding, perforation, and stricture or by systemic invasion. Barium swallow may be normal or show multiple nodular filling defects of various sizes (Fig. 284-2). Large nodular defects may resemble grape clusters. Endoscopy shows small, yellow-white raised plaques with surrounding erythema in mild disease. Confluent linear and nodular plaques reflect extensive disease. Diagnosis is made by demonstration of yeast or hyphal forms in plaque smears and exudate stained with periodic acid-Schiff or Gomori silver stains. Histologic examination is often negative. Culture is not useful in diagnosis but may define the species and the drug sensitivities of the yeast (Chap. 205). Fluconazole (200 mg on the first day, followed by 100 mg daily) is the preferred treatment of esophageal candidiasis because it is effective and its absorption is not affected by high gastric pH. Fluconazole is available in oral and intravenous formulations. Ketoconazole (200 to 400 mg in a single daily oral dose) is also effective

treatment, and the higher dose is used in severely immunocompromised hosts; however, its bioavailability is severely reduced at increased gastric pH. Patients who respond poorly are treated with amphotericin, 10 to 15 mg as an intravenous infusion for 6 h daily to a total dose of 300 to 500 mg. Nystatin oral suspension (100,000 units per ml) in doses of 10 to 20 mL every 6 h is effective for oral thrush. In resistant cases, amphotericin lozenges are used for 7 to 10 days followed by nystatin or fluconazole for as long as the host resistance remains low.

OTHER TYPES OF ESOPHAGITIS

Radiation esophagitis is a common occurrence during radiation treatment for thoracic cancers. The frequency and severity of esophagitis increase with the amount of radiation delivered and may be enhanced by radiosensitizing drugs like doxorubicin, bleomycin, cyclophosphamide, and cisplatin. Dysphagia and odynophagia may last several weeks to several months after therapy. The esophageal mucosa becomes erythematous, edematous, and friable. Superficial erosions coalesce to form larger superficial ulcers. Submucosal fibrosis and degenerative changes in the blood vessels, muscles, and myenteric neurons may occur. The treatment is relief of pain with viscous lidocaine during the acute phase; indomethacin treatment may reduce radiation damage. Esophageal stricture may develop.

Corrosive esophagitis is caused by the ingestion of caustic agents, such as strong alkali or acid. Severe corrosive injury may lead to esophageal perforation, bleeding, and death. Glucocorticoids are not useful in acute corrosive esophagitis. Healing is usually associated with stricture formation. Caustic strictures are usually long and rigid (Fig. 284-2) and generally require dilatation with dilators passed over a guidewire through the stricture. *Pill-induced esophagitis* is associated with the ingestion of certain types of pills and occurs most often in bedridden patients. Antibiotics such as doxycycline, tetracycline, oxytetracycline, minocycline, penicillin, and clindamycin account for more than half the cases. Nonsteroidal anti-inflammatory agents such as aspirin, indomethacin, and ibuprofen may cause injury. Other commonly prescribed pills that cause esophageal injury include potassium chloride, ferrous sulfate or succinate, quinidine, alprenolol, theophylline, ascorbic acid, pinaverum bromide, alendronate, and pamidronate. Pill esophagitis can be prevented by avoiding the offending agents or by having patients take pills in the upright position and wash them down with copious amounts of fluids.

Sclerotherapy for bleeding esophageal varices usually produces transient retrosternal chest pain and dysphagia; esophageal ulcer, stricture, hematoma, or perforation may occur. Variceal banding causes similar complications but less frequently. *Esophagitis associated with mucocutaneous and systemic diseases* is usually associated with blister and bulla formation, epithelial desquamation, and thin, weblike, or dense esophageal strictures. Pemphigus vulgaris and bullous pemphigoid form intraepithelial and subepithelial bullae, respectively, and can be distinguished by specific immunohistology; both are characterized by sloughing of epithelium or the presence of esophageal casts. Glucocorticoid treatment is usually effective. Cicatricial pemphigoid, Stevens-Johnson syndrome, and toxic epidermolysis bullosa can produce esophageal bullous lesions and strictures requiring gentle dilatation. Graft-versus-host disease occurs in patients who have received allogeneic bone marrow transplants and is associated with generalized

desquamation and esophageal strictures. Behcet's disease and eosinophilic gastroenteritis may involve the esophagus and may respond to glucocorticoid therapy. An erosive lichen planus also can involve the esophagus. Crohn's disease may cause inflammatory strictures, sinus tracts, filiform polyps, and fistulas in the esophagus.

OTHER ESOPHAGEAL DISORDERS

DIVERTICULA

Diverticula are outpouchings of the wall of the esophagus. A *Zenker's diverticulum* appears in the natural zone of weakness in the posterior hypopharyngeal wall (Killian's triangle) and causes halitosis and regurgitation of saliva and food particles consumed several days previously. When it becomes large and filled with food, such a diverticulum can compress the esophagus and cause dysphagia or complete obstruction. Nasogastric intubation and endoscopy should be performed with utmost care in these patients, since they may cause perforation of the diverticulum. A *midesophageal diverticulum* may be caused by traction from old adhesions or by propulsion associated with esophageal motor abnormalities. An *epiphrenic diverticulum* may be associated with achalasia. Small or medium-sized diverticula and midesophageal and epiphrenic diverticula are usually asymptomatic. *Diffuse intramural diverticulosis* of the esophagus is due to dilation of the deep esophageal glands and may lead to chronic candidiasis or to the development of a stricture high up in the esophagus. These patients may present with dysphagia. Symptomatic Zenker's diverticula are treated by cricopharyngeal myotomy with or without diverticulectomy. Very large symptomatic esophageal diverticula are removed surgically. When they are associated with motor abnormalities, distal myotomy is performed. Strictures associated with diffuse intramural diverticulosis are treated with rubber dilators.

WEBS AND RINGS

Weblike constrictions of the esophagus are usually congenital or inflammatory in origin. Asymptomatic hypopharyngeal webs are demonstrated in <10% of normal individuals. When concentric, they cause intermittent dysphagia to solids. The combination of symptomatic hypopharyngeal webs and iron-deficiency anemia in middle-aged women constitutes *Plummer-Vinson syndrome*. The clinical importance of this syndrome is uncertain. Midesophageal webs are rare. A *lower esophageal mucosal ring* (Schatzki ring) is a thin, weblike constriction located at the squamocolumnar mucosal junction at or near the border of theLES(Fig. 284-2). It invariably produces dysphagia when the lumen diameter is <1.3 cm. Dysphagia to solids is the only symptom, and it is usually episodic. Asymptomatic rings may be present in ~10% of normal individuals. A lower esophageal ring is one of the common causes of dysphagia. Symptomatic webs and mucosal lower esophageal rings are easily treated by dilatation. A *lower esophageal muscular ring* (contractile ring) is located proximal to the site of mucosal rings and may represent an abnormal uppermost segment of the LES. These rings can be recognized by the fact that they are not constant in size and shape. They also may cause dysphagia and should be differentiated from peptic strictures, achalasia, and lower esophageal mucosal ring. Muscular rings do not respond well to dilatation.

HIATAL HERNIA

A *hiatal hernia* is a herniation of part of the stomach into the thoracic cavity through the esophageal hiatus in the diaphragm. A *sliding hiatal hernia* is one in which the gastroesophageal junction and fundus of the stomach slide upward. A sliding hernia may result from weakening of the anchors of the gastroesophageal junction to the diaphragm, from longitudinal contraction of the esophagus, or from increased intraabdominal pressure. Small sliding hernias can be demonstrated commonly during barium studies if intraabdominal pressure is increased. Incidence increases with age; in individuals in the sixth decade of life, the prevalence of such hernias is ~60%. Small sliding hiatal hernias alone probably produce no symptoms but can contribute to reflux esophagitis. A *paraesophageal hernia* is one in which the esophagogastric junction remains fixed in its normal location and a pouch of stomach is herniated beside the gastroesophageal junction through the esophageal hiatus. A paraesophageal or mixed paraesophageal and sliding hernia may become incarcerated and strangulate, leading to acute chest pain, dysphagia, and a mediastinal mass and requiring surgery. A herniated gastric pouch may cause dysphagia, develop gastritis, or ulcerate, causing chronic blood loss. Large paraesophageal hernias should be surgically repaired.

MECHANICAL TRAUMA

Esophageal rupture may be caused by (1) iatrogenic damage from instrumentation of the esophagus or external trauma, (2) increased intraesophageal pressure associated with forceful vomiting or retching (*spontaneous rupture* or *Boerhaave's syndrome*), or (3) diseases of the esophagus such as corrosive esophagitis, esophageal ulcer, and neoplasm. The site of perforation depends on the cause. Instrumental perforation usually occurs in the pharynx or lower esophagus, just above the diaphragm in the posterolateral wall. Esophageal perforation causes severe retrosternal chest pain, which may be worsened by swallowing and breathing. Free air enters the mediastinum and spreads to neighboring structures, causing palpable subcutaneous emphysema in the neck, mediastinal crackling sounds on auscultation, and pneumothorax. With time, secondary infection supervenes, and mediastinal abscess may develop. Esophageal perforation associated with vomiting usually deposits gastric contents in the mediastinum and causes severe mediastinal complications. By contrast, instrumental perforation may be clinically mild and free of severe complications. Spontaneous rupture of the esophagus may mimic myocardial infarction, pancreatitis, or rupture of an abdominal viscus. Symptoms of chest pain may be mild, particularly in the elderly. Mediastinal emphysema may develop late. An x-ray of the chest shows abnormalities in most patients, but computed tomography of the chest is more sensitive in detecting mediastinal air. Fluid from pleural effusions may have a high content of (salivary) amylase. The diagnosis is confirmed by swallow of radiopaque contrast material. Gastrografin is used initially, and if no leak is found, a small amount of thin barium is used to confirm the diagnosis. Treatment includes esophageal and gastric suction and parenteral broad-spectrum antibiotics. Surgical drainage and repair of the laceration should be performed as soon as possible. In patients with terminal carcinoma, surgical repair may not be feasible, and patients with minor instrumental perforation can be treated conservatively. Extensive corrosive damage may require esophageal diversion and excision of the damaged portion.

Mucosal Tear (Mallory-Weiss Syndrome) This tear is usually caused by vomiting,

retching, or vigorous coughing. The tear usually involves the gastric mucosa near the squamocolumnar mucosal junction. Patients present with upper gastrointestinal bleeding, which may be severe. In most patients bleeding ceases spontaneously; continued bleeding may respond to vasopressin therapy or angiographic embolization. Surgery is rarely needed.

Intramural Hematoma Emetogenic injury, particularly in patients with bleeding abnormalities, can cause bleeding between the mucosal and muscle layers of the esophagus. The patients develop sudden dysphagia. The diagnosis is made by barium swallow and computed tomography. Resolution is usually spontaneous.

FOREIGN BODIES

Foreign bodies may lodge in the cervical esophagus just beyond theUES, near the aortic arch, or above theLES. Impaction of a bolus of food, particularly a piece of meat or bread, may occur when the esophageal lumen is narrowed due to stricture, carcinoma, or a lower esophageal ring. Acute impaction causes a complete inability to swallow and severe chest pain. Both foreign bodies and food boluses may be removed endoscopically. Use of a meat tenderizer to facilitate passage of a meat bolus is discouraged because of potential esophageal perforation and aspiration pneumonia.

285. PEPTIC ULCER DISEASE AND RELATED DISORDERS - *John Del Valle*

PEPTIC ULCER DISEASE

Burning epigastric pain exacerbated by fasting and improved with meals is a symptom complex associated with peptic ulcer disease (PUD). An *ulcer* is defined as disruption of the mucosal integrity of the stomach and/or duodenum leading to a local defect or excavation due to active inflammation. Ulcers occur within the stomach and/or duodenum and are often chronic in nature. Acid peptic disorders are very common in the United States, with 4 million individuals (new cases and recurrences) affected per year. Lifetime prevalence of PUD in the United States is approximately 12% in men and 10% in women. Moreover, an estimated 15,000 deaths per year occur as a consequence of complicated PUD. The financial impact of these common disorders has been substantial, with an estimated burden on health care costs of >$15 billion per year in the United States.

GASTRIC PHYSIOLOGY

Despite the constant attack on the gastroduodenal mucosa by a host of noxious agents (acid, pepsin, bile acids, pancreatic enzymes, drugs, and bacteria), integrity is maintained by an intricate system that provides mucosal defense and repair.

Gastric Anatomy The gastric epithelial lining consists of rugae that contain microscopic gastric pits, each branching into four or five gastric glands made up of highly specialized epithelial cells. The makeup of gastric glands varies with their anatomic location. Glands within the gastric cardia comprise<5% of the gastric gland area and contain mucous and endocrine cells. The majority of gastric glands (75%) are found within the oxyntic mucosa and contain mucous neck, parietal, chief, endocrine, and enterochromaffin cells (Fig. 285-1). Pyloric glands contain mucous and endocrine cells (including gastrin cells) and are found in the antrum.

The parietal cell, also known as the oxyntic cell, is usually found in the neck, or isthmus, or the oxyntic gland. The resting, or unstimulated, parietal cell has prominent cytoplasmic tubulovesicles and intracellular canaliculi containing short microvilli along its apical surface (Fig. 285-2). H^+, K^+-ATPase is expressed in the tubulovesicle membrane; upon cell stimulation, this membrane, along with apical membranes, transforms into a dense network of apical intracellular canaliculi containing long microvilli. Acid secretion, a process requiring high energy, occurs at the apical canalicular surface. Numerous mitochondria (30 to 40% of total cell volume) generate the energy required for secretion.

Gastroduodenal Mucosal Defense The gastric epithelium is under a constant assault by a series of endogenous noxious factors including HCl, pepsinogen/pepsin, and bile salts. In addition, a steady flow of exogenous substances such as medications, alcohol, and bacteria encounter the gastric mucosa. A highly intricate biologic system is in place to provide defense from mucosal injury and to repair any injury that may occur.

The mucosal defense system can be envisioned as a three-level barrier, composed of preepithelial, epithelial, and subepithelial elements (Fig. 285-3). The first line of defense is a mucus-bicarbonate layer, which serves as a physicochemical barrier to multiple

molecules including hydrogen ions. Mucus is secreted in a regulated fashion by gastroduodenal surface epithelial cells. It consists primarily of water (95%) and a mixture of lipids and glycoproteins. Mucin is the constituent glycoprotein that, in combination with phospholipids (also secreted by gastric mucous cells), forms a hydrophobic surface with fatty acids that extend into the lumen from the cell membrane. The mucous gel functions as a nonstirred water layer impeding diffusion of ions and molecules such as pepsin. Bicarbonate, secreted by surface epithelial cells of the gastroduodenal mucosa into the mucous gel, forms a pH gradient ranging from 1 to 2 at the gastric luminal surface and reaching 6 to 7 along the epithelial cell surface. Bicarbonate secretion is stimulated by calcium, prostaglandins, cholinergic input, and luminal acidification.

Surface epithelial cells provide the next line of defense through several factors, including mucus production, epithelial cell ionic transporters that maintain intracellular pH and bicarbonate production, and intracellular tight junctions. If the preepithelial barrier were breached, gastric epithelial cells bordering a site of injury can migrate to restore a damaged region (*restitution*). This process occurs independent of cell division and requires uninterrupted blood flow and an alkaline pH in the surrounding environment. Several growth factors including epidermal growth factor (EGF), transforming growth factor (TGF)a, and basic fibroblast growth factor (FGF) modulate the process of restitution. Larger defects that are not effectively repaired by restitution require cell proliferation. Epithelial cell regeneration is regulated by prostaglandins and growth factors such as EGF and TGF-a. In tandem with epithelial cell renewal, formation of new vessels (*angiogenesis*) within the injured microvascular bed occurs. Both FGF and vascular endothelial growth factor (VEGF) are important in regulating angiogenesis in the gastric mucosa.

An elaborate microvascular system within the gastric submucosal layer is the key component of the subepithelial defense/repair system. A rich submucosal circulatory bed provides HCO_3^-, which neutralizes the acid generated by parietal cell secretion of HCl. Moreover, this microcirculatory bed provides an adequate supply of micronutrients and oxygen while removing toxic metabolic by-products.

Prostaglandins play a central role in gastric epithelial defense/repair (Fig. 285-4). The gastric mucosa contains abundant levels of prostaglandins. These metabolites of arachidonic acid regulate the release of mucosal bicarbonate and mucus, inhibit parietal cell secretion, and are important in maintaining mucosal blood flow and epithelial cell restitution. Prostaglandins are derived from esterified arachidonic acid, which is formed from phospholipids (cell membrane) by the action of phospholipase A_2. A key enzyme that controls the rate-limiting step in prostaglandin synthesis is cyclooxygenase (COX), which is present in two isoforms (COX-1, COX-2), each having distinct characteristics regarding structure, tissue distribution, and expression. COX-1 is expressed in a host of tissues including the stomach, platelets, kidneys, and endothelial cells. This isoform is expressed in a constitutive manner and plays an important role in maintaining the integrity of renal function, platelet aggregation, and gastrointestinal mucosal integrity. In contrast, the expression of COX-2 is inducible by inflammatory stimuli, and it is expressed in macrophages, leukocytes, fibroblasts, and synovial cells. The beneficial effects of nonsteroidal anti-inflammatory drugs (NSAIDs) on tissue inflammation are due to inhibition of COX-2; the toxicity of these drugs (e.g., gastrointestinal mucosal

ulceration and renal dysfunction) is related to inhibition of the COX-1 isoform. The highly COX-2-selective NSAIDs have the potential to provide the beneficial effect of decreasing tissue inflammation while minimizing toxicity in the gastrointestinal tract (see below).

Physiology of Gastric Secretion Hydrochloric acid and pepsinogen are the two principal gastric secretory products capable of inducing mucosal injury. Acid secretion should be viewed as occurring under basal and stimulated conditions. Basal acid production occurs in a circadian pattern, with highest levels occurring during the night and lowest levels during the morning hours. Cholinergic input via the vagus nerve and histaminergic input from local gastric sources (see below) are the principal contributors to basal acid secretion. Stimulated gastric acid secretion occurs primarily in three phases based on the site where the signal originates (cephalic, gastric, and intestinal). Sight, smell, and taste of food are the components of the cephalic phase, which stimulates gastric secretion via the vagus nerve. The gastric phase is activated once food enters the stomach. This component of secretion is driven by nutrients (amino acids and amines) that directly stimulate the G cell to release gastrin, which in turn activates the parietal cell via direct and indirect mechanisms (see below). Distention of the stomach wall also leads to gastrin release and acid production. The last phase of gastric acid secretion is initiated as food enters the intestine and is mediated by luminal distention and nutrient assimilation. A series of pathways that inhibit gastric acid production are also set into motion during these phases. The gastrointestinal hormone somatostatin is released from endocrine cells found in the gastric mucosa (D cells) in response to HCl. Somatostatin can inhibit acid production by both direct (parietal cell) and indirect mechanisms [decreased histamine release from enterochromaffin-like (ECL) cells and gastrin release from G cells]. Additional neural (central and peripheral) and hormonal (secretin, cholecystokinin) factors play a role in counterbalancing acid secretion. Under physiologic circumstances, these phases are occurring simultaneously.

The acid-secreting parietal cell is located in the oxyntic gland, adjacent to other cellular elements (ECL cell, D cell) important in the gastric secretory process (Fig. 285-5). This unique cell also secretes intrinsic factor. The parietal cell expresses receptors for several stimulants of acid secretion including histamine (H_2), gastrin (cholecystokinin B/gastrin receptor) and acetylcholine (muscarinic, M_3). Each of these are G protein-linked, seven transmembrane-spanning receptors. Binding of histamine to the H_2receptor leads to activation of adenylate cyclase and an increase in cyclic AMP. Activation of the gastrin and muscarinic receptors results in activation of the protein kinase C/phosphoinositide signaling pathway. Each of these signaling pathways in turn regulates a series of downstream kinase cascades, which control the acid-secreting pump, H^+, K^+-ATPase. The discovery that different ligands and their corresponding receptors lead to activation of different signaling pathways explains the potentiation of acid secretion that occurs when histamine and gastrin or acetylcholine are combined. More importantly, this observation explains why blocking one receptor type (H_2) decreases acid secretion stimulated by agents that activate a different pathway (gastrin, acetylcholine). Parietal cells also express receptors for ligands that inhibit acid production (prostaglandins, somatostatin, andEGF).

The enzyme H^+, K^+-ATPase is responsible for generating the large concentration of H^+. It is a membrane-bound protein that consists of two subunits,a and b. The active

catalytic site is found within the a subunit; the function of the b subunit is unclear. This enzyme uses the chemical energy of ATP to transfer H^+ ions from parietal cell cytoplasm to the secretory canaliculi in exchange for K^+. The H^+,K^+-ATPase is located within the secretory canaliculus and in nonsecretory cytoplasmic tubulovesicles. The tubulovesicles are impermeable to K^+, which leads to an inactive pump in this location. The distribution of pumps between the nonsecretory vesicles and the secretory canaliculus varies according to parietal cell activity (Fig. 285-2). Under resting conditions, only 5% of pumps are within the secretory canaliculus, whereas upon parietal cell stimulation, tubulovesicles are immediately transferred to the secretory canalicular membrane, where 60 to 70% of the pumps are activated. Proton pumps are recycled back to the inactive state in cytoplasmic vesicles once parietal cell activation ceases.

The chief cell, found primarily in the gastric fundus, synthesizes and secretes pepsinogen, the inactive precursor of the proteolytic enzyme pepsin. The acid environment within the stomach leads to cleavage of the inactive precursor to pepsin and provides the low pH (<2.0) required for pepsin activity. Pepsin activity is significantly diminished at a pH of 4 and irreversibly inactivated and denatured at a pH of ³7. Many of the secretagogues that stimulate acid secretion also stimulate pepsinogen release. The precise role of pepsin in the pathogenesis ofPUDremains to be established.

PATHOPHYSIOLOGIC BASIS OF PEPTIC ULCER DISEASE

PUDencompasses both gastric and duodenal ulcers. Ulcers are defined as a break in the mucosal surface >5 mm in size, with depth to the submucosa. Duodenal (DU) and gastric ulcers (GU) share many common features in terms of pathogenesis, diagnosis, and treatment, but several factors distinguish them from one another.

Epidemiology

Duodenal Ulcers DUs are estimated to occur in 6 to 15% of the western population. The incidence of DUs declined steadily from 1960 to 1980 and has remained stable since then. The death rates, need for surgery, and physician visits have decreased by>50% over the past 30 years. The reason for the reduction in the frequency of DUs is likely related to the decreasing frequency of *Helicobacter pylori*. Before the discovery of *H. pylori*, the natural history of DUs was typified by frequent recurrences after initial therapy. Eradication of *H. pylori* has greatly reduced these recurrence rates.

Gastric Ulcers GUs tend to occur later in life than duodenal lesions, with a peak incidence reported in the sixth decade. More than half of GUs occur in males and are less common thanDUs, perhaps due to the higher likelihood of GUs being silent and presenting only after a complication develops. Autopsy studies suggest a similar incidence of DUs and GUs.

Pathology

Duodenal Ulcers DUsoccur most often in the first portion of duodenum (>95%), with ~90% located within 3 cm of the pylorus. They are usually £1 cm in diameter but can occasionally reach 3 to 6 cm (giant ulcer). Ulcers are sharply demarcated, with depth at

times reaching the muscularis propria. The base of the ulcer often consists of a zone of eosinophilic necrosis with surrounding fibrosis. Malignant duodenal ulcers are extremely rare.

Gastric Ulcers In contrast toDUs,GUs can represent a malignancy. Benign GUs are most often found distal to the junction between the antrum and the acid secretory mucosa. This junction is variable, but in general the antral mucosa extends about two thirds of the distance of the lesser curvature and one third the way up the greater curvature. Benign GUs are quite rare in the gastric fundus and are histologically similar to DUs. Benign GUs associated with *H. pylori* are associated with antral gastritis. In contrast,NSAID-related GUs are not accompanied by chronic active gastritis but may instead have evidence of a chemical gastropathy.

Pathophysiology It is now clear that *H. pylori* andNSAID-induced injury account for the majority ofDUs. Gastric acid contributes to mucosal injury but does not play a primary role.

Duodenal Ulcers Many acid secretory abnormalities have been described inDUpatients (Table 285-1). Of these, average basal and nocturnal gastric acid secretion appear to be increased in DU patients as compared to control; however, the level of overlap between DU patients and control subjects is substantial. The reason for this altered secretory process is unclear, but *H. pylori* infection may contribute to this finding. Accelerated gastric emptying of liquids has been noted in some DU patients but is not consistently observed; its role in DU formation, if any, is unclear. Bicarbonate secretion is significantly decreased in the duodenal bulb of patients with an active DU as compared to control subjects. *H. pylori* infection may also play a role in this process.

Gastric Ulcer As inDUs, the majority ofGUs can be attributed to either *H. pylori* orNSAID-induced mucosal damage. GUs that occur in the prepyloric area or those in the body associated with a DU or a duodenal scar are similar in pathogenesis to DUs. Gastric acid output (basal and stimulated) tends to be normal or decreased in GU patients. When GUs develop in the presence of minimal acid levels, impairment of mucosal defense factors may be present.

Abnormalities in resting and stimulated pyloric sphincter pressure with a concomitant increase in duodenal gastric reflux have been implicated in someGUpatients. Although bile acids, lysolecithin, and pancreatic enzymes may injure gastric mucosa, a definite role for these in GU pathogenesis has not been established. Delayed gastric emptying of solids has been described in GU patients but has not been reported consistently. The observation that patients who have undergone disruption of the normal pyloric barrier (pyloroplasty, gastroenterostomy) often have superficial gastritis without frank ulceration decreases enthusiasm for duodenal gastric reflux as an explanation for GU pathogenesis.

H. pylori and acid peptic disorders Gastric infection with the bacterium *H. pylori* accounts for the majority ofPUD. This organism also plays a role in the development of gastric mucosal-associated lymphoid tissue (MALT) lymphoma and gastric adenocarcinoma. Although the entire genome of *H. pylori* has been sequenced, it is still not clear how this organism, which is in the stomach, causes ulceration in the

duodenum, or whether its eradication will lead to a decrease in gastric cancer.

THE BACTERIUM The bacterium, initially named *Campylobacter pyloridis*, is a gram-negative microaerophilic rod found most commonly in the deeper portions of the mucous gel coating the gastric mucosa or between the mucous layer and the gastric epithelium. It may attach to gastric epithelium but under normal circumstances does not appear to invade cells. It is strategically designed to live within the aggressive environment of the stomach. It is S-shaped (~0.5´ 3 um in size) and contains multiple sheathed flagella. Initially, *H. pylori* resides in the antrum but, over time, migrates towards the more proximal segments of the stomach. The organism is capable of transforming into a coccoid form, which represents a dormant state that may facilitate survival in adverse conditions. The bacterium expresses a host of factors that contribute to its ability to colonize the gastric mucosa and produce mucosal injury. Several of the key bacterial factors include urease (converting urea to NH_3 and water, thus alkalinizing the surrounding acidic environment), catalase, lipase, adhesins, platelet-activating factor, cytotoxin-associated gene protein (Cag A), pic B (induces cytokines), and vacuolating cytotoxin (Vac A). Multiple strains of *H. pylori* exist and are characterized by their ability to express several of these factors (Cag A, Vac A, etc.). It is possible that the different diseases related to *H. pylori* infection can be attributed to different strains of the organism with distinct pathogenic features.

EPIDEMIOLOGY The prevalence of *H. pylori* varies throughout the world and depends to a great extent on the overall standard of living in the region. In developing parts of the world, 80% of the population may be infected by the age of 20. In contrast, in the United States, this organism is rare in childhood. The overall prevalence of *H. pylori* in the United States is ~30%, with individuals born before 1950 having a higher rate of infection than those born later. About 10% of Americans<30 are colonized with the bacteria. This rate of colonization increases with age, with about 50% of individuals age 50 being infected. Factors that predispose to higher colonization rates include poor socioeconomic status and less education. These factors, not race, are responsible for the rate of *H. pylori* infection in blacks and Hispanic Americans being double the rate seen in whites of comparable age. A summary of risk factors for *H. pylori* infection is shown inTable 285-2.

Transmission of *H. pylori* occurs from person to person, following an oral-oral or fecal-oral route. The risk of *H. pylori* infection is declining in developing countries. The rate of infection in the United States has fallen by>50% when compared to 30 years ago.

PATHOPHYSIOLOGY H. pylori infection is virtually always associated with a chronic active gastritis, but only 10 to 15% of infected individuals develop frank peptic ulceration. The basis for this difference is unknown. Initial studies suggested that>90% of all DUs were associated with *H. pylori*, but *H. pylori* is present in only 30 to 60% of individuals withDU and 70% of patients withGU. The pathophysiology of ulcers not associated with *H. pylori* orNSAIDingestion [or the rare Zollinger-Ellison syndrome (ZES)] is unclear.

The particular end result of *H. pylori* infection (gastritis,PUD, gastricMALTlymphoma, gastric cancer) is determined by a complex interplay between bacterial and host factors

(Fig. 285-6).

1. *Bacterial factors*: *H. pylori* is able to facilitate gastric residence, induce mucosal injury, and avoid host defense. Different strains of *H. pylori* produce different virulence factors. A specific region of the bacterial genome, the pathogenicity island, encodes the virulence factors Cag A and pic B. Vac A also contributes to pathogenicity, though it is not encoded within the pathogenicity island. These virulence factors, in conjunction with additional bacterial constituents, can cause mucosal damage. Urease, which allows the bacteria to reside in the acidic stomach, generates NH_3, which can damage epithelial cells. The bacteria produce surface factors that are chemotactic for neutrophils and monocytes, which in turn contribute to epithelial cell injury (see below). *H. pylori* makes proteases and phospholipases that break down the glycoprotein lipid complex of the mucous gel, thus reducing the efficacy of this first line of mucosal defense. *H. pylori* expresses adhesins, which facilitate attachment of the bacteria to gastric epithelial cells. Although lipopolysaccharide (LPS) of gram-negative bacteria often plays an important role in the infection, *H. pylori* LPS has low immunologic activity compared to that of other organisms. It may promote a smoldering chronic inflammation.

2. *Host factors*: The host responds to *H. pylori* infection by mounting an inflammatory response, which contributes to gastric epithelial cell damage without providing immunity against infection. The neutrophil response is strong both in acute and chronic infection. In addition, T lymphocytes and plasma cells are components of the chronic inflammatory infiltrate, supporting the involvement of antigen-specific cellular and humoral responses. A number of cytokines are released from both epithelial and immune modulatory cells in response to *H. pylori* infection including the proinflammatory cytokines tumor necrosis factor (TNF)a, interleukin (IL)1a/b, IL-6, interferon (IFN)g, and granulocyte-macrophage colony stimulating factor. Several chemokines such as IL-8 and growth-regulated oncogene (GRO)a, involved in neutrophil recruitment/activation, and RANTES, which recruits mononuclear cells, have been observed in *H. pylori*-infected mucosa.

The reason for *H. pylori*-mediated duodenal ulceration remains unclear. One potential explanation is that gastric metaplasia in the duodenum ofDUpatients permits *H. pylori* to bind to it and produce local injury secondary to the host response. Another hypothesis is that *H. pylori* antral infection could lead to increased acid production, increased duodenal acid, and mucosal injury. Basal and stimulated [meal, gastrin-releasing peptide (GRP)] gastrin release are increased in *H. pylori*-infected individuals, and somatostatin-secreting D cells may be decreased. *H. pylori* infection might induce increased acid secretion through both direct and indirect actions of *H. pylori* and proinflammatory cytokines (IL-8,TNF, and IL-1) on G, D, and parietal cells (Fig. 285-7). *H. pylori* infection has also been associated with decreased duodenal mucosal bicarbonate production. Data supporting and contradicting each of these interesting theories have been demonstrated. Thus, the mechanism by which *H pylori* infection of the stomach leads to duodenal ulceration remains to be established.

NSAIDs-induced disease

EPIDEMIOLOGY NSAIDsrepresent one of the most commonly used medications in the United States. More than 30 billion over-the-counter tablets and 70 million prescriptions

are sold yearly in the United States alone. The spectrum of NSAID-induced morbidity ranges from nausea and dyspepsia (prevalence reported as high as 50 to 60%) to a serious gastrointestinal complication such as frank peptic ulceration complicated by bleeding or perforation in as many as 3 to 4% of users per year. About 20,000 patients die each year from serious gastrointestinal complications from NSAIDs. Unfortunately, dyspeptic symptoms do not correlate with NSAID-induced pathology. Over 80% of patients with serious NSAID-related complications did not have preceding dyspepsia. In view of the lack of warning signs, it is important to identify patients who are at increased risk for morbidity and mortality related to NSAID usage. A summary of established and possible risk factors is presented in Table 285-3.

PATHOPHYSIOLOGY Prostaglandins play a critical role in maintaining gastroduodenal mucosal integrity and repair. It therefore follows that interruption of prostaglandin synthesis can impair mucosal defense and repair, thus facilitating mucosal injury via a systemic mechanism. A summary of the pathogenetic pathways by which systemically administered NSAIDs may lead to mucosal injury is shown in Fig. 285-8.

Injury to the mucosa also occurs as a result of the topical encounter with NSAIDs. Aspirin and many NSAIDs are weak acids that remain in a nonionized lipophilic form when found within the acid environment of the stomach. Under these conditions, NSAIDs migrate across lipid membranes of epithelial cells, leading to cell injury once trapped intracellularly in an ionized form. Topical NSAIDs can also alter the surface mucous layer, permitting back diffusion of H^+ and pepsin, leading to further epithelial cell damage.

Miscellaneous Pathogenetic Factors in Acid Peptic Disease Cigarette smoking has been implicated in the pathogenesis of PUD. Not only have smokers been found to have ulcers more frequently than do nonsmokers, but smoking appears to decrease healing rates, impair response to therapy, and increase ulcer-related complications such as perforation. The mechanism responsible for increased ulcer diathesis in smokers is unknown. Theories have included altered gastric emptying, decreased proximal duodenal bicarbonate production, and cigarette-induced generation of noxious mucosal free radicals. Acid secretion is *not* abnormal in smokers. Despite these interesting theories, a unifying mechanism for cigarette-induced peptic ulcer diathesis has not been established.

Genetic predisposition has also been considered to play a role in ulcer development. First-degree relatives of DU patients are three times as likely to develop an ulcer; however, the potential role of *H. pylori* infection in contacts is a major consideration. Increased frequency of blood group O and of the nonsecretor status have also been implicated as genetic risk factors for peptic diathesis. However, *H. pylori* preferentially binds to group O antigens. Therefore, the role of genetic predisposition in common PUD has not been established.

Psychological stress has been thought to contribute to PUD, but studies examining the role of psychological factors in its pathogenesis have generated conflicting results. Although PUD is associated with certain personality traits (neuroticism), these same traits are also present in individuals with nonulcer dyspepsia (NUD) and other functional and organic disorders. Although more work in this area is needed, no typical PUD

personality has been found.

Diet has also been thought to play a role in peptic diseases. Certain foods can cause dyspepsia, but no convincing studies indicate an association between ulcer formation and a specific diet. This is also true for beverages containing alcohol and caffeine. Specific chronic disorders have been associated withPUD(Table 285-4).

Multiple factors play a role in the pathogenesis ofPUD. The two predominant causes are *H. pylori* infection andNSAIDingestion. PUD not related to *H. pylori* or NSAIDs may be increasing. Independent of the inciting or injurious agent, peptic ulcers develop as a result of an imbalance between mucosal protection/repair and aggressive factors. Gastric acid plays an essential role in mucosal injury.

CLINICAL FEATURES

History Abdominal pain is common to many gastrointestinal disorders, includingDU andGU, but has a poor predictive value for the presence of either DU or GU. Up to 10% of patients withNSAID-induced mucosal disease can present with a complication (bleeding, perforation, and obstruction) without antecedent symptoms. Despite this poor correlation, a careful history and physical examination are essential components of the approach to a patient suspected of having peptic ulcers.

Epigastric pain described as a burning or gnawing discomfort can be present in bothDU andGU. The discomfort is also described as an ill-defined, aching sensation or as hunger pain. The typical pain pattern in DU occurs 90 min to 3 h after a meal and is frequently relieved by antacids or food. Pain that awakes the patient from sleep (between midnight and 3 A.M.) is the most discriminating symptom, with two-thirds of DU patients describing this complaint. Unfortunately, this symptom is also present in one-third of patients withNUD. The pain pattern in GU patients may be different from that in DU patients, where discomfort may actually be precipitated by food. Nausea and weight loss occur more commonly in GU patients. In the United States, endoscopy detects ulcers in<30% of patients who have dyspepsia. Despite this, 40% of these individuals with typical ulcer symptoms had an ulcer crater, and 40% had gastroduodenitis on endoscopic examination.

The mechanism for development of abdominal pain in ulcer patients is unknown. Several possible explanations include acid-induced activation of chemical receptors in the duodenum, enhanced duodenal sensitivity to bile acids and pepsin, or altered gastroduodenal motility.

Variation in the intensity or distribution of the abdominal pain, as well as the onset of associated symptoms such as nausea and/or vomiting, may be indicative of an ulcer complication. Dyspepsia that becomes constant, is no longer relieved by food or antacids, or radiates to the back may indicate a penetrating ulcer (pancreas). Sudden onset of severe, generalized abdominal pain may indicate perforation. Pain worsening with meals, nausea, and vomiting of undigested food suggest gastric outlet obstruction. Tarry stools or coffee ground emesis indicate bleeding.

Physical Examination Epigastric tenderness is the most frequent finding in patients

withGU orDU. Pain may be found to the right of the midline in 20% of patients. Unfortunately, the predictive value of this finding is rather low. Physical examination is critically important for discovering evidence of ulcer complication. Tachycardia and orthostasis suggest dehydration secondary to vomiting or active gastrointestinal blood loss. A severely tender, boardlike abdomen suggests a perforation. Presence of a succussion splash indicates retained fluid in the stomach, suggesting gastric outlet obstruction.

PUD-Related Complications

Gastrointestinal Bleeding Gastrointestinal bleeding is the most common complication observed in PUD. It occurs in ~15% of patients and more often in individuals>60 years old. The higher incidence in the elderly is likely due to the increased use ofNSAIDsin this group. As many as 20% of patients with ulcer-related hemorrhage bleed without any preceding warning signs or symptoms.

Perforation The second most common ulcer-related complication is perforation, being reported in as many as 6 to 7% ofPUDpatients. As in the case of bleeding, the incidence of perforation in the elderly appears to be increasing secondary to increased use ofNSAIDs. Penetration is a form of perforation in which the ulcer bed tunnels into an adjacent organ.DUs tend to penetrate posteriorly into the pancreas, leading to pancreatitis, whereasGUs tend to penetrate into the left hepatic lobe. Gastrocolic fistulas associated with GUs have also been described.

Gastric Outlet Obstruction Gastric outlet obstruction is the least common ulcer-related complication, occurring in 1 to 2% of patients. A patient may have relative obstruction secondary to ulcer-related inflammation and edema in the peripyloric region. This process often resolves with ulcer healing. A fixed, mechanical obstruction secondary to scar formation in the peripyloric areas is also possible. The latter requires endoscopic (balloon dilation) or surgical intervention. Signs and symptoms relative to mechanical obstruction may develop insidiously. New onset of early satiety, nausea, vomiting, increase of postprandial abdominal pain, and weight loss should make gastric outlet obstruction a possible diagnosis.

Differential Diagnosis The list of gastrointestinal and nongastrointestinal disorders that can mimic ulceration of the stomach or duodenum is quite extensive. The most commonly encountered diagnosis among patients seen for upper abdominal discomfort isNUD. NUD, also known as *functional dyspepsia* or *essential dyspepsia*, refers to a group of heterogeneous disorders typified by upper abdominal pain without the presence of an ulcer. Dyspepsia has been reported to occur in up to 30% of the U.S. population. Up to 60% of patients seeking medical care for dyspepsia have a negative diagnostic evaluation. The etiology of NUD is not established, and the potential role of *H. pylori* in NUD remains controversial.

Several additional disease processes that may present with "ulcer-like" symptoms include proximal gastrointestinal tumors, gastroesophageal reflux, vascular disease, pancreaticobiliary disease (biliary colic, chronic pancreatitis), and gastroduodenal Crohn's disease.

Diagnostic Evaluation In view of the poor predictive value of abdominal pain for the presence of a gastroduodenal ulcer and the multiple disease processes that can mimic this disease, the clinician is often confronted with having to establish the presence of an ulcer. Documentation of an ulcer requires either a radiographic (barium study) or an endoscopic procedure.

Barium studies of the proximal gastrointestinal tract are still commonly used as a first test for documenting an ulcer. The sensitivity of older single-contrast barium meals for detecting aDU is as high as 80%, with a double-contrast study providing detection rates as high as 90%. Sensitivity for detection is decreased in small ulcers (<0.5 cm), presence of previous scarring, or in postoperative patients. A DU appears as a well-demarcated crater, most often seen in the bulb. AGU may represent benign or malignant disease. Typically, a benign GU also appears as a discrete crater with radiating mucosal folds originating from the ulcer margin. Ulcers >3 cm in size or those associated with a mass are more often malignant. Unfortunately, up to 8% of GUs that appear to be benign by radiographic appearance are malignant by endoscopy or surgery. Radiographic studies that show a GU must be followed by endoscopy and biopsy.

Endoscopy provides the most sensitive and specific approach for examining the upper gastrointestinal tract. In addition to permitting direct visualization of the mucosa, endoscopy facilitates photographic documentation of a mucosal defect and tissue biopsy to rule out malignancy (GU) or *H. pylori*. Endoscopic examination is particularly helpful in identifying lesions too small to detect by radiographic examination, for evaluation of atypical radiographic abnormalities, or to determine if an ulcer is a source of blood loss.

Although the methods for diagnosing *H. pylori* are outlined in Chap. 154, a brief summary will be included here (Table 285-5). PyloriTek, a biopsy urease test, has a sensitivity and specificity of >90 to 95%. In the interest of making a diagnosis of *H. pylori* without the need for performing endoscopy, several noninvasive methods for detecting this organism have been developed. Three types of studies routinely used include serologic testing, the^{13}C- or^{14}C-urea breath test, and the fecal *H. pylori* antigen test.

Occasionally, specialized testing such as serum gastrin and gastric acid analysis or sham feeding may be needed in individuals with complicated or refractoryPUD (see "Zollinger-Ellison Syndrome," below). Screening for aspirin orNSAIDS(blood or urine) may also be necessary in refractory, *H. pylori*-negative PUD patients.

TREATMENT

Before the discovery of *H. pylori*, the therapy ofPUDdisease was centered on the old dictum by Schwartz of "no acid, no ulcer." Although acid secretion is still important in the pathogenesis of PUD, eradication of *H. pylori* and therapy/prevention ofNSAID-induced disease is the mainstay. A summary of commonly used drugs for treatment of acid peptic disorders is shown in Table 285-6.

Acid Neutralizing/Inhibitory Drugs

Antacids Before we understood the important role of histamine in stimulating parietal cell activity, neutralization of secreted acid with antacids constituted the main form of therapy for peptic ulcers. They are now rarely, if ever, used as the primary therapeutic agent but instead are often used by patients for symptomatic relief of dyspepsia. The most commonly used agents are mixtures of aluminum hydroxide and magnesium hydroxide. Aluminum hydroxide can produce constipation and phosphate depletion; magnesium hydroxide may cause loose stools. Many of the commonly used antacids (e.g., Maalox, Mylanta) have a combination of both aluminum and magnesium hydroxide in order to avoid these side effects. The magnesium-containing preparation should not be used in chronic renal failure patients because of possible hypermagnesemia, and aluminum may cause chronic neurotoxicity in these patients.

Calcium carbonate and sodium bicarbonate are potent antacids with varying levels of potential problems. The long-term use of calcium carbonate (converts to calcium chloride in the stomach) can lead to milk-alkali syndrome (hypercalcemia, hyperphosphatemia with possible renal calcinosis and progression to renal insufficiency). Sodium bicarbonate may induce systemic alkalosis.

H_2Receptor antagonists Four of these agents are presently available (cimetidine, ranitidine, famotidine, and nizatidine), and their structures share homology with histamine (Fig. 285-9). Although each has different potency, all will significantly inhibit basal and stimulated acid secretion to comparable levels when used at therapeutic doses. Moreover, similar ulcer-healing rates are achieved with each drug when used at the correct dosage. Presently, this class of drug is often used for treatment of active ulcers (4 to 6 weeks) in combination with antibiotics directed at eradicating *H. pylori* (see below).

Cimetidine was the first H_2receptor antagonist used for the treatment of acid peptic disorders. The initial recommended dosing profile for cimetidine was 300 mg four times per day. Subsequent studies have documented the efficacy of using 800 mg at bedtime for treatment of active ulcer, with healing rates approaching 80% at 4 weeks. Cimetidine may have weak antiandrogenic side effects resulting in reversible gynecomastia and impotence, primarily in patients receiving high doses for prolonged periods of time (months to years, as inZES). In view of cimetidine's ability to inhibit cytochrome P450, careful monitoring of drugs such as warfarin, phenytoin, and theophylline is indicated with long-term usage. Other rare reversible adverse effects reported with cimetidine include confusion and elevated levels of serum aminotransferases, creatinine, and serum prolactin. Ranitidine, famotidine, and nizatidine are more potent H_2receptor antagonists than cimetidine. Each can be used once a day at bedtime. Comparable nighttime dosing regimens are ranitidine, 300 mg, famotidine, 40 mg, and nizatidine, 300 mg.

Additional rare, reversible systemic toxicities reported with H_2receptor antagonists include pancytopenia, neutropenia, anemia, and thrombocytopenia, with a prevalence rate varying from 0.01 to 0.2%. Cimetidine and rantidine (to a lesser extent) can bind to hepatic cytochrome P450, whereas the newer agents, famotidine and nizatidine, do not.

Proton pump (H^+,K^+-ATPase) inhibitors Omeprazole, lansoprazole, and the newest additions, rabeprazole and pantoprazole, are substituted benzimidazole derivatives that

covalently bind and irreversibly inhibit H^+,K^+-ATPase. These are the most potent acid inhibitory agents available. Omeprazole and lansoprazole are the proton pump inhibitors (PPIs) that have been used for the longest time. Both are acid labile and are administered as enteric-coated granules in a sustained-release capsule that dissolves within the small intestine at a pH of 6. These agents are lipophilic compounds; upon entering the parietal cell, they are protonated and trapped within the acid environment of the tubulovesicular and canalicular system. These agents potently inhibit all phases of gastric acid secretion. Onset of action is rapid, with a maximum acid inhibitory effect between 2 and 6 h after administration and duration of inhibition lasting up to 72 to 96 h. With repeated daily dosing, progressive acid inhibitory effects are observed, with basal and secretagogue-stimulated acid production being inhibited by >95% after 1 week of therapy. The half-life of PPIs is approximately 18 h, thus it can take between 2 and 5 days for gastric acid secretion to return to normal levels once these drugs have been discontinued. Because the pumps need to be activated for these agents to be effective, their efficacy is maximized if they are administered before a meal (e.g., in the morning before breakfast). Standard dosing for omeprazole and lansoprazole is 20 mg and 30 mg once per day, respectively. Mild to moderate hypergastrinemia has been observed in patients taking these drugs. Carcinoid tumors developed in some animals given the drugs preclinically; however, extensive experience has failed to demonstrate gastric carcinoid tumor development in humans. Serum gastrin levels return to normal levels within 1 to 2 weeks after drug cessation. As with any agent that leads to significant hypochlorhydria, PPIs may interfere with absorption of drugs such as ketoconazole, ampicillin, iron, and digoxin. Hepatic cytochrome P450 can be inhibited by these agents, but the overall clinical significance of this observation is not definitely established. Caution should be taken when using warfarin, diazepam, and phenytoin concomitantly with PPIs.

Cytoprotective Agents

Sucralfate Sucralfate is a complex sucrose salt in which the hydroxyl groups have been substituted by aluminum hydroxide and sulfate. This compound is insoluble in water and becomes a viscous paste within the stomach and duodenum, binding primarily to sites of active ulceration. Sucralfate may act by several mechanisms. In the gastric environment, aluminum hydroxide dissociates, leaving the polar sulfate anion, which can bind to positively charged tissue proteins found within the ulcer bed, and providing a physicochemical barrier impeding further tissue injury by acid and pepsin. Sucralfate may also induce a trophic effect by binding growth factors such asEGF, enhance prostaglandin synthesis, stimulate mucous and bicarbonate secretion, and enhance mucosal defense and repair. Toxicity from this drug is rare, with constipation being the most common one reported (2 to 3%). It should be avoided in patients with chronic renal insufficiency to prevent aluminum-induced neurotoxicity. Hypophosphatemia and gastric bezoar formation have also been rarely reported. Standard dosing of sucralfate is 1 g four times per day.

Bismuth-containing preparations Sir William Osler considered bismuth-containing compounds the drug of choice for treatingPUD. The resurgence in the use of these agents is due to their effect against *H. pylori*. Colloidal bismuth subcitrate (CBS) and bismuth subsalicylate (BSS, Pepto-Bismol) are the most widely used preparations. The mechanism by which these agents induce ulcer healing is unclear. Potential

mechanisms include ulcer coating; prevention of further pepsin/HCl-induced damage; binding of pepsin; and stimulation of prostaglandins, bicarbonate, and mucous secretion. Adverse effects with short-term usage are rare with bismuth compounds. Long-term usage with high doses, especially with the avidly absorbed CBS, may lead to neurotoxicity. These compounds are commonly used as one of the agents in an anti-*H. pylori* regimen (see below).

Prostaglandin analogues In view of their central role in maintaining mucosal integrity and repair, stable prostaglandin analogues were developed for the treatment ofPUD. The prostaglandin E_1derivative misoprostal is the only agent of this class approved by the U.S. Food and Drug Administration for clinical use in the prevention ofNSAID-induced gastroduodenal mucosal injury (see below). The mechanism by which this rapidly absorbed drug provides its therapeutic effect is through enhancement of mucosal defense and repair. Prostaglandin analogues enhance mucous bicarbonate secretion, stimulate mucosal blood flow, and decrease mucosal cell turnover. The most common toxicity noted with this drug is diarrhea (10 to 30% incidence). Other major toxicities include uterine bleeding and contractions; misoprostal is contraindicated in women who may be pregnant, and women of childbearing age must be made clearly aware of this potential drug toxicity. The standard therapeutic dose is 200 ug four times per day.

Miscellaneous drugs A number of drugs aimed at treating acid peptic disorders have been developed over the years. In view of their limited utilization in the United States, if any, they will only be listed briefly. Anticholinergics, designed to inhibit activation of the muscarinic receptor in parietal cells, met with limited success due to their relatively weak acid-inhibiting effect and significant side effects (dry eyes, dry mouth, urinary retention). Tricyclic antidepressants have been suggested by some, but again the toxicity of these agents in comparison to the safe, effective drugs already described, precludes their utility. Finally, the licorice extract carbenoxolone has aldosterone-like side effects with fluid retention and hypokalemia, making it an undesirable therapeutic option.

Therapy of *H. pylori* Extensive effort has been placed into determining who of the many individuals with *H. pylori* infection should be treated. The common conclusion arrived at by multiple consensus conferences (National Institutes of Health Consensus Development, American Digestive Health Foundation International Update Conference, European Maastricht Consensus, and Asia Pacific Consensus Conference) is that *H. pylori* should be eradicated in patients with documentedPUD. This holds true independent of time of presentation (first episode or not), severity of symptoms, presence of confounding factors such as ingestion ofNSAIDs, or whether the ulcer is in remission. Some have advocated treating patients with a history of documented PUD who are found to be *H. pylori*-positive by serology or breath testing. Over half of patients with gastricMALTlymphoma experience complete remission of the tumor in response to *H. pylori* eradication. Treating patients withNUD or to prevent gastric cancer remains controversial.

Multiple drugs have been evaluated in the therapy of *H. pylori*. No single agent is effective in eradicating the organism. Combination therapy for 14 days provides the greatest efficacy. A short-time course administration (7 to 10 days), although attractive,

has not proven as successful as the 14-day regimens. The agents used with the greatest frequency include amoxicillin, metronidazole, tetracycline, clarithromycin, and bismuth compounds.

The physician's goal in treatingPUD is to provide relief of symptoms (pain or dyspepsia), promote ulcer healing, and ultimately prevent ulcer recurrence and complications. The greatest impact of understanding the role of *H. pylori* in peptic disease has been the ability to prevent recurrence of what was often a recurring disease. Documented eradication of *H. pylori* in patients with PUD is associated with a dramatic decrease in ulcer recurrence to 4% (as compared to 59%) inGUpatients and 6% (compared to 67%) inDUpatients. Eradication of the organism may lead to diminished recurrent ulcer bleeding. The impact of its eradication on ulcer perforation is unclear.

Suggested treatment regimens for *H. pylori* are outlined in Table 285-7. Choice of a particular regimen will be influenced by several factors including efficacy, patient tolerance, existing antibiotic resistance, and cost of the drugs. The aim for initial eradication rates should be 85 to 90%. Dual therapy [PPIplus amoxicillin, PPI plus clarithromycin, ranitidine bismuth citrate (Tritec) plus clarithromycin] are not recommended in view of studies demonstrating eradication rates of <80 to 85%. The combination of bismuth, metronidazole, and tetracycline was the first triple regimen found effective against *H. pylori*. The combination of two antibiotics plus either a PPI, H_2blocker, or bismuth compound has comparable success rates. Addition of acid suppression assists in providing early symptom relief and may enhance bacterial eradication.

Triple therapy, although effective, has several drawbacks, including the potential for poor patient compliance and drug-induced side effects. Compliance is being addressed somewhat by simplifying the regimens so that patients can take the medications twice a day. Simpler (dual therapy) and shorter regimens (7 and 10 days) are not as effective as triple therapy for 14 days. Two anti-*H. pylori* regimens are available in prepackaged formulation: Prevpac (lansoprazole, clarithromycin, and amoxicillin) and Helidac (bismuth subsalicylate, tetracycline, and metronidazole). The contents of the Prevpac are to be taken twice per day for 14 days, whereas Helidac constituents are taken four times per day with an antisecretory agent (PPI or H_2blocker), also taken for at least 14 days.

Side effects have been reported in up to 20 to 30% of patients on triple therapy. Bismuth may cause black stools, constipation, or darkening of the tongue. The most feared complication with amoxicillin is pseudomembranous colitis, but this occurs in <1 to 2% of patients. Amoxicillin can also lead to antibiotic-associated diarrhea, nausea, vomiting, skin rash, and allergic reaction. Tetracycline has been reported to cause rashes and very rarely hepatotoxicity and anaphylaxis.

One important concern with treating patients who may not need treatment is the potential for development of antibiotic-resistant strains. The incidence and type of antibiotic-resistant *H. pylori* strains vary worldwide. Strains resistant to metronidazole, clarithromycin, amoxicillin, and tetracycline have been described, with the latter two being uncommon. Antibiotic-resistant strains are the most common cause for treatment failure in compliant patients. Unfortunately, in vitro resistance does not predict outcome

in patients. Culture and sensitivity testing of *H. pylori* is not performed routinely. Although resistance to metronidazole has been found in as many as 30% and 95% of isolates in North America and Asia, respectively, triple therapy is effective in eradicating the organism in >50% of patients infected with a resistant strain.

Failure of *H. pylori* eradication with triple therapy is usually due to infection with a resistant organism. Quadruple therapy (Table 285-7) where clarithromycin is substituted for metronidazole (or vice versa) should be the next step. If eradication is still not achieved in a compliant patient, then culture and sensitivity of the organism should be considered.

Reinfection after successful eradication of *H. pylori* is rare in the United States (<1%/year). If recurrent infection occurs within the first 6 months after completing therapy, the most likely explanation is recrudescence as opposed to reinfection, which occurs later in time.

Therapy ofNSAID-Related Gastric or Duodenal Injury Medical intervention for NSAID-related mucosal injury includes treatment of an active ulcer and prevention of future injury. Recommendations for the treatment and prevention of NSAID-related mucosal injury are in Table 285-8. Ideally the injurious agent should be stopped as the first step in the therapy of an active NSAID-induced ulcer. If that is possible, then treatment with one of the acid inhibitory agents (H_2blockers,PPIs) is indicated. Cessation of NSAIDs is not always possible because of the patient's severe underlying disease. Only PPIs can healGUs orDUs, independent of whether NSAIDs are discontinued.

Prevention ofNSAID-induced ulceration can be accomplished by misoprostol (200 ug qid) or aPPI. High-dose H_2blockers (famotidine, 40 mg bid) have also shown some promise. The use ofCOX-2-selective NSAIDs may also reduce injury to gastric mucosa. Two highly selective COX-2 inhibitors, celecoxib and rofecoxib, are 100 times more selective inhibitors of COX-2 than standard NSAIDs, leading to gastric or duodenal mucosal injury that is comparable to placebo. However, evaluation of possible drug toxicities, such as altered renal function and induction of thrombosis, requires more data.

Approach and Therapy: Summary Controversy continues regarding the best approach to the patient who presents with dyspepsia (Chap. 41). The discovery of *H. pylori* and its role in pathogenesis of ulcers has added a new variable to the equation. Previously, if a patient <50 presented with dyspepsia and without alarming signs or symptoms suggestive of an ulcer complication or malignancy, an empirical therapeutic trial with acid suppression was commonly recommended. Although this approach is practiced by some today, an approach presently gaining approval for the treatment of patients with dyspepsia is outlined in Fig. 285-10. The referral to a gastroenterologist is for the potential need of endoscopy and subsequent evaluation and treatment if the endoscopy is negative.

Once an ulcer (GU orDU) is documented, then the main issue at stake is whether *H. pylori* or anNSAID is involved. With *H. pylori* present, independent of the NSAID status, triple therapy is recommended for 14 days, followed by continued acid-suppressing drugs (H_2receptor antagonist orPPIs) for a total of 4 to 6 weeks. Selection of patients for

documentation of *H. pylori* eradication is an area of some debate. The test of choice for documenting eradication is the urea breath test (UBT). The stool antigen study may also hold promise for this purpose and should certainly be performed if UBT is not available. Serologic testing is not useful for the purpose of documenting eradication since antibody titers fall slowly and often do not become undetectable. Two approaches toward documentation of eradication exist: (1) test for eradication only in individuals with a complicated course or in individuals who are frail or with multisystem disease who would do poorly with an ulcer recurrence, and (2) test all patients for successful eradication. Some recommend that patients with complicated ulcer disease or who are frail should be treated with long-term acid suppression, thus making documentation of *H. pylori* eradication a moot point. In view of this discrepancy in practice, it would be best to discuss with the patient the different options available.

Several issues differentiate the approach to aGUversus aDU. GUs, especially of the body and fundus, have the potential of being malignant. Multiple biopsies of a GU should be taken initially; even if these are negative for neoplasm, repeat endoscopy to document healing at 8 to 12 weeks should be performed, with biopsy if the ulcer is still present. About 70% of GUs eventually found to be malignant undergo significant (usually incomplete) healing.

The majority (>90%) ofGUs andDUs heal with the conventional therapy outlined above. A GU that fails to heal after 12 weeks and a DU that doesn't heal after 8 weeks of therapy should be considered refractory. Once poor compliance and persistent *H. pylori* infection have been excluded,NSAIDuse, either inadvertent or surreptitious, must be excluded. In addition, cigarette smoking must be eliminated. For a GU, malignancy must be meticulously excluded. Next, consideration should be given to a gastric hypersecretory state, which can be excluded with gastric acid analysis. Although a subset of patients have gastric acid hypersecretion of unclear etiology as a contributing factor to refractory ulcers,ZESshould be excluded with a fasting gastrin or secretin stimulation test (see below). More than 90% of refractory ulcers (either DUs or GUs) heal after 8 weeks of treatment with higher doses ofPPI(omeprazole, 40 mg/d). This higher dose is also effective in maintaining remission. Surgical intervention may be a consideration at this point; however, other rare causes of refractory ulcers must be excluded before recommending surgery. Rare etiologies of refractory ulcers that may be diagnosed by gastric or duodenal biopsies include: ischemia, Crohn's disease, amyloidosis, sarcoidosis, lymphoma, eosinophilic gastroenteritis, or infection [cytomegalovirus (CMV), tuberculosis, or syphilis].

Surgical Therapy Surgical intervention inPUD can be viewed as being either elective, for treatment of medically refractory disease, or as urgent/emergent, for the treatment of an ulcer-related complication. Refractory ulcers are an exceedingly rare occurrence. Surgery is more often required for treatment of an ulcer-related complication. Gastrointestinal bleeding (Chap. 44), perforation, and gastric outlet obstruction are the three complications that may require surgical intervention.

Hemorrhage is the most common ulcer-related complication, occurring in ~15 to 25% of patients. Bleeding may occur in any age group but is most often seen in older patients (sixth decade or beyond). The majority of patients stop bleeding spontaneously, but in some, endoscopic therapy (Chap. 283) is necessary. Patients unresponsive or

refractory to endoscopic intervention will require surgery (~5% of transfusion-requiring patients).

Free peritoneal perforation occurs in ~2 to 3% ofDUpatients. As in the case of bleeding, up to 10% of these patients will not have antecedent ulcer symptoms. Concomitant bleeding may occur in up to 10% of patients with perforation, with mortality being increased substantially. Peptic ulcer can also penetrate into adjacent organs, especially with a posterior DU, which can penetrate into the pancreas, colon, liver, or biliary tree.

Pyloric channel ulcers orDUs can lead to gastric outlet obstruction in ~2 to 3% of patients. This can result from chronic scarring or from impaired motility due to inflammation and/or edema with pylorospasm. Patients may present with early satiety, nausea, vomiting of undigested food, and weight loss. Conservative management with nasogastric suction, intravenous hydration/nutrition, and antisecretory agents is indicated for 7 to 10 days with the hope that a functional obstruction will reverse. If a mechanical obstruction persists, endoscopic intervention with balloon dilation may be effective. Surgery should be considered if all else fails.

Specific Operations for Duodenal Ulcers Surgical treatment is designed to decrease gastric acid secretion. Operations most commonly performed include vagotomy and drainage (by pyloroplasty, gastroduodenostomy, or gastrojejunostomy), highly selective vagotomy (which does not require a drainage procedure), and vagotomy with antrectomy. The specific procedure performed is dictated by the underlying circumstances: elective vs. emergency, the degree and extent of duodenal ulceration, and the expertise of the surgeon.

Vagotomy is a component of each of these procedures and is aimed at decreasing acid secretion through ablating cholinergic input to the stomach. Unfortunately, both truncal and selective vagotomy (preserves the celiac and hepatic branches) result in gastric atony despite successful reduction of both basal acid output (BAO, decreased by 85%) and maximal acid output (MAO, decreased by 50%). Drainage procedure through pyloroplasty or gastroduodenostomy is required in an effort to compensate for the vagotomy-induced gastric motility disorder. To minimize gastric dysmotility, highly selective vagotomy (also known as parietal cell, super selective, and proximal vagotomy) was developed. Only the vagal fibers innervating the portion of the stomach that contains parietal cells is transected, thus leaving fibers important for regulating gastric motility intact. Although this procedure leads to an immediate decrease in both BAO and stimulated acid output, acid secretion recovers over time. By the end of the first postoperative year, basal and stimulated acid output are ~30 and 50%, respectively, of preoperative levels. Ulcer recurrence rates are higher with highly selective vagotomy, although the overall complication rates are lower (Table 285-9).

The procedure that provides the lowest rates of ulcer recurrence but has the highest complication rate is vagotomy (truncal or selective) in combination with antrectomy. Antrectomy is aimed at eliminating an additional stimulant of gastric acid secretion, gastrin. Gastrin originates from G cells found in the antrum. Two principal types of reanastomoses are used after antrectomy, gastroduodenostomy (Billroth I) or gastrojejunostomy (Billroth II) (Fig. 285-11). Although Billroth I is often preferred over II, severe duodenal inflammation or scarring may preclude its performance.

Of these procedures, highly selective vagotomy may be the one of choice in the elective setting, except in situations where ulcer recurrence rates are high (prepyloric ulcers and those refractory to H_2therapy). Selection of vagotomy and antrectomy may be more appropriate in these circumstances.

These procedures have been traditionally performed by standard laparotomy. The advent of laparoscopic surgery has led several surgical teams to successfully perform highly selective vagotomy, truncal vagotomy/pyloroplasty, and truncal vagotomy/antrectomy through this approach. An increase in the number of laparoscopic procedures for treatment ofPUD is expected.

Specific Operations for Gastric Ulcers The location and the presence of a concomitantDUdictate the operative procedure performed for aGU. Antrectomy (including the ulcer) with a Billroth I anastomosis is the treatment of choice for an antral ulcer. Vagotomy is performed only if a DU is present. Although ulcer excision with vagotomy and drainage procedure has been proposed, the higher incidence of ulcer recurrence makes this a less desirable approach. Ulcers located near the esophagogastric junction may require a more radical approach, a subtotal gastrectomy with a Roux-en-Y esophagogastrojejunostomy (Csende's procedure). A less aggressive approach including antrectomy, intraoperative ulcer biopsy, and vagotomy (Kelling-Madlener procedure) may be indicated in fragile patients with a high GU. Ulcer recurrence approaches 30% with this procedure.

Surgery-Related Complications Complications seen after surgery forPUD are related primarily to the extent of the anatomical modification performed. Minimal alteration (highly selective vagotomy) is associated with higher rates of ulcer recurrence and less gastrointestinal disturbance. More aggressive surgical procedures have a lower rate of ulcer recurrence but a greater incidence of gastrointestinal dysfunction. Overall, morbidity and mortality related to these procedures are quite low. Morbidity associated with vagotomy and antrectomy or pyloroplasty is £5%, with mortality ~1%. Highly selective vagotomy has lower morbidity and mortality rates of 1 and 0.3%, respectively.

In addition to the potential early consequences of any intraabdominal procedure (bleeding, infection, thromboembolism), gastroparesis, duodenal stump leak, and efferent loop obstruction can be observed.

Recurrent Ulceration The risk of ulcer recurrence is directly related to the procedure performed (Table 285-9). Ulcers that recur after partial gastric resection tend to develop at the anastomosis (stomal or marginal ulcer). Epigastric abdominal pain is the most frequent presenting complaint. Severity and duration of pain tend to be more progressive than observed withDUsbefore surgery.

Ulcers may recur for several reasons including incomplete vagotomy, retained antrum, and, less likely, persistent or recurrent *H. pylori* infection.ZESshould have been excluded preoperatively. More recently, surreptitious use ofNSAIDshas been found to be a reason for recurrent ulcers after surgery, especially if the initial procedure was done for an NSAID-induced ulcer. Once *H. pylori* and NSAIDs have been excluded as etiologic factors, the question of incomplete vagotomy or retained gastric antrum should

be explored. For the latter, fasting plasma gastrin levels should be determined. If elevated, retained antrum or ZES (see below) should be considered. A combination of acid secretory analysis and secretin stimulation (see below) can assist in this differential diagnosis. Incomplete vagotomy can be ruled out by gastric acid analysis coupled with sham feeding. In this test, gastric acid output is measured while the patient sees, smells, and chews a meal (without swallowing). The cephalic phase of gastric secretion, which is mediated by the vagus, is being assessed with this study. An increase in gastric acid output in response to sham feeding is evidence that the vagus nerve is intact.

Medical therapy with H_2blockers will heal postoperative ulceration in 70 to 90% of patients. The efficacy ofPPIs has not been fully assessed in this group, but one may anticipate greater rates of ulcer healing compared to those obtained with H_2blockers. Repeat operation (complete vagotomy, partial gastrectomy) may be required in a small subgroup of patients who have not responded to aggressive medical management.

Afferent Loop Syndromes Two types of afferent loop syndrome can occur in patients who have undergone partial gastric resection with Billroth II anastomosis. The most common of the two is bacterial overgrowth in the afferent limb secondary to stasis. Patients may experience postprandial abdominal pain, bloating, and diarrhea with concomitant malabsorption of fats and vitamin B_{12}. Cases refractory to antibiotics may require surgical revision of the loop. The less common afferent loop syndrome can present with severe abdominal pain and bloating that occur 20 to 60 min after meals. Pain is often followed by nausea and vomiting of bile-containing material. The pain and bloating may improve after emesis. The cause of this clinical picture is theorized to be incomplete drainage of bile and pancreatic secretions from an afferent loop that is partially obstructed. Cases refractory to dietary measures may need surgical revision.

Dumping Syndrome Dumping syndrome consists of a series of vasomotor and gastrointestinal signs and symptoms and occurs in patients who have undergone vagotomy and drainage (especially Billroth procedures). Two phases of dumping, early and late, can occur. Early dumping takes place 15 to 30 min after meals and consists of crampy abdominal discomfort, nausea, diarrhea, belching, tachycardia, palpitations, diaphoresis, light-headedness, and, rarely, syncope. These signs and symptoms arise from the rapid emptying of hyperosmolar gastric contents into the small intestine, resulting in a fluid shift into the gut lumen with plasma volume contraction and acute intestinal distention. Release of vasoactive gastrointestinal hormones (vasoactive intestinal polypeptide, neurotensin, motilin) is also theorized to play a role in early dumping.

The late phase of dumping typically occurs 90 min to 3 h after meals. Vasomotor symptoms (light-headedness, diaphoresis, palpitations, tachycardia, and syncope) predominate during this phase. This component of dumping is thought to be secondary to hypoglycemia from excessive insulin release.

Dumping syndrome is most noticeable after meals rich in simple carbohydrates (especially sucrose) and high osmolarity. Ingestion of large amounts of fluids may also contribute. Up to 50% of postvagotomy and drainage patients will experience dumping syndrome to some degree. Signs and symptoms often improve with time, but a severe

protracted picture can occur in up to 1% of patients.

Dietary modification is the cornerstone of therapy for patients with dumping syndrome. Small, multiple (six) meals devoid of simple carbohydrates coupled with elimination of liquids during meals is important. Antidiarrheals and anticholinergic agents are complimentary to diet. The somatostatin analogue octreotide has been successful in diet refractory cases. This drug is administered subcutaneously (50 ug tid), titrated according to clinical response. Recently a long-acting formulation has become available, but its use in dumping syndrome has not been examined.

Postvagotomy Diarrhea Up to 10% of patients may seek medical attention for the treatment of postvagotomy diarrhea. This complication is most commonly observed after truncal vagotomy. Patients may complain of intermittent diarrhea that occurs typically 1 to 2 h after meals. Occasionally the symptoms may be severe and relentless. This is due to a motility disorder from interruption of the vagal fibers supplying the luminal gut. Other contributing factors may include decreased absorption of nutrients (see below), increased excretion of bile acids, and release of luminal factors that promote secretion. Diphenoxylate or loperamide is often useful in symptom control. The bile salt-binding agent cholestyramine may be helpful in severe cases. Surgical reversal of a 10-cm segment of jejunum may yield a substantial improvement in bowel frequency in a subset of patients.

Bile Reflux Gastropathy A subset of post-partial gastrectomy patients will present with abdominal pain, early satiety, nausea, and vomiting, who have as the only finding mucosal erythema of the gastric remnant. Histologic examination of the gastric mucosa reveals minimal inflammation but the presence of epithelial cell injury. This clinical picture is categorized as bile or alkaline reflux gastropathy/gastritis. Although reflux of bile is implicated as the reason for this disorder, the mechanism is unknown. Prokinetic agents (cisapride, 10 to 20 mg before meals and at bedtime) and cholestyramine have been effective treatments. Cisapride may cause cardiac arrhythmias. Severe refractory symptoms may require using either nuclear scanning with ^{99m}Tc-HIDA, to document reflux, or an alkaline challenge test, where 0.1 *N* NaOH is infused into the stomach in an effort to reproduce the patient's symptoms. Surgical diversion of pancreaticobiliary secretions away from the gastric remnant with a Roux-en-Y gastrojejunostomy consisting of a long (50 to 60 cm) Roux limb has been used in severe cases. Bilious vomiting improves, but early satiety and bloating may persist in up to 50% of patients.

Maldigestion and Malabsorption Weight loss can be observed in up to 60% of patients after partial gastric resection. A significant component of this weight reduction is due to decreased oral intake. However, mild steatorrhea can also develop. Reasons for maldigestion/malabsorption include decreased gastric acid production, rapid gastric emptying, decreased food dispersion in the stomach, reduced luminal bile concentration, reduced pancreatic secretory response to feeding, and rapid intestinal transit.

Decreased serum vitamin B_{12} levels can be observed after partial gastrectomy. This is usually not due to deficiency of intrinsic factor (IF), since a minimal amount of parietal cells (source of IF) are removed during antrectomy. Reduced vitamin B_{12} may be due to competition for the vitamin by bacterial overgrowth or inability to split the vitamin from its

protein-bound source due to hypochlorhydria.

Iron-deficiency anemia may be a consequence of impaired absorption of dietary iron in patients with a Billroth II gastrojejunotomy. Absorption of iron salts is normal in these individuals; thus a favorable response to oral iron supplementation can be anticipated. Folate deficiency with concomitant anemia can also develop in these patients. This deficiency may be secondary to decreased absorption or diminished oral intake.

Malabsorption of vitamin D and calcium resulting in osteoporosis and osteomalacia is common after partial gastrectomy and gastrojejunostomy (Billroth II). Osteomalacia can occur as a late complication in up to 25% of post-partial gastrectomy patients. Bone fractures occur twice as commonly in men after gastric surgery as in a control population. It may take years before x-ray findings demonstrate diminished bone density. Elevated alkaline phosphatase, reduced serum calcium, bone pain, and pathologic fractures may be seen in patients with osteomalacia. The high incidence of these abnormalities in this subgroup of patients justifies treating them with vitamin D and calcium supplementation indefinitely. Therapy is especially important in females.

Gastric Adenocarcinoma The incidence of adenocarcinoma in the gastric stump is increased 15 years after resection. Some have reported a four- to fivefold increase in gastric cancer 20 to 25 years after resection. The pathogenesis is unclear but may involve alkaline reflux, bacterial proliferation, or hypochlorhydria. Endoscopic screening every other year may detect surgically treatable disease.

RELATED CONDITIONS

ZOLLINGER-ELLISON SYNDROME

Severe peptic ulcer diathesis secondary to gastric acid hypersecretion due to unregulated gastrin release from a non-b cell endocrine tumor (gastrinoma) defines the components of theZES. Initially, ZES was typified by aggressive and refractory ulceration in which total gastrectomy provided the only chance for enhancing survival. Today ZES can be cured by surgical resection in up to 30% of patients.

Epidemiology The incidence ofZESvaries from 0.1 to 1% of individuals presenting withPUD. Males are more commonly affected than females, and the majority of patients are diagnosed between ages 30 and 50. Gastrinomas are classified into sporadic tumors (more common) and those associated with multiple endocrine neoplasia (MEN) type I (see below).

Pathophysiology Hypergastremia originating from an autonomous neoplasm is the driving force responsible for the clinical manifestations inZES. Gastrin stimulates acid secretion through gastrin receptors on parietal cells and by inducing histamine release fromECLcells. Gastrin also has a trophic action on gastric epithelial cells. Longstanding hypergastrinemia leads to markedly increased gastric acid secretion through both parietal cell stimulation and increased parietal cell mass. The increased gastric acid output leads to the peptic ulcer diathesis, erosive esophagitis, and diarrhea.

Tumor Distribution Although early studies suggested that the vast majority of

gastrinomas occurred within the pancreas, a significant number of these lesions are extrapancreatic. Over 80% of these tumors are found within the hypothetical gastrinoma triangle (confluence of the cystic and common bile ducts superiorly, junction of the second and third portions of the duodenum inferiorly, and junction of the neck and body of the pancreas medially). Duodenal tumors constitute the most common nonpancreatic lesion; up to 50% of gastrinomas are found here. Less common extrapancreatic sites include stomach, bones, ovaries, heart, liver, and lymph nodes. More than 60% of tumors are considered malignant, with up to 30 to 50% of patients having multiple lesions or metastatic disease at presentation. Histologically, gastrin-producing cells appear well differentiated, expressing markers typically found in endocrine neoplasms (chromogranin, neuron-specific enolase).

Clinical Manifestations Gastric acid hypersecretion is responsible for the signs and symptoms observed in patients withZES. Peptic ulcer is the most common clinical manifestation, occurring in>90% of gastrinoma patients. Initial presentation and ulcer location (duodenal bulb) may be indistinguishable from commonPUD. Clinical situations that should create suspicion of gastrinoma are ulcers in unusual locations (second part of the duodenum and beyond), ulcers refractory to standard medical therapy, ulcer recurrence after acid-reducing surgery, or ulcers presenting with frank complications (bleeding, obstruction, and perforation). Symptoms of esophageal origin are present in up to two-thirds of patients with ZES, with a spectrum ranging from mild esophagitis to frank ulceration with stricture and Barrett's mucosa.

Diarrhea is the next most common clinical manifestation in up to 50% of patients. Although diarrhea often occurs concomitantly with acid peptic disease, it may also occur independent of an ulcer. Etiology of the diarrhea is multifactorial, resulting from marked volume overload to the small bowel, pancreatic enzyme inactivation by acid, and damage of the intestinal epithelial surface by acid. The epithelial damage can lead to a mild degree of maldigestion and malabsorption of nutrients. The diarrhea may also have a secretory component due to the direct stimulatory effect of gastrin on enterocytes or the cosecretion of additional hormones from the tumor, such as vasoactive intestinal peptide.

Gastrinomas can develop in the presence ofMEN I syndrome (Chap. 93) in approximately 25% of patients. This autosomal dominant disorder involves primarily three organ sites: the parathyroid glands (80 to 90%), pancreas (40 to 80%), and pituitary gland (30 to 60%). The genetic defect in MEN I is in the long arm of chromosome 11 (11q11-q13). In view of the stimulatory effect of calcium on gastric secretion, the hyperparathyroidism and hypercalcemia seen in MEN I patients may have a direct effect on ulcer disease. Resolution of hypercalcemia by parathyroidectomy reduces gastrin and gastric acid output in gastrinoma patients. An additional distinguishing feature inZESpatients with MEN I is the higher incidence of gastric carcinoid tumor development (as compared to patients with sporadic gastrinomas). Gastrinomas tend to be smaller, multiple, and located in the duodenal wall more often than is seen in patients with sporadic ZES. Establishing the diagnosis of MEN I is critical not only from the standpoint of providing genetic counseling to the patient and his or her family but also from the surgical approach recommended.

Diagnosis The first step in the evaluation of a patient suspected of havingZES is to

obtain a fasting gastrin level. A list of clinical scenarios that should arouse suspicion regarding this diagnosis is shown inTable 285-10. Fasting gastrin levels are usually<150 pg/mL. Virtually all gastrinoma patients will have a gastrin level >150 to 200 pg/mL. Measurement of fasting gastrin should be repeated to confirm the clinical suspicion.

Multiple processes can lead to an elevated fasting gastrin level (Table 285-11), with gastric hypochlorhydria or achlorhydria being the most frequent causes. Gastric acid induces feedback inhibition of gastrin release. A decrease in acid production will subsequently lead to failure of the feedback inhibitory pathway, resulting in net hypergastrinemia. Gastrin levels will thus be high in patients using antisecretory agents for the treatment of acid peptic disorders and dyspepsia. *H. pylori* infection can also cause hypergastrinemia.

The next step in establishing a biochemical diagnosis of gastrinoma is to assess acid secretion. Nothing further needs to be done if decreased acid output is observed. In contrast, normal or elevated gastric acid output suggests a need for additional tests. Gastric acid analysis is performed by placing a nasogastric tube in the stomach and drawing samples at 15-min intervals for 1 h during unstimulated or basal state (BAO), followed by continued sampling after administration of intravenous pentagastrin (MAO). Up to 90% of gastrinoma patients may have a BAO of³15 meq/h (normal <4 meq/h). Up to 12% of patients with commonPUD may have comparable levels of acid secretion. A BAO/MAO ratio>0.6 is highly suggestive ofZES, but a ratio <0.6 does not exclude the diagnosis.

Gastrin provocative tests have been developed in an effort to differentiate between the causes of hypergastrinemia and are especially helpful in patients with indeterminant acid secretory studies. The tests are the secretin stimulation test, the calcium infusion study, and a standard meal test. In each of these, a fasted patient has an indwelling intravenous catheter in place for serial blood sampling and an intravenous line in place for secretin or calcium infusion. The patient receives either secretion (intravenous bolus of 2 ug/kg) or calcium (calcium gluconate, 5 mg/kg body weight over 3 h) or is fed a meal. Blood is then drawn at predetermined intervals (10 min and 1 min before and at 2, 5, 10, 15, 20, and 30 min after injection for secretin stimulation and at 30-min intervals during the calcium infusion). The most sensitive and specific gastrin provocative test for the diagnosis of gastrinoma is the secretin study. An increase in gastrin of³200 pg within 15 min of secretin injection has a sensitivity and specificity of >90% forZES. The calcium infusion study is less sensitive and specific than the secretin test, with a rise of >400 pg/mL observed in ~80% of gastrinoma patients. The lower accuracy, coupled with it being a more cumbersome study with greater potential for adverse effects, makes calcium infusion less useful and therefore rarely, if ever, utilized. Rarely, one may observe increasedBAO and hypergastrinemia in a patient who in the past has been categorized as having G cell hyperplasia or hyperfunction. This set of findings may have been due to *H. pylori*. The standard meal test was devised to assist in making the diagnosis of G cell-related hyperactivity, by observing a dramatic increase in gastrin after a meal (>200%). This test is not useful in differentiating between G cell hyperfunction and ZES.

Tumor Localization Once the biochemical diagnosis of gastrinoma has been confirmed, the tumor must be located. Multiple imaging studies have been utilized in an

effort to enhance tumor localization (Table 285-12). The broad range of sensitivity is due to the variable success rates achieved by the different investigative groups. Endoscopic ultrasound (EUS) permits imaging of the pancreas with a high degree of resolution (<5 mm). This modality is particularly helpful in excluding small neoplasms within the pancreas and in assessing the presence of surrounding lymph nodes and vascular involvement. Several types of endocrine tumors express cell-surface receptors for somatostatin. This permits the localization of gastrinomas by measuring the uptake of the stable somatostatin analogue,^{111}In-pentriotide (*octreoscan*) with sensitivity and specificity rates of>75%.

Up to 50% of patients have metastatic disease at diagnosis. Success in controlling gastric acid hypersecretion has shifted the emphasis of therapy towards providing a surgical cure. Detecting the primary tumor and excluding metastatic disease are critical in view of this paradigm shift. Once a biochemical diagnosis has been confirmed, the patient should first undergo an abdominal computed tomographic scan, magnetic resonance imaging, or octreoscan (depending on availability) to exclude metastatic disease. Once metastatic disease has been excluded, an experienced endocrine surgeon may opt for exploratory laparotomy with intraoperative ultrasound or transillumination. In other centers, careful examination of the peripancreatic area withEUS, accompanied by endoscopic exploration of the duodenum for primary tumors, will be performed before surgery. Selective arterial secretin injection (SASI) may be a useful adjuvant for localizing tumors in a subset of patients.

TREATMENT

Treatment of functional endocrine tumors is directed at ameliorating the signs and symptoms related to hormone overproduction, curative resection of the neoplasm, and attempts to control tumor growth in metastatic disease.

PPIsare the treatment of choice and have decreased the need for total gastrectomy. Initial doses of omeprazole or lansoprazole should be in the range of 60 mg/d. Dosing can be adjusted to achieve aBAO<10 meq/h (at the drug trough) in surgery-naive patients and to <5 meq/h in individuals who have previously undergone an acid-reducing operation. Although the somatostatin analogue has inhibitory effects on gastrin release from receptor-bearing tumors and inhibits gastric acid secretion to some extent, PPIs have the advantage of reducing parietal cell activity to a greater degree.

The ultimate goal of surgery would be to provide a definitive cure. Improved understanding of tumor distribution has led to 10-year disease-free intervals as high as 34% in sporadic gastrinoma patients undergoing surgery. A positive outcome is highly dependent on the experience of the surgical team treating these rare tumors. Surgical therapy of gastrinoma patients withMEN I remains controversial because of the difficulty in rendering these patients disease free with surgery. In contrast to the encouraging postoperative results observed in patients with sporadic disease, only 6% of MEN I patients are disease free 5 years after an operation. Some groups suggest surgery only if a clearly identifiable, nonmetastatic lesion is documented by structural studies. Others advocate a more aggressive approach, where all patients free of hepatic metastasis are explored and all detected tumors in the duodenum are resected; this is followed by enucleation of lesions in the pancreatic head, with a distal pancreatectomy to follow.

The outcome of the two approaches has not been clearly defined.

Therapy of metastatic endocrine tumors in general remains suboptimal; gastrinomas are no exception. A host of medical therapeutic approaches including chemotherapy (streptozotocin, 5-fluorouracil, and doxorubicin),IFN-a, and hepatic artery embolization lead to significant toxicity without a substantial improvement in overall survival. Surgical approaches including debulking surgery and liver transplantation for hepatic metastasis have also produced limited benefit. Therefore, early recognition and surgery are the only chances for curing this disease.

The 5- and 10-year survival rates for gastrinoma patients are 62 to 75% and 47 to 53%, respectively. Individuals with the entire tumor resected or those with a negative laparotomy have 5- and 10-year survival rates>90%. Patients with incompletely resected tumors have 5- and 10-year survival of 43% and 25%, respectively. Patients with hepatic metastasis have <20% survival at 5 years. Favorable prognostic indicators include primary duodenal wall tumors, isolated lymph node tumor, and undetectable tumor upon surgical exploration. Poor prognostic indicators include hepatic metastases or the presence of Cushing's syndrome in a sporadic gastrinoma patient.

STRESS-RELATED MUCOSAL INJURY

Patients suffering from shock, sepsis, massive burns, severe trauma, or head injury can develop acute erosive gastric mucosal changes or frank ulceration with bleeding. Classified as stress-induced gastritis or ulcers, injury is most commonly observed in the acid-producing (fundus and body) portions of the stomach. The most common presentation is gastrointestinal bleeding, which is usually minimal but can occasionally be life-threatening. Respiratory failure requiring mechanical ventilation and underlying coagulopathy are risk factors for bleeding, which tends to occur 48 to 72 h after the acute injury or insult.

Histologically, stress injury does not contain inflammation or *H. pylori*; thus "gastritis" is a misnomer. Although elevated gastric acid secretion may be noted in patients with stress ulceration after head trauma (Cushing's ulcer) and severe burns (Curling's ulcer), mucosal ischemia and breakdown of the normal protective barriers of the stomach also play an important role in the pathogenesis. Acid must contribute to injury in view of the significant drop in bleeding noted when acid inhibitors are used as a prophylactic measure for stress gastritis.

Improvement in the general management of intensive care unit patients has led to a significant decrease in the incidence of gastrointestinal bleeding due to stress ulceration. The estimated decrease in bleeding is from 20 to 30% to<15%. This improvement has led to some debate regarding the need for prophylactic therapy. The limited benefit of medical (endoscopic, angiographic) and surgical therapy in a patient with hemodynamically compromising bleeding associated with stress ulcer/gastritis supports the use of preventive measures in high-risk patients (mechanically ventilated, coagulopathy, multiorgan failure, or severe burns). Maintenance of gastric pH >3.5 with continuous infusion of H_2blockers or liquid antacids administered every 2 to 3 h are viable options. Sucralfate slurry (1 g every 4 to 6 h) has also been successful. If bleeding occurs despite these measures, endoscopy, intraarterial vasopressin, or

embolization are options. If all else fails, then surgery should be considered. Although vagotomy and antrectomy may be used, the better approach would be a total gastrectomy, which has an exceedingly high mortality rate in this setting.

GASTRITIS

The term *gastritis* should be reserved for histologically documented inflammation of the gastric mucosa. Gastritis is *not* the mucosal erythema seen during endoscopy and is *not* interchangeable with "dyspepsia." The etiologic factors leading to gastritis are broad and heterogeneous. Gastritis has been classified based on time course (acute vs. chronic), histologic features, and anatomic distribution or proposed pathogenic mechanism (Table 285-13).

The correlation between the histologic findings of gastritis, the clinical picture of abdominal pain or dyspepsia, and endoscopic findings noted on gross inspection of the gastric mucosa is poor. Therefore, there is no typical clinical manifestation of gastritis.

Acute Gastritis The most common causes of acute gastritis are infectious. Acute infection with *H. pylori* induces gastritis. However, *H. pylori* acute gastritis has not been extensively studied. Reported as presenting with sudden onset of epigastric pain, nausea, and vomiting, limited mucosal histologic studies demonstrate a marked infiltrate of neutrophils with edema and hyperemia. If not treated, this picture will evolve into one of chronic gastritis. Hypochlorhydria lasting for up to 1 year may follow acute *H. pylori* infection.

The highly acidic gastric environment may be one reason why infectious processes of the stomach are rare. Bacterial infection of the stomach or phlegmonous gastritis is a rare potentially life-threatening disorder, characterized by marked and diffuse acute inflammatory infiltrates of the entire gastric wall, at times accompanied by necrosis. Elderly individuals, alcoholics, and AIDS patients may be affected. Potential iatrogenic causes include polypectomy and mucosal injection with India ink. Organisms associated with this entity include streptococci, staphylococci, *Escherichia coli*, *Proteus*, and *Haemophilus*. Failure of supportive measures and antibiotics may result in gastrectomy.

Other types of infectious gastritis may occur in immunocompromised individuals such as AIDS patients. Examples include herpetic (herpes simplex) orCMVgastritis. The histologic finding of intranuclear inclusions would be observed in the latter.

Chronic Gastritis Chronic gastritis is identified histologically by an inflammatory cell infiltrate consisting primarily of lymphocytes and plasma cells, with very scant neutrophil involvement. Distribution of the inflammation may be patchy, initially involving superficial and glandular portions of the gastric mucosa. This picture may progress to more severe glandular destruction, with atrophy and metaplasia. Chronic gastritis has been classified according to histologic characteristics. These include superficial atrophic changes and gastric atrophy.

The early phase of chronic gastritis is *superficial gastritis*. The inflammatory changes are limited to the lamina propria of the surface mucosa, with edema and cellular infiltrates separating intact gastric glands. Additional findings may include decreased

mucus in the mucous cells and decreased mitotic figures in the glandular cells. The next stage is *atrophic gastritis*. The inflammatory infiltrate extends deeper into the mucosa, with progressive distortion and destruction of the glands. The final stage of chronic gastritis is *gastric atrophy*. Glandular structures are lost; there is a paucity of inflammatory infiltrates. Endoscopically the mucosa may be substantially thin, permitting clear visualization of the underlying blood vessels.

Gastric glands may undergo morphologic transformation in chronic gastritis. Intestinal metaplasia denotes the conversion of gastric glands to a small intestinal phenotype with small-bowel mucosal glands containing goblet cells. The metaplastic changes may vary in distribution from patchy to fairly extensive gastric involvement. Intestinal metaplasia is an important predisposing factor for gastric cancer (Chap. 90).

Chronic gastritis is also classified according to the predominant site of involvement. Type A refers to the body-predominant form (autoimmune) and type B is the central-predominant form (*H. pylori*-related). This classification is artificial in view of the difficulty in distinguishing these two entities. The term *AB gastritis* has been used to refer to a mixed antral/body picture.

Type A Gastritis The less common of the two forms involves primarily the fundus and body, with antral sparing. Traditionally, this form of gastritis has been associated with pernicious anemia (Chap. 107) in the presence of circulating antibodies against parietal cells and intrinsic factor; thus it is also called *autoimmune gastritis*. *H. pylori* infection can lead to a similar distribution of gastritis. The characteristics of an autoimmune picture are not always present.

Antibodies to parietal cells have been detected in >90% of patients with pernicious anemia and in up to 50% of patients with type A gastritis. Anti-parietal cell antibodies are cytotoxic for gastric mucous cells. The parietal cell antibody is directed against H^+,K^+-ATPase. T cells are also implicated in the injury pattern of this form of gastritis.

Parietal cell antibodies and atrophic gastritis are observed in family members of patients with pernicious anemia. These antibodies are observed in up to 20% of individuals over age 60 and in ~20% of patients with vitiligo and Addison's disease. About half of patients with pernicious anemia have antibodies to thyroid antigens, and about 30% of patients with thyroid disease have circulating anti-parietal cell antibodies. Anti-intrinsic factor antibodies are more specific than parietal cell antibodies for type A gastritis, being present in ~40% of patients with pernicious anemia. Another parameter consistent with this form of gastritis being autoimmune in origin is the higher incidence of specific familial histocompatibility haplotypes such as HLA-B8 and -DR3.

The parietal cell-containing gastric gland is preferentially targeted in this form of gastritis, and achlorhydria results. Parietal cells are the source of intrinsic factor, lack of which will lead to vitamin B_{12}deficiency and its sequelae (megaloblastic anemia, neurologic dysfunction).

Gastric acid plays an important role in feedback inhibition of gastrin release from G cells. Achlorhydria, coupled with relative sparing of the antral mucosa (site of G cells), leads to hypergastrinemia. Gastrin levels can be markedly elevated (>500 pg/mL) in

patients with pernicious anemia.ECL cell hyperplasia with frank development of gastric carcinoid tumors may result from gastrin trophic effects. The role of gastrin in carcinoid development is confirmed by the observation that antrectomy leads to regression of these lesions. Hypergastrinemia and achlorhydria may also be seen in non-pernicious anemia-associated type A gastritis.

Type B gastritis Type B, or antral-predominant, gastritis is the more common form of chronic gastritis. *H. pylori* infection is the cause of this entity. Although described as "antral-predominant," this is likely a misnomer in view of studies documenting the progression of the inflammatory process towards the body and fundus of infected individuals. The conversion to a pan-gastritis is time-dependent -- estimated to require 15 to 20 years. This form of gastritis increases with age, being present in up to 100% of people over age 70. Histology improves after *H. pylori* eradication. The number of *H. pylori* organisms decreases dramatically with progression to gastric atrophy, and the degree of inflammation correlates with the level of these organisms. Early on, with antral-predominant findings, the quantity of *H. pylori* is highest and a dense chronic inflammatory infiltrate of the lamina propria is noted accompanied by epithelial cell infiltration with polymorphonuclear leukocytes (Fig. 285-12).

Multifocal atrophic gastritis, gastric atrophy with subsequent metaplasia, has been observed in chronic *H. pylori*-induced gastritis. This may ultimately lead to development of gastric adenocarcinoma (Fig. 285-13;Chap. 90). *H. pylori* infection is now considered an independent risk factor for gastric cancer. Worldwide epidemiologic studies have documented a higher incidence of *H. pylori* infection in patients with adenocarcinoma of the stomach as compared to control subjects. Seropositivity for *H. pylori* is associated with a three- to sixfold increased risk of gastric cancer. This risk may be as high as ninefold after adjusting for the inaccuracy of serologic testing in the elderly. The mechanism by which *H. pylori* infection leads to cancer is unknown. However, eradication of *H. pylori* as a general preventative measure for gastric cancer is not recommended.

Infection with *H. pylori* is also associated with development of a low grade B cell lymphoma, gastricMALTlymphoma (Chap. 112). The chronic T cell stimulation caused by the infection leads to production of cytokines that promote the B cell tumor. Tumor growth remains dependent upon the presence of *H. pylori* in that its eradication is often associated with complete regression of the tumor. The tumor may take more than a year to regress after treating the infection. Such patients should be followed byEUSevery 2 to 3 months. If the tumor is stable or decreasing in size, no other therapy is necessary. If the tumor grows, it may have become a high-grade B cell lymphoma. When the tumor becomes a high-grade aggressive lymphoma histologically, it loses responsiveness to *H. pylori* eradication.

TREATMENT

Treatment in chronic gastritis is aimed at the sequelae and not the underlying inflammation. Patients with pernicious anemia will require parenteral vitamin B_{12}supplementation on a long-term basis. Eradication of *H. pylori* is not routinely recommended unlessPUD or a low-gradeMALTlymphoma is present.

Miscellaneous Forms of Gastritis *Lymphocytic gastritis* is characterized histologically by intense infiltration of the surface epithelium with lymphocytes. The infiltrative process is primarily in the body of the stomach and consists of mature T cells and plasmacytes. The etiology of this form of chronic gastritis is unknown. It has been described in patients with celiac sprue, but whether there is a common factor associating these two entities is unknown. No specific symptoms suggest lymphocytic gastritis. A subgroup of patients has thickened folds noted on endoscopy. These folds are often capped by small nodules that contain a central depression or erosion; this form of the disease is called *varioliform gastritis*. *H. pylori* probably plays no significant role in lymphocytic gastritis. Therapy with glucocorticoids or sodium cromoglycate has obtained unclear results.

Marked eosinophilic infiltration involving any layer of the stomach (mucosa, muscularis propria, and serosa) is characteristic of *eosinophilic gastritis*. Affected individuals will often have circulating eosinophilia with clinical manifestation of systemic allergy. Involvement may range from isolated gastric disease to diffuse eosinophilic gastroenteritis. Antral involvement predominates, with prominent edematous folds being observed on endoscopy. These prominent antral folds can lead to outlet obstruction. Patients can present with epigastric discomfort, nausea, and vomiting. Treatment with glucocorticoids has been successful.

Several systemic disorders may be associated with *granulomatous gastritis*. Gastric involvement has been observed in Crohn's disease. Involvement may range from granulomatous infiltrates noted only on gastric biopsies to frank ulceration and stricture formation. Gastric Crohn's disease usually occurs in the presence of small-intestinal disease. Several rare infectious processes can lead to granulomatous gastritis, including histoplasmosis, candidiasis, syphilis, and tuberculosis. Other unusual causes of this form of gastritis include sarcoidosis, idiopathic granulomatous gastritis, and eosinophilic granulomas involving the stomach. Establishing the specific etiologic agent in this form of gastritis can be difficult, at times requiring repeat endoscopy with biopsy and cytology. Occasionally, a surgically obtained full-thickness biopsy of the stomach may be required to exclude malignancy.

MENETRIER'S DISEASE

Menetrier's disease is a rare entity characterized by large, tortuous gastric mucosal folds. The differential diagnosis of large gastric folds includesZES, malignancy, infectious etiologies (CMV, histoplasmosis, syphilis), and infiltrative disorders such as sarcoidosis. The mucosal folds in Menetrier's disease are often most prominent in the body and fundus. Histologically, massive foveolar hyperplasia (hyperplasia of surface and glandular mucous cells) is noted, which replaces most of the chief and parietal cells. This hyperplasia produces the prominent folds observed. The pits of the gastric glands elongate and may become extremely tortuous. Although the lamina propria may contain a mild chronic inflammatory infiltrate, Menetrier's disease is *not* considered a form of gastritis. The etiology of this unusual clinical picture is unknown. Overexpression of growth factors such asTGF-amay be involved in the process.

Epigastric pain at times accompanied by nausea, vomiting, anorexia, and weight loss are signs and symptoms in patients with Menetrier's disease. Occult gastrointestinal

bleeding may occur, but overt bleeding is unusual and, when present, is due to superficial mucosal erosions. Between 20 and 100% of patients (depending on time of presentation) develop a protein-losing gastropathy accompanied by hypoalbuminemia and edema. Gastric acid secretion is usually reduced or absent because of the replacement of parietal cells. Large gastric folds are readily detectable by either radiographic (barium meal) or endoscopic methods. Endoscopy with deep mucosal biopsy (and cytology) is required to establish the diagnosis and exclude the other entities that may present in a similar manner. A nondiagnostic biopsy may lead to a surgically obtained full-thickness biopsy to exclude malignancy.

TREATMENT

Medical therapy with anticholinergic agents, prostaglandins,PPIs, prednisone, and H_2receptor antagonists has obtained varying results. Anticholinergics decrease protein loss. A high-protein diet should be recommended to replace protein loss in patients with hypoalbuminemia. Ulcers should be treated with a standard approach. Severe disease with persistent and substantial protein loss may require total gastrectomy. Subtotal gastrectomy is performed by some; it may be associated with higher morbidity and mortality secondary to the difficulty in obtaining a patent and long-lasting anastomosis between normal and hyperplastic tissues.

ACKNOWLEDGEMENT

The author acknowledges the contribution of material to this chapter by Dr. Lawrence Friedman and Dr. Walter Peterson from their chapter on this subject in the 14th edition and is grateful to Pamela Glazer for typing this manuscript.

286. DISORDERS OF ABSORPTION - *Henry J. Binder*

Disorders of absorption represent a broad spectrum of conditions with multiple etiologies and varied clinical manifestations. Almost all of these clinical problems are associated with *diminished* intestinal absorption of one or more dietary nutrients and are often referred to as the *malabsorption syndrome*. This latter term is not ideal as it represents a pathophysiologic state, does *not* provide an etiologic explanation for the underlying problem, and should not be considered an adequate final diagnosis. The only clinical situations in which absorption is *increased* are hemochromatosis and Wilson's disease, in which there is increased absorption of iron and copper, respectively.

Most, but not all, of these clinical conditions are associated with *steatorrhea*, an increase in stool fat excretion of >6% of dietary fat intake. Some disorders of absorption are not associated with steatorrhea: Primary lactase deficiency, which represents a congenital absence of the small intestinal brush border disaccharidase enzyme lactase, is only associated with lactose "malabsorption," and pernicious anemia is associated with a marked decrease in intestinal absorption of cobalamin (vitamin B_{12}) due to an absence of gastric parietal cell intrinsic factor required for cobalamin absorption.

Disorders of absorption must be included in the differential diagnosis of diarrhea (Chap. 42) for several reasons. First, diarrhea is frequently associated with and/or is a consequence of the diminished absorption of one or more dietary nutrients. The diarrhea may be secondary either to the intestinal process that is responsible for the steatorrhea or to steatorrhea per se. Thus, celiac sprue (see below) is associated with both extensive morphologic changes in the small intestinal mucosa and reduced absorption of several dietary nutrients; in contrast, the diarrhea of steatorrhea is the result of the effect of nonabsorbed dietary fatty acids on intestinal, usually colonic, ion transport. For example, oleic acid and ricinoleic acid (a bacterially hydroxylated fatty acid that is also the active ingredient in castor oil, a widely used laxative) induce active colonic Cl secretion, most likely secondary to increasing intracellular Ca. In addition, diarrhea per se may result in mild steatorrhea (<11 g fat excretion while on a 100-g fat diet). Second, as diarrhea is both a symptom and a sign, most patients will indicate that they have diarrhea, not that they have fat malabsorption. Third, many intestinal disorders that have diarrhea as a prominent symptom (e.g., ulcerative colitis, traveler's diarrhea secondary to an enterotoxin produced by *Escherichia coli*) do not necessarily have diminished absorption of any dietary nutrient.

Diarrhea as a *symptom* (i.e., when used by patients to describe their bowel movement pattern) may be either a decrease in stool consistency, an increase in stool volume, an increase in number of bowel movements, or any combination of these three changes. In contrast, diarrhea as a *sign* is a quantitative increase in stool water or weight of >200 to 225 mL, or g per 24 h, when a western-type diet is consumed. Individuals consuming a diet with a higher fiber content may normally have a stool weight of up to 400 g/24 h. Thus, it is essential that the clinician clarify what an individual patient means by diarrhea, especially since 10% of patients referred to gastroenterologists for further evaluation of unexplained diarrhea do not have an increase in stool water when it is determined quantitatively. Such patients may have small, frequent, somewhat loose bowel movements with stool urgency that is indicative of proctitis but do not have an increase in stool weight or volume.

It is also critical to establish whether a patient's diarrhea is secondary to diminished absorption of one or more dietary nutrients, in contrast to diarrhea that is due to small- and/or large-intestinal fluid and electrolyte secretion. The former has often been termed *osmotic diarrhea*, while the latter has been referred to as *secretory diarrhea*. Unfortunately, as there can be both secretory and osmotic elements present simultaneously in the same disorder, this separation is not always precise. Nonetheless, two studies, determination of stool electrolytes, and observation of the effect of a fast on stool output can help make this distinction.

The demonstration of the effect of prolonged (>24 h) fasting on stool output can be very effective in suggesting that a *dietary nutrient* is responsible for the individual's diarrhea. A secretory diarrhea associated with enterotoxin-induced traveler's diarrhea would not be affected by prolonged fasting, as enterotoxin-induced stimulation of intestinal fluid and electrolyte secretion is not altered by eating. In contrast, diarrhea secondary to lactose malabsorption in primary lactase deficiency would undoubtedly cease during a prolonged fast. Thus, a substantial decrease in stool output while fasting during a quantitative stool collection of at least 24 h is presumptive evidence that the diarrhea is related to malabsorption of a dietary nutrient. The persistence of stool output while fasting indicates the likelihood that the diarrhea is secretory and that the cause of diarrhea is *not* due to a dietary nutrient. Either a luminal (e.g., *E. coli* enterotoxin) or circulating (e.g., vasoactive intestinal peptide) secretogogue could be responsible for the patient's diarrhea persisting unaltered during a prolonged fast. The observed effects of fasting can be compared and correlated with stool electrolyte and osmolality determinations.

Measurement of stool electrolytes and osmolality requires the comparison of stool Na^+ and K^+concentrations determined in liquid stool to the stool osmolality to determine the presence or absence of a so-called stool osmotic gap. The following formula is used:

The cation concentrations are doubled to estimate stool anion concentrations. The presence of a significant osmotic gap suggests the presence in stool water of a substance(s) other than Na/K/anions that presumably is responsible for the patient's diarrhea. Originally, stool osmolality was measured, but it is almost invariably greater than the required 290 to 300 mosmol/kg H_2O, reflecting bacterial degradation of nonabsorbed carbohydrate either immediately before defecation or in the stool jar while awaiting chemical analysis, even when the stool is refrigerated. As a result, the stool osmolality should be assumed to be 300 mosmol/kg H_2O. When the calculated difference is >50, an osmotic gap is present, suggesting that the diarrhea is due to a nonabsorbed dietary nutrient, e.g., a fatty acid and/or carbohydrate. When this difference is<25 to 50, it is presumed that a dietary nutrient is not responsible for the diarrhea. Since elements of both osmotic (i.e., malabsorption of a dietary nutrient) and secretory diarrhea may be present simultaneously, this separation at times is less clear-cut at the bedside than when used as a teaching example. Ideally, the presence of an osmotic gap will be associated with a marked decrease in stool output during a prolonged fast, while the absence of an osmotic gap will likely be present in an individual whose stool output had not been reduced substantially during a period of

fasting.

NUTRIENT DIGESTION AND ABSORPTION

The lengths of the small intestine and colon are ~300 cm and ~80 cm, respectively. However, the effective functional surface area is approximately 600-fold greater than that of a hollow tube as a result of the presence of folds, villi (in the small intestine), and microvilli. The functional surface area of the small intestine is somewhat greater than that of a doubles tennis court. In addition to nutrient digestion and absorption, the intestinal epithelia have several other functions:

1. *Barrier and immune defense*. The intestine is exposed to a large number of potential antigens, enteric and invasive microorganisms, and is extremely effective preventing the entry of almost all these agents. The intestinal mucosa also synthesizes and secretes secretory IgA globulin.

2. *Fluid and electrolyte absorption and secretion*. The intestine absorbs approximately 7 to 8 L of fluid daily, comprising dietary fluid intake (1 to 2 L/d) and salivary, gastric, pancreatic, biliary, and intestinal fluid (6 to 7 L/d). The intestine also responds to several stimuli, especially bacteria and bacterial enterotoxins, that induce fluid and electrolyte secretion, often leading to diarrhea (Chap. 131).

3. *Synthesis and secretion of several proteins*. The intestinal mucosa is a major site for the production of proteins, including apolipoproteins.

4. *Production of several bioactive amines and peptides*. The intestine presents one of the largest endocrine organs in the body and produces several amines and peptides that serve as paracrine and hormonal mediators of intestinal function.

The small and large intestine are anatomically distinct in that villi are present in the small intestine but are absent in the colon and functionally distinct in that nutrient digestion and absorption take place in the small intestine but not in the colon. No precise anatomic characteristics separate duodenum, jejunum, and ileum, although certain nutrients are absorbed exclusively in specific areas of the small intestine. However, villus cells in the small intestine (and surface epithelial cells in the colon) and crypt cells have distinct anatomic and functional characteristics. Intestinal epithelial cells are continuously renewed, with new proliferating epithelial cells at the base of the crypt migrating over 48 to 72 h to the tip of the villus (or surface of the colon), where they are well-developed epithelial cells with digestive and absorptive function. This high rate of cell turnover explains the relatively rapid resolution of diarrhea and other digestive tract side effects during chemotherapy as new cells not exposed to these toxic agents are produced. Equally important is the paradigm of separation of villus/surface cell and crypt cell function: digestive hydrolytic enzymes are present primarily in the brush border of villus epithelial cells. Absorptive and secretory functions are also separated, with villus/surface cells largely being the site for absorptive function, while secretory function is present in crypts of both the small and large intestine.

Nutrients, minerals, and vitamins are absorbed by one or more active transport mechanisms. (The mechanisms of intestinal fluid and electrolyte absorption and

secretion are discussed inChap. 42.) Active transport mechanisms are energy-dependent and mediated by membrane transport proteins. These transport processes will result in the *net* movement of a substance against or in the absence of an electrochemical concentration gradient. Intestinal absorption of amino acids and monosaccharides, e.g., glucose, is also a specialized form of active transport -- *secondary active transport*. The movement of these actively transported nutrients against a concentration gradient is Na^+-dependent and is due to a Na^+gradient across the apical membrane. The Na^+gradient is maintained by Na^+,K^+-ATPase, the so-called Na^+ pump located on the basolateral membrane, which extrudes Na^+ and maintains a low intracellular [Na] as well as the Na^+gradient across the apical membrane. As a result, active glucose absorption and glucose-stimulated Na^+absorption require both the apical membrane transport protein, SGLT, and the basolateral Na^+,K^+-ATPase. In addition to glucose absorption being Na^+-dependent, glucose also stimulates Na^+ and fluid absorption, which is the physiologic basis of oral rehydration therapy for the treatment of diarrhea (Chap. 42).

Although the intestinal epithelial cells are crucial mediators of absorption and ion and water flow, the several cell types in the lamina propria (e.g., mast cells, macrophages, myofibroblasts) and the enteric nervous system interact with the epithelium to regulate mucosal cell function. The function of the intestine is the result of the integrated responses of and interactions between both intestinal epithelial cells and intestinal muscle.

ENTEROHEPATIC CIRCULATION OF BILE ACIDS

Bile acids are not present in the diet but are synthesized in the liver by a series of enzymatic steps that also represent cholesterol catabolism. Indeed, interruption of the enterohepatic circulation of bile acids can reduce serum cholesterol levels by 10% before a new steady state is established. Bile acids are either primary or secondary: primary bile acids are synthesized in the liver from cholesterol, and secondary bile acids are synthesized from primary bile acids in the intestine by colonic bacterial enzymes. The two primary bile acids are cholic acid and chenodeoxycholic acid; the two most abundant secondary bile acids are deoxycholic acid and lithocholic acid. Approximately 500 mg bile acids are synthesized in the liver daily, conjugated to either taurine or glycine to form tauro-conjugated or glyco-conjugated bile acids, respectively, that are secreted into the duodenum in bile. The primary functions of bile acids are (1) to promote bile flow, (2) to solubilize cholesterol and phospholipid in the gall bladder by mixed micelle formation, and (3) to enhance dietary lipid digestion and absorption by forming mixed micelles in the proximal small intestine.

Bile acids are primarily absorbed by an active, Na^+-dependent process that is located exclusively in the ileum, though bile acids can also be absorbed to a lesser extent by non-carrier-mediated transport processes in the jejunum, ileum, and colon. Conjugated bile acids that enter the colon are deconjugated by colonic bacterial enzymes to unconjugated bile acids and are rapidly absorbed. Colonic bacterial enzymes also dehydroxylate bile acids to secondary bile acids.

Bile acids absorbed from the intestine return to the liver via the portal vein where they are resecreted (Fig. 286-1). Bile acid synthesis is largely autoregulated by

7a-hydroxylase, the initial enzyme in cholesterol degradation. A decrease in the amount of bile acids returning to the liver from the intestine is associated with an increase in bile acid synthesis/cholesterol catabolism, which helps maintain the bile acid pool size relatively constant. However, there is a relatively limited capacity for an increase in bile acid synthesis -- about two to two and one-half times (see below). The bile acid pool size is approximately 4 g and is circulated via the enterohepatic circulation about twice during each meal, or six to eight times during a 24-h period. A relatively small quantity of bile acids is not absorbed and is excreted in stool daily; this fecal loss is matched by hepatic bile acid synthesis.

Defects in any of the steps of the enterohepatic circulation of bile acids can result in a decrease in duodenal concentration of conjugated bile acids and, as a result, steatorrhea. Thus, steatorrhea can be caused by abnormalities in bile acid synthesis and excretion, their physical state in the intestinal lumen, and reabsorption (Table 286-1).

Synthesis Decreased bile acid synthesis and steatorrhea have been demonstrated in chronic liver disease, but steatorrhea is often not a major component of the illness of these patients.

Secretion Although bile acid secretion may be reduced or absent in biliary obstruction, steatorrhea is rarely a significant medical problem in these patients. In contrast, primary biliary cirrhosis represents a defect in canalicular excretion of organic anions, including bile acids, and not infrequently is associated with steatorrhea and its consequences, e.g., chronic bone disease. Thus, the osteomalacia and other chronic bone abnormalities often present in patients with primary biliary cirrhosis and other cholestatic syndromes are secondary to steatorrhea that then leads to calcium and vitamin D malabsorption.

Maintenance of Conjugated Bile Acids In bacterial overgrowth syndromes associated with diarrhea, steatorrhea, and macrocytic anemia, there is an increase in a colonic-type of bacterial flora in the small intestine. The steatorrhea is primarily a result of the decrease in conjugated bile acids secondary to their deconjugation by colonic-type bacteria. Two complementary explanations account for the resulting impairment of micelle formation: (1) unconjugated bile acids are rapidly absorbed in the jejunum by nonionic diffusion resulting in a reduced concentration of duodenal bile acids; and (2) the critical micellar concentration (CMC) of unconjugated bile acids is higher than that of conjugated bile acids, and therefore unconjugated bile acids are less effective than conjugated bile acids in micelle formation.

Reabsorption Ileal dysfunction caused by either Crohn's disease or surgical resection results in a decrease in bile acid reabsorption in the ileum and an *increase* in the delivery of bile acids to the large intestine. The resulting clinical consequences -- diarrhea with or without steatorrhea -- is determined by the *degree* of ileal dysfunction and the *response* of the enterohepatic circulation to bile acid losses (Table 286-2). Patients with limited ileal disease or resection will often have diarrhea, but not steatorrhea. The diarrhea, a result of bile acids in the colon stimulating active Cl secretion, has been called *bile acid diarrhea*, or cholorrheic enteropathy, and responds promptly to cholestyramine, an anion-binding resin. Such patients do not develop

steatorrhea because hepatic synthesis of bile acids increases to compensate for the rate of fecal bile acid losses resulting in maintenance of both the bile acid pool size and the intraduodenal concentrations of bile acids. In contrast, patients with greater degrees of ileal disease and/or resection will often have diarrhea and steatorrhea that does not respond to cholestyramine. In this situation, ileal disease is also associated with increased amounts of bile acids entering the colon; however, hepatic synthesis can no longer increase sufficiently to maintain the bile acid pool size. As a consequence, the intraduodenal concentration of bile acids is also reduced to less than theCMC, resulting in impaired micelle formation and steatorrhea. This second situation is often called *fatty acid diarrhea*. Although cholestyramine may not be effective (and may even increase the diarrhea by further depleting the intraduodenal bile acid concentration), a low-fat diet to reduce fatty acids entering the colon can be effective. Two clinical features, the length of ileum removed and the degree of steatorrhea, can predict whether an individual patient will or will not respond to cholestyramine. Unfortunately, these predictors are imperfect, and a therapeutic trial of cholestyramine is often necessary to establish whether an individual patient will benefit from cholestyramine.Table 286-2 contrasts the characteristics of bile acid diarrhea (small ileal dysfunction) and fatty acid diarrhea (large ileal dysfunction).

LIPIDS

Steatorrhea is caused by one or more defects in the digestion and absorption of dietary fat. Average intake of dietary fat in the United States is approximately 120 to 150 g/d, and fat absorption is linear to dietary fat intake. The total load of fat presented to the small intestine is considerably greater, as substantial amounts of lipid are secreted in bile each day. (See above for discussion of enterohepatic circulation of bile acids.) Three types of fatty acids compose fats: long-chain fatty acids (LCFAs), medium-chain fatty acids (MCFAs), and short-chain fatty acids (SCFAs) (Table 286-3). Dietary fat is exclusively composed of long-chain triglycerides (LCTs), i.e., glycerol that is bound via ester-linkages to three LCFAs. While the majority of dietary LCFAs have carbon chain lengths of 16 or 18, fatty acids of carbon chain length >12 are metabolized in the same manner; saturated and unsaturated fatty acids are handled identically.

Assimilation of dietary lipid requires several integrated processes that can be divided into (1) an intraluminal, or digestive, phase; (2) a mucosal, or absorptive, phase; and (3) a delivery, or postabsorptive, phase. An abnormality at any site of this process can cause steatorrhea (Table 286-4). Therefore, it is essential that any patient with steatorrhea be evaluated to identify the specific physiologic defect in overall lipid digestion-absorption as therapy will be determined by the specific cause responsible for the steatorrhea.

The digestive phase has two components, *lipolysis* and *micellar formation*. Although dietary lipid is in the form ofLCTs, the intestinal mucosa does not absorb triglycerides; they must first be hydrolyzed (Fig. 286-2). The initial step in lipid digestion is the formation of emulsions of finely dispersed lipid, which is accomplished by mastication and gastric contractions. Lipolysis, the hydrolysis of triglycerides to free fatty acids, monoglycerides, and glycerol by lipase, is initiated in the stomach by a gastric lipase that has a pH optimum of 4.5 to 6.0. About 20 to 30% of total lipolysis occurs in the stomach. Lipolysis is completed in the duodenum and proximal jejunal by pancreatic

lipase, which is inactivated by pH<7.0. Pancreatic lipolysis is greatly enhanced by the presence of a second pancreatic enzyme, colipase, which facilitates the movement of lipase to the triglyceride.

Impaired lipolysis can lead to steatorrhea and can occur in the presence of pancreatic insufficiency due to chronic pancreatitis in adults or cystic fibrosis in children and adolescents. Normal lipolysis can be maintained by approximately 5% of maximal pancreatic lipase secretion; thus, steatorrhea is a late manifestation of these disorders. A reduction in intraduodenal pH can also result in altered lipolysis as pancreatic lipase is inactivated at pH <7. Thus, ~15% of patients with gastrinoma (Chap. 285) with substantial increases in gastric acid secretion from ectopic production of gastrin (usually from an islet cell adenoma) have diarrhea, and some will have steatorrhea believed secondary to acid-inactivation of pancreatic lipase. Similarly, patients with chronic pancreatitis (who have reduced lipase secretion) often have a decrease in pancreatic bicarbonate secretion, which will also result in a decrease in intraduodenal pH and inactivation of endogenous pancreatic lipase or of therapeutically administered lipase.

Overlying the microvillus membrane of the small intestine is the so-called unstirred water layer, a relatively stagnant aqueous phase that must be traversed by the products of lipolysis that are primarily water-insoluble. Water-soluble mixed micelles provide a mechanism for the water-insoluble products of lipolysis to reach the luminal plasma membrane of villus epithelial cells, the site for lipid absorption. Mixed micelles are molecular aggregates composed of fatty acids, monoglycerides, phospholipids, cholesterol, and conjugated bile acids. Mixed micelles are formed when the concentration of conjugated bile acids is greater than itsCMC, which differs among the several bile acids present in the small intestinal lumen. Conjugated bile acids, synthesized in the liver and excreted into the duodenum in bile, are regulated by the enterohepatic circulation (see above). Steatorrhea can result from impaired movement of fatty acids across the unstirred aqueous fluid layer in two situations: (1) an increase in the relative thickness of the unstirred water layer that occurs in bacterial overgrowth syndromes (see below) secondary to functional stasis (e.g., scleroderma), and (2) a decrease in the *duodenal* concentration of conjugated bile acids below its CMC, resulting in impaired micelle formation. Thus, steatorrhea can be caused by one or more defects in the enterohepatic circulation of bile acids.

Uptake and reesterification represent the *absorptive phase* of lipid digestion-absorption. Although passive diffusion has been thought responsible, a carrier-mediated process may mediate fatty acid and monoglyceride uptake. Regardless of the uptake process, fatty acids and monoglycerides are reesterified by a series of enzymatic steps in the endoplasmic reticulum and Golgi to form triglycerides, the form in which lipid exits from the intestinal epithelial cell. Impaired lipid absorption as a result of either mucosal inflammation (e.g., celiac sprue) and/or intestinal resection can also lead to steatorrhea.

The reesterified triglycerides require the formation of *chylomicrons* to permit their exit from the small-intestinal epithelial cell and their delivery to the liver via the *lymphatics*. Chylomicrons are composed ofb-lipoprotein and contain triglycerides, cholesterol, cholesterol esters, and phospholipids and enter the lymphatics, not the portal vein. Defects in the *postabsorptive phase* of lipid digestion-absorption can also result in steatorrhea, but these disorders are uncommon. Abetalipoproteinemia, or

acanthocytosis, is a rare disorder of impaired synthesis of b-lipoprotein associated with abnormal erythrocytes (acanthocytes), neurologic problems, and steatorrhea. Lipolysis, micelle formation, and lipid uptake are all normal in patients with abetalipoproteinemia, but the reesterified triglyceride cannot exit from the epithelial cell because of the failure to produce chylomicrons. Small-intestinal biopsies of these rare patients in the postprandial state reveal lipid-laden small-intestinal epithelial cells that become perfectly normal in appearance following a 72- to 96-fast. Similarly, abnormalities of intestinal lymphatics (e.g., intestinal lymphangiectasia) may also be associated with steatorrhea as well as protein loss (see below). Steatorrhea can result from defects at any of the several steps in lipid digestion-absorption. The mechanism of lipid digestion-absorption outlined above is limited to *dietary* lipid that is almost exclusively in the form ofLCTs(Table 286-3). Medium-chain triglycerides (MCTs), composed of fatty acids with carbon chain lengths of 8 to 10, are present in large amounts in coconut oil and are used as a nutritional supplement. MCTs can be digested and absorbed by a different pathway from LCTs and at one time held promise as an important treatment of steatorrhea of almost all etiologies. Unfortunately, their therapeutic effects have been less than expected because their use is often not associated with an increase in body weight for reasons that are not completely understood.

MCTs, in contrast toLCTs, do not require pancreatic lipolysis as the triglyceride can be absorbed intact by the intestinal epithelial cell. Further, micelle formation is not necessary for the absorption of MCTs or medium-chain fatty acids, if hydrolyzed by pancreatic lipase. MCTs are absorbed more efficiently than LCTs for the following reasons: (1) the rate of MCT absorption is greater than that of long-chain fatty acids; (2) medium-chain fatty acids following absorption are not reesterified; (3) following absorption, MCTs are hydrolyzed to medium-chain fatty acids; (4) MCTs do not require chylomicron formation for their exit from the intestinal epithelial cells; and (5) their route of exit is via the portal vein and not via lymphatics. Thus, the absorption of MCTs is greater than that of LCTs in pancreatic insufficiency, conditions with reduced intraduodenal bile acid concentrations, small-intestinal mucosal disease, abetalipoproteinemia, and intestinal lymphangiectasia.

SCFAsare not dietary lipids but are synthesized by colonic bacterial enzymes from nonabsorbed carbohydrate and are the anions in highest concentration in stool (between 80 and 130 m*M*). The SCFAs present in stool are primarily acetate, propionate, and butyrate whose carbon chain lengths are 2, 3, and 4, respectively. Butyrate is the primary nutrient for colonic epithelial cells, and its deficiency may be associated with one or more colitides. SCFAs conserve calories and carbohydrate, because carbohydrates not completely absorbed in the small intestine will not be absorbed in the large intestine due to the absence of both disaccharidases and SGLT, the transport protein that mediates monosaccharide absorption. In contrast, SCFAs are rapidly absorbed and stimulate colonic Na-Cl and fluid absorption. Most non-*Clostridium difficile* antibiotic-associated diarrhea is due to antibiotic suppression of colonic microflora, with a resulting decrease in SCFA production. As *C. difficile* accounts for about 10 to 15% of all antibiotic-associated diarrhea, a relative decrease in colonic production of SCFAs is the cause of most antibiotic-associated diarrhea.

The clinical manifestations of steatorrhea are a consequence of both the underlying disorder responsible for the development of steatorrhea and steatorrhea per se.

Depending on the degree of steatorrhea and the level of dietary intake, significant fat malabsorption may lead to weight loss. Steatorrhea per se can be responsible for diarrhea; if the primary cause of the steatorrhea has not been identified, a low-fat diet can often ameliorate the diarrhea by decreasing fecal fat excretion. Steatorrhea is often associated with fat-soluble vitamin deficiency, which will require replacement with water-soluble preparations of these vitamins.

Disorders of absorption may also be associated with malabsorption of other dietary nutrients, most often carbohydrates, with or without a decrease in dietary lipid digestion and absorption. Therefore, knowledge of the mechanism of the digestion and absorption of carbohydrates, proteins, and other minerals and vitamins is useful in the evaluation of patients with altered intestinal nutrient absorption.

CARBOHYDRATES

Carbohydrates in the diet are present in the form of starch, disaccharides (sucrose and lactose), and glucose. Carbohydrates are absorbed only in the small intestine and only in the form of monosaccharides. Therefore, before their absorption, starch and disaccharides must first be digested by pancreatic amylase and intestinal brush border disaccharidases to monosaccharides. Monosaccharide absorption occurs by a Na-dependent process mediated by the brush border transport protein, SGLT.

Lactose malabsorption is the only clinically important disorder of carbohydrate absorption. Lactose, the disaccharide present in milk, requires digestion by brush border lactase to its two constituent monosaccharides, glucose and galactose. Lactase is present in almost all species in the postnatal period but then disappears throughout the animal kingdom, except in humans. Lactase activity persists in many individuals throughout life. Two different types of lactase deficiency exist -- primary and secondary. In *primary lactase deficiency*, a genetically determined decrease or absence of lactase is noted, while all other aspects of both intestinal absorption and brush border enzymes are normal. In a number of non-Caucasian groups, primary lactase deficiency is common in adulthood.Table 286-5 presents the incidence of primary lactase deficiency in several different ethnic groups. Northern European and North American Caucasians are the only population group to maintain small-intestinal lactase activity throughout adult life. It is lactase persistence that is unusual. In contrast, *secondary lactase deficiency* occurs in association with small-intestinal mucosal disease with abnormalities in both structure and function of other brush border enzymes and transport processes. Secondary lactase deficiency is often seen in celiac sprue.

As lactose digestion is rate-limiting compared to glucose/galactose absorption, lactase deficiency is associated with significant lactose malabsorption. Some individuals with lactose malabsorption develop symptoms such as diarrhea, abdominal pain, cramps, and/or flatus. Most individuals with primary lactase deficiency do not have symptoms. Since lactose intolerance may be associated with symptoms suggestive of an irritable bowel syndrome, persistence of such symptoms in an individual with lactose intolerance while on a strict lactose-free diet would suggest that the individual's symptoms were related to irritable bowel syndrome.

Development of symptoms of lactose intolerance is related to several factors:

1. *Amount of lactose in the diet*.

2. *Rate of gastric emptying*. Symptoms are more likely when gastric emptying is rapid than when gastric emptying is slower. Therefore, it is more likely that skim milk will be associated with symptoms of lactose intolerance than whole milk as the rate of gastric emptying following skim milk intake is more rapid. Similarly, the diarrhea observed following subtotal gastrectomy is often a result of lactose intolerance as gastric emptying is accelerated in patients with a gastrojejunostomy.

3. *Small-intestinal transit time*. Although both the small and large intestine contribute to the development of symptoms, many of the symptoms of lactase deficiency are related to the interaction of colonic bacteria and nonabsorbed lactose. More rapid small-intestinal transit makes symptoms more likely.

4. *Colonic compensation by production of*SCFAsfrom nonabsorbed lactose. Reduced levels of colonic microflora, which can occur following antibiotic use, will also be associated with increased symptoms following lactose ingestion, especially in a lactase-deficient individual.

Glucose-galactose or monosaccharide malabsorption may also be associated with diarrhea and is due to a congenital absence of SGLT. Diarrhea is present when these individuals ingest carbohydrates that contain actively transported monosaccharides (e.g., glucose, galactose) but not monosaccharides that are not actively transported (e.g., fructose). Fructose is absorbed by the brush border transport protein, GLUT 5, a facilitated diffusion process that is not Na-dependent and is distinct from SGLT. In contrast, some individuals develop diarrhea as a result of consuming large quantities of sorbitol, a sugar used in diabetic candy; sorbitol is only minimally absorbed due to the absence of an intestinal absorptive transport mechanism for sorbitol.

PROTEINS

Protein is present in food almost exclusively as polypeptides and requires extensive hydrolysis to di- and tripeptides and amino acids before absorption. Proteolysis occurs in both the stomach and small intestine; it is mediated by pepsin secreted as pepsinogen by gastric chief cells and trypsinogen and other peptidases from pancreatic acinar cells. These proenzymes, pepsinogen and trypsinogen, must be activated to pepsin (by pepsin in the presence of a pH< 5) and trypsin (by the intestinal brush border enzyme, enterokinase, and subsequently by trypsin). Proteins are absorbed by separate transport systems for di- and tripeptides and for different types of amino acids, e.g., neutral, dibasic. Alterations in either protein or amino acid digestion and absorption are rarely observed clinically, even in the presence of extensive small-intestinal mucosal inflammation. However, three rare genetic disorders involve protein digestion-absorption: (1) *enterokinase deficiency* is due to an absence of the brush border enzyme that converts the proenzyme trypsinogen to trypsin and is associated with diarrhea, growth retardation, and hypoproteinemia; (2) *Hartnup syndrome*, a defect in neutral amino acid transport, is characterized by a pellagra-like rash and neuropsychiatric symptoms; and (3) *cystinuria*, a defect in dibasic amino acid transport, is associated with renal calculi and chronic pancreatitis.

EVALUATION OF MALABSORPTION

The clues provided by the history, symptoms, and initial preliminary observations will serve to limit extensive, ill-focused, and expensive laboratory and imaging studies. For example, a clinician evaluating a patient with symptoms suggestive of malabsorption who recently had extensive small-intestinal resection for mesenteric ischemia should direct the initial assessment almost exclusively to define whether a short-bowel syndrome might explain the entire clinical picture. Similarly, the development of a pattern of bowel movements suggestive of steatorrhea in a patient with long-standing alcohol abuse and chronic pancreatitis should lead toward assessing pancreatic exocrine function.

The classic picture of malabsorption described in textbooks [3]30 years ago is rarely seen today in most parts of the United States. As a consequence, diseases with malabsorption must be suspected in individuals with less severe symptoms and signs and with subtle evidence of the altered absorption of only a *single* nutrient rather than obvious evidence of the malabsorption of multiple nutrients.

Although diarrhea can be caused by changes in fluid and electrolyte movement in either the small or the large intestine, dietary nutrients are absorbed almost exclusively in the small intestine. Therefore, the demonstration of diminished absorption of a dietary nutrient provides unequivocal evidence of small-intestinal disease, although colonic dysfunction may also be present (e.g., Crohn's disease may involve both small and large intestine). Dietary nutrient absorption may be segmental or heterogeneous along the small intestine and is site-specific. Thus, for example, calcium, iron, and folic acid are exclusively absorbed by active transport processes in the proximal small intestine, especially the duodenum; in contrast, the active transport mechanisms for both cobalamin and bile acids are present only in the ileum. Therefore, in an individual who years previously had had an intestinal resection, the details of which are not presently available, a presentation with evidence of calcium, folic acid, and iron malabsorption but without cobalamin deficiency would make it likely that the duodenum and jejunum, but not ileum, had been resected.

Some nutrients, e.g., glucose, amino acids, and lipids, are absorbed throughout the small intestine, though there is evidence that their rate of absorption is greater in the proximal than in the distal segments. However, following segmental resection of the small intestine, the remaining segments will undergo both morphologic and functional "adaptation" to enhance absorption. Such adaptation is secondary to both the presence of luminal nutrients and hormonal stimuli and may not be complete in humans for several months following the resection. Adaptation is critical for individuals who have undergone massive resection of the small intestine and/or colon to help ensure survival.

Establishing the presence of steatorrhea and identifying its specific cause are often quite difficult for several reasons. Despite attempts to develop tests that do *not* require the collection of stool to document the presence of steatorrhea, the "gold standard" still remains a timed, quantitative stool fat determination. On a practical basis, stool collections are invariably difficult and often incomplete as nobody wants to handle stool. A qualitative test -- Sudan III stain -- has long been available to establish the presence

of an increase in stool fat. This test is rapid and inexpensive but, as a qualitative test, does not establish the degree of fat malabsorption and is best used as a preliminary screening study. Many of the blood, breath, and isotopic tests that have been developed either: (1) do not directly measure fat absorption, (2) have excellent sensitivity when steatorrhea is obvious and severe but have poor sensitivity when steatorrhea is mild, or (3) have not survived the transition from their development in a laboratory to commercial utilization and dissemination.

Despite this situation, the use of routine laboratory studies (i.e., complete blood count, prothrombin time, serum protein determination, alkaline phosphatase) may suggest the presence of dietary nutrient depletion, especially iron, folate, cobalamin, and vitamins D and K. Additional studies include measurement of serum carotene, cholesterol, albumin, iron, folate, and cobalamin levels. The serum carotene level can also be reduced if the patient has poor dietary intake of leafy vegetables.

If steatorrhea and/or altered absorption of other nutrients are suspected, the history, clinical observations, and laboratory testing can help detect deficiency of a dietary nutrient, especially the fat-soluble vitamins A, D, E, or K. Thus, evidence of metabolic bone disease with elevated alkaline phosphatase and/or reduced serum calcium levels would suggest vitamin D malabsorption. A deficiency of vitamin K would be suggested by an elevated prothrombin time in an individual without liver disease who was not taking anticoagulants. Macrocytic anemia would lead to evaluation of whether cobalamin or folic acid malabsorption was present. The presence of iron-deficiency anemia in the absence of occult bleeding from the gastrointestinal tract in either a male or a nonmenstruating female would require evaluation of iron malabsorption and the exclusion of celiac sprue, as iron is absorbed exclusively in the proximal small intestine.

At times, however, a timed (72-h) quantitative stool collection, preferably on a defined diet, must be obtained to determine stool fat content and establish the presence of steatorrhea. The presence of steatorrhea then requires further assessment to establish the pathophysiologic process(es) responsible for the defect in dietary lipid digestion-absorption (Table 286-4). Some of the other studies include the Schilling test, D-xylose test, duodenal mucosal biopsy, small-intestinal radiologic examination, and tests of pancreatic exocrine function.

THE SCHILLING TEST

This test is performed to determine the cause for cobalamin malabsorption. Since cobalamin absorption requires multiple steps, including gastric, pancreatic, and ileal processes, the Schilling test can also be used to assess the integrity of these other organs (Chap. 107). Cobalamin is present primarily in meat. Except in strict vegans, *dietary* cobalamin deficiency is exceedingly uncommon. Dietary cobalamin is bound in the stomach to a glycoprotein called *R-binder protein*, which is synthesized in both the stomach and salivary glands. This cobalamin-R binder complex is formed in the acid milieu of the stomach. Cobalamin absorption has an absolute requirement for intrinsic factor, another glycoprotein synthesized and released by gastric parietal cells, to promote its uptake by specific cobalamin receptors on the brush border of ileal enterocytes. Pancreatic protease enzymes split the cobalamin-R binder complex to release cobalamin in the proximal small intestine, where cobalamin is then bound by

intrinsic factor.

As a consequence, cobalamin absorption may be abnormal in the following:

1. Pernicious anemia, a disease in which immunologically mediated atrophy of gastric parietal cells leads to an absence of both gastric acid and intrinsic factor secretion.

2. Chronic pancreatitis as a result of deficiency of pancreatic proteases to split the cobalamin-R binder complex. Although 50% of patients with chronic pancreatitis have been reported to have an abnormal Schilling test that was corrected by pancreatic enzyme replacement, the presence of a cobalamin-responsive macrocytic anemia in chronic pancreatitis is extremely rare. Although this probably reflects a difference in the digestion/absorption of cobalamin in food versus that in a crystalline form, the Schilling test can still be used to assess pancreatic exocrine function.

3. Achlorhydria or absence of another factor secreted with acid that is responsible for splitting cobalamin away from the proteins in food to which it is bound can lead to vitamin B_{12}malabsorption. Up to one-third of individuals over>60 years have marginal vitamin B_{12}absorption because of the inability to release cobalamin from food; these people have no defects in absorbing crystalline vitamin B_{12}.

4. Bacterial overgrowth syndromes, which are most often secondary to stasis in the small intestine, produce cobalamin deficiency from bacterial utilization of cobalamin (often referred to as *stagnant bowel syndrome*) (see below).

5. Ileal dysfunction (either as a result of inflammation or prior intestinal resection) due to impaired function of the mechanism of cobalamin-intrinsic factor uptake by ileal intestinal epithelial cells.

The Schilling test is performed by administering^{58}Co-labeled cobalamin and collecting urine for 24 h and is dependent upon normal renal and bladder function. Urinary excretion of cobalamin will reflect cobalamin absorption provided that intrahepatic binding sites for cobalamin are fully occupied. To ensure saturation of hepatic cobalamin binding sites so that all absorbed radiolabeled cobalamin will be excreted in urine, 1 mg cobalamin is administered intramuscularly 1 h following ingestion of the radiolabeled cobalamin. The Schilling test may be abnormal (usually defined as<10% excretion in 24 h) in pernicious anemia, chronic pancreatitis, blind loop syndrome, and ileal disease (Table 286-6). Therefore, whenever an abnormal Schilling test is found,^{58}Co-labeled cobalamin should be administered on another occasion either bound to intrinsic factor, with pancreatic enzymes, or following a 5-day course of antibiotics (often tetracycline). A variation of the Schilling test can detect failure to split cobalamin from food proteins. The labeled cobalamin is cooked together with a scrambled egg and administered orally. People with achlorydria will excrete <10% of the labeled cobalamin in the urine. In addition to establishing the etiology for cobalamin deficiency, the Schilling test can be used to help delineate the pathologic process responsible for steatorrhea by assessing ileal, pancreatic, and small-intestinal luminal function.

URINARY D-XYLOSE TEST

THE URINARY D-xylose test for carbohydrate absorption provides an assessment of proximal small-intestinal mucosal function. D-Xylose, a pentose, is absorbed almost exclusively in the proximal small intestine. The D-xylose test is usually performed by giving 25 g D-xylose and collecting urine for 5 h. An abnormal test (<4.5 g excretion) primarily reflects the presence of duodenal/jejunal mucosal disease. The D-xylose test can also be abnormal in patients with blind loop syndrome (as a consequence primarily of abnormal intestinal mucosa) and, as a false-positive study, in patients with large collections of fluid in a third space (i.e., ascites, pleural fluid). The ease of obtaining a mucosal biopsy of the small intestine by endoscopy and the false-negative rate of the D-xylose test have led to its diminished use. When small-intestinal mucosal disease is suspected, a small-intestinal mucosal biopsy should be performed.

RADIOLOGIC EXAMINATION

Radiologic examination of the small intestine using barium contrast (small-bowel series or study) can provide important information in the evaluation of the patient with presumed or suspected malabsorption. These studies are most often performed in conjunction with the examination of the esophagus, stomach, and duodenal bulb, and insufficient barium is given the patient to permit an adequate examination of the small-intestinal mucosa, especially the ileum. As a result, many gastrointestinal radiologists alter the procedure of a barium contrast examination of the small intestine by performing either a small-bowel series in which a large amount of barium is given by mouth without concurrent examination of the esophagus and stomach or an enteroclysis study in which a large amount of barium is introduced into the duodenum via a fluoroscopically placed tube. In addition, many of the diagnostic features initially described by radiologists to denote the presence of small-intestinal disease (e.g., flocculation, segmentation) are rarely seen with current barium suspensions. Nonetheless, in skilled hands barium contrast examination of the small intestine can yield important information. For example, with extensive mucosal disease, dilatation of intestine can be seen as well as dilution of barium from increased intestinal fluid secretion (Fig. 286-3). A normal barium contrast study does *not* exclude the possibility of small-intestinal disease. However, a small-bowel series remains a very useful examination to assess for the presence of anatomic abnormalities, such as strictures and fistulas (as in Crohn's disease) or blind loop syndrome (e.g., multiple jejunal diverticula), and to define the extent of a previous surgical resection.

BIOPSY OF SMALL-INTESTINAL MUCOSA

A small-intestinal mucosal biopsy is essential in the evaluation of a patient with documented steatorrhea or chronic diarrhea (lasting >3 weeks) (Chap. 42). The ready availability of endoscopic equipment to examine the stomach and duodenum has led to their almost uniform use as the preferred method to obtain histologic material of proximal small-intestinal mucosa. The primary indications for a small-intestinal biopsy are (1) evaluation of a patient either with documented or suspected steatorrhea or with chronic diarrhea, and (2) diffuse or focal abnormalities of the small intestine defined on a small-intestinal series. Lesions seen on small-bowel biopsy can be classified into three different categories (Table 286-7): (1) diffuse, specific; (2) patchy, specific; and (3) diffuse, nonspecific.

1. *Diffuse, specific lesions*. There are relatively few diseases associated with altered nutrient absorption that have specific histopathologic abnormalities on small-intestinal mucosal biopsy, and they are uncommon. *Whipple's disease* is characterized by the presence of periodic acid-Schiff (PAS)-positive macrophages in the lamina propria, while the bacilli that are also present may require electron-microscopic examination for identification (Fig. 286-4). *Abetalipoproteinemia* is characterized by a normal mucosal appearance except for the presence of mucosal absorptive cells that contain lipid postprandially and disappear following a prolonged period of either fat-free intake or fasting. *Immune globulin deficiency* is associated with a variety of histopathologic findings on small-intestinal mucosal biopsy. The characteristic feature is the absence or substantial reduction in the number of plasma cells in the lamina propria; the mucosal architecture may be either perfectly normal or flat, i.e., villus atrophy. As patients with immune globulin deficiency are often infected with *Giardia lamblia*, *Giardia* trophozoites may also be seen in the biopsy.

2. *Patchy, specific lesions*. Several diseases are associated with abnormal small-intestinal mucosal biopsies, but the characteristic features that are present have a patchy distribution. As a result, biopsies obtained randomly or in the absence of abnormalities visualized endoscopically may not reveal these diagnostic features. Intestinal *lymphoma* can at times be diagnosed on mucosal biopsy by the identification of malignant lymphoma cells in the lamina propria and submucosa (Chap. 112). The presence of dilated lymphatics in the submucosa and sometimes in the lamina propria indicates the presence of *lymphangiectasia* associated with hypoproteinemia secondary to protein loss into the intestine. *Eosinophilic gastroenteritis* represents a heterogeneous group of disorders with a spectrum of presentations and symptoms with a eosinophilic infiltrate of the lamina propria, with or without peripheral eosinophilia. The patchy nature of the infiltrate as well as its presence in the submucosa often leads to an absence of histopathologic findings on mucosal biopsy. As the involvement of the duodenum in *Crohn's disease* is also submucosal and not necessarily continuous, mucosal biopsies are not the most direct approach to the diagnosis of duodenal Crohn's disease (Chap. 287). Amyloid deposition can be identified by Congo Red stain in some patients with *amyloidosis* involving the duodenum (Chap. 319).

Several microorganisms can be identified on small-intestinal biopsies, establishing a correct diagnosis. Many of these microorganisms are associated with diarrhea that occurs in immunodeficient individuals, especially those with HIV infection, and include *Cryptosporidium*, *Isospora belli*, cytomegalovirus, *Mycobacterium avium intracellulare*, and *G. lamblia*.

3. *Diffuse, nonspecific lesions*. *Celiac sprue* presents with a characteristic mucosal appearance on duodenal/proximal jejunal mucosal biopsy that is not diagnostic of the disease. The diagnosis of celiac sprue is established by clinical, histologic, and immunologic response to a gluten-free diet. *Tropical sprue* is associated with histopathologic findings similar to those of celiac sprue after a tropical or subtropical exposure but does not respond to gluten restriction; most often symptoms improve with antibiotics and folate administration.

Patients with steatorrhea require assessment of *pancreatic exocrine function*, which is often abnormal in chronic pancreatitis. No test assesses pancreatic exocrine function

well. Endoscopic approaches provide excellent assessment of pancreatic duct anatomy but do not assess exocrine function (Chap. 303). One noninvasive study (bentiromide test) of pancreatic exocrine function is based on the feeding of a tripeptide containing *p*-aminobenzoic acid (PABA). Following splitting of PABA by pancreatic proteases, PABA is liberated, absorbed, and excreted in urine. Reduced proteolysis results in reduced urinary excretion of PABA. This test is neither sensitive nor specific.

Table 286-8 summarizes the results of the D-xylose test, Schilling test, and small-intestinal mucosal biopsy in patients with five different causes of steatorrhea.

SPECIFIC DISEASE ENTITIES

CELIAC SPRUE

Celiac sprue is a not uncommon cause of malabsorption of one or more nutrients in Caucasians, especially those of European descent. Celiac sprue has had several other names including nontropical sprue, celiac disease (in children), adult celiac disease, and gluten-sensitive enteropathy. The etiology of celiac sprue is not known, but environmental, genetic, and immunologic factors are important. Celiac sprue has protean manifestations, almost all of which are secondary to nutrient malabsorption, and a varied natural history, with the onset of symptoms occurring at ages ranging from the first year of life through the eighth decade.

The hallmark of celiac sprue is the presence of an abnormal small-intestinal biopsy (Fig. 286-4) and the response of both symptoms, evidence of malabsorption and the histopathologic changes on the small-intestinal biopsy, to the elimination of gluten from the diet. The histopathologic changes have a proximal to distal intestinal distribution of severity, which probably reflects the exposure of the intestinal mucosa to varied amounts of dietary gluten; the degree of symptoms is related to the extent of these histopathologic changes.

The symptoms of celiac sprue may appear with the introduction of cereals in an infant's diet, although there is frequently a spontaneous remission during the second decade of life that may be either permanent or followed by the reappearance of symptoms over several years. Alternatively, the symptoms of celiac sprue may first become evident at almost any age throughout adulthood. In many patients, frequent spontaneous remissions and exacerbations occur. The symptoms range from significant malabsorption of multiple nutrients with diarrhea, steatorrhea, weight loss, and the consequences of nutrient depletion (i.e., anemia and metabolic bone disease) to the absence of any gastrointestinal symptoms but with evidence of the depletion of a single nutrient (e.g., folate deficiency, osteomalacia, edema from protein loss). Asymptomatic relatives of patients with celiac sprue have been identified as having this disease either by small-intestinal biopsy or by serologic studies (e.g., antiendomysial antibodies).

Etiology The etiology of celiac sprue is not known, but environmental, genetic, and immunologic factors all appear to contribute to the disease.

One *environmental* factor is the clear association of the disease with gliadin, a component of gluten that is present in wheat, barley, rice, and, in smaller amounts, oats.

In addition to the role of gluten restriction in treatment, the instillation of gluten into both normal-appearing rectum and distal ileum of patients with celiac sprue results within hours in morphologic changes.

An *immunologic* component to etiology is suspected for three reasons. First, serum antibodies, IgA antigliadin and antiendomysial antibodies, are present, but it is also not known whether such antibodies are primary or secondary to the tissue damage. The antiendomysial antibody has 90 to 95% sensitivity and 90 to 95% specificity, and the antigen recognized by the antiendomysial antibody test is tissue transglutaminase. The relationship of this autoantibody to pathogenetic mechanism(s) responsible for celiac sprue remains to be established. Nonetheless, this antibody will undoubtedly prove extremely useful in establishing the true prevalence of celiac sprue in the general population and may provide important clues to its etiology. Second, treatment with prednisolone for 4 weeks of a patient with celiac sprue who continues to eat gluten will induce a remission and convert the "flat" abnormal duodenal biopsy to a more normal appearing one. Third, gliadin peptides may interact with gliadin-specific T cells that may either mediate tissue injury or induce the release of one or more cytokines that are responsible for the tissue injury.

Genetic factor(s) also appear to be involved in celiac sprue. The incidence of celiac sprue varies widely in different population groups (high in Caucasians, low in blacks and orientals) and is 10% in first-degree relatives of celiac sprue patients. Furthermore, about 95% of patients with celiac sprue express the HLA-DQ2 allele, though only a minority of all persons expressing DQ2 have celiac sprue.

Diagnosis A small-intestinal biopsy is required to establish a diagnosis of celiac sprue (Fig. 286-4). A biopsy should be performed in patients with symptoms and laboratory findings suggestive of nutrient malabsorption and/or deficiency. Since the presentation of celiac sprue is often subtle, without overt evidence of malabsorption or nutrient deficiency, it is important to have a relatively low threshold to perform a biopsy. It is more prudent to perform a biopsy than to obtain another test of intestinal absorption, which can never completely exclude or establish this diagnosis.

The diagnosis of celiac sprue requires the presence of characteristic histopathologic changes on small-intestinal biopsy together with a prompt clinical and histopathologic response following the institution of a gluten-free diet. If serologic studies have detected the presence of IgA antiendomysial antibodies, they too should disappear after a gluten-free diet is started. The changes seen on duodenal/jejunal biopsy are restricted to the mucosa and include: (1) absence or reduced height of villi, resulting in a "flat" appearance; (2) increased loss of villus cells in association with increased crypt cell proliferation resulting in crypt hyperplasia and loss of villus structure, with consequent villus, but not mucosal, atrophy; (3) cuboidal appearance and nuclei that are no longer oriented basally in surface epithelial cells and increased intraepithelial lymphocytes; and (4) increased lymphocytes and plasma cells in the lamina propria. Although these histopathologic features are characteristic of celiac sprue, they are *not* diagnostic because a similar appearance can be seen in tropical sprue, eosinophilic enteritis, and milk-protein intolerance in children and occasionally in lymphoma, bacterial overgrowth, Crohn's disease, and gastrinoma with acid hypersecretion. However, the presence of a characteristic histopathologic appearance that reverts to normal following the initiation of

a gluten-free diet establishes the diagnosis of celiac sprue. Readministration of gluten with or without an additional small-intestinal biopsy is not necessary.

Failure to Respond to Gluten Restriction The most common cause of persistent symptoms in a patient who fulfills all the criteria of the diagnosis of celiac sprue is continued intake of gluten. Gluten is ubiquitous, and significant effort must be made to exclude all gluten from the diet. Use of rice in place of wheat flour is very helpful, and several support groups provide important aid to patients with celiac sprue and to their families. About 90% of patients who have the characteristic findings of celiac sprue will respond to complete dietary gluten restriction. The remainder represent a heterogeneous group (whose condition is often called *refractory sprue*) that includes some patients who (1) respond to restriction of other dietary protein, e.g., soy; (2) respond to glucocorticoids; (3) are "temporary," i.e., the clinical and morphologic findings disappear after several months or years; or (4) fail to respond to all measures and have a fatal outcome, with or without documented complications of celiac sprue.

Mechanism of Diarrhea The diarrhea in celiac sprue has several pathogenetic mechanisms. Diarrhea may be secondary to (1) steatorrhea, which is primarily a result of the changes in jejunal mucosal function; (2) secondary lactase deficiency, a consequence of changes in jejunal brush border enzymatic function; (3) bile acid malabsorption resulting in bile acid-induced fluid secretion in the colon, in cases with more extensive disease involving the ileum; and (4) endogenous fluid secretion resulting from the crypt hyperplasia. Patients with more severe involvement with celiac sprue may obtain temporary improvement with *dietary lactose and fat restriction* while awaiting the full effects of total gluten restriction, which represents primary therapy.

Associated Diseases Celiac sprue is associated with dermatitis herpetiformis (DH), though the association has not been explained. Patients with DH have characteristic papulovesicular lesions that respond to dapsone. Almost all patients with DH have histopathologic changes in the small intestine consistent with celiac sprue, although usually much milder and less diffuse in distribution. Most patients with DH have mild, or no, gastrointestinal symptoms. In contrast, relatively few patients with celiac sprue have DH.

Celiac sprue is also associated with insulin-dependent diabetes mellitus and IgA globulin deficiency. The clinical importance of the former association is that although severe watery diarrhea without evidence of malabsorption is most often seen in patients with "diabetic diarrhea" (Chap. 333), a small-intestinal biopsy must at times be considered to exclude this association.

Complications The most important complication of celiac sprue is the development of a malignancy. An increased incidence of both gastrointestinal and nongastrointestinal neoplasms as well as intestinal lymphoma exists in patients with celiac sprue. For unexplained reasons the occurrence of lymphoma in patients with celiac sprue is higher in Ireland and the United Kingdom than in the United States. The possibility of lymphoma must be considered whenever a patient with celiac sprue previously doing well on a gluten-free diet is no longer responsive to gluten restriction or a patient who presents with clinical and histopathologic features consistent with celiac sprue does not respond to a gluten-free diet. Other complications of celiac sprue include the

development of intestinal ulceration independent of lymphoma and so-called refractory sprue (see above) and collagenous sprue. In *collagenous sprue*, a layer of collagen-like material is present beneath the basement membrane; these patients generally do not respond to a gluten-free diet and often have a poor prognosis.

TROPICAL SPRUE

Tropical sprue is a poorly understood syndrome that affects both expatriates and natives in certain but not all tropical areas and is manifested by chronic diarrhea, steatorrhea, weight loss, and nutritional deficiencies, including those of both folate and cobalamin. This disease affects 5 to 10% of the population in some tropical areas.

Chronic diarrhea in a tropical environment is most often caused by infectious agents including *G. lamblia*, *Yersinia enterocolitica*, *C. difficile*, *Cryptosporidium parvum*, and *Cyclospora cayetanensis*, among other organisms. Tropical sprue should not be entertained as a possible diagnosis until the presence of cysts and trophozoites has been excluded in three stool samples.**Chronic infections of the gastrointestinal tract and diarrhea in patients with or without AIDS are discussed in Chaps. 309 and 131.*

The small-intestinal mucosa in individuals living in tropical areas is not identical to that of individuals who reside in temperate climates. Biopsies reveal a mild alteration of villus architecture with a modest increase in mononuclear cells in the lamina propria, which on occasion can be as severe as that seen in celiac sprue. These changes are observed both in native residents and in expatriates living in tropical regions, are usually associated with mild decreases in absorptive function, but revert to "normal" when an individual moves or returns to a temperate area. Some have suggested that the changes seen in tropical enteropathy and in tropical sprue represent different ends of the spectrum of a single entity, but convincing evidence to support this concept is lacking.

Etiology The etiology of tropical sprue is not known, though because tropical sprue responds to antibiotics, the consensus is that tropical sprue may be caused by one or more infectious agents. Nonetheless, multiple uncertainties regarding the etiology and pathogenesis of tropical sprue exist. First, its occurrence is not evenly distributed in all tropical areas; rather, it is found in specific locations including South India, the Philippines, and several Caribbean islands (e.g., Puerto Rico, Haiti) but is rarely observed in Africa, Jamaica, or Southeast Asia. Second, an occasional individual will not develop symptoms of tropical sprue until long after having left an endemic area. This is the reason why the original term for celiac sprue was *nontropical sprue* to distinguish it from tropical sprue. Third, multiple microorganisms have been identified on jejunal aspirate with relatively little consistency among studies. *Klebsiella pneumoniae*, *Enterobacter cloacae*, or *E. coli* have been implicated in some studies of tropical sprue, while other investigations have favored a role for a toxin produced by one or more of these bacteria. Fourth, the incidence of tropical sprue appears to have decreased substantially during the past decade. One speculation for this reduced occurrence of tropical sprue is the wider use of antibiotics in acute diarrhea especially in travelers to tropical areas from temperate countries. Fifth, the role of folic acid deficiency in the pathogenesis of tropical sprue requires clarification. Folic acid is absorbed exclusively in the duodenum and proximal jejunum, and most patients with tropical sprue have

evidence of folate malabsorption and depletion. Although folate deficiency can cause changes in small-intestinal mucosa that are corrected by folate replacement, the several earlier studies reporting that tropical sprue could be cured by folic acid did not provide an explanation for the "insult" that was initially responsible for folate malabsorption.

The clinical pattern of tropical sprue varies in different areas of the world (e.g., India vs. Puerto Rico). Not infrequently, individuals in India initially will report the occurrence of an acute enteritis before the development of steatorrhea and malabsorption. In contrast, in Puerto Rico, a most insidious onset of symptoms and a more dramatic response to antibiotics is seen than in some other locations. Tropical sprue in different areas of the world may not be the same disease; there may be similar clinical entities but with different etiologies.

Diagnosis The diagnosis of tropical sprue is best made by the presence of an abnormal small-intestinal mucosal biopsy in an individual with chronic diarrhea and evidence of malabsorption who is either residing or has recently lived in a tropic country. The small-intestinal biopsy in tropical sprue does not have pathognomonic features but resembles, and can often be indistinguishable from, that seen in celiac sprue (Fig. 286-4). The biopsy in tropical sprue will have less villus architectural alteration and more mononuclear cell infiltrate in the lamina propria. In contrast to celiac sprue, the histopathologic features of tropical sprue are present with a similar degree of severity throughout the small intestine, and a gluten-free diet does not result in either clinical or histopathologic improvement in tropical sprue.

TREATMENT

Broad-spectrum antibiotics and folic acid are most often curative, especially if the patient leaves the tropical area and does not return. Tetracycline should be used for up to 6 months and may be associated with improvement within 1 to 2 weeks. Folic acid alone will induce a hematologic remission as well as improvement in appetite, weight gain, and some morphologic changes in small intestinal biopsy. Because of the presence of marked folate deficiency, folic acid is most often given together with antibiotics.

SHORT BOWEL SYNDROME

This is a descriptive term for the myriad clinical problems that often occur following resection of varying lengths of small intestine. The factors that determine both the type and degree of symptoms include: (1) the specific segment (jejunum vs. ileum) resected, (2) the length of the resected segment, (3) the integrity of the ileocecal valve, (4) whether any large intestine has also been removed, (5) residual disease in the remaining small and/or large intestine (e.g., Crohn's disease, mesenteric artery disease), and (6) the degree of adaptation in the remaining intestine. Short bowel syndrome can occur at any age from neonates through the elderly.

Three different situations in adults demand intestinal resections: (1) mesenteric vascular disease including both atherosclerosis, thrombotic phenomena, and vasculitidies; (2) primary mucosal and submucosal disease, e.g., Crohn's disease; and (3) operations without preexisting small intestinal disease, such as trauma and jejunoileal bypass for

obesity.

Following resection of the small intestine, the residual intestine undergoes adaptation of both structure and function that may last for up to 6 to 12 months. Adaptation requires the continued intake of dietary nutrients and calories to stimulate it via direct contact with ileal mucosa, the release of one or more intestinal hormones, and pancreatic and biliary secretions. Thus, enteral nutrition and calorie administration must be maintained, especially in the early postoperative period, even if an extensive intestinal resection requiring total parenteral nutrition (TPN) was required. The subsequent ability of such patients to absorb nutrients will not be known for several months until after adaptation is completed.

Multiple factors besides the absence of intestinal mucosa (required for both lipid and fluid and electrolyte absorption) contribute to the diarrhea and steatorrhea in these patients. Removal of the ileum and especially the ileocecal valve is often associated with more severe diarrhea than jejunal resection. Without part or all of the ileum, diarrhea can be caused by an increase in bile acids entering the colon, leading to their stimulation of colonic fluid and electrolyte secretion. Absence of the ileocecal valve is also associated with a decrease in intestinal transit time and bacterial overgrowth from the colon. Lactose intolerance as a result of the removal of lactase-containing mucosa as well as gastric hypersecretion will also contribute to the diarrhea.

In addition to diarrhea and/or steatorrhea, a range of nonintestinal symptoms are also observed in some patients. A significant increase in renal calcium oxalate calculi is observed in patients with a small-intestinal resection with an intact colon and is due to an increase in oxalate absorption by the large intestine, with subsequent hyperoxaluria. Since oxalate is high in relatively few foods (e.g., spinach, rhubarb, tea), dietary restrictions alone are not adequate treatment. Cholestyramine, an anion-binding resin, and calcium have proved useful in reducing the hyperoxaluria. Similarly, an increase in cholesterol gall stones is seen that is related to a decrease in the bile acid pool size, which results in the generation of cholesterol supersaturation in gall bladder bile. Gastric hypersecretion of acid occurs in many patients following large resections of the small intestine. The etiology is unclear but may be related to either reduced hormonal inhibition of acid secretion or increased gastrin levels due to reduced small-intestinal catabolism of circulating gastrin. The resulting gastric acid secretion may be an important factor contributing to the diarrhea and steatorrhea. A reduced pH in the duodenum can inactivate pancreatic lipase and/or precipitate duodenal bile acids, thereby increasing steatorrhea, and an increase in gastric secretion can create a volume overload relative to the reduced small-intestinal absorptive capacity. Inhibition of gastric acid secretion with either proton pump inhibitors or H_2receptor antagonists can help in reducing the diarrhea and steatorrhea.

TREATMENT

Treatment of short bowel syndrome depends on the severity of symptoms and whether the individual is able to maintain caloric and electrolyte balance with oral intake alone. Initial treatment includes judicious use of opiates to reduce stool output and to establish an effective diet. An initial diet should be low-fat, high-carbohydrate to minimize the diarrhea from fatty acid stimulation of colonic fluid secretion. BothMCT (see above), a

low-lactose diet, and various fiber-containing diets should also be tried. In the absence of an ileocecal valve, the possibility of bacterial overgrowth must be considered and treated. If gastric acid hypersecretion is contributing to the diarrhea and steatorrhea, a proton pump inhibitor may be helpful. Usually none of these therapeutic approaches will provide an instant solution but will reduce disabling diarrhea.

The patient's vitamin and mineral status must also be monitored, and replacement therapy initiated, if indicated. Fat-soluble vitamins, folate, cobalamin, calcium, iron, magnesium, and zinc are the most critical factors to monitor on a regular basis. If these approaches are not successful, homeTPNrepresents an established therapy that can be maintained for many years. Intestinal transplantation is beginning to become established as a possible approach for individuals with extensive intestinal resection who cannot be maintained without TPN.

BACTERIAL OVERGROWTH SYNDROME

Bacterial overgrowth syndrome comprises a group of disorders with diarrhea, steatorrhea, and macrocytic anemia whose common feature is the proliferation of colon-type bacteria within the small intestine. This bacterial proliferation is due to stasis caused by impaired peristalsis (i.e., *functional stasis*), changes in intestinal anatomy (i.e., *anatomic stasis*), or direct communication between the small and large intestine. These conditions have also been referred to as *stagnant bowel syndrome* or *blind loop syndrome*.

Pathogenesis The manifestations of bacterial overgrowth syndromes are a direct consequence of the presence of increased amounts of a colonic-type bacterial flora, such as *E. coli* or *Bacteroides*, in the small intestine. *Macrocytic anemia* is due to cobalamin, not folate, deficiency. Most bacteria require cobalamin for growth, and increasing concentrations of bacteria use up the relatively small amounts of dietary cobalamin. *Steatorrhea* is due to impaired micelle formation as a consequence of a reduced intraduodenal concentration of bile acids and the presence of unconjugated bile acids. Certain bacteria, e.g., *Bacteroides*, deconjugate conjugated bile acids to unconjugated bile acids. In the presence of bacterial overgrowth, unconjugated bile acids will be absorbed more rapidly than conjugated bile acids, and, as a result, the intraduodenal concentration of bile acids will be reduced. In addition, theCMC of unconjugated bile acids is higher than that of conjugated bile acids, resulting in a decrease in micelle formation. *Diarrhea* is due, at least in part, to the steatorrhea, when it is present. However, some patients manifest diarrhea *without* steatorrhea, and it is assumed that the colonic-type bacteria in these patients are producing one or more bacterial enterotoxins that are responsible for fluid secretion and diarrhea.

Etiology The etiology of these different disorders is bacterial proliferation in the small intestinal lumen secondary to either anatomic or functional stasis or to a communication between the relatively sterile small intestine and the colon with its high levels of aerobic and anaerobic bacteria. Several examples of anatomic stasis have been identified: (1) one or more diverticula (both duodenal and jejunal) (Figure 286-3C); (2) fistulas and strictures related to Crohn's disease (Figure 286-3D); (3) a proximal duodenal afferent loop following a subtotal gastrectomy and gastrojejunostomy; (4) a bypass of the intestine, e.g., jejunoileal bypass for obesity; and (5) dilatation at the site of a previous

intestinal anastomosis. The common feature of all of these anatomic derangements is the presence of a segment(s) of intestine that is out of continuity of propagated peristalsis, resulting in stasis and bacterial proliferation. Bacterial overgrowth syndromes can also occur in the absence of an anatomic blind loop when functional stasis is present. The best example of impaired peristalsis and bacterial overgrowth in the absence of a blind loop is scleroderma, where motility abnormalities exist in both the esophagus and small intestine (Chap. 313). Functional stasis and bacterial overgrowth can also occur in association with diabetes mellitus and in the small intestine when a direct connection exists between the small and large intestine, including an ileocolonic resection, or occasionally following an enterocolic anastomosis that permits entry of bacteria into the small intestine as a result of bypassing the ileocecal valve.

Diagnosis The diagnosis may be suspected from the combination of a low serum cobalamin level and an elevated serum folate level as enteric bacteria frequently produce folate compounds that will be absorbed in the duodenum. Ideally, the diagnosis of the bacterial overgrowth syndrome is the demonstration of increased levels of aerobic and/or anaerobic colonic-type bacteria in a jejunal aspirate obtained by intubation. This specialized test is rarely available, and bacterial overgrowth is best established by a Schilling test (Table 286-6), which should be abnormal following the administration of ^{58}Co-labeled cobalamin, with or without the administration of intrinsic factor. Following the administration of tetracycline for 5 days, the Schilling test will become normal, confirming the diagnosis of bacterial overgrowth.

TREATMENT

Primary treatment should be directed, if at all possible, to the surgical correction of an anatomic blind loop. In the absence of functional stasis, it is important to define the anatomic relationships responsible for stasis and bacterial overgrowth. For example, bacterial overgrowth secondary to strictures, one or more diverticula, or a proximal afferent loop can potentially be cured by surgical correction of the anatomic state. In contrast, the functional stasis of scleroderma or certain anatomic stasis states (e.g., multiple jejunal diverticula), cannot be corrected surgically, and these conditions should be treated with broad-spectrum antibiotics. Tetracycline used to be the initial treatment of choice but with increasing resistance, other antibiotics such as metronidazole, amoxicillin/clavulinic acid (Augmentin), and cephalosporin have been employed. The antibiotic should be given for approximately 3 weeks or until symptoms remit. Since the natural history of these conditions is chronic, antibiotics should not be given continuously, and symptoms usually remit within 2 to 3 weeks of initial antibiotic therapy. Therapy need not be repeated until symptoms recur. In the presence of frequent recurrences several treatment strategies exist, but the use of antibiotics for 1 week per month whether or not symptoms are present is often most effective.

Unfortunately, therapy for bacterial overgrowth syndrome is largely empirical, with an absence of clinical trials on which to base decisions regarding the antibiotic to be used, the duration of treatment, and/or the best approach for treating recurrences. Bacterial overgrowth may also occur as a component of another chronic disease, e.g., Crohn's disease, radiation enteritis, or short bowel syndrome. Treatment of the bacterial overgrowth in these settings will not cure the underlying problem but may be very important in ameliorating a subset of clinical problems that are related to bacterial

overgrowth.

WHIPPLE'S DISEASE

Whipple's disease is a chronic multisystem disease associated with diarrhea, steatorrhea, weight loss, arthralgia, and central nervous system and cardiac problems that is caused by the bacteria *Tropheryma whippelii*. Until the identification of *T. whippelii* by polymerase chain reaction during the past decade, the hallmark of Whipple's disease had been the presence ofPAS-positive macrophages in the small intestine and other organs with evidence of disease. Long before the establishment of *T. whippelii* as the causative agent of Whipple's disease, gram-positive bacilli had been identified both within and outside of macrophages.

Etiology Whipple's disease is caused by a small gram-positive bacillus, *T. whippelii*. The bacillus, an actinobacterium, has low virulence but high infectivity, and relatively minimal symptoms are observed compared to the extent of the bacilli in multiple tissues.

Clinical Presentation The onset of Whipple's disease is insidious and is characterized by diarrhea, steatorrhea, abdominal pain, weight loss, migratory large-joint arthropathy, and fever as well as ophthalmologic and central nervous system symptoms. The development of dementia is a relatively late symptom and is an extremely poor prognostic sign, especially in patients who relapse following the induction of a remission with antibiotics. For unexplained reasons, the disease occurs primarily in middle-aged (50-year-old) Caucasian men. The steatorrhea in these patients is generally believed secondary to both small-intestinal mucosal injury and lymphatic obstruction secondary to the increased number ofPAS-positive macrophages in the lamina propria of the small intestine.

Diagnosis The diagnosis of Whipple's disease is suggested by a multisystem disease in a 50-year-old Caucasian male with diarrhea and steatorrhea. Obtaining tissue biopsies from the small intestine and/or other organs that may be involved (e.g., liver, lymph nodes, heart, eyes, central nervous system, or synovial membranes), based on the patient's symptoms, is the primary approach to establish the diagnosis of Whipple's disease. The presence ofPAS-positive macrophages containing the characteristic small (0.25´ 1 to 2 um) bacilli is suggestive of this diagnosis. However, Whipple's disease can be confused with the PAS-positive macrophages containing *M. avian* complex, which may be a cause of diarrhea in AIDS. The presence of the *T. whippelii* bacillus outside of macrophages is a more important indicator of active disease than their presence within the macrophages. *T. whippelii* has now been successfully grown in culture.

TREATMENT

The treatment for Whipple's disease is prolonged use of antibiotics. At the present time the drug of choice is double-strength trimethoprim/sulfamethoxazole for approximately 1 year.PAS-positive macrophages can persist following successful treatment, and the presence of bacilli outside of macrophages is indicative of persistent infection or an early sign of recurrence. Recurrence of disease activity, especially with dementia, is an extremely poor prognostic sign and requires an antibiotic that crosses the blood-brain barrier. If trimethoprim/sulfamethoxazole is not tolerated, chloramphenicol is an

appropriate second choice.

PROTEIN-LOSING ENTEROPATHY

Protein-losing enteropathy is not a specific disease but rather describes a group of gastrointestinal and nongastrointestinal disorders with hypoproteinemia and edema in the absence of either proteinuria or defects in protein synthesis, e.g., chronic liver disease. These diseases are characterized by excess protein loss into the gastrointestinal tract. Normally, about 10% of the total protein catabolism occurs via the gastrointestinal tract. Evidence of increased protein loss into the gastrointestinal tract has been established in>65 different diseases, which can be classified into three primary groups: (1) mucosal ulceration such that the protein loss primarily represents exudation across damaged mucosa, e.g., ulcerative colitis, gastrointestinal carcinomas, peptic ulcer; (2) nonulcerated mucosa but with evidence of mucosal damage so that the protein loss represents loss across epithelia with altered permeability, e.g., celiac sprue and Menetrier's disease in the small intestine and stomach, respectively; (3) lymphatic dysfunction, either representing primary lymphatic disease or secondary to partial lymphatic obstruction that may occur as a result of enlarged lymph nodes or cardiac disease.

Diagnosis The diagnosis of protein-losing enteropathy is suggested by the presence of peripheral edema and low serum albumin and globulin levels in the absence of renal and hepatic disease. It is extremely rare for an individual with protein-losing enteropathy to have selective loss of *only* albumin or *only* globulins. Therefore, marked reduction of serum albumin with normal serum globulins should not initiate an evaluation for protein-losing enteropathy but should suggest the presence of renal and/or hepatic disease. Likewise, reduced serum globulins with normal serum albumin levels is more likely a result of reduced globulin synthesis rather than enhanced globulin loss into the intestine. Documentation of an increase in protein loss into the gastrointestinal tract has been established by the administration of one of several radiolabeled proteins and its quantitation in stool during a 24- or 48-h period. Unfortunately, none of these radiolabeled proteins are available for routine clinical use.a_1-Antitrypsin, a protein that represents approximately 4% of total serum proteins and is resistant to proteolysis, can be used to document enhanced rates of serum protein loss into the intestinal tract but cannot be used to assess gastric protein loss due to its degradation in an acid milieu.a_1-Antitrypsin clearance is measured by determining stool volume and both stool and plasmaa_1-antitrypsin concentrations. In addition to the loss of protein via abnormal and distended lymphatics, peripheral lymphocytes may also be lost via lymphatics, resulting in a relative lymphopenia. Thus, the presence of lymphopenia in a patient with hypoproteinemia supports the presence of increased loss of protein into the gastrointestinal tract.

Patients with increased protein loss into the gastrointestinal tract from lymphatic obstruction often have steatorrhea and diarrhea. The steatorrhea is a result of altered lymphatic flow as lipid-containing chylomicrons exit from intestinal epithelial cells via intestinal lymphatics (Table 286-4;Fig. 286-4). In the absence of mechanical or anatomic lymphatic obstruction, instrinsic intestinal lymphatic dysfunction, with or without lymphatic dysfunction in the peripheral extremities, has been named *intestinal lymphangiectasia*. Similarly, about 50% of individuals with intrinsic peripheral lymphatic

disease (Milroy's disease) will also have intestinal lymphangiectasia and hypoproteinemia. Other than steatorrhea and enhanced protein loss into the gastrointestinal tract, all other aspects of intestinal absorptive function are normal in intestinal lymphangiectasia.

Other Causes Patients who appear to have idiopathic protein-losing enteropathy without any evidence of gastrointestinal disease should be examined for cardiac disease and especially right-sided valvular disease and chronic pericarditis (Chap. 236). On occasion, hypoproteinemia can be the only presentation for these two types of heart disease. Menetrier's disease (also called *hypertrophic gastropathy*) is an uncommon entity that involves the body and fundus of the stomach and is characterized by large gastric folds, reduced gastric acid secretion, and, at times, enhanced protein loss into the stomach.

TREATMENT

As excess protein loss into the gastrointestinal tract is most often secondary to a specific disease, treatment should be directed primarily to the underlying disease process and not to the hypoproteinemia. For example, if significant hypoproteinemia with resulting peripheral edema is present secondary to either celiac sprue or ulceratic colitis, a gluten-free diet or mesalamine, respectively, would be the initial therapy. When enhanced protein loss is secondary to lymphatic obstruction, it is critical to establish the nature of this obstruction. Identification of mesenteric nodes or lymphoma may be possible by imaging studies. Similarly, it is important to exclude cardiac disease as a cause of protein-losing enteropathy either by echosonography or, on occasion, by a right-heart catheterization.

The increased protein loss that occurs in intestinal lymphangiectasia is a result of distended lymphatics associated with lipid malabsorption. Treatment of the hypoproteinemia is accomplished by a low-fat diet and the administration ofMCTs(Table 286-3), which do not exit from the intestinal epithelial cells via lymphatics but are delivered to the body via the portal vein.

SUMMARY

A pathophysiologic classification of the many conditions that can produce malabsorption is given in Table 286-9. A summary of the pathophysiology of the various clinical manifestations of malabsorption is given inTable 286-10.

287. INFLAMMATORY BOWEL DISEASE - *Sonia Friedman*, *Richard S. Blumberg*

Inflammatory bowel disease (IBD) is an idiopathic and chronic intestinal inflammation. Ulcerative colitis (UC) and Crohn's disease (CD) are the two major types of IBD.

EPIDEMIOLOGY

The incidence ofIBDvaries within different geographic areas. Northern countries, such as the United States, United Kingdom, Norway, and Sweden, have the highest rates. The incidence rates ofUC andCD in the United States are about 11 per 100,000 and 7 per 100,000, respectively (Table 287-1). Countries in southern Europe, South Africa, and Australia have lower incidence rates: 2 to 6.3 per 100,000 for UC, and 0.9 to 3.1 per 100,000 for CD. In Asia and South America, IBD is rare; incidence rates of UC and CD are 0.5 and 0.08 per 100,000, respectively. The highest mortality in IBD patients is during the first years of disease and in long duration disease due to the risk of colon cancer. In a Swedish population study, the standardized mortality ratios for CD and UC were 1.51 and 1.37, respectively.

The peak age of onset ofUC andCD is between 15 and 30 years. A second peak occurs between the ages of 60 and 80. The male to female ratio for UC is 1:1 and for CD is 1.1 to 1.8:1. A two- to fourfold increased frequency of UC and CD in Jewish populations has been described in the United States, Europe, and South Africa. Furthermore, disease frequency differs within the Jewish populations. The prevalence ofIBD in Ashkenazi Jews is about twice that of Israeli-born, Sephardic, or Oriental Jews. The prevalence decreases progressively in non-Jewish Caucasian, African-American, Hispanic, and Asian populations. Urban areas have a higher prevalence of IBD than rural areas and high socioeconomic classes have a higher prevalence than lower socioeconomic classes.

The effects of cigarette smoking are different inUC andCD. The risk of UC in smokers is 40% that of nonsmokers. Additionally, former smokers have a 1.7-fold increased risk for UC than people who have never smoked. In contrast, smoking is associated with a twofold increased risk of CD. Oral contraceptives are also linked to CD; the relative risk of CD for oral contraceptive users is about 1.9. Appendectomy appears to be protective against UC but further studies are needed.

IBDruns in families. If a patient has IBD, the lifetime risk that a first-degree relative will be affected is ~10%. If two parents have IBD, each child has a 36% chance of being affected. In twin studies, 67% of monozygotic twins are concordant forCD and 20% are concordant forUC, whereas 8% of dizygotic twins are concordant for CD and none are concordant for UC. There is also concordance for anatomic site and clinical type of CD within families.

Additional evidence for genetic predisposition toIBDcomes from its association with certain genetic syndromes.UC andCD are both associated with Turner's syndrome, and Hermansky-Pudlak syndrome is associated with a granulomatous colitis. Glycogen storage disease type 1b can present with Crohn's-like lesions of the large and small bowel. Other immunodeficiency disorders, such as hypogammaglobulinemia, selective IgA deficiency, and hereditary angioedema, also exhibit an increased association with

IBD.

ETIOLOGY AND PATHOGENESIS

AlthoughIBD has been described as a clinical entity for over 100 years, its etiology and pathogenesis have not been definitively elaborated. Various studies have led to a consensus hypothesis that in genetically predisposed individuals, both exogenous factors (e.g., infectious agents, normal lumenal flora) and host factors (e.g., intestinal epithelial cell barrier function, vascular supply, neuronal activity) together cause a chronic state of dysregulated mucosal immune function that is further modified by specific environmental factors (e.g., smoking). Although it is possible that the chronic activation of the mucosal immune system may represent an appropriate response to a chronic unidentified infectious agent, a search for such an agent has thus far been unrewarding. As such, IBD must currently be considered an inappropriate response to either the endogenous microbial flora within the intestine, with or without some component of autoimmunity. Importantly, the normal intestine contains a significant concentration of immune cells in a chronic state of so-called *physiologic inflammation*, in which the gut is poised for, but actively restrained from, full immunologic responses. During the course of infections in the normal host, full activation of the gut-associated lymphoid tissue occurs but is rapidly superceded by downregulation of the immune response and tissue repair. In IBD this process is not regulated normally.

GENETIC CONSIDERATIONS

IBDis a polygenic disorder that gives rise to multiple clinical subgroups withinUC andCD. Genome-wide searches have shown that potential disease-associated loci are present on chromosomes 16, 12, 7, 3, and 1, although the specific gene associations are undefined. HLA alleles may play a role. UC patients disproportionately express DR2-related alleles, whereas in CD an increased use of the DR5 DQ1 haplotype or the DRB*0301 allele has been described. In UC patients with pancolitis undergoing total proctocolectomy, 14.3% versus 3.2% of non-IBD controls express the HLA DRB1*0103 allele. This allele is associated with extensive disease and extraintestinal manifestations such as mouth ulcers, arthritis, and uveitis. Other associations with immunoregulatory genes include the intercellular adhesion molecule R241 allele in UC and CD and the interleukin (IL) 1 receptor antagonist allele 2 in UC patients that is associated with total colonic inflammation. Although not proven at the genetic level, patients with IBD and their first-degree relatives may exhibit diminished intestinal epithelial cell barrier function.

DEFECTIVE IMMUNE REGULATION IN IBD

The normal state of the mucosal immune system is one of inhibited immune responses to lumenal contents due to oral tolerance that occurs in the normal individual. When soluble antigens are administered orally rather than subcutaneously or intramuscularly, antigen-specific non-responsiveness is induced. Multiple mechanisms are involved in the induction of oral tolerance and include deletion or anergy of antigen-reactive T cells or activation of CD4+ T cells that suppress gut inflammation through secretion of inhibitory cytokines (IL-10, TGF-b). Oral tolerance may be responsible for the lack of immune responsiveness to dietary antigens and the commensal flora in the intestinal

lumen. In IBD this tightly regulated state of suppression of inflammation is altered, leading to uncontrolled inflammation. The mechanisms that maintain this regulated state of immune suppression are unknown.

Gene knockout (-/-) or transgenic (Tg) mouse models of colitis have revealed that deleting specific cytokines (e.g.,IL-2, IL-10, TGF-b) or their receptors, deleting molecules associated with T-cell antigen recognition (e.g., T-cell antigen receptors, MHC class II), or interfering with intestinal epithelial cell barrier function (e.g., blocking N-cadherin, deleting multidrug resistance gene 1a or trefoil factor) leads to colitis. Thus, a variety of specific alterations can lead to unregulated autoimmunity directed at the colon in mice.

In bothUC andCD, activated CD4+ T cells present in the lamina propria and peripheral blood secrete inflammatory cytokines. Some directly activate other inflammatory cells (macrophages and B cells) and others act indirectly to recruit other lymphocytes, inflammatory leukocytes, and mononuclear cells from the peripheral vasculature into the gut through interactions between homing receptors on leukocytes (e.g.,a4b7 integrin) and addressins on vascular endothelium (e.g., MadCAM1). CD4+ T cells can be subdivided into two major categories both of which may be associated with colitis in animal models and humans: T_H1 cells (IFN-g, TNF) and T_H2 cells (IL-4, IL-5, IL-13). T_H1 cells appear to induce transmural granulomatous inflammation that resembles CD, and T_H2 cells appear to induce superficial mucosal inflammation more characteristic of UC. The T_H1 cytokine pathway is initiated by IL-12, a key cytokine in the pathogenesis of experimental models of mucosal inflammation. Thus, use of antibodies to block proinflammatory cytokines (e.g., anti-TNF-a, anti-IL-12) or molecules associated with leukocyte recruitment (e.g., anti-a4b7) or use of cytokines that inhibit inflammation (e.g., IL-10) or promote intestinal barrier function (e.g., IL-11) may be beneficial to humans with colitis.

THE INFLAMMATORY CASCADE INIBD

Once initiated in IBD, the immune inflammatory response is perpetuated as a consequence of T-cell activation. A sequential cascade of inflammatory mediators acts to extend the response; each step is a potential target for therapy. Inflammatory cytokines, such asIL-1, IL-6, and tumor necrosis factor (TNF) have diverse effects on tissue. They promote fibrogenesis, collagen production, activation of tissue metalloproteinases, and the production of other inflammatory mediators; they also activate the coagulation cascade in local blood vessels (e.g., increased production of von Willebrand's factor). These cytokines are normally produced in response to infection, but are usually turned off or inhibited at the appropriate time to limit tissue damage. In IBD their activity is not regulated, resulting in an imbalance between the proinflammatory and anti-inflammatory mediators. Therapies such as the 5-ASA compounds are potent inhibitors of these inflammatory mediators through inhibition of transcription factors such as NF-kB that regulate their expression.

EXOGENOUS FACTORS

IBDmay have an as yet undefined infectious etiology. Three specific agents have received the greatest attention, *Mycobacterium paratuberculosis*, *Paramyxovirus*, and

Helicobacter species. The immune response to a specific organism could be expressed differently, depending upon the individual's genetic background. Although *M. paratuberculosis* had initially been identified inCDpatients, further studies have not confirmed a disease association. In addition, antimycobacterial agents have not been effective in treating CD. A role for the measles virus or paramyxoviruses in the development of CD has been suggested based on an increase in the incidence of CD in England that paralleled use of the measles vaccine. However, studies in the United States have not substantiated this finding. In an animal model of IBD, *Helicobacter hepaticus* has been implicated as a trigger for the inflammatory response; evidence in people is lacking.

Multiple pathogens (e.g., *Salmonella*, *Shigella sp.*, *Campylobacter sp.*) may initiateIBD by triggering an inflammatory response that the mucosal immune system may fail to control. However, in an IBD patient the normal flora is likely perceived as if it were a pathogen. Anaerobic organisms, particularly *Bacteroides* species, may be responsible for the induction of inflammation. Such a notion is supported by the response in patients withCD to agents that alter the intestinal flora, such as metronidazole, ciprofloxacin, and elemental diets. CD also responds to fecal diversion, demonstrating the ability of lumenal contents to exacerbate disease. On the other hand, other bacterial organisms, so-called probiotics such as *Lactobacillus sp.*, downregulate inflammation in animal models and humans.

Psychosocial factors can contribute to clinical exacerbation of symptoms. Major life events such as illness or death in the family, divorce or separation, interpersonal conflict, or other major loss, are associated with an increase inIBDsymptoms such as pain, bowel dysfunction, and bleeding. Acute daily stress can exacerbate bowel symptoms even after controlling for major life events. When the *sickness impact profile*, a measurement of overall psychological and physical functioning is used, IBD patients have functional impairment greater than that of a health maintenance organization population but less than that of patients with chronic back pain or amyotrophic lateral sclerosis. IBD patients have been hypothesized to have a characteristic personality that renders them susceptible to emotional stresses. However, emotional dysfunction could also be the result of chronic illness and should be considered when treating these patients.

PATHOLOGY

ULCERATIVE COLITIS: MACROSCOPIC FEATURES

UCis a mucosal disease that usually involves the rectum and extends proximally to involve all or part of the colon. Approximately 40 to 50% of patients have disease limited to the rectum and rectosigmoid, 30 to 40% have disease extending beyond the sigmoid but not involving the whole colon, and 20% have a total colitis. Proximal spread occurs in continuity without areas of uninvolved mucosa. When the whole colon is involved, the inflammation extends 1 to 2 cm into the terminal ileum in 10 to 20% of patients. This is called *backwash ileitis* and has little clinical significance. Although variations in macroscopic activity may suggest skip areas, biopsies from normal-appearing mucosa are usually abnormal. Thus, it is important to obtain multiple biopsies from apparently uninvolved mucosa, whether proximal or distal, during endoscopy.

With mild inflammation, the mucosa is erythematous and has a fine granular surface that looks like sandpaper. In more severe disease, the mucosa is hemorrhagic, edematous, and ulcerated (Fig. 287-1). In long-standing disease, inflammatory polyps (pseudopolyps) may be present as a result of epithelial regeneration (Fig. 287-2). The mucosa may appear normal in remission but in patients with many years of disease it appears atrophic and featureless and the entire colon becomes narrowed and foreshortened (Fig. 287-3). Patients with fulminant disease can develop a toxic colitis or a toxic megacolon where the bowel wall becomes very thin and the mucosa is severely ulcerated, which may lead to perforation.

ULCERATIVE COLITIS: MICROSCOPIC FEATURES

Histologic findings correlate well with the endoscopic appearance and clinical course ofUC. The process is limited to the mucosa and superficial submucosa with deeper layers unaffected except in fulminant disease (Fig. 287-4). In UC, two major histologic features are indicative of chronicity and help distinguish it from infectious or acute self-limited colitis. First, the crypt architecture of the colon is distorted; crypts may be bifid and reduced in number, often with a gap between the crypt bases and the muscularis mucosae. Second, some patients have basal plasma cells and multiple basal lymphoid aggregates. Mucosal vascular congestion with edema and focal hemorrhage, and an inflammatory cell infiltrate of neutrophils, lymphocytes, plasma cells, and macrophages may be present. The neutrophils invade the epithelium, usually in the crypts, and give rise to cryptitis and, ultimately, to crypt abscesses (Fig. 287-5). The cryptitis is associated with mucus discharge from goblet cells and increased epithelial cell turnover. Histologically, this results in goblet cell depletion. Other chronic changes that are sometimes seen are neuronal hypertrophy and fibromuscular hyperplasia of the muscularis mucosae.

CROHN'S DISEASE: MACROSCOPIC FEATURES

CDcan affect any part of the gastrointestinal tract from the mouth to the anus. Some 30 to 40% of patients have small bowel disease alone, 40 to 55% have disease involving both the small and large intestines, and 15 to 25% have colitis alone. In the 75% of patients with small intestinal disease, the terminal ileum is involved in 90%. UnlikeUC, which almost always involves the rectum, the rectum is often spared in CD. CD is segmental, with skip areas in the midst of diseased intestine (Fig. 287-6). Perirectal fistulas, fissures, abscesses, and anal stenosis are present in one-third of patients with CD, particularly those with colonic involvement. CD may also involve the liver and the pancreas.

UnlikeUC,CD is a transmural process (Fig. 287-7). Endoscopically, aphthous or small superficial ulcerations characterize mild disease; in more active disease, stellate ulcerations fuse longitudinally and transversely to demarcate islands of mucosa that frequently are histologically normal. This "cobblestone" appearance is characteristic of CD, both endoscopically and by barium radiography. As in UC, pseudopolyps can form in CD.

Active CD is characterized by focal inflammation and formation of fistula tracts, which

resolve by fibrosis and stricturing of the bowel. The bowel wall thickens and becomes narrowed and fibrotic, leading to chronic, recurrent bowel obstructions. Projections of thickened mesentery encase the bowel ("creeping fat") and serosal and mesenteric inflammation promote adhesions and fistula formation.

CROHN'S DISEASE: MICROSCOPIC FEATURES

The earliest lesions are aphthoid ulcerations and focal crypt abscesses with loose aggregations of macrophages, which form noncaseating granulomas in all layers of the bowel wall from mucosa to serosa (Fig. 287-8). Granulomas can be seen in lymph nodes, mesentery, peritoneum, liver, and pancreas. Although granulomas are a pathognomonic feature ofCD, only half of cases reveal granulomas on surgical or endoscopic biopsy specimens. Other histologic features of CD include submucosal or subserosal lymphoid aggregates, particularly away from areas of ulceration, gross and microscopic skip areas, and transmural inflammation that is accompanied by fissures that penetrate deeply into the bowel wall and sometimes form fistulous tracts or local abscesses.

CLINICAL PRESENTATION

ULCERATIVE COLITIS

Signs and Symptoms The major symptoms ofUC are diarrhea, rectal bleeding, tenesmus, passage of mucus, and crampy abdominal pain. The severity of symptoms correlates with the extent of disease. Although UC can present acutely, symptoms usually have been present for weeks to months. Occasionally, diarrhea and bleeding are so intermittent and mild that the patient does not seek medical attention.

Patients with proctitis usually pass fresh blood or blood-stained mucus, either mixed with stool or streaked onto the surface of a normal or hard stool. They also have tenesmus, or urgency with a feeling of incomplete evacuation. They rarely have abdominal pain. With proctitis or proctosigmoiditis, proximal transit slows, which may account for the constipation that is commonly seen in patients with distal disease.

When the disease extends beyond the rectum, blood is usually mixed with stool, or grossly bloody diarrhea may be noted. Colonic motility is altered by inflammation with rapid transit through the inflamed intestine. When the disease is severe, patients pass a liquid stool containing blood, pus, and fecal matter. Diarrhea is often nocturnal and/or postprandial. Although severe pain is not a prominent symptom, some patients with active disease may experience vague lower abdominal discomfort or mild central abdominal cramping. Severe cramping and abdominal pain can occur in association with severe attacks of the disease. Other symptoms in moderate to severe disease include anorexia, nausea, vomiting, fever, and weight loss.

Physical signs of proctitis include a tender anal canal and blood on rectal exam. With more extensive disease, patients have tenderness to palpation directly over the colon. Patients with a toxic colitis have severe pain and bleeding, and those with megacolon have hepatic tympany. Both may have signs of peritonitis if a perforation has occurred. The classification of disease activity is shown inTable 287-2.

Laboratory, Endoscopic, and Radiographic Features Active disease can be associated with a rise in acute phase reactants (C-reactive protein, orosomucoid levels), platelet count, erythrocyte sedimentation rate (ESR) and a decrease in hemoglobin. In severely ill patients, the serum albumin level will fall rather quickly. Leukocytosis may be present but is not a specific indicator of disease activity. Proctitis or proctosigmoiditis rarely causes a rise in C-reactive protein. Diagnosis relies upon the patient's history; clinical symptoms, negative stool examination for bacteria, *Clostridium difficile* toxin, and ova and parasites; sigmoidoscopic appearance; and histology of rectal or colonic biopsy specimens.

Sigmoidoscopy is used to assess disease activity and is often performed before treatment. Histologic features change more slowly than clinical features but can also be used to grade disease activity (Table 287-3).

Patients with a severe attack ofUCshould have a plain, supine film of the abdomen. In the presence of severe disease, the margin of the colon becomes edematous and irregular (Fig. 287-9). Colonic thickening and toxic dilation can both be seen on a plain radiograph.

The earliest radiologic change ofUC seen on single-contrast barium enema is a fine mucosal granularity (Fig. 287-10). With increasing severity, the mucosa becomes thickened and superficial ulcers are seen. Deep ulcerations can appear as "collar-button" ulcers, which indicate that the ulceration has penetrated the mucosa. Haustral folds may be normal in mild disease, but as activity progresses they become edematous and thickened. Loss of haustration can occur, especially in patients with long-standing disease. In addition, the colon becomes shortened and narrowed. Polyps in the colon may be postinflammatory polyps or pseudopolyps (Fig. 287-11), adenomatous polyps, or carcinoma.

Computed tomography (CT) scanning is not as helpful as endoscopy and barium enema in making the diagnosis ofUC, but typical findings include mild mural thickening (<1.5 cm), inhomogeneous wall density, absence of small bowel thickening, increased perirectal and presacral fat, target appearance of the rectum, and adenopathy.

Complications Only 15% of patients withUCpresent initially with catastrophic illness. Massive hemorrhage occurs with severe attacks of disease in 1% of patients and treatment for the disease usually stops the bleeding. However, if patients require 6 to 8 units of blood within 24 to 48 h, colectomy is indicated. Toxic megacolon is defined as a transverse colon with a diameter of more than 5.0 cm to 6.0 cm, with loss of haustration in patients with severe attacks of UC. It occurs in about 5% of attacks and can be triggered by electrolyte abnormalities and narcotics. Approximately 50% of acute dilations will resolve with medical therapy alone, but urgent colectomy is required for those that do not improve. Perforation is the most dangerous of the local complications, and the physical signs of peritonitis may not be obvious, especially if the patient is receiving glucocorticoids. Although perforation is rare, the mortality rate for perforation complicating a toxic megacolon is about 15%. In addition, patients can develop a toxic colitis and such severe ulcerations that the bowel may perforate without first dilating.

Obstructions caused by benign stricture formation occur in 10% of patients, with one-third of the strictures occurring in the rectum. These should be surveyed endoscopically for carcinoma.UCpatients occasionally develop anal fissures, perianal abscesses, or hemorrhoids but the occurrence of extensive perianal lesions should suggestCD.

CROHN'S DISEASE

Signs and Symptoms AlthoughCDusually presents as acute or chronic bowel inflammation, the inflammatory process evolves toward one of two patterns of disease: a fibrostenotic-obstructing pattern or a penetrating-fistulous pattern, each with different treatments and prognoses. The site of disease influences the clinical manifestations.

Ileocolitis Because the most common site of inflammation is the terminal ileum, the usual presentation of ileocolitis is a chronic history of recurrent episodes of right lower quadrant pain and diarrhea. Sometimes the initial presentation mimics acute appendicitis with pronounced right lower quadrant pain, a palpable mass, fever, and leukocytosis. Only at laparotomy, when the appendix is found to be normal, is the ileitis discovered. Pain is usually colicky; it precedes and is relieved by defecation. A low-grade fever is usually noted. High-spiking fever suggests intraabdominal abscess formation. Weight loss is common -- typically 10 to 20% of body weight -- and develops as a consequence of diarrhea, anorexia, and fear of eating.

An inflammatory mass may be palpated in the right lower quadrant of the abdomen. The mass is composed of inflamed bowel, adherent and indurated mesentery, and enlarged abdominal lymph nodes. Extension of the mass can cause obstruction of the right ureter or bladder inflammation, manifested by dysuria and fever. Edema, bowel wall thickening, and fibrosis of the bowel wall within the mass account for the radiographic "string sign" of a narrowed intestinal lumen.

Bowel obstruction may take several forms. In the early stages of the disease, bowel wall edema and spasm produce intermittent obstructive manifestations and increasing symptoms of postprandial pain. Over several years, this persistent inflammation gradually progresses to fibrostenotic narrowing and stricture. Diarrhea will decrease and eventually lead to chronic bowel obstruction and obstipation. Acute episodes of obstruction occur as well, precipitated by bowel inflammation and spasm or sometimes by impaction of undigested food. These episodes usually resolve with intravenous fluids and gastric decompression.

Severe inflammation of the ileocecal region may lead to localized wall thinning, with microperforation and fistula formation to the adjacent bowel, the skin, the urinary bladder, or to an abscess cavity in the mesentery. Enterovesical fistulas typically present as dysuria or recurrent bladder infections or less commonly as pneumaturia or fecaluria. Enterocutaneous fistulas follow tissue planes of least resistance, usually draining through abdominal surgical scars. Enterovaginal fistulas are rare and present as dyspareunia or as a feculent or foul-smelling, often painful vaginal discharge. They are unlikely to develop without a prior hysterectomy.

Jejunoileitis Extensive inflammatory disease is associated with a loss of digestive and

absorptive surface, resulting in malabsorption and steatorrhea. Nutritional deficiencies can also result from poor intake and enteric losses and protein and other nutrients. Intestinal malabsorption can cause hypoalbuminemia, hypocalcemia, hypomagnesemia, coagulopathy, and hyperoxaluria with nepholithiasis. Vertebral fractures are caused by a combination of vitamin D deficiency, hypocalcemia, and prolonged glucocorticoid use. Pellagra from niacin deficiency has been reported in extensive small bowel disease, and malabsorption of vitamin B12 can lead to a megaloblastic anemia.

Diarrhea is characteristic of active disease; its causes include: (1) bacterial overgrowth in obstructive stasis or fistulization, (2) bile-acid malabsorption due to a diseased or resected terminal ileum, (3) intestinal inflammation with decreased water absorption and increased secretion of electrolytes.

Colitis and Perianal Disease Patients with colitis present with low-grade fevers, malaise, diarrhea, crampy abdominal pain, and sometimes hematochezia. Gross bleeding due to deep colonic ulceration is not as common as inUC and appears in about half of patients with exclusively colonic disease. Only 1 to 2% bleed massively. Pain is caused by passage of fecal material through narrowed and inflamed segments of large bowel. Decreased rectal compliance is another cause for diarrhea in Crohn's colitis patients. Toxic megacolon has been associated with severe inflammation and short-duration disease.

Stricturing can occur in the colon, and patients can develop fibrous strictures with symptoms of bowel obstruction. Also, colonic disease may fistulize into the stomach or duodenum, causing feculent vomiting, or to the proximal or mid small bowel, causing malabsorption by "short circuiting" and bacterial overgrowth. Approximately 10% of women with Crohn's colitis will develop a rectovaginal fistula.

Perianal disease affects about one-third of patients with Crohn's colitis and is manifested by incontinence, large hemorrhoidal tags, anal strictures, anorectal fistulae, and perirectal abscesses. Not all patients with perianal fistula will have endoscopic evidence of colonic inflammation.

Gastroduodenal Disease Symptoms and signs of upper gastrointestinal tract disease include nausea, vomiting, and epigastric pain. Patients usually have a *H. pylori*-negative gastritis. The second portion of the duodenum is more commonly involved than the bulb. Fistulas involving the stomach or duodenum arise from the small or large bowel and do not necessarily signify the presence of upper gastrointestinal tract involvement. Patients with advanced gastroduodenalCD may develop a chronic gastric outlet obstruction.

Laboratory, Endoscopic, and Radiographic Features Laboratory abnormalities include elevated sedimentation rate and C-reactive protein. In more severe disease, findings include hypoalbuminemia, anemia, and leukocytosis.

Endoscopic features ofCDinclude rectal sparing, aphthous ulcerations, fistulas, and skip lesions. Endoscopy is useful for biopsy of mass lesions or strictures, or for visualization of filling defects seen on barium enema. Colonoscopy allows examination and biopsy of the terminal ileum, and upper endoscopy is useful in diagnosing gastroduodenal involvement in patients with upper tract symptoms. Ileal or colonic strictures may be

dilated with balloons introduced through the colonoscope. Endoscopic appearance correlates poorly with clinical remission; thus, repeated endoscopy is not used to monitor the inflammation.

InCD early radiographic findings in the small bowel include thickened folds and aphthous ulcerations. "Cobblestoning" from longitudinal and transverse ulcerations most frequently involves the small bowel (Fig. 287-12). In more advanced disease, strictures, fistulas (Fig. 287-13), inflammatory masses, and abscesses may be detected. The earliest macroscopic findings of colonic CD are aphthous ulcers. These small ulcers are often multiple and separated by normal intervening mucosa. As more severe disease develops, aphthous ulcers become enlarged, deeper, and occasionally connected to one another, forming longitudinal stellate, serpiginous, and linear ulcers.

The transmural inflammation ofCD leads to decreased luminal diameter and limited distensibility. As ulcers progress deeper, they can lead to fistula formation. The radiographic "string sign" (Figs. 287-14 and287-15) represents long areas of circumferential inflammation and fibrosis, resulting in long segments of luminal narrowing. The segmental nature of CD results in wide gaps of normal or dilated bowel between involved segments (Fig. 287-16).

CTfindings include mural thickening >2 cm, homogeneous wall density, mural thickening of small bowel, mesenteric fat stranding, perianal disease, and adenopathy. CT scanning can help identify abscesses, fistulas, and sinus tracts. Magnetic resonance imaging (MRI) may prove superior for demonstrating pelvic lesions such as ischiorectal abscesses.

Complications BecauseCD is a transmural process, serosal adhesions develop that provide direct pathways for fistula formation and reduce the incidence of free perforation. Free perforation occurs in 1 to 2% of patients, usually in the ileum but occasionally in the jejunum or as a complication of toxic megacolon. The peritonitis of free perforation, especially colonic, may be fatal. Generalized peritonitis may also result from the rupture of an intraabdominal abscess. Other complications include intestinal obstruction in 40%, massive hemorrhage, malabsorption, and severe perianal disease.

Serologic Markers Several serologic markers may be used to differentiate betweenCD andUC and help to predict the course of disease. Two antibodies that can be detected in the serum ofIBDpatients are perinuclear antineutrophil cytoplasmic antibody (pANCA) and anti-*Saccharomyces cerevisiae* antibodies (ASCA). A distinct set of antineutrophil cytoplasmic antibodies with perinuclear staining by indirect immunofluorescence is associated with UC. The antigens to which these antibodies are directed have not been identified, but they are distinct from those associated with vasculitis and may be related to histones. pANCA positivity is found in about 60 to 70% of UC patients and 5 to 10% of CD patients; 5 to 15% of first-degree relatives of UC patients are pANCA positive, whereas only 2 to 3% of the general population is pANCA positive. pANCA may also identify specific disease phenotypes. pANCA positivity is more often associated with pancolitis, early surgery, pouchitis, or inflammation of the pouch after ileal pouch-anal anastamosis (IPAA) and primary sclerosing cholangitis. pANCA in CD is associated with colonic disease that resembles UC.

ASCAantibodies recognize mannose sequences in the cell wall mannan of *S. cerevisiae*; 60 to 70% ofCDpatients, 10 to 15% of UC patients, and up to 5% of non-IBDcontrols are ASCA positive. The combined measurement ofpANCAand ASCA has been advocated as a valuable diagnostic approach to IBD. In one report, pANCA positivity with ASCA negativity yielded a 57% sensitivity and 97% specificity for UC, whereas pANCA negativity with ASCA positivity yielded a 49% sensitivity and 97% specificity for CD. ASCA was associated with small bowel CD. These antibody tests may help decide whether a patient with indeterminate colitis should undergo an IPAA, because patients with predominant features of CD often have a more difficult postoperative course.

Anti-goblet cell autoantibodies (GABs) -- autoantibodies against two target antigens in colonic epithelial cells -- are present in 39% ofUCpatients, 30% ofCDpatients, 21% of first-degree relatives of UC patients, 19% of first-degree relatives of CD patients, and 2% of healthy controls. An anti-colon antibody is found in 36% of UC patients and 13% of CD patients and healthy controls. In addition, 31% of CD patients and 4% of UC patients have serum antibodies against pancreatic acinar cells or pancreatic autoantibodies (PABs). Antibodies to red cell membrane antigens that cross-react with enteropathogens such as *Campylobacter sp.* may be associated with hemolytic anemia in CD. None of these antibodies are useful in the diagnosis and management of patients withIBD.

DIFFERENTIAL DIAGNOSIS OF UC AND CD

UC and CD have similar features to many other diseases. In the absence of a key diagnostic test, a combination of clinical, laboratory, histopathologic, radiographic, and therapeutic observations is required (Table 287-4). Once a diagnosis ofIBD is made, distinguishing between UC and CD is impossible in 10 to 20% of cases. These are termed *indeterminate* colitis.

INFECTIOUS DISEASE

Infections of the small intestines and colon can mimicCD orUC. They may be bacterial, fungal, viral, or protozoal in origin (Table 287-5). *Campylobacter* colitis can mimic the endoscopic appearance of severe UC and can cause a relapse of established UC. *Salmonella* can cause watery or bloody diarrhea, nausea, and vomiting. Shigellosis causes watery diarrhea, abdominal pain, and fever followed by rectal tenesmus and by the passage of blood and mucus per rectum. All three are usually self-limited but 1% of patients infected with *Salmonella* become asymptomatic carriers. *Yersinia enterocolitica* infection occurs mainly in the terminal ileum and causes mucosal ulceration, neutrophil invasion, and thickening of the ileal wall. Other bacterial infections that may mimicIBDinclude *C. difficile*, which presents with watery diarrhea, tenesmus, nausea, and vomiting, and *Escherichia coli*, three categories of which can cause colitis. These are enterohemorrhagic, enteroinvasive, and enteroadherent *E. coli*, all of which can cause bloody diarrhea and abdominal tenderness. Diagnosis of bacterial colitis is made by sending stool specimens for bacterial culture and *C. difficile* toxin analysis. Gonorrhea, *Chlamydia*, and syphilis can also cause proctitis

Gastrointestinal involvement with mycobacterial infection occurs primarily in the

immunosuppressed patient but may occur in patients with normal immunity. Distal ileal and cecal involvement predominates and patients present with symptoms of small bowel obstruction and a tender abdominal mass. The diagnosis is made most directly by colonoscopy with biopsy and culture. *Mycobacterium avium intracellulare* complex infection occurs in advanced stages of HIV infection and in other profoundly immunocompromised states, and usually manifests as a systemic infection with diarrhea, abdominal pain, weight loss, fever, and malabsorption. Diagnosis is established by acid-fast smear and culture of mucosal biopsies.

Although most of the patients with viral colitis are immunosuppressed, cytomegalovirus (CMV) and herpes simplex proctitis may occur in immunocompetent individuals. CMV occurs most commonly in the esophagus, colon, and rectum, but may also involve the small intestine. Symptoms include abdominal pain, bloody diarrhea, fever, and weight loss. With severe disease, necrosis and perforation can occur. Diagnosis is made by identification of intranuclear inclusions in mucosal cells on biopsy. Herpes simplex infection of the gastrointestinal tract is limited to the oropharynx, anorectum, and perianal areas. Symptoms include anorectal pain, tenesmus, constipation, inguinal adenopathy, difficulty with urinary voiding, and sacral paresthesias. Diagnosis is made by rectal biopsy. HIV itself can cause diarrhea, nausea, vomiting, and anorexia. Small intestinal biopsies show partial villus atrophy; small bowel bacterial overgrowth and fat malabsorption may also be noted.

Protozoan parasites include *Isospora belli*, which can cause a self-limited infection in healthy hosts but causes a chronic profuse, watery diarrhea and weight loss in AIDS patients. *Entamoeba histolytica* or related species infect about 10% of the world's population; symptoms include abdominal pain, tenesmus, frequent loose stool containing blood and mucus, and abdominal tenderness. Colonoscopy reveals focal punctate ulcers with normal intervening mucosa; diagnosis is made by biopsy or serum amebic antibodies. Fulminant amebic colitis is rare but has a mortality rate of>50%.

Other parasitic infections that may mimic IBD include hookworm (*Necator americanus*), whipworm (*Trichuris trichiura*), and *Strongyloides stercoralis*. In severely immunocompromised patients *Candida* or *Aspergillus* can be identified in the submucosa. Disseminated histoplasmosis can involve the ileocecal area.

NONINFECTIOUS DISEASE

Many diseases may mimicIBD(Table 287-5). Diverticulitis can be confused withCDclinically and radiographically. Both diseases cause fever, abdominal pain, tender abdominal mass, leukocytosis, elevatedESR, partial obstruction, and fistulas. Perianal disease or ileitis on small bowel series favors the diagnosis of CD. Significant endoscopic mucosal abnormalities are more likely in CD than in diverticulitis. Endoscopic or clinical recurrence following segmental resection favors CD. Diverticular-associated colitis is similar to CD, but mucosal abnormalities are limited to the sigmoid and descending colon.

Ischemic colitis is commonly confused withIBD. The ischemic process can be chronic and diffuse as inUC, or segmental as inCD. Colonic inflammation due to ischemia may resolve quickly or may persist and result in transmural scarring and stricture formation.

Ischemic bowel disease should be considered in the elderly following abdominal aortic aneurysm repair or when a patient has a hypercoagulable state or a severe cardiac or peripheral vascular disorder. Patients usually present with sudden onset of left lower quadrant pain, urgency to defecate, and the passage of bright red blood per rectum. Endoscopic examination often demonstrates a normal-appearing rectum and a sharp transition to an area of inflammation in the descending colon and splenic flexure.

The effects of radiation therapy on the gastrointestinal tract can be difficult to distinguish fromIBD. Acute symptoms can occur within 1 to 2 weeks of starting radiotherapy. When the rectum and sigmoid are irradiated, patients develop bloody, mucoid diarrhea and tenesmus, as in distalUC. With small bowel involvement, diarrhea is common. Late symptoms include malabsorption and weight loss. Stricturing with obstruction and bacterial overgrowth may occur. Fistulas can penetrate the bladder, vagina, or abdominal wall. Flexible sigmoidoscopy reveals mucosal granularity, friability, numerous telangiectasias, and occasionally discrete ulcerations. Biopsy can be diagnostic.

Solitary rectal ulcer syndrome is uncommon and can be confused withIBD. It occurs in mostly young females and may be caused by impaired evacuation and failure of relaxation of the puborectalis muscle. Ulceration may arise from anal sphincter overactivity, higher intrarectal pressures during defecation, and digital removal of stool. Patients complain of constipation with straining and pass blood and mucus per rectum. Other symptoms include abdominal pain, diarrhea, tenesmus, and perineal pain. The ulceration, which can be as large as 5 cm in diameter, is usually seen anteriorly or anteriorlaterally 3 to 15 cm from the anal verge. Biopsies can be diagnostic.

Several types of colitis have been associated with nonsteroidal anti-inflammatory drugs (NSAID), including de novo colitis, reactivation ofIBD, and proctitis caused by use of suppositories. Most patients with NSAID-related colitis present with diarrhea and abdominal pain and complications include stricture, bleeding, obstruction, perforation, and fistulization. Withdrawal of these agents is crucial, and in cases of reactivated IBD, standard therapies are indicated.

INDETERMINITE COLITIS

Cases ofIBD that cannot be categorized asUC orCD are called *indeterminate* colitis. Long-term follow-up reduces the number of patients labeled indeterminate to about 10%. The disease course of indeterminate colitis is unclear and surgical recommendations are difficult, especially since up to 20% of pouches fail, requiring ileosotomy. A multistage ileal pouch-anal anastamosis (the initial stage consisting of a subtotal colectomy with Hartman pouch) with careful histologic evaluation of the resected specimen to exclude CD is advised. Medical therapy is similar to UC and CD; most clinicians use 5-ASA drugs, glucocorticoids, and immunomodulators as necessary.

THE ATYPICAL COLITIDIES

Two atypical colitides -- collagenous colitis and lymphocytic colitis -- have completely normal endoscopic appearances. Collagenous colitis has two main histologic components: increased subepithelial collagen deposition and colitis with increased intraepithelial lymphocytes. Female to male ratio is 9:1, and most patients present in the

sixth or seventh decades of life. The main symptom is chronic watery diarrhea. Treatments range from sulfasalazine and lomotil to bismuth to glucocorticoids for refractory disease.

Lymphocytic colitis has features similar to collagenous colitis including age at onset and clinical presentation, but it has almost equal incidence in men and women and no subepithelial collagen deposition on pathologic section. However, intraepithelial lymphocytes are increased. Diarrhea stops in the majority of patients treated with sulfasalazine or prednisone.

Diversion colitis is an inflammatory process that arises in segments of the large intestine that are excluded from the fecal stream. It usually occurs in patients with ileostomy or colostomy when a mucus fistula or a Hartman's pouch has been created. Diversion colitis is reversible by surgical reanastamosis. Clinically, patients have mucus or bloody discharge from the rectum. Erythema, granularity, friability, and, in more severe cases, ulceration can be seen on endoscopy. Histopathology shows areas of active inflammation with foci of cryptitis and crypt abscesses. Crypt architecture is normal and this differentiates it fromUC. It may be impossible to distinguish fromCD. Short-chain fatty acid enemas will help in diversion colitis, but the definitive therapy is surgical reanastamosis.

EXTRAINTESTINAL MANIFESTATIONS

IBDis associated with a variety of extraintestinal manifestations; up to one-third of patients have at least one. Patients with perianalCD are at higher risk for developing extraintestinal manifestations than other IBD patients.

DERMATOLOGIC

Erythema nodosum (EN) occurs in up to 15% ofCDpatients and 10% ofUCpatients. Attacks usually correlate with bowel activity; skin lesions develop after the onset of bowel symptoms, and patients frequently have concomitant active peripheral arthritis. The lesions of EN are hot, red, tender nodules measuring 1 to 5 cm in diameter and are found on the anterior surface of the lower legs, ankles, calves, thighs, and arms. Therapy is directed toward the underlying bowel disease.

Pyoderma gangrenosum (PG) is seen in 1 to 12% ofUCpatients and less commonly inCDcolitis. Although it usually presents after the diagnosis ofIBD, PG may occur years before the onset of bowel symptoms, run a course independent of the bowel disease, respond poorly to colectomy, and even develop years after proctocolectomy. It is usually associated with severe disease. Lesions are commonly found on the dorsal surface of the feet and legs but may occur on the arms, chest, stoma, and even the face. PG usually begins as a pustule and then spreads concentrically to rapidly undermine healthy skin. Lesions then ulcerate with violaceous edges surrounded by a margin of erythema. Centrally, they contain necrotic tissue with blood and exudates. Lesions may be single or multiple and grow as large as 30 cm. They are sometimes very difficult to treat and often require intravenous antibiotics, intravenous glucocorticoids, dapsone, purinethinol, thalidomide, or intravenous cyclosporine.

Other dermatologic manifestations include pyoderma vegetans that occurs in intertriginous areas, pyostomatitis vegetans that involves the mucous membranes, and metastaticCD, a rare disorder defined by cutaneous granuloma formation. Psoriasis affects 5 to 10% of patients withIBD and is unrelated to bowel activity. Perianal skin tags are found in 75 to 80% of patients with CD, especially those with colonic involvement. Oral mucosal lesions are seen often in CD and rarely inUC and include aphthous stomatitis and "cobblestone" lesions of the buccal mucosa.

RHEUMATOLOGIC

Peripheral arthritis develops in 15 to 20% ofIBDpatients, is more common inCD, and worsens with exacerbations of bowel activity. It is asymmetric, polyarticular, and migratory, and most often affects large joints of the upper and lower extremities. Treatment is directed at reducing bowel inflammation. In severe UC, colectomy frequently cures the arthritis.

Ankylosing spondylitis (AS) occurs in about 10% ofIBDpatients and is more common inCD thanUC. About two-thirds of IBD patients with AS test positive for the HLA-B27 antigen. The activity of AS is not related to bowel activity and does not remit with glucocorticoids or colectomy. It most often affects the spine and pelvis, producing symptoms of diffuse low-back pain, buttock pain, and morning stiffness. The course is continuous and progressive leading to permanent skeletal damage and deformity.

Sacroiliitis is symmetrical, occurs equally inUC andCD, is often asymptomatic, does not correlate with bowel activity, and does not necessarily progress toAS. Other rheumatic manifestations include hypertrophic osteoarthropathy, osteoporosis and osteomalacia secondary to malabsorption of calcium and vitamin D as well as glucocorticoid therapy, pelvic/femoral osteomyelitis, and relapsing polychondritis.

OCULAR

The incidence of ocular complications inIBDpatients is 1 to 10%. The most common are conjunctivitis, anterior uveitis/iritis, and episcleritis. Uveitis is associated with bothUC andCDcolitis, may be found during periods of remission, and may develop in patients following bowel resection. Symptoms include ocular pain, photophobia, blurred vision, and headache. Prompt intervention, sometimes with systemic glucocorticoids, is required to prevent scarring and visual impairment. Episcleritis is a benign disorder that presents with symptoms of mild ocular burning. It occurs in 3 to 4% of IBD patients, more commonly in CD colitis, and is treated with topical glucocorticoids.

HEPATOBILIARY

Hepatic steatosis is detectable in about half of the abnormal liver biopsies from patients withCD andUC; patients usually present with hepatomegaly. Fatty liver usually results from a combination of chronic debilitating illness, malnutrition, and glucocorticoid therapy. Cholelithiasis is more common in CD than UC and occurs in 10 to 35% of patients with ileitis or ileal resection. Gallstone formation is caused by malabsorption of bile acids resulting in depletion of the bile salt pool and the secretion of lithogenic bile.

Primary sclerosing cholangitis (PSC) is characterized by both intrahepatic and extrahepatic bile duct inflammation and fibrosis (Fig. 287-17), frequently leading to biliary cirrhosis and hepatic failure; 1 to 5% of patients withIBD have PSC, but 50 to 75% of patients with PSC have IBD. Although it can be recognized after the diagnosis of IBD, PSC can be detected earlier or even years after proctocolectomy. Most patients have no symptoms at the time of diagnosis; when symptoms are present they consist of fatigue, jaundice, abdominal pain, fever, anorexia, and malaise. Diagnosis is made by endoscopic retrograde cholangiopancreatography (ERCP), which demonstrates multiple bile duct strictures alternating with relatively normal segments. The bile acid ursodeoxycholic acid (ursodiol) may reduce alkaline phosphatase and serum aminotransferase levels, but histologic improvement has been marginal and it has no definitive long-term benefit. Endoscopic stenting may be palliative for cholestasis secondary to bile duct obstruction. Patients with symptomatic disease develop cirrhosis and liver failure over 5 to 10 years and eventually require liver transplantation. Ten percent of PSC patients develop cholangiocarcinoma and cannot be transplanted. Pericholangitis is a subset of PSC found in about 30% of IBD patients; it is confined to small bile ducts and is usually benign.

UROLOGIC

The most frequent genitourinary complications are calculi, ureteral obstruction, and fistulas. The highest frequency of nephrolithiasis (10 to 20%) occurs in patients withCDfollowing small bowel resection or ileostomy. Calcium oxalate stones develop secondary to hyperoxaluria, which results from increased absorption of dietary oxalate. Normally, dietary calcium combines with luminal oxalate to form insoluble calcium oxalate, which is eliminated in the stool. In patients with ileal dysfunction, however, nonabsorbed fatty acids bind calcium and leave oxalate unbound. The unbound oxalate is then delivered to the colon, where it is readily absorbed, especially in the presence of colonic inflammation.

OTHER

The risk of thromboembolic disease increases whenIBDbecomes active, and patients may present with deep vein thrombosis, pulmonary embolism, cerebrovascular accidents, and arterial emboli. Factors responsible for the hypercoagulable state include reactive thrombocytosis, increased levels of fibrinopeptide A, factor V, factor VIII, fibrinogen, accelerated thromboplastin generation, antithrombin III deficiency secondary to increased gut losses or increased catabolism, and free protein S deficiency. A spectrum of vasculitidies involving small, medium, and large vessels has also been observed in IBD patients.

Patients withIBD have an increased prevalence of osteoporosis secondary to vitamin D deficiency, calcium malabsorption, malnutrition, and corticosteroid use. Deficiencies of vitamin B12 and fat-soluble vitamins may occur after ileal resection or with ileal disease.

More common cardiopulmonary manifestations include endocarditis, myocarditis, pleuropericarditis, and interstitial lung disease. A secondary or reactive amyloidosis can occur in patients with long-standingIBD, especially in patients withCD. Amyloid material is deposited systemically and can cause diarrhea, constipation, and renal failure. The

renal disease can be successfully treated with colchicine. Pancreatitis is a rare extra-intestinal manifestation of IBD and results from duodenal fistulas, ampullary CD, gallstones, PSC, drugs such as 6-mercaptopurine or azathioprine, autoimmune pancreatitis, and primary CD of the pancreas.

TREATMENT

5-ASA Agents The mainstay of therapy for mild to moderateUC andCDcolitis is sulfasalazine and the other 5-ASA agents. Sulfasalazine was originally developed to deliver both antibacterial (sulfapyridine) and anti-inflammatory (5-aminosalicylic acid, 5-ASA) therapy into the connective tissues of joints and the colonic mucosa. The molecular structure provides a convenient delivery system to the colon by allowing the intact molecule to pass through the small intestine after only partial absorption, and to be broken down in the colon by bacterial azo reductases that cleave the azo bond linking the sulfa and 5-ASA moieties. Sulfasalazine is effective in inducing and maintaining remission in mild to moderate UC and CD ileocolitis and colitis, but its high rate of side effects limits its use. Although sulfasalazine is more effective at higher doses, at 6 or 8 g/d up to 30% of patients experience allergic reactions or intolerable side effects such as headache, anorexia, nausea, and vomiting that are attributable to the sulfapyridine moiety. Hypersensitivity reactions, independent of sulfapyridine levels, include rash, fever, hepatitis, agranulocytosis, hypersensitivity pneumonitis, pancreatitis, worsening of colitis, and reversible sperm abnormalities. Sulfasalazine can also impair folate absorption and patients should be supplemented with folic acid.

Newer sulfa-free aminosalicylate preparations deliver increased amounts of the pharmacologically active ingredient of sulfasalazine (5-ASA, mesalamine) to the site of active bowel disease while limiting systemic toxicity. 5-ASA may function through inhibition of NF-kB activity. Sulfa-free aminosalicylate formulations include alternative azo-bonded carriers, 5-ASA dimers, pH-dependent tablets, and continuous-release preparations. Each has the same efficacy as sulfasalazine when equimolar concentrations are used. Olsalazine is composed of two 5-ASA radicals linked by an azo bond which is split in the colon by bacterial reduction and two 5-ASA molecules are released. Olsalazine is similar in effectiveness to sulfasalazine in treatingCD andUC, but up to 17% of patients experience non-bloody diarrhea caused by increased secretion of fluid in the small bowel. Balsalazide contains an azo bond binding mesalamine to the carrier molecule 4-amino benzoyl balanine; it is effective in the colon. Claversal is an enteric-coated form of 5-ASA that consists of mesalamine surrounded by an acrylic-based polymer resin and a cellulose coating that releases mesalamine at pH> 6.0, a level that is present from the mid-jejunum continuously to the distal colon.

The most commonly used drugs besides sulfasalazine in the United States are Asacol and Pentasa. Asacol is also an enteric-coated form of mesalamine, but it has a slightly different release pattern, with 5-ASA liberated at pH> 7.0. The disintegration of Asacol is variable with complete break-up of the tablet occurring in many different parts of the gut ranging from the small intestine to the splenic flexure; it has increased gastric residence when taken with a meal. Asacol is used to induce and maintain remission inUC and in CDileitis, ileocolitis, and colitis. Appropriate doses of Asacol and the other 5-ASA compounds are shown in Table 287-6. Some 50 to 75% of patients with mild to moderate UC and CD improve when treated with 2 g/d of 5-ASA; the dose response

continues up to at least 4.8 g/d. Doses of 1.5-4 g/d maintain remission in 50 to 75% of patients with UC and CD.

Pentasa is another mesalamine formulation that uses an ethylcellulose coating to allow water absorption into small beads containing the mesalamine. Water dissolves the 5-ASA, which then diffuses out of the bead into the lumen. Disintegration of the capsule occurs in the stomach. The microspheres then disperse throughout the entire gastrointestinal tract from the small intestine through the distal colon in both fasted or fed conditions. Controlled trials of Pentasa and Asacol in activeCDdemonstrate a 40 to 60% clinical improvement or remission, and meta-analyses demonstrate maintenance of CD remission with 1.5 to 3 g/d of 5-ASA in 68 to 95% of patients. Pentasa at a dose of 2 g/d is more effective than placebo in postoperative prophylaxis of CD.

Topical mesalamine enemas are effective in mild-to-moderate distalUC andCD. Clinical response occurs in up to 80% of UC patients with colitis distal to the splenic flexure. Mesalamine suppositories, which are no longer available in the United States but are available in Canada, at doses of 500 mg twice a day are effective in treating proctitis.

Glucocorticoids The majority of patients with moderate to severeUCbenefit from oral or parenteral glucocorticoids. Prednisone is usually started at doses of 40 to 60 mg/d for active UC that is unresponsive to 5-ASA therapy. Parenteral glucocorticoids may be administered as intravenous hydrocortisone 300 mg/d or methylprednisolone 40 to 60 mg/d. Adrenocorticotropic hormone (ACTH) is occasionally preferred for glucocorticoid-naive patients despite a risk of adrenal hemorrhage. ACTH has equivalent efficacy to intravenous hydrocortisone in both glucocorticoid-naive and -experiencedCDpatients.

Topically applied glucocorticoids are also beneficial for distal colitis and may serve as an adjunct in those who have rectal involvement plus more proximal disease. Hydrocortisone enemas or foam may control active disease, although they have no proven role as maintenance therapy. These glucocorticoids are significantly absorbed from the rectum and can lead to adrenal suppression with prolonged administration. The systemic effects of standard glucocorticoid formulations have led to the development of more potent formulations that are less well absorbed and have increased first-pass metabolism. Budesonide is being used in enema form with favorable preliminary results in distalUC.

Glucocorticoids are also effective for treatment of moderate-to-severeCD and induce a 60 to 70% remission rate compared to a 30% placebo response. Controlled ileal-release budesonide has been nearly equal to prednisone for ileocolonic CD at a dose of 9 mg/d.

Glucocorticoids play no role in maintenance therapy in eitherUC orCD. Once clinical remission has been induced, they should be tapered according to the clinical activity, normally at a rate of no more than 5 mg per week. They can usually be tapered to 20 mg/d within 4 to 5 weeks but often take several months to be discontinued altogether. The side effects are numerous, including fluid retention, abdominal striae, fat redistribution, hyperglycemia, subcapsular cataracts, osteonecrosis, myopathy, emotional disturbances, and withdrawal symptoms. Most of these side effects, aside from osteonecrosis, are related to the dose and duration of therapy.

Antibiotics Despite numerous trials, antibiotics have no role in the treatment of active or quiescentUC. However, pouchitis, which occurs in about a third of UC patients after colectomy and ileal pouch-anal anastamosis, usually responds to treatment with metronidazole or ciprofloxacin.

Metronidazole is effective in active inflammatory, fistulous, and perianalCD and may prevent recurrence after ileal resection. The most effective dose is 15 to 20 mg/kg per day in three divided doses; it is usually continued for several months. Common side effects include nausea, metallic taste, and disulfiram-like reaction. Peripheral neuropathy can occur with prolonged administration (several months) and on rare occasions is permanent despite discontinuation. Ciprofloxacin (500 mg bid) is also beneficial for inflammatory, perianal, and fistulous CD. These two antibiotics should be used as second-line drugs in active CD after 5-ASA agents and as first-line drugs in perianal and fistulous CD.

Azathioprine and 6-Mercaptopurine Azathioprine and 6-mercaptopurine (6-MP) are purine analogues commonly employed in the management of glucocorticoid-dependentIBD. Azathioprine is rapidly absorbed and converted to 6-MP, which is then metabolized to the active end product, thioinosinic acid, an inhibitor of purine ribonucleotide synthesis and cell proliferation. These agents also inhibit the immune response. Efficacy is seen at 3 to 4 weeks. Compliance can be monitored by measuring the level of 6-thioguanine, an end product of 6-MP metabolism. Azathioprine (2.0 to 2.5 mg/kg per day) or 6-MP (1.0-1.5 mg/kg per day) have been employed successfully as glucocorticoid-sparing agents in up to two-thirds of UCand CDpatients previously unable to be weaned from glucocorticoids. The role of these immunomodulators as maintenance therapy in UC and CD and for treating active perianal disease and fistulas in CD appears promising. In addition, 6-MP at a dose of 50 mg/d is more effective than Pentasa or placebo for postoperative prophylaxis of CD.

Although azathioprine and6-MP are usually well tolerated, pancreatitis occurs in 3 to 4% of patients, typically presents within the first few weeks of therapy, and is always completely reversible when the drug is stopped. Other side effects include nausea, fever, rash, and hepatitis. Bone marrow suppression (particularly leukopenia) is dose-related and often delayed, necessitating regular monitoring of the complete blood count. Additionally, 1 in 300 individuals lacks thiopurine methyltransferase, the enzyme responsible for drug metabolism; an additional 11% of the population are heterozygotes with intermediate enzyme activity. Both are at increased risk of toxicity because of increased accumulation of thioguanine metabolites. No increased risk of cancer has been documented inIBDpatients taking these medications long-term.

Methotrexate Methotrexate (MTX) inhibits dihydrofolate reductase, resulting in impaired DNA synthesis. Additional anti-inflammatory properties may be related to decreasedIL-1 production. Intramuscular or subcutaneous MTX (25 mg per week) is effective in inducing remission and reducing glucocorticoid dosage and 15 mg per week is effective in maintaining remission in activeCD. Potential toxicities include leukopenia and hepatic fibrosis, necessitating periodic evaluation of complete blood counts and liver enzymes. The role of liver biopsy in patients on long-term MTX is uncertain. Hypersensitivity pneumonitis is a rare but serious complication of therapy. MTX should only be used

when either6-MP or azathioprine are ineffective or poorly tolerated.

Cyclosporine Cyclosporine (CSA) alters the immune response by acting as a potent inhibitor of T cell-mediated responses. Although CSA acts primarily via inhibition ofIL-2 production from T helper cells, it also decreases recruitment of cytotoxic T cells and blocks other cytokines, including IL-3, IL-4, interferona, andTNF. It has a more rapid onset of action than6-MP and azathioprine.

CSAis most effective given at 4 mg/kg per day IV in severeUC that is refractory to intravenous glucocorticoids, with 82% of patients responding. CSA can be an alternative to colectomy. The long-term success of oral CSA is not as dramatic, but if patients are started on6-MP or azathioprine at the time of hospital discharge, remission can be maintained. Intravenous CSA is effective in 80% of patients with refractory fistulas, but 6-MP or azathioprine must be used to maintain remission. Oral CSA alone is only effective at a higher dose (7.5 mg/kg per day) in active disease but is not effective in maintaining remission without 6-MP/azathioprine. Serum levels should be monitored and kept in the range of 200 to 400 ng/mL.

CSAhas the potential for significant toxicity, and renal function should be frequently monitored. Hypertension, gingival hyperplasia, hypertrichosis, paresthesias, tremors, headaches, and electrolyte abnormalities are common side effects. Creatinine elevation calls for dose reduction or discontinuation. Seizures may also complicate therapy, especially if serum cholesterol levels are less than 120 mg/dL. Opportunistic infections, most notably *Pneumocystis carinii* pneumonia, have occurred with combination immunosuppressive treatment; prophylaxis should then be given.

Nutritional Therapies Dietary antigens may act as stimuli of the mucosal immune response. Patients with activeCDrespond to bowel rest, along with total enteral or total parenteral nutrition (TPN). Bowel rest and TPN are as effective as glucocorticoids for inducing remission of active CD but are not as effective as maintenance therapy. Enteral nutrition in the form of elemental or peptide-based preparations are also as effective as glucocorticiods or TPN, but these diets are not palatable. Enteral diets may provide the small intestine with nutrients vital to cell growth and do not have the complications of TPN. In contrast to CD, activeUC is not effectively treated with either elemental diets or TPN. Standard medical management of UC and CD is reviewed inTable 287-7.

Newer Medical Therapies

Anti-tumor Necrosis Factor Antibody TNF is a key inflammatory cytokine and mediator of intestinal inflammation. The expression of TNF is increased inIBD. Infliximab is a chimeric mouse-human monoclonal antibody against TNF that is extremely effective in CD. It blocks TNF in the serum and at the cell surface and likely lyses TNF-producing macrophages and T cells through complement fixation and antibody-dependent cytotoxicity. Of activeCDpatients refractory to glucocorticoids, 6-MP, or 5-ASA, 65% will respond to intravenous infliximab (5 mg/kg); one-third will enter complete remission. Patients who experience an initial response will respond again to repeated infusions of infliximab every 8 weeks up to 44 weeks. Thus infliximab may be also be efficacious in maintaining remission. However, more trials need to be completed on remission

maintenance after infliximab therapy.

Infliximab is also effective inCDpatients with refractory perianal and enterocutaneous fistulas, with a 68% response rate (50% reduction in fistula drainage) and a 50% complete remission rate. The effects of infliximab for both inflammatory and fistulous disease last 12 weeks on average but longer in some patients.

The incidence of antibodies to infliximab (25% of the molecule is murine) is 13%. One side effect is a lupus-like syndrome, which is rare and reversible after stopping the drug. Anti-double-stranded DNA antibodies occur in 9% but are not associated with clinical lupus.

Among more than 1000 patients treated with infliximab, four developed lymphoma: one patient withCD, two with rheumatoid arthritis, and one with AIDS. Since the risk of lymphoma is already increased in these conditions, it is unclear whether infliximab is the cause. Thus, infliximab is extremely effective in refractory inflammatory and fistulous CD, but should be used only when necessary. Results on the efficacy of infliximab in UC are mixed.

Newer Immunosuppressive Agents Tacrolimus has a mechanism of action similar to cyclosporine. It has shown efficacy in children with refractoryIBD and in adults with extensive involvement of the small bowel.

Mycophenolate mofetil inhibits the de novo pathway of purine synthesis in lymphocytes, disrupting the conversion of inosine monophosphate to guanosine monophosphate (GMP) by reversible inhibition of inosine monophosphate dehydrogenase. The resulting depletion of intracellular GMP suppresses the generation of cytotoxic T cells and formation of antibodies by activated B cells. Patients withCD orUC who received either 500 mg twice a day or 15 mg/kg per day in two divided doses have tolerated the drug well and have experienced benefit with reduction of glucocorticoid requirements.

Thalidomide has been shown to inhibitTNFproduction by monocytes and other cells. Thalidomide is effective in glucocorticoid refractory and fistulousCD, but randomized controlled trials still need to be performed.

The Anti-Inflammatory Cytokines IL-10 is an anti-inflammatory and immunosuppressive cytokine produced by subsets of T and B cells, macrophages, and monocytes. It decreases T_H1 production of IL-2 and interferon g, and limits production of IL-1, IL-6, IL-8,TNF, IL-12, and granulocyte-macrophage colony-stimulating factor. IL-10 has a moderate benefit in activeCD.

IL-11 is a cytokine with thrombopoietic activity and mucosal protective effects that is effective in reducing inflammation in animal models of colitis. It seems to be effective in activeCD, but more trials are needed.

Surgical Therapy

Ulcerative Colitis Nearly half of patients with extensive chronicUCundergo surgery within the first 10 years of their illness. The indications for surgery are listed in Table

287-7. Morbidity is about 20% in elective, 30% for urgent, and 40% for emergency proctocolectomy. The risks are primarily hemorrhage, contamination and sepsis, and neural injury. Although single-stage total proctocolectomy with ileostomy has been the operation of choice, newer operations maintain continence while surgically removing the involved rectal mucosa.

TheIPAA is the most frequent continence-preserving operation performed. BecauseUC is a mucosal disease, the rectal mucosa can be dissected out and removed down to the dentate line of the anus or about 2 cm proximal to it. The ileum is fashioned into a pouch that serves as a neorectum. This ileal pouch is then sutured circumferentially to the anus in an end-to-end fashion. If performed carefully, this operation preserves the anal sphincter and maintains continence. The overall operative morbidity is 10%, with the major complication being bowel obstruction. Pouch failure necessitating conversion to permanent ileostomy occurs in 5 to 10% of patients. Some inflamed rectal mucosa is usually left behind, and thus endoscopic surveillance is necessary. Primary dysplasia of the ileal mucosa of the pouch has occurred rarely.

Patients withIPAAs usually have about six to eight bowel movements a day. On validated quality of life indices, they report better performance in sports and sexual activities than ileostomy patients. The most frequent late complication of IPAA is pouchitis in about one-third of patients withUC. This syndrome consists of increased stool frequency, watery stools, cramping, urgency, nocturnal leakage of stool, arthralgias, malaise, and fever. Although it usually responds to antibiotics, in 3% of patients it is refractory and requires pouch take-down.

Crohn's Disease Most patients withCDrequire at least one operation in their lifetime. The need for surgery is related to duration of disease and the site of involvement. Patients with small bowel disease have an 80% chance of requiring surgery. Those with colitis alone have a 50% chance. The indications for surgery are shown inTable 287-7.

SMALL INTESTINAL DISEASE BecauseCD is chronic and recurrent with no clear surgical cure, as little intestine as possible is resected. Current surgical alternatives for treatment of obstructing CD include resection of the diseased segment and strictureplasty. Surgical resection of the diseased segment is the most frequently performed operation, and in most cases primary anastomosis can be done to restore continuity. If much of the small bowel has already been resected and the strictures are short with intervening areas of normal mucosa, strictureplasties should be done to avoid a functionally insufficient length of bowel. The strictured area of intestine is incised longitudinally and the incision sutured transversely, thus widening the narrowed area. Complications of strictureplasty include prolonged ileus, hemorrhage, fistula, abscess, leak, and restricture.

Colorectal Disease A greater percentage of patients withCDcolitis require surgery for intractability, fulminant disease, and anorectal disease. Several alternatives are available, ranging from the use of a temporary loop ileostomy to resection of segments of diseased colon or even the entire colon and rectum. For patients with segmental involvement, segmental colon resection with primary anastomosis can be performed. In 20 to 25% of patients with extensive colitis, the rectum is spared sufficiently to consider rectal preservation. Most surgeons believe that anIPAA is contraindicated in CD due to

the high incidence of pouch failure. A diverting colostomy may help heal severe perianal disease or rectovaginal fistulas, but disease almost always recurs with reanastomosis. Often, these patients require a total proctocolectomy and ileostomy.

INFLAMMATORY BOWEL DISEASE AND PREGNANCY

When adjusted for patient age, the fertility rate inUC is probably normal. In contrast, fertility is reduced inCD in proportion to disease activity and can be restored when remission is induced. The ovaries and fallopian tubes can be affected by the inflammatory process of CD, especially on the right side because of the proximity of the terminal ileum. In addition, perirectal, perineal, rectovaginal abscesses, and fistulae can result in dyspareunia. Infertility in men can be caused by sulfasalazine but reverses when treatment is stopped.

InUC, fetal outcome approximates that in the normal population. InCD, spontaneous abortions, stillbirths, and developmental defects are increased with increased disease activity, not medications. The courses of CD and UC during pregnancy mostly correlate with disease activity at the time of conception. Most CD patients can deliver vaginally, but cesarean section may be the preferred route of delivery for patients with anorectal and perirectal abscesses and fistulas to reduce the likelihood of fistulas developing or extending into the episiotomy scar.

Sulfasalazine, mesalamine, and olsalazine are safe for use in pregnancy, but folate supplementation must be given with sulfasalazine. No adverse affects have been reported from sulfasalazine in nursing infants. Topical 5-ASA agents are also safe during pregnancy. Glucocorticoids are generally safe for use during pregnancy and are indicated for patients with moderate to severe disease activity. The amount of glucocorticoids received by the nursing infant is minimal. The safest antibiotics to use forCD in pregnancy are ampicillin, cephalosporin, or ciprofloxicin. Flagyl is teratogenic and tumorigenic in high doses, passes into breast milk, and should be avoided.

6-MPand azathioprine pose minimal or no risk during pregnancy, but experience is limited. If the patient cannot be weaned from the drug or has an exacerbation that requires 6-MP/azathioprine during pregnancy, she should continue the drug with informed consent. Their effects during nursing are unknown.

There is little data on cyclosporine in pregnancy. In a small number of patients with severeIBDtreated with intravenous cyclosporine during pregnancy, 80% of pregnancies were successfully completed without development of renal toxicity, congenital malformations, or developmental defects. However, because of the lack of data, cyclosporine should probably be avoided unless the patient would otherwise require surgery. Methotrexate is contraindicated in pregnancy and nursing.

Surgery inUCshould be performed only for emergency indications, including severe hemorrhage, perforation, and megacolon refractory to medical therapy. Total colectomy and ileostomy carries a 60% risk of postoperative spontaneous abortion. Fetal mortality is also high in CD requiring surgery. Patients with ileostomies andIPAAs tolerate pregnancy well.

INFLAMMATORY BOWEL DISEASE IN THE ELDERLY

The most common presenting symptoms in the elderly are diarrhea, weight loss, and abdominal pain. CDin the elderly is mostly colonic with a distal distribution and occurs predominantly in women. Proctitis has been documented in 50% of elderly patients and the diagnosis is often delayed. Diseases that can mimic CD in the elderly are ischemic colitis, diverticular disease, irritable bowel, infectious colitides, and malignancies, including carcinoma, lymphoma, and carcinoid. The incidence of surgery is high in elderly patients, with up to 50% of patients with ileitis, ileocolitis, or extensive colitis requiring urgent or early surgery for first-time disease. In addition, surgery has a much higher morbidity than in younger patients, although the rate of postoperative recurrence is less. Most elderly patients respond as well as younger individuals to medical management.

UCin the elderly is more common in men, presents usually with diarrhea and weight loss, and may have a more distal distribution than in younger patients. Most elderly patients have a favorable response to medical therapy, especially 5-ASA agents, and immunosuppressives used in conjunction with low doses of glucocorticoids. Cyclosporine has been used more frequently in the elderly, but the age-related decreases in renal clearance may affect dosing. Glucocorticoid complications such as osteoporosis and hyperglycemia are also increased in the elderly.6-MP and azathioprine are well tolerated in the elderly. Surgery also has a higher morbidity and mortality in UC, and elderly patients have a longer hospital stay than younger patients. The risk of colon cancer in UC andCDcolitis is no greater than that in the general population since the duration of disease is short and the extent of disease is often distal.

CANCER IN INFLAMMATORY BOWEL DISEASE

ULCERATIVE COLITIS

Patients with long-standingUC are at increased risk for developing colonic epithelial dysplasia and carcinoma (Figs. 287-18,287-19, and Fig. 287-20). Several features distinguish sporadic (SCC) and colitis-associated (CAC) colon cancers. First, SCC usually arise from an adenomatous polyp; CAC typically arise from either flat dysplasia or a dysplasia-associated lesion or mass (DALM). Second, multiple synchronous colon cancers occur in 3 to 5% of SCC but in 12% of CAC. Third, the mean age of individuals with SCC is in the sixties; the mean age of those with CAC is in the thirties. Fourth, SCC exhibits a left-sided predominance, whereas CAC is distributed more uniformly throughout the colon. Fifth, mucinous and anaplastic cancers are more common in CAC than SCC. At the molecular level, p53 mutations occur much earlier and *APC* gene mutations much later in CAC than SCC.

The risk of neoplasia in chronicUCincreases with duration and extent of disease. For patients with pancolitis, the risk of cancer rises 0.5 to 1% per year after 8 to 10 years of disease. This observed increase in cancer rates has led to the endorsement of surveillance colonoscopies with biopsies for patients with chronic UC as the standard of care. Annual or biennial colonoscopy with multiple biopsies has been advocated for patients with more than 8 to 10 years of pancolitis or 12 to 15 years of left-sided colitis and has been widely employed to screen and survey for subsequent dysplasia and

carcinoma.

CROHN'S DISEASE

Risk factors for developing colorectal cancer inCD are a history of colonic (or ileocolonic) involvement and long disease duration. The cancer risks in CD andUC are probably equivalent for similar extent and duration of disease. In patients with extensive colonic involvement, the overall risk is increased 18-fold and the cumulative risk is 8% at 22 years. Thus, the same endoscopic surveillance strategy used for UC is recommended for patients with chronic CD colitis. A pediatric colonoscope can be used to pass narrow strictures in CD patients and impassable strictures can be surveyed with annual barium enemas. A colon resection should be performed if there is evidence of malignancy.

MANAGEMENT OF DYSPLASIA AND CANCER

If high grade dysplasia (HGD) is encountered on colonoscopic surveillance, the usual treatment forUC is colectomy and forCD is either colectomy or segmental resection. If low grade dysplasia (LGD) is found, the management is controversial. Many investigators recommend immediate colectomy, but some repeat the colonoscopy in 1 to 6 months and search for recurrent dysplasia. Polyps in chronic colitis can be removed endoscopically provided that biopsies of the surrounding mucosa are free of dysplasia.

IBDpatients are also at greater risk for other malignancies. Patients withCD may have an increased risk of developing non-Hodgkin's lymphoma and squamous cell carcinoma of the skin. Although CD patients have a twelvefold increased risk of developing small bowel cancer, this type of carcinoma is extremely rare.

QUALITY OF LIFE IN INFLAMMATORY BOWEL DISEASE

The assessment of health-related quality of life plays an important role in the evaluation and treatment ofIBDpatients. Although clinical trials have generally relied upon traditional disease activity indices such as the Crohn's Disease Activity Index (CDAI) to measure therapeutic efficacy, these measures do not reflect quality of life. The Inflammatory Bowel Disease Questionnaire (IBDQ) is a validated, disease-specific instrument that has been used to measure quality of life. It is a 32-item questionnaire that measures global function, systemic and bowel symptoms, functional and social impairment, and emotional function. When compared to the general population, IBD patients have an impaired quality of life in all six categories. The most frequent concerns ofUCpatients are having an ostomy bag, developing cancer, effects of medication, the uncertain nature of the disease, and having surgery. The most frequent concerns of CDpatients are the uncertain nature of the disease, energy level, effects of medication, having surgery, and having an ostomy bag.

288. IRRITABLE BOWEL SYNDROME - *Chung Owyang*

Irritable bowel syndrome (IBS) is a gastrointestinal (GI) disorder characterized by altered bowel habits and abdominal pain in the absence of detectable structural abnormalities. No clear diagnostic markers exist for IBS, so all definitions of the disease are based on the clinical presentation. The Rome criteria for the diagnosis of IBS are summarized inTable 288-1. IBS is one of the most common conditions encountered in clinical practice but one of the least well understood. Until recently, many physicians did not consider IBS to be a disease at all; they viewed it as nothing more than a somatic manifestation of psychological stress. With the availability of better techniques to study colonic and GI motility and visceral sensory function, along with the development of newer concepts about the importance of the brain in regulating gut function, significant progress has been made toward a better understanding of the pathogenesis of IBS. Improved methods of treatment may result from these insights.

CLINICAL FEATURES

IBSis a disorder of young people, with most new cases presenting before age 45. However, some reports suggest that the elderly are troubled by IBS symptoms up to 92% as often as middle-aged persons. Indeed, many of the diagnoses of "painful diverticular disease" given the elderly patients may represent IBS. Women are diagnosed with IBS two to three times as often as men and make up 80% of the population with severe IBS. Patients with IBS may fall into two broad clinical groups. Most commonly, patients have abdominal pain associated with altered bowel habits that include constipation, diarrhea, or both. In the second group, patients have painless diarrhea. This latter group accounts for<20% of patients with IBS; their condition may be a separate entity but is generally considered a variant of IBS.

Abdominal Pain Abdominal pain inIBS is highly variable in intensity and location. Pain in IBS is localized to the hypogastrum in 25%, the right side in 20%, to the left side in 20%, and the epigastrum in 10% of patients. Pain is frequently episodic and crampy but may be superimposed on a background of constant ache. Pain may be mild enough to be ignored or it may interfere with daily activities. Despite this, malnutrition due to inadequate caloric intake is exceedingly rare with IBS. Sleep deprivation is also unusual because abdominal pain is almost uniformly present only during waking hours. Pain is often exacerbated by eating or emotional stress and relieved by passage of flatus or stools.

Altered Bowel Habits Alteration in bowel habits is the most consistent clinical feature inIBS. Symptoms usually begin in adult life. The most common pattern is constipation alternating with diarrhea, usually with one of these symptoms predominating. At first, constipation may be episodic, but eventually it becomes continuous and increasingly intractable to treatment with laxatives. Stools are usually hard with narrowed caliber, possibly reflecting excessive dehydration caused by prolonged colonic retention and spasm. Most patients also experience a sense of incomplete evacuation, thus leading to repeated attempts at defecation in a short time span. Patients whose predominant symptom is constipation may have weeks or months of constipation interrupted with brief periods of diarrhea. In other patients, diarrhea may be the predominant symptom. Diarrhea resulting from IBS usually consists of small volumes of loose stools, and most

patients have stool volumes of <200 mL. Nocturnal diarrhea does not occur in IBS. Diarrhea may be aggravated by emotional stress or eating. Stool may be accompanied by passage of large amounts of mucus; hence, the term *mucous colitis* has been used to describe IBS. This is a misnomer, since inflammation is not present. Bleeding is not a feature of IBS unless hemorrhoids are present, and malabsorption or weight loss does not occur.

Gas and Flatulence Patients with IBS frequently complain of abdominal distention and increased belching or flatulence, all of which they attribute to increased gas. Although some patients with these symptoms actually may have a larger amount of gas, quantitative measurements reveal that most patients who complain of increased gas generate no more than a normal amount of intestinal gas. Most IBS patients develop symptoms even with minimal gut distention, suggesting that the basis of their complaints is reduced tolerance of distention rather than an abnormal quantity of intraluminal gas. In addition, patients with IBS tend to reflux gas from the distal to the more proximal intestine, which may explain the belching.

Upper Gastrointestinal Symptoms Between 25 and 50% of patients withIBScomplain of dyspepsia, heartburn, nausea, and vomiting. This suggests that areas of the gut other than the colon may be involved. Prolonged ambulant recordings of small bowel motility in patients with IBS show a high incidence of abnormalities in the small bowel during the waking period; nocturnal motor patterns are no different from those of healthy controls. A characteristic finding is the frequent occurrence of episodes of clustered contractions recurring at 0- to 9-min intervals. These episodes have a mean duration of 46 min and are often associated with transient abdominal pain and discomfort. A similar pattern has been observed in patients with IBS by the application of psychological stressors and by intravenous neostigmine. In addition, temporary abolition of migrating motor complexes is observed in IBS patients under mental stress. Thus, IBS appears to be a paroxysmal motor disorder that may be detected in the small bowel.

PATHOPHYSIOLOGY

The pathogenesis ofIBS is poorly understood, although roles for abnormal gut motor and sensory activity, central neural dysfunction, psychological disturbances, stress, and luminal factors have been proposed.

Colonic myoelectrical and motor activity under unstimulated conditions are generally normal, but abnormalities are more prominent under stimulated conditions inIBS. IBS patients may exhibit increased rectosigmoid motor activity for up to 3 h after eating. Provocative stimuli also induce exaggerated colonic motor responses in IBS patients compared to healthy volunteers. For example, inflation of rectal balloons both in diarrhea- and constipation-predominant IBS patients leads to marked distention-evoked contractile activity, which may be prolonged.

As with studies of motor activity,IBSpatients frequently exhibit exaggerated sensory responses to visceral stimulation. Postprandial pain has been temporally related to entry of food bolus into the cecum in 74% of patients. Exaggerated symptoms can be induced by visceral distention in IBS patients. Rectal balloon inflation produces both nonpainful and painful sensations at lower volumes in IBS patients than in healthy controls without

altering rectal tension, suggestive of visceral afferent dysfunction in IBS. The visceral hyperalgesia of IBS appears to be selective for mechanoreceptor-activated stimuli, as perception of intestinal mucosal electrical stimulation is normal in IBS. Similar studies show gastric and esophageal hypersensitivity in patients with nonulcer dyspepsia and noncardiac chest pain, raising the possibility that these conditions have a similar pathophysiologic basis. In contrast to their enhanced gut sensitivity, IBS patients do not exhibit heightened sensitivity elsewhere in the body. Thus the afferent pathway disturbances in IBS appear to be selective for visceral innervation, with sparing of somatic pathways. The mechanisms responsible for visceral hypersensitivity are unclear. These exaggerated responses may be due to: (1) increased end organ sensitivity with recruitment of "silent" nociceptors; (2) spinal hyperexcitability with activation of nitric oxide and possibly other neurotransmitters; (3) endogenous (cortical and brainstem) modulation of caudad nociceptive transmission; and (4) over time, the possible development of long-term hyperalgesia due to development of neuroplasticity, resulting in permanent or semipermanent changes in neural responses to chronic or recurrent visceral stimulation.

The role of central nervous system (CNS) factors in the pathogenesis ofIBS is strongly suggested by (1) the clinical association of emotional disorders and stress with symptom exacerbation, and (2) the therapeutic response to therapies that act on cerebral cortical sites. Positron emission tomography has shown alterations in regional cerebral blood flow in IBS patients. In healthy individuals, rectal distention increases blood flow in the anterior cingulate cortex, a region with an abundance of opiate receptors, which, when activated, may help to reduce sensory input. In contrast, IBS patients exhibit no increased blood flow in the anterior cingulate gyrus but show activation of the prefrontal cortex, either in response to rectal activation or in anticipation of rectal distention. Activation of the frontal lobes may activate a vigilance network within the brain that increases alertness. The anterior cingulate cortex and the prefrontal cortex appear to have reciprocal inhibitory associations. In patients with IBS, the preferential activation of the prefrontal lobe without activation of the anterior cingulate cortex may represent a form of cerebral dysfunction leading to the increased perception of visceral pain.

Abnormal psychiatric features are recorded in up to 80% ofIBSpatients; however, no single psychiatric diagnosis predominates. An association between prior sexual or physical abuse and development of IBS has been reported. Forms of sexual abuse associated with IBS include verbal aggression, exhibitionism, sexual harassment, sexual touching, and rape. The pathophysiologic relationship between IBS and sexual or physical abuse is unknown. However, physical and sexual abuse may result in hypervigilence to body sensations at theCNSlevel and visceral hypersensitivity at the gut level.

Thus patients withIBSfrequently demonstrate increased motor reactivity of the colon and small bowel to a variety of stimuli and altered visceral sensation associated with lowered sensation thresholds. These may result fromCNS(enteric nervous system) dysregulation.

Approach to the Patient

BecauseIBS is a disorder for which no pathognomonic abnormalities have been identified, its diagnosis relies on recognition of positive clinical features and elimination of other organic diseases. A careful history and physical examination are frequently helpful in establishing the diagnosis. Clinical features suggestive of IBS include the following: recurrence of lower abdominal pain with altered bowel habits over a period of time without progressive deterioration, onset of symptoms during periods of stress or emotional upset, absence of other systemic symptoms such as fever and weight loss, and small-volume stool without any evidence of blood.

On the other hand, the appearance of the disorder for the first time in old age, progressive course from time of onset, persistent diarrhea after a 48-h fast, and presence of nocturnal diarrhea or steatorrheal stools argue against the diagnosis ofIBS.

Because the major symptoms ofIBS -- abdominal pain, abdominal bloating, and alteration in bowel habits -- are common complaints of manyGIorganic disorders, the list of differential diagnoses is long. The quality, location, and timing of pain may be helpful in suggesting specific disorders. Pain due to IBS that occurs in the epigastric or periumbilical area must be differentiated from biliary tract disease, peptic ulcer disorders, intestinal ischemia, and carcinoma of the stomach and pancreas. If pain occurs mainly in the lower abdomen, the possibility of diverticular disease of the colon, inflammatory bowel disease (including ulcerative colitis and Crohn's disease), and carcinoma of the colon must be considered. Postprandial pain accompanied by bloating, nausea, and vomiting suggests gastroparesis or partial intestinal obstruction. Intestinal infestation with *Giardia lamblia* or other parasites may cause similar symptoms. When diarrhea is the major complaint, the possibility of lactase deficiency, laxative abuse, malabsorption, hyperthyroidism, inflammatory bowel disease, and infectious diarrhea must be ruled out. On the other hand, constipation may be a side effect of many different drugs, such as anticholinergic, antihypertensive, and antidepressant medications. Endocrinopathies such as hypothyroidism and hypoparathyroidism must also be considered in the differential diagnosis of constipation, particularly if other systemic signs or symptoms of these endocrinopathies are present. In addition, acute intermittent porphyria and lead poisoning may present in a fashion similar to IBS, with painful constipation as the major complaint. These possibilities are suspected on the basis of their clinical presentations and are confirmed by appropriate serum and urine tests.

BecauseIBS is in part a diagnosis of exclusion, certain diagnostic tests should be performed routinely; others may be required depending on the specific presenting symptoms. Factors to be considered when determining the aggressiveness of the diagnostic evaluation include the duration of symptoms, the change in symptoms over time, the age and sex of the patient, the referral status of the patient, prior diagnostic studies, a family history of colorectal malignancy, and the degree of psychosocial dysfunction. Thus a younger individual with mild symptoms requires a minimal diagnostic evaluation, while an older person or an individual with rapidly progressive symptoms should undergo a more thorough exclusion of organic disease. In general most patients should have a complete blood count and sigmoidoscopic examination; in addition, stool specimens should be examined for ova and parasites. In those >40 years, an air-contrast barium enema or colonoscopy should also be done. In patients whose main symptoms are diarrhea and increased gas, the possibility of lactase

deficiency should be ruled out with a hydrogen breath test or a lactose-free diet should be prescribed for 3 weeks. In patients with concurrent symptoms of dyspepsia, upperGIradiographs or esophagogastroduodenoscopy may be advisable. In patients with postprandial right upper quadrant pain, ultrasound of the gallbladder should be obtained. Laboratory features that argue against IBS include evidence of anemia, elevated sedimentation rate, presence of leukocytes or blood in stool, and stool volume >200 to 300 mL/d. These findings suggest other diagnostic considerations.

TREATMENT

Patient Counseling and Dietary Alterations Reassurance and careful explanation of the functional nature of the disorder and of how to avoid obvious food precipitants are important first steps in patient counseling and dietary change. Occasionally, a meticulous dietary history may reveal substances (such as coffee, disaccharides, legumes, and cabbage) that aggravate symptoms. As a therapeutic trial, patients should be encouraged to eliminate any foodstuffs that appear to produce symptoms.

Stool Bulking Agents High-fiber diets and bulking agents, such as bran or hydrophilic colloid, are frequently used in treatingIBS. Dietary fiber has multiple effects on colonic physiology. The water-holding action of fibers may contribute to increased stool bulk. Fiber also speeds up colonic transit in most people. In diarrhea-prone patients, whole-colonic transit is faster than average; however, dietary fiber can delay transit. Furthermore, because of their hydrophilic properties, stool-bulking agents bind water and thus prevent both excessive hydration or dehydration of stool. A high-fiber diet relieves diarrhea in some IBS patients. Dietary fiber has also been shown to lower pressures in the sigmoid colon in IBS patients. The effects of fiber on pressure in the rest of the colon are unknown; however, the whole colon is affected by IBS, and the pain of colon spasm often originates from the ascending and transverse segments. Fiber supplementation with psyllium reduces the perception of rectal distention, indicating that fiber may have an effect on visceral afferent function.

The beneficial effects of dietary fiber on colonic physiology suggest that dietary fiber should be an effective treatment forIBSpatients, but controlled trials of dietary fiber have produced variable results. IBS is not purely a colonic disorder; many patients may have symptoms originating from the upper gut. Despite the equivocal data regarding efficacy, most gastroenterologists consider stool-bulking agents worth trying in patients with IBS. Patients should be advised to take increasing quantities of bran supplements, such as whole-meal bread, high-bran cereal, or raw bran, until they are passing one or two soft stools daily. Alternatively, psyllium preparations may be used. About 20% of patients, however, complain that a high-fiber diet aggravates such symptoms as bloating and distention. These undesirable effects usually disappear spontaneously after several weeks.

Antispasmodics Anticholinergic drugs may provide temporary relief for symptoms such as painful cramps related to intestinal spasm. Although controlled clinical trials have produced mixed results, evidence generally supports use of anticholinergic drugs for pain. Meta-analysis of 26 double-blind clinical trials of antispasmodic agents inIBSshowed better global improvement (62%) and abdominal pain reduction (64%) compared to placebo (35% and 45%, respectively). The drugs are most effective when

prescribed in anticipation of predictable pain. Physiologic studies demonstrate that anticholinergic drugs inhibit the gastrocolic reflex; hence, postprandial pain is best managed by giving antispasmodics 30 min before meals so that effective blood levels are achieved shortly before the anticipated onset of pain. Most anticholinergics contain natural belladonna alkaloids, which may cause xerostomia, urinary hesitancy and retention, blurred vision, and drowsiness. Some physicians prefer to use synthetic anticholinergics, such as dicyclomine, that have less effect on mucous membrane secretions and therefore produce fewer undesirable side effects.

Antidiarrheal Agents When diarrhea is severe, especially in the painless diarrhea variant ofIBS, small doses of diphenoxylate (Lomotil), 2.5 to 5 mg every 4 to 6 h, can be prescribed. These agents are less addictive than paregoric, codeine, or tincture of opium. In general, the intestines do not become tolerant of the antidiarrheal effect of opiates, and increasing doses are not required to maintain antidiarrheal potency. These agents are most useful if taken before anticipated stressful events that are known to cause diarrhea. Treatment with antidiarrheals, however, should be considered only as temporary management; the final goal of treatment is gradual withdrawal of medication with substitution of a high-fiber diet.

Drug Antidepressants In addition to their mood-elevating effects, antidepressent medications have several physiologic effects that may be beneficial inIBS. In diarrhea-predominant IBS patients, the tricyclic antidepressant imipramine slows jejunal migrating motor complex transit propagation and delays orocecal and whole-gut transit, indicative of a motor inhibitory effect. Tricyclic agents may alter visceral afferent neural function.

Tricyclic antidepressants may be effective in someIBSpatients. In a 2-month study of desipramine, abdominal pain improved in 86% of patients compared to 59% given a placebo. Another study of desipramine in 28 IBS patients showed improvement in stool frequency, diarrhea, pain, and depression. Improvements were mainly observed in diarrhea-predominant patients, with no improvement noted in constipated patients. The efficacy of other antidepressant agents is less well evaluated. An uncontrolled review of antidepressant therapy in 138 patients with IBS, including both tricyclic agents and the newer selective serotonin reuptake inhibitors (e.g., fluxetine, paroxetine, and sertraline), reported symptomatic improvement in 89% of individuals, especially those in the pain-predominant subtype. However, no placebo-controlled trials of the selective serotonin inhibitors have been reported in IBS to date.

Antiflatulence Therapy The management of excessive gas is seldom satisfactory, except in cases of obvious aerophagia or disaccharidase deficiency. Patients should be advised to eat slowly; not chew gum or drink carbonated beverages; and avoid artificial sweeteners, legumes, and foods of the cabbage family. Simethicone, antacids, and activated charcoal have all been tried, usually with disappointing results.

FUTURE DIRECTIONS IN MEDICAL TREATMENT OF IBS

Medications that blunt the visceral hyperalgesia ofIBS are in development. Such "antiafferent" agents might act via one or more mechanisms, including (1) modification of release of pain-inducing mediators in the gut wall, (2) blockade or activation of

peripheral afferent nerve receptors, (3) inhibition of afferent nerve transmission, or (4) modification of afferent activity in theCNS. These include the kappa opioid compounds and serotonin receptor ($5HT_3$) antagonists such as alosetron and octreotide.

Such compounds have been shown to reduce perception of painful mechanical visceral stimulation in patients withIBS. Furthermore, placebo-controlled trials with IBS patients have shown that alosetron or fedotozine, a kappa opioid analogue, reduces both pain and the severity of disease. Additional clinical studies of this group of compounds may lead to new therapeutic approaches for the treatment of IBS.

289. DIVERTICULAR, VASCULAR, AND OTHER DISORDERS OF THE INTESTINE AND PERITONEUM - *Kurt J. Isselbacher, Alan Epstein*

DIVERTICULAR DISEASE

Diverticula may be either congenital or acquired and may affect either the small or large intestine. Congenital diverticula are herniations of the entire thickness of intestinal wall, while the more common acquired diverticula consist of herniations of the mucosa through the muscularis, generally at the site of a nutrient artery.

SMALL-INTESTINAL DIVERTICULA

Diverticula may occur in any portion of the small intestine; however, with the exception of Meckel's diverticulum, the most common locations are in the duodenum and jejunum. Most often diverticula are asymptomatic and discovered incidentally on upper gastrointestinal x-rays. On occasion, however, they may cause symptoms either because of their anatomic proximity to other structures or rarely from inflammation or bleeding.

Duodenal diverticula arise singly from the medial surface of the second portion of the duodenum. In most patients they cause no symptoms. Rarely, they may present as acute diverticulitis with abdominal pain, fever, gastrointestinal bleeding, or, most rarely, perforation. Periampullary diverticula are occasionally associated with cholangitis or pancreatitis. Jejunal diverticula, while less common, may also be the site of acute inflammation, bleeding, or perforation with resulting abscess or peritonitis.

Multiple jejunal diverticula may be associated with malabsorption related to bacterial overgrowth within the diverticula, similar to other situations where intestinal stasis (e.g., blind loops) permits bacterial proliferation.**The consequences of bacterial proliferation with resultant mucosal damage, deconjugation of bile salts, and vitamin B_{12} malabsorption are discussed in Chap. 286.*

Meckel's diverticulum, a persistent omphalomesenteric duct, is the most frequent congenital anomaly of the digestive tract, occurring in ~2% of autopsied adults. The diverticulum is wide-mouthed, about 5 cm long, and arises from the antimesenteric border of the ileum, usually within 100 cm of the ileocecal valve. The sac may be lined with normal ileal mucosa (approximately half) or contain gastric, duodenal, pancreatic, or colonic mucosa. While rarely symptomatic after age 5, Meckel's diverticulum may produce hemorrhage, inflammation, and obstruction in children and teenagers.

Hemorrhage occurs almost exclusively before age 10 and invariably results from peptic ulceration of ileal mucosa adjacent to a Meckel's diverticulum lined with gastric mucosa. The diagnosis may be established by isotope scanning of the abdomen after injection of technetium-99, which is taken up by the ectopic gastric mucosa in the diverticulum. False-negative and false-positive Meckel's scans are not uncommon; thus, other clinical and laboratory features must be assessed carefully before recommending surgery. In older children and young adults, inflammation of the diverticulum may mimic acute appendicitis. Mechanical obstruction may also occur if the diverticulum intussuscepts into the lumen of the bowel or twists on a fibrous remnant of the omphalomesenteric

duct that extends from the diverticulum to the abdominal wall. The treatment of any of these complications of Meckel's diverticulum is surgical excision.

COLONIC DIVERTICULA

Diverticula of the colon are herniations or saclike protrusions of the mucosa through the muscularis, at the point where a nutrient artery penetrates the muscularis. Diverticula occur most commonly in the sigmoid colon and decrease in frequency in the proximal colon. They increase with age; the incidence is 20 to 50% in western populations over age 50. The exact mechanism for their formation is unknown but may be related to an increase in intraluminal pressure. Thickening of the muscle coat of the colon in most patients with diverticula suggests that herniations of mucosa are caused by increased pressure produced by colonic muscle contractions. The rarity of colonic diverticula in underdeveloped nations has led to the speculation that diverticula result from the highly refined western diet, which is deficient in dietary fiber or roughage. It is proposed that such diets result in decreased fecal bulk, narrowing of the colon, and an increase in intraluminal pressure in order to move the smaller fecal mass. However, the role of dietary fiber in the etiology and treatment of diverticular disease remains to be determined.

Colonic diverticula are usually asymptomatic and are an incidental finding on barium enema or colonoscopy. The major complications of inflammation, both acute and chronic, and hemorrhage occur in only a small percentage of individuals with diverticulosis. Since diverticulosis is quite common in older patients, one must avoid the temptation of attributing pain or bleeding to the diverticula unless other conditions, especially colon cancer, have been excluded.

DIVERTICULITIS

Inflammation can occur in or around the diverticular sac. The cause of diverticulitis is probably mechanical, related to retention in the diverticula of undigested food residue and bacteria, which may form a hard mass called a *fecalith*. This compromises the blood supply to the thin-walled sac (made up solely of mucosa and serosa) and renders it susceptible to invasion by colonic bacteria. The inflammatory process may vary from a small intramural or pericolic abscess to generalized peritonitis. Some attacks are accompanied by minimal symptoms and seem to heal spontaneously. Studies of resected specimens indicate that most perforations of the diverticular sac are small and result in inflammation of the sac itself and the adjacent serosal surface. Diverticulitis occurs more often in men than in women and three times as often in the left as in the right colon. This suggests that diverticulitis may be related to the higher intraluminal pressures and the more solid fecal material in the sigmoid and descending colon.

Acute colonic diverticulitis is a disease of variable severity characterized by fever, left lower quadrant abdominal pain, and signs of peritoneal irritation -- muscle spasm, guarding, rebound tenderness. Rectal examination may reveal a tender mass if the area of inflammation is close to the rectum. Although constipation may not have been noted before onset of the illness, the inflammation around the colon often results in some degree of acute constipation or obstipation. Rectal bleeding, usually microscopic, is noted in 25% of cases; it is rarely massive. Polymorphonuclear leukocytosis is common.

Complications include free perforation, which results in acute peritonitis, sepsis, and shock, particularly in the elderly. The perforation may be walled off by adherent omentum or neighboring structures such as the bladder or small bowel. Abscess formation or fistulas then occur as the inflammatory mass burrows into other organs. Severe pericolitis may cause a fibrous stricture around the bowel, which can be associated with colonic obstruction and may mimic a neoplasm.

Diagnosis During the acute phase of diverticulitis, barium enema and sigmoidoscopy may be hazardous, since contrast material or air under pressure may lead to rupture of an inflamed diverticulum and convert a walled-off inflammatory lesion to a free perforation. These examinations are usually safe after adequate treatment and healing of the diverticulitis. The radiologic findings on barium enema suggestive of diverticulitis are leakage of barium from a diverticular sac, stricture formation, and the presence of a pericolic inflammatory mass. In many patients the distortion caused by inflammation prevents a clear distinction between cancer and diverticulitis. In these cases, colonoscopy or surgical excision may be required for accurate diagnosis. Abdominal computed tomography scan may demonstrate the presence of a pericolic abscess.

TREATMENT

Most patients with acute diverticulitis require bowel rest, intravenous fluids, and broad-spectrum antibiotics. Repeated attacks of diverticulitis in the same area generally require surgical resection. Severe attacks with acute peritoneal signs, suspected abscess, or perforation require intravenous antibiotics directed against gram-negative anaerobic bacteria, followed by surgical drainage or resection. The usual procedure is a diverting colostomy with resection of the involved colon; reanastomosis is then performed at a second operation.

PAINFUL DIVERTICULAR DISEASE WITHOUT DIVERTICULITIS

Some patients with diverticulosis develop recurrent left lower quadrant colicky pain without clinical or pathologic evidence of acute diverticulitis. They often have bouts of alternating constipation and diarrhea; the pain may be relieved by defecation or passage of flatus. These features suggest the coexistence of the irritable bowel syndrome. Examination during a bout of pain reveals tenderness of the sigmoid colon, but signs of peritoneal inflammation such as rebound tenderness, muscle guarding, fever, and leukocytosis are absent. Barium enema shows typical diverticula without evidence of inflammation and stricture, plus a "sawtooth" irregularity of the lumen, reflecting muscle hypertrophy and spasm. In some patients the pain is severe enough to warrant observation in a hospital and restriction of food, since feeding aggravates the pain by causing colonic contraction. Anticholinergics, which reduce sigmoid contractions, and mild sedation are usually all that is required. After recovery, the patient should be started on a high-residue diet or given a bulk laxative such as hemicellulose, unprocessed bran, or psyllium extract. Surgical excision is usually not indicated unless acute diverticulitis or its complications occur.

HEMORRHAGE FROM DIVERTICULA

Massive hemorrhage from colonic diverticula is one of the most common causes of

hematochezia in patients over age 60. This complication of diverticulosis is caused by erosion of a vessel by a fecalith within the diverticular sac. The bleeding is painless and not accompanied by signs or symptoms of diverticulitis. Most cases of mild or moderate hemorrhage stop spontaneously with bed rest and blood transfusion. Localization of bleeding can be obtained by bleeding scan or angiography. In patients with severe hemorrhage, mesenteric angiography can be both diagnostic in localizing the bleeding site and therapeutic, since vasoconstrictive drugs or artificial blood clot infused intraarterially can sometimes effectively control hemorrhage. Colonoscopy is also useful in evaluating acute hematochezia, and the endoscopist may be able to cauterize angiodysplasias (Chap. 44). The location of bleeding diverticula is more commonly in the right colon, particularly the ascending colon, in contrast to the sigmoid colon, where diverticula are more numerous.

MOTILITY DISORDERS

Normal intestinal motility involves the delicate interplay of the gut motor system, neural influences of the autonomic and central nervous system, as well as hormonal factors, specifically gut neuropeptides. In addition, many drugs used in the treatment of disease (e.g., opioids, antibiotics) affect and influence intestinal motility directly or indirectly. Table 289-1 lists some of the disorders of the enteric motor and neural system. Only the more clinically relevant ones are discussed.

MEGACOLON

Megacolon, or giant colon, is characterized by massive distention of the colon, usually accompanied by severe constipation or obstipation. This condition can be either congenital or acquired and is seen in all age groups. Acute toxic megacolon is a severe complication of ulcerative colitis (Chap. 287).

Aganglionic Megacolon (Hirschsprung's Disease) This is a congenital disorder due to absence of enteric neurons (ganglions) in the distal colon and rectum. This aganglionic segment loses its neural inhibition and remains contracted. Hirschsprung's disease is a heterogeneous genetic disorder -- some patients have an autosomal dominant form of the disease with mutations in the *RET* gene; many have an autosomal recessive form with a mutation in the endothelin-B receptor gene. Hirschsprung's disease is a multigenic trait; genes on 9q31 affect the phenotype of the *RET* gene mutations. These defects result in the gestational failure of neural crest cells to migrate to the distal colon. The disease manifests in early infancy, occurring more frequently in males, and is often familial. These infants have massive abdominal distention, absent bowel movements, and impaired nutrition due to chronic obstruction of the colon. In some individuals with less severe symptoms, the disease may not be diagnosed until adolescence or early adulthood. The aganglionic and contracted segment of bowel is unable to relax to permit passage of stool, causing the normal proximal colon to become greatly dilated. On rectal examination the ampulla is empty of feces and the anal sphincter is normal. Barium enema reveals a narrowed segment in the rectosigmoid, with massive dilation above. Diagnosis is made by full-thickness surgical biopsy under anesthesia and demonstration of absent ganglion cells in the diseased segment. In most patients the aganglionic segment is in the rectosigmoid colon. The treatment of choice is a pull-through procedure in which normally innervated colon is anastomosed to

the distal rectum just above the internal sphincter, thus bypassing the contracted aganglionic segment and restoring normal defecation.

Acquired Megacolon In Central and South America, infection with *Trypanosoma cruzi* (Chagas' disease) can result in destruction of the ganglion cells of the colon, producing a clinical picture similar to congenital megacolon, except that the onset is in adult life rather than in childhood. A number of other diseases are associated with megacolon in adults. Patients with schizophrenia or depression, particularly institutionalized patients, may have obstipation and massive colonic dilatation. Severe neurologic disorders, including cerebral atrophy, spinal cord injury, and parkinsonism, also may cause megacolon. Myxedema, infiltrative diseases such as amyloidosis, and primary systemic sclerosis also can reduce colonic motility and produce marked colonic distention. Narcotic drugs, particularly morphine and codeine, can cause severe constipation, especially when administered to bedridden patients. Digital rectal examination of adults with acquired megacolon reveals a rectum distended with feces, as opposed to the empty rectum in aganglionic megacolon. Treatment is aimed at the underlying disease, as well as the careful use of enemas and cathartics.

Intestinal Pseudoobstruction Intestinal pseudoobstruction is an acute or chronic motility disorder characterized by distention or dilation of the small and large intestine. Abdominal pain, nausea, and vomiting may lead to diagnostic confusion with mechanical obstruction; but as the name of this condition implies, the underlying cause is not obstruction but rather a severe dysmotility resulting in distention. Pseudoobstruction may be primary or secondary and acute or chronic. In primary or idiopathic pseudoobstruction no other contributing condition can be identified, and the motility disorder is attributed to abnormalities of sympathetic innervation or of the muscle layers of the intestine. Secondary pseudoobstruction may result from primary systemic sclerosis, diabetes, amyloidosis, neurologic diseases, drugs, or sepsis.

Chronic or Intermittent Secondary Pseudoobstruction Numerous medical conditions can cause chronic dilation of the large and small bowel. Some of these may involve the intestinal smooth muscle, such as primary systemic sclerosis, amyloidosis, or muscular dystrophy. Endocrine disorders, including myxedema and diabetes mellitus, may result in chronic distention, which in the diabetic patient results from autonomic visceral neuropathy. Chronic neurologic diseases, including Parkinson's disease and stroke, may be complicated by chronic pseudoobstruction; in these patients drugs and relative immobility are contributing features. Finally, institutionalized psychotic patients may suffer from prolonged megacolon.

The symptoms of chronic secondary pseudoobstruction are chronic or intermittent constipation, crampy abdominal pain, anorexia, and bloating. Gastric distention and disordered swallowing may be present. Abdominal x-rays reveal gaseous distention of the large and small bowel and occasionally of the stomach. Air-fluid levels are unusual and should raise the possibility of mechanical obstruction. Upper gastrointestinal series and barium enema do not reveal specific abnormalities of the intestine such as tumor, stricture, or volvulus. The presence of an autoimmune disorder or endocrinopathy may require confirmation by serologic or blood tests; biopsy may be needed as in amyloidosis or muscular dystrophy.

The treatment of chronic intestinal pseudoobstruction is made difficult by the complexity and chronicity of the underlying systemic disease. Patients with primary systemic sclerosis may respond to broad-spectrum antibiotics if intestinal bacterial overgrowth is suspected. Metoclopramide may benefit gastric dysmotility in the diabetic patient. Discontinuation of psychotropic or anti-Parkinson drugs may occasionally result in improvement. Cathartics and enemas may be required to relieve fecal impaction, and the regular use of stool softeners and a high-fiber diet may help prevent recurrences.

Idiopathic Intestinal Pseudoobstruction This term describes the condition of patients with signs and symptoms of pseudoobstruction in whom no systemic disease can be identified. The typical patient has recurrent attacks of abdominal pain and distention with nausea and vomiting. The small intestine is primarily involved, and chronic constipation is much less frequent than in secondary pseudoobstruction. Steatorrhea secondary to bacterial overgrowth of the small intestine is common and may lead to chronic diarrhea and malnutrition. Many patients exhibit abnormalities of motility in the esophagus and urinary bladder, in addition to the small and large intestine. Neuromuscular defects have been described in patients with this syndrome, including abnormalities of the mesenteric plexus and myopathy of the intestinal and urinary bladder smooth muscle (so-called hollow visceral myopathy). Elevated prostaglandin E levels have been reported in some patients.

Management of idiopathic pseudoobstruction is unsatisfactory. Surgery to relieve "obstruction" is to be avoided, since the condition is often worsened by abdominal surgery. Medical therapy with metoclopramide and cholinergic agents has been unsuccessful. Nutritional support in the form of low-residue elemental diets or parenteral hyperalimentation may be helpful. Unfortunately, the lack of effective therapy and the progressive nature of the illness make the prognosis of idiopathic pseudoobstruction rather poor. Death from malnutrition and steatorrhea are common. The long-term impact of total parenteral nutrition on this disease is not yet clear.

Acute Intestinal Pseudoobstruction This entity, sometimes referred to as *Ogilvie's syndrome*, is characterized by acute intestinal dilation involving primarily the colon but occasionally also the small intestine. As in other forms of pseudoobstruction, the clinical features are difficult to distinguish from mechanical obstruction. The patient may complain of colicky lower abdominal pain and acute constipation. Examination reveals a distended, tympanitic abdomen, with reduced or absent bowel sounds. Localized tenderness over the distended colon is common, but diffuse abdominal tenderness, rigidity, or rebound tenderness are unusual. Abdominal films reveal massive dilation of the colon and small intestine, occasionally with the presence of air-fluid levels. The cecum, being the most capacious part of the colon, is often massively dilated and tender. The onset of these symptoms usually occurs in patients who have recently undergone severe surgical or medical stress, such as major surgery, myocardial infarction, sepsis, or respiratory failure. Patients with acute pseudoobstruction are frequently on respirators, have received narcotics or sedatives, and have metabolic and electrolyte disturbances. Ogilvie's syndrome may also be due to paraneoplastic obstruction.

Management of acute pseudoobstruction requires careful correction of fluid and electrolyte abnormalities, intubation of the stomach or small intestine for

decompression, and avoidance of drugs that depress intestinal motility. Barium enema may be hazardous because of the risk of perforating the already dilated bowel. Decompressive colonoscopy is beneficial in some patients, and cecostomy may be required in some patients with massive cecal dilation. The outcome depends in large part on the prognosis of the associated medical or surgical conditions. Patients who recover from the underlying medical or surgical conditions usually have a return of normal colonic function.

IRRITABLE BOWEL SYNDROME

SeeChap. 288.

CHRONIC CONSTIPATION

Chronic constipation is widespread in western society, with ~10% of the population taking laxatives on a regular basis. Most cases of chronic constipation arise from habitual neglect of afferent impulses, failure to initiate defecation, and accumulation of large, dry fecal masses in the rectum. This voluntary suppression of the call to stool may arise during the period of toilet training in childhood or later in life because of a sense of social impropriety, unaccustomed surroundings, uncomfortable toilet facilities, or illnesses that require confinement to bed. Chronic constipation is much more common in women, with onset typically in late adolescence or early adulthood. As constant distention of the rectum with feces becomes chronic, the patient grows less aware of rectal fullness. Bowel movements become progressively more difficult, and painful hemorrhoids or anal fissures reinforce suppression of the urge to defecate. To avoid these problems the patient begins the chronic use of laxatives or enemas, without which defecation becomes impossible.**The mechanism of defecation is discussed in Chap. 42.*

TREATMENT

The physician should make every attempt to educate the patient about the chain of events that has led to chronic constipation. Attempts should be made to alter patterns of many years' duration, and the patient must recognize the importance of responding to, rather than suppressing, the urge to defecate. Defecation should be attempted at a given time each day. In most individuals the call to stool occurs in the morning after breakfast. Physical exercise such as a brisk walk just before attempts at defecation may be helpful. Patients are instructed to increase dietary bulk with foods rich in fiber, such as green vegetables and unprocessed cereal grains, or by the regular use of bulk laxatives, such as hemicellulose, psyllium extract, and powdered unprocessed bran. The success of such a regimen depends to some extent on the duration of symptoms. Elderly patients with long-standing constipation and reliance on enemas or laxatives are more resistant to these measures than younger patients whose bowel patterns are less established. Moreover, poor muscle tone, reduced physical activity, and increased incidence of other medical conditions make the problem more difficult in the older age group. Bedridden elderly patients often develop severe constipation and even fecal impaction unless preventive measures are taken. This applies not only to patients with previous constipation but also to those with regular bowel movements before their confining illness. Regular administration of stool softeners, bulk laxatives, or mild

cathartics is necessary until full ambulation and a normal diet are resumed. The onset of fecal impaction in bedridden patients is heralded by a feeling of rectal distention, urgency of defecation, or tenesmus. Occasionally, the fecal impaction will result in low-grade chronic obstruction with dilation and increased fluid content proximal to the impaction; "paradoxical diarrhea" may thus occur as fluid moves past the obstructing fecal mass. This situation will be aggravated if antidiarrheal drugs are given because the underlying constipation will be worsened. The appropriate maneuver is to disimpact the rectum manually or to administer gentle enemas if the impaction is beyond the reach of the finger.

DISORDERS OF THE MESENTERIC CIRCULATION

Ischemia of the intestine is the end result of interruption or reduction of its blood supply. However, the clinical manifestations of intestinal ischemia range from mild chronic symptoms to a catastrophic acute episode, depending on the vascular supply involved, the extent of the occlusion or ischemia, and the rapidity of the process. The clinician should be aware of the spectrum of clinical manifestations (Table 289-2). The gut derives its arterial blood supply from the celiac axis and the superior and inferior mesenteric arteries. The small intestine is supplied by the celiac and superior mesenteric arteries, the colon by branches of the superior and inferior mesenteric arteries. A rich network of anastomotic vessels and the possible development of collateral circulation determine the clinical picture of acute or chronic intestinal arterial insufficiency.

MESENTERIC ISCHEMIA AND INFARCTION

Acute intestinal ischemia may be classified as occlusive or nonocclusive. *Occlusion* accounts for about 75% of acute intestinal ischemia and may result from an arterial thrombus (one-third of arterial occlusions) or embolus (two-thirds of arterial occlusions) of the celiac or superior mesenteric arteries, or from venous occlusion (<5% of occlusions) in the same distribution. Arterial embolus occurs most commonly in patients with chronic or recurrent atrial fibrillation, artificial heart valves, or valvular heart disease; arterial thrombosis is usually associated with extensive atherosclerosis or low cardiac output. Venous occlusion is rare; it is occasionally seen in women taking oral contraceptives. Approximately one-fourth of patients with mesenteric ischemia have no definite occlusion of a major vessel, a condition referred to as *nonocclusive ischemia*. The exact cause of nonocclusive disease is obscure; systemic arterial hypotension, cardiac arrhythmias, prolonged heart failure, digitalis therapy, dehydration, and endotoxemia can be contributing factors.

The major clinical feature of acute mesenteric ischemia is severe abdominal pain, often colicky and periumbilical at the onset, later becoming diffuse and constant. Vomiting, anorexia, diarrhea, and constipation are also frequent but of little diagnostic help. Examination of the abdomen may reveal tenderness and distention. Bowel sounds are often normal even in the face of severe infarction. Some patients have a surprisingly normal abdominal examination in spite of severe pain. Mild gastrointestinal bleeding is often detected by examination of stool for occult blood; gross hemorrhage is unusual except in ischemic colitis. Leukocytosis is often present. Late in the course of the disease (24 to 72 h), gangrene of the bowel occurs with diffuse peritonitis, sepsis, and

shock. Abdominal plain films in patients with mesenteric ischemia may reveal air-fluid levels and distention. Barium study of the small intestine reveals nonspecific dilation, poor motility, and evidence of thick mucosal folds ("thumbprinting") (Fig. 289-1).

Acute mesenteric ischemia is a grave condition with a high morbidity and mortality. Patients suspected of having acute arterial embolus should undergo immediate celiac and mesenteric angiography to localize the embolus, followed by embolectomy. Restoration of normal circulation may allow complete recovery if performed before irreversible necrosis or gangrene has occurred. Unfortunately, infarction and transmural necrosis are frequently found at surgery, necessitating resection. Arterial or venous thrombosis is not generally amenable to surgical removal of the thrombus, and resection of the affected bowel is required. Similarly, patients with nonocclusive ischemia are not candidates for corrective vascular surgery (as major vessels are patent). These individuals often have extensive necrosis of the small or large intestine because of the widespread nature of the ischemic event. The decision to operate when mesenteric ischemia is suspected is often difficult, because the typical patient is a poor surgical risk owing to advanced age, dehydration, sepsis, and other serious medical conditions.

Chronic arterial insufficiency may precede acute vascular insufficiency, producing so-called abdominal angina. As in angina pectoris, the pain of chronic mesenteric insufficiency occurs under conditions of increased demand for splanchnic blood flow. The patient complains of intermittent dull or cramping midabdominal pain 15 to 30 min after a meal, lasting for several hours postprandially. Significant weight loss due to decreased food intake may be present. Chronic intestinal ischemia also may produce mucosal damage and malabsorption, which in turn aggravates the weight loss. Since abdominal angina may progress to bowel infarction, arteriographic studies should be performed to confirm the diagnosis in those patients who are candidates for abdominal vascular surgery. The only definitive treatment is vascular surgery or balloon angioplasty to remove the thrombus or the construction of bypass arterial grafts to the ischemic bowel.

A number of systemic conditions are associated with *vasculitis* of the large and small arteries supplying the intestine. Most often these disorders can be recognized by the associated extraintestinal manifestations, as in polyarteritis nodosa, lupus erythematosus, dermatomyositis, Henoch-Schonlein purpura (allergic vasculitis), and rheumatoid vasculitis. When larger arteries are involved, as in polyarteritis nodosa, the picture of acute intestinal infarction is similar to that of embolic or atherosclerotic vascular occlusion. Often the involvement of smaller vessels leads to areas of intramural hemorrhage and edema resulting in abdominal pain, variable degrees of intestinal obstruction, and bleeding. Barium enema may show "thumbprinting" and "spiculation" due to localized edema, hemorrhage, and ulceration (Fig. 289-1). In many instances, treatment of the underlying disorder may lead to regression of symptoms. If signs of an acute abdomen develop, surgical exploration is usually indicated.

Intramural small-intestinal hemorrhage may occur with vasculitis, trauma, or impaired coagulation, especially in patients receiving anticoagulants. The clinical and radiologic features resemble those seen with vasculitis and local mucosal hemorrhage.

ISCHEMIC COLITIS

Ischemia of the colon most often affects the elderly because of their greater frequency of vascular disease. Ischemic colitis is almost always nonocclusive. Shunting of blood away from the mucosa may contribute to this condition, but the mechanism of ischemia is not known.

The clinical picture depends on the degree of ischemia and its rate of development. In *acute fulminant ischemic colitis*, the major manifestations are severe lower abdominal pain, rectal bleeding, and hypotension. Dilation of the colon and physical signs of peritonitis are seen in severe cases. Abdominal films may reveal thumbprinting from submucosal hemorrhage and edema (Fig. 289-1). Barium enema is hazardous in the acute situation because of the risk of perforation. Sigmoidoscopy or colonoscopy may detect ulcerations, friability, and bulging folds from submucosal hemorrhage. Angiography is not helpful in the management of patients with presumed ischemic colitis because a remediable occlusive lesion is very rarely found. Surgical resection may be required in some patients with fulminant ischemic colitis to remove gangrenous bowel; others with lesser degrees of ischemia may respond to conservative medical management.

Subacute ischemic colitis is the most common clinical variant of ischemic colonic disease. It produces lesser degrees of pain and bleeding, often occurring over several days or weeks. The left colon may be involved, but the rectum is usually spared because of the collateral blood supply, a feature distinguishing it from acute ulcerative colitis. Barium enema reveals edema, cobblestoning, thumbprinting, and occasionally superficial ulceration. Angiography is not indicated because almost all cases are nonocclusive. Occasionally, *stricture formation* may follow a bout of ischemic colitis or may present de novo without a history of antecedent pain or bloody diarrhea. Most cases of nonocclusive ischemic colitis resolve in 2 to 4 weeks and do not recur. Surgery is not required except for obstruction secondary to postischemic stricture.

ANGIODYSPLASIA OF THE COLON

These are vascular ectasias or arteriovenous malformations (AVMs) that occur in the right colon of many older individuals and may cause bleeding (Chap. 44). Angiodysplasia is a degenerative lesion consisting of dilated, distorted, thin-walled vessels lined by vascular endothelium. It may result from partial obstruction of the submucosal venous plexus by the tension generated in the cecal wall during muscular contraction. Grossly, angiodysplasias look similar to spider angiomas of the skin and on colonoscopy appear as star-shaped branching vessels in the submucosa measuring from 2 mm to 1 cm in diameter. The lesions are usually multiple and are found primarily in the cecum and ascending colon, but in some patients they may be distributed from the stomach to rectum.

Cecal angiodysplasia is important because of the likelihood of bleeding, either massively or chronically. In patients over age 60, ~1/4 of colonic bleeding episodes are secondary to angiodysplasia. The diagnosis is easiest to establish by colonoscopy, which allows treatment by laser photocoagulation, electrocautery, or injection with sclerosant. Some patients with massive uncontrolled bleeding or multiple sites of angiodysplasia may require right hemicolectomy. Angiodysplasias may also respond to

chronic estrogen-progesterone therapy.

ANORECTAL PROBLEMS

HEMORRHOIDS

The internal hemorrhoidal plexus of veins is located in the submucosal space above the valves of Morgagni. The anal canal separates it from the external hemorrhoidal venous plexus, but the two spaces communicate under the anal canal, the submucosa of which is attached to underlying tissue to form the interhemorrhoidal depression. Whenever the internal hemorrhoidal plexus is enlarged, the associated supporting tissue mass is increased, and the resultant venous swelling is called an *internal hemorrhoid*. When veins in the external hemorrhoidal plexus become enlarged or thrombosed, the resultant bluish mass is called an *external hemorrhoid*.

Both types of hemorrhoids are very common and are associated with increased hydrostatic pressure in the portal venous system, such as during pregnancy, straining at stool, or with cirrhosis. When internal hemorrhoids enlarge, pain is not a usual feature until the situation is complicated by thrombosis, infection, or erosion of the overlying mucosal surface. Most persons complain of bright red blood on the toilet tissue or coating the stool, with a feeling of vague anal discomfort. The discomfort is increased when the hemorrhoid enlarges or prolapses through the anus; prolapse is often accompanied by edema and sphincteric spasm. If not treated, prolapse usually becomes chronic as the muscularis stays stretched, and the patient complains of constant soiling of underclothing with very little pain. Prolapsed hemorrhoids may become thrombosed; the overlying mucous membrane may bleed profusely from the trauma of defecation.

Because they lie under the skin, external hemorrhoids are quite often painful, particularly if there is a sudden increase in their mass. These episodes result in a tender blue swelling at the anal verge due to thrombosis of a vein in the external plexus and need not be associated with enlargement of the internal veins. Since the thrombus usually lies at the level of the sphincteric muscles, anal spasm often occurs.

The diagnosis of internal and external hemorrhoids is made by inspection, digital examination, and direct vision through the anoscope and proctoscope. Since such lesions are very common, they must not be regarded as the cause of rectal bleeding or iron deficiency anemia until a thorough investigation has been made of the more proximal gastrointestinal tract. Acute blood loss can occasionally be attributed to internal hemorrhoids. Chronic anemia or occult blood in the stool in the presence of large but not definitely bleeding hemorrhoids requires a search for a polyp, cancer, or ulcer.

TREATMENT

Most hemorrhoids respond to conservative therapy such as sitz baths or other forms of moist heat, suppositories, stool softeners, and bed rest. Internal hemorrhoids that remain permanently prolapsed are best treated surgically; milder degrees of prolapse or enlargement with pruritus ani or intermittent bleeding can be handled successfully by banding or injection of sclerosing solutions. External hemorrhoids that become acutely

thrombosed are treated by incision, extraction of the clot, and compression of the incised area following clot removal. No surgical procedure should be carried out in the presence of acute inflammation of the anus, ulcerative proctitis, or ulcerative colitis. Proctoscopy or colonoscopy should always be performed before a patient undergoes hemorrhoidectomy.

ANAL INFLAMMATION

Perianal inflammatory lesions may be primary or may be associated with inflammatory bowel disease or diverticular disease. *Anal fissures* are superficial erosions of the anal canal which usually heal rapidly with conservative therapy. *Anal ulcers* are more chronic and deep and give symptoms largely as the result of painful spasm of the external anal sphincter during and after defecation. Bleeding may occur with either fissure or ulcer; healing of the ulcer is often associated with a hypertrophied anal papilla and some degrees of anal contracture. The spasm associated with chronic anal fissure/ulcer can be managed with oral nifedipine or local botulinum toxin. *Fistula in ano*, a tract leading from the rectal lumen to the perianal skin, usually results from local crypt abscesses. The fistula is a chronically inflamed canal made up of fibrous tissue surrounding granulation tissue, the lumen of which may be difficult to demonstrate. *Perirectal abscesses* often represent the tracking down into the anal area of purulent material escaping from the rectosigmoid; diverticulitis, Crohn's disease, ulcerative colitis, or previous surgery may be the underlying cause. Fistulas between the rectum and vagina or the rectum and bladder represent serious complications of granulomatous, septic, or malignant disorders and require the patient to be hospitalized for definitive diagnostic and therapeutic procedures.

PERITONEAL AND MESENTERIC DISEASES

ACUTE PERITONITIS

Peritonitis is a localized or generalized inflammatory process of the peritoneum that may appear in both acute and chronic forms. In the acute form the motor activity of the intestine is decreased, and the intestinal lumen becomes distended with gas and fluid. Fluid accumulates as a result of failure to reabsorb the 7 or 8 L normally secreted daily into the lumen and absorbed from the distal small bowel and colon. Because of accumulation of fluid in the peritoneal cavity as well as decreased oral intake, rapid depletion of the plasma volume with impaired cardiac and renal function may occur.

Etiology *Bacterial peritonitis* may be due to entry of bacteria into the peritoneal cavity from a perforation in the gastrointestinal tract or from an external penetrating wound. *Chemical peritonitis* results from spillage of pancreatic enzymes, gastric acid, or bile as a result of injury or perforation of the intestine or biliary tract. *Sterile peritonitis* occurs in patients with systemic lupus erythematosus, porphyria, and familial Mediterranean fever (FMF) during disease attacks.

The most common causes of bacterial peritonitis are appendicitis; perforations associated with diverticulitis; peptic ulcer; gangrenous gallbladder; and gangrenous obstruction of the small bowel from adhesive bands, incarcerated hernia, or volvulus. Any lesion leading to the escape of intestinal bacteria may be a source, including a

perforating carcinoma, foreign body, and ulcerative colitis. The peritoneal cavity is remarkably resistant to contamination, and unless continuing contamination occurs, the peritonitis remains localized. Patients with alcoholic cirrhosis and ascites have an increased susceptibility to *spontaneous bacterial peritonitis*, usually from enteric pathogens. This complication occurs in the absence of recognizable perforation of a viscus and may be due to leakage of bacteria through the intestinal wall (Chap. 299).

Clinical Features The cardinal manifestations of peritonitis are acute abdominal pain and tenderness. The location of the pain and tenderness depends on the underlying cause and whether the inflammation is localized or generalized. In *localized peritonitis*, as seen in uncomplicated appendicitis or diverticulitis, the physical findings are limited to the area of inflammation. With widespread peritoneal inflammation there is *generalized peritonitis* with diffuse abdominal tenderness and rebound. Rigidity of the abdominal wall is a common finding in peritonitis and may be localized or generalized.

Peristalsis may be present initially but usually disappears as the illness progresses and bowel sounds disappear. Hypotension, tachycardia, oliguria, and leukocytosis with cell counts>20,000/uL, are common, especially in generalized peritonitis. Plain abdominal films may reveal dilation of the large and small bowel with edema of the small-bowel wall, as evidenced by the distance between adjacent loops of gas-filled small intestine. Diagnostic paracentesis is sometimes valuable in determining the nature of the exudate as well as whether bacteria can be demonstrated or cultured.

GONOCOCCAL PERITONITIS

This usually involves an extension of gonococcal infection from a primary focus in the female reproductive tract. The signs of inflammation usually are limited to the pelvis, but there may be findings of a mild generalized peritonitis. Occasionally, the patient has right upper quadrant pain and tenderness caused by gonococcal perihepatitis involving the liver capsule and adjacent peritoneum (Fitz-Hugh-Curtis syndrome) (Chap. 147).

STARCH PERITONITIS

An acute granulomatous peritonitis can develop in some patients as a foreign-body reaction to cornstarch used to powder surgical gloves. The clinical picture is that of acute abdominal pain and fever 10 to 30 days after an abdominal operation. The diagnosis can be made by paracentesis and demonstration of starch granules in monocytes. However, most patients are reexplored because of the fear of abscess or bacterial peritonitis, with the finding of foreign-body granuloma studding the peritoneum.

PSEUDOMYXOMA PERITONEI

This is a rare condition resulting from rupture of a mucocele of the appendix, a mucinous ovarian cyst, or mucin-secreting intestinal or ovarian adenocarcinoma. The abdomen becomes filled with masses of jelly-like mucus. Occasional patients are cured with removal of the mucocele or the ovarian cyst and most of the myxomatous material. In other cases, however, the mucoid material recurs, leading to progressive wasting and eventual death. Colloid carcinoma arising from the stomach or colon with peritoneal implants may resemble pseudomyxoma at laparotomy. The course of this type of highly

malignant tumor is one of rapid cachexia and early death. The diagnosis usually can be made by the appearance of many highly malignant cells in the peritoneal implants.

PNEUMATOSIS CYSTOIDES INTESTINALIS

This is a condition in which multiple gas-filled blebs or cysts accumulate in the intestinal wall beneath the serosal surface of the bowel. The exact source of the gas has not been explained satisfactorily. In some instances, this disease is associated with specific ulceration of the intestinal mucosa, in particular peptic ulcer with outlet obstruction. Cysts in the wall of the small bowel are seen as an occasional complication of mesenteric vascular occlusion. In the large bowel, these cysts are usually benign, may be seen with a variety of other disorders, and usually disappear over time.

Physical findings are not specific and the diagnosis is made either by x-ray or at laparotomy. Occasionally, the subserosal cysts may rupture, resulting in pneumoperitoneum.

CHYLOUS ASCITES

SeeChap. 46.

MESENTERIC LIPODYSTROPHY

This is a rare disorder usually affecting middle-aged women and characterized pathologically by infiltration of the mesentery with lipid-laden macrophages and fibrous tissue. These patients present with ill-defined abdominal pain and occasionally an abdominal mass. The diagnosis is made at laparotomy by demonstration of thick fibrofatty masses at the root of the mesentery with retraction and distortion of the bowel loops.

FAMILIAL MEDITERRANEAN FEVER

Familial Mediterranean fever (FMF, familial paroxysmal polyserositis) is an inherited disorder, characterized by recurrent episodes of fever, peritonitis, and/or pleuritis. Arthritis, skin lesions, and amyloidosis are seen in some patients.

FMFoccurs predominantly in patients of non-Ashkenazi (Sephardic) Jewish, Armenian, and Arabic ancestry. However, the disease has been seen in patients of Italian, Ashkenazi Jewish, and Anglo-Saxon descent as well as others.

ETIOLOGY

FMFis an autosomal recessive trait characterized by mutations in the *MEFV* gene located on 16p. The gene encodes a 781-amino acid protein called *pyrin* expressed in cells of the myeloid lineage. The gene is in the *RoRet* family, and the product appears to function as a transcription factor based on the presence of a nuclear localization signal, a zinc finger, and a coiled-coil domain. Its expression in granulocytes is increased by proinflammatory cytokines and reduced by anti-inflammatory cytokines. Mutations associated with FMF cluster in exon 10. Different mutations appear to be associated

with distinct disease manifestations; replacement of methionine 694 by valine is common in patients who have amyloidosis as a feature of the disease. Valine 726 replacement by alanine is rarely associated with amyloidosis. Other as yet unknown genes may modify the phenotype or be responsible for FMF in non-Mediterranean populations.

PATHOLOGY

Despite the striking clinical manifestations during an acute attack ofFMF, no specific pathologic alterations have been found. At laparotomy there is acute peritoneal inflammation with an exudate that contains a predominance of polymorphonuclear leukocytes. A disproportionately large number of male patients develop gallbladder disease with and without cholelithiasis. Pleural and joint inflammation are also nonspecific.

In the amyloidosis that accompaniesFMF, amyloid is deposited in the intima and media of the arterioles, the subendothelial region of venules, the glomeruli, and the spleen. Aside from their vessels, the heart and liver are uninvolved.

MANIFESTATIONS

The symptoms ofFMFoften begin between the ages of 5 and 15, although attacks sometimes commence during infancy and onset has occurred as late as age 50. The duration and frequency of attacks vary greatly in the same patient, and their occurrence follows no set pattern. The usual acute episode lasts 1 to 2 days, but some may be prolonged for 7 to 10 days. The attacks range in frequency from twice weekly to once a year, but 2 to 4 weeks is the most common interval. Spontaneous remissions lasting years have been seen. The severity and frequency of the attacks decrease with age or with development of amyloidosis.

Fever Fever is a cardinal manifestation and is present during most attacks. Rarely, fever may be present without serositis. The temperature may be preceded by a chill and will peak in 12 to 24 h. Defervescence is often accompanied by diaphoresis. The fever ranges from 38.5° to 40°C but is quite variable.

Abdominal Pain Abdominal pain occurs in >95% of patients and may vary in severity in the same patient. Minor premonitory discomfort may precede an acute episode by 24 to 48 h. The pain usually starts in one quadrant and then spreads to involve the whole abdomen. The initial site is usually very tender. Tenderness may remain localized with referred pain in other areas, and may radiate to the back. Diaphragmatic irritation may lead to splinting of the chest and pain in one or both shoulders. Nausea and vomiting sometimes occur. The abdomen is usually distended and may become rigid, with decreased or absent bowel sounds. On x-ray the wall of the small intestine may appear edematous, transit of barium is slowed, and fluid levels may be seen. An abdominal operation may precipitate an acute attack ofFMF, which may be confused with other postoperative complications.

Chest Pain Most patients with abdominal attacks have referred chest pain at one time or another, and 75% also develop acute pleuritic pain with or without abdominal

symptoms. In 30%, the attacks of pleuritis precede the onset of abdominal attacks by varying periods of time, and a small number of patients never develop abdominal attacks. Chest pain is usually unilateral and is associated with diminished breath sounds, a friction rub, or a transient pleural effusion.

Joint Pain In Israel, 75% of patients report at least one episode of acute arthritis. Arthritis can be distinct from abdominal or pleural attacks, can be acute or, rarely, chronic, and may involve one or several joints. Effusions are common, with large joints most frequently involved. Radiologic findings are nonspecific. Despite careful search, frank arthritis rarely has been seen in the United States. Some patients have a history of rheumatic fever-like illness in childhood, but in a large series of patients, including 30 from the Middle East, acute arthritis was not observed. Mild arthralgia is common during acute attacks but is nonspecific.

Skin Manifestations Skin involvement occurs in one-third of patients. These lesions consist of painful, erythematous areas of swelling from 5 to 20 cm in diameter, usually located on the lower legs, the medial malleolus, or the dorsum of the foot. They may occur without abdominal or pleural pain and subside within 24 to 48 h.

Other Signs and Symptoms Involvement of other serosal membranes has been reported, but pericarditis and meningitis are rare. Hematuria, splenomegaly, and small white dots called *colloid bodies* in the ocular fundus are findings of questionable significance. Rarely, migraine-like headaches accompany acute abdominal attacks, and some patients have become somewhat irrational or show extreme emotional lability during attacks. Whether these are primary manifestations ofFMF or secondary effects of pain and fever is unclear.

Complications Depression and lack of motivation are common, and patients withFMFrequire considerable support. A striking number of patients have developed gallbladder disease.

Amyloidosis has been reported in Israel, North Africa, and elsewhere in the Middle East, but its occurrence is rare in the United States. These findings are even more striking because there are probably as many knownFMFpatients in the United States as in Israel. Thus, environmental or nutritional, as well as genetic, factors may play a role in the development of amyloidosis in FMF.

LABORATORY FINDINGS

Polymorphonuclear leukocytosis ranging from 10,000 to 30,000 cells/uL is almost invariable during acute attacks. The erythrocyte sedimentation rate is elevated during attacks but returns to normal between attacks. Plasma fibrinogen, serum haptoglobin, ceruloplasmin, and C-reactive protein increase during the episodes. Plasma lipids are normal, and no consistent abnormalities of hepatic or renal function are seen. When amyloidosis is present, laboratory findings are typical of a nephrotic syndrome followed by renal insufficiency.

DIAGNOSIS

When the typical acute attacks ofFMFoccur in an individual of appropriate ethnic background with a family history of FMF, the diagnosis is easy. When a patient is seen for the first time, a variety of other febrile illnesses must be excluded, such as acute appendicitis, pancreatitis, porphyria, cholecystitis, intestinal obstruction, and other major abdominal catastrophes.

Some inherited hyperlipidemias may mimic the clinical picture ofFMF, but lipid analysis will eliminate them from consideration. The FMF patient is not immune to other diseases, and when an attack differs from the usual pattern or is more prolonged, consideration should be given to other diagnostic possibilities. The pleural form of the disease is sometimes difficult to differentiate from acute pulmonary infection or infarction, but the rapid disappearance of signs and symptoms resolves the problem. The erythema is sometimes difficult to differentiate from superficial thrombophlebitis or cellulitis.

The most difficult diagnostic problem inFMF is the patient who presents with fever alone. In this situation an extensive diagnostic workup for fever of unknown origin may be required. Fortunately, such patients are rare, and all eventually develop serosal involvement. Until specific diagnostic tests for FMF are available, patients with recurrent fever but without signs of inflammation of one of the serosal membranes should not be categorized as having FMF.

PROGNOSIS

Despite the severity of the symptoms during some acute attacks, most patients are remarkably free of debilitation between attacks and are able to lead fairly normal lives. The greatest hazard to patients is prolonged periods of hospitalization due to erroneous diagnoses or failure to understand the disease. In the United States, the prognosis of patients withFMF does not seem to be different from that of patients with other chronic nonfatal illnesses. Death usually results from causes unrelated to the underlying disease.

In the past, ~25% ofFMFpatients in Israel developed amyloidosis, and this complication usually led to death. However, the widespread use of colchicine has resulted in a dramatic decrease in the incidence of amyloidosis.

TREATMENT

During the past 25 years, the outlook of patients withFMF has been altered dramatically. Chronic administration of colchicine greatly reduces the number of acute attacks of FMF. It is recommended that 0.6 mg colchicine be taken by mouth three times a day. If patients develop gastrointestinal side effects with this dose, it should be reduced to 0.6 mg taken twice a day. Although an occasional patient will respond to 0.6 mg taken only once a day, this amount is less likely to be beneficial. Most FMF patients will respond favorably to colchicine prophylaxis.

290. ACUTE INTESTINAL OBSTRUCTION - *William Silen*

ETIOLOGY AND CLASSIFICATION

Intestinal obstruction may be *mechanical* or *nonmechanical* (resulting from neuromuscular disturbances that produce either adynamic or dynamic ileus). The causes of mechanical obstruction of the lumen are conveniently divided into (1) lesions *extrinsic* to the intestine, e.g., adhesive bands, internal and external hernias; (2) lesions *intrinsic* to the wall of the intestine, e.g., diverticulitis, carcinoma, regional enteritis; and (3) obturation of the lumen, e.g., gallstone obstruction, intussusception. Clinically, however, it is most useful to consider whether the obstructive mechanism involves the small or large intestine, because the causes, symptoms, and treatments are different (see below). Adhesions and external hernias are the most common causes of obstruction of the small intestine, constituting 70 to 75% of cases of this type. Adhesions, however, almost never produce obstruction of the colon, where carcinoma, sigmoid diverticulitis, and volvulus, in that order, are the most common causes and together account for about 90% of the cases. Primary intestinal pseudoobstruction (Chap. 289) is a chronic motility disorder that frequently mimics mechanical obstruction. Unnecessary operations in such patients should be avoided.

Adynamic ileus is probably the most common overall cause of obstruction. The development of this condition is mediated via the hormonal component of the sympathoadrenal system. Adynamic ileus may occur after any peritoneal insult, and its severity and duration will be dependent to some degree on the type of peritoneal injury. Hydrochloric acid, colonic contents, and pancreatic enzymes are among the most irritating substances, whereas blood and urine are less so. Adynamic ileus occurs to some degree after any abdominal operation. Retroperitoneal hematomas, particularly associated with vertebral fracture, commonly cause severe adynamic ileus, and the latter may occur with other retroperitoneal conditions, such as ureteral calculus or severe pyelonephritis. Thoracic diseases, including lower-lobe pneumonia, fractured ribs, and myocardial infarction, frequently produce adynamic ileus, as do electrolyte disturbances, particularly potassium depletion. Finally, intestinal ischemia, whether the result of vascular occlusion or intestinal distention itself, may perpetuate an adynamic ileus.

Spastic ileus or *dynamic ileus* is very uncommon and results from extreme and prolonged contraction of the intestine. It has been observed in heavy metal poisoning, uremia, porphyria, and extensive intestinal ulcerations.

PATHOPHYSIOLOGY

Distention of the intestine is caused by the accumulation of gas and fluid proximal to and within the obstructed segment. Between 70 and 80% of intestinal gas consists of swallowed air, and because this is composed mainly of nitrogen, which is poorly absorbed from the intestinal lumen, removal of air by continuous gastric suction is a useful adjunct in the treatment of intestinal distention. The accumulation of fluid proximal to the obstructing mechanism results not only from ingested fluid, swallowed saliva, gastric juice, and biliary and pancreatic secretions but also from interference with normal sodium and water transport. During the first 12 to 24 h of obstruction, there is a

marked depression of flux from lumen to blood of sodium and consequently water in the distended proximal intestine. After 24 h, there is movement of sodium and water into the lumen, contributing further to the distention and fluid losses. Intraluminal pressure rises from a normal of 2 to 4 cmH_2O to 8 to 10 cmH_2O. During peristalsis, when simple obstruction or a "closed loop" is present, pressures reach 30 to 60 cmH_2O. Closed-loop obstruction of the small intestine results when the lumen is occluded at two points by a single mechanism such as a hernial ring or adhesive band, thus producing a closed loop whose blood supply is often obstructed at the same time. Strangulation of the loop itself is thus common in association with marked distention proximal to the involved loop. A form of closed-loop obstruction is encountered when complete obstruction of the colon exists in the presence of a competent ileocecal valve (85% of individuals). Although the blood supply of the colon is not entrapped within the obstructing mechanism, distention of the cecum is extreme because of its greater diameter (Laplace's law), and impairment of the intramural blood supply is considerable with consequent gangrene of the cecal wall, usually anteriorly. Necrosis of the small intestine may occur by the same mechanism of interference with intramural blood flow when distention is extreme, but this sequence is uncommon in the small intestine. Once impairment of blood supply occurs, bacterial invasion supervenes, and peritonitis develops. The systemic effects of extreme distention include elevation of the diaphragm with restricted ventilation and subsequent atelectasis. Venous return via the inferior vena cava may also be impaired.

The loss of fluids and electrolytes may be extreme and, unless replacement is prompt, leads to hemoconcentration, hypovolemia, renal insufficiency, shock, and death. Vomiting, accumulation of fluids within the lumen by the mechanisms described above, and the sequestration of fluid into the edematous intestinal wall and peritoneal cavity as a result of impairment of venous return from the intestine all contribute to massive loss of fluid and electrolytes, especially potassium. As soon as significant impedance to venous return is present, the intestine becomes severely congested, and blood begins to seep into the intestinal lumen. Blood loss may reach significant levels when long segments of intestine are involved.

SYMPTOMS

Mechanical small-intestinal obstruction is characterized by cramping midabdominal pain, which tends to be more severe the higher the obstruction. The pain occurs in paroxysms, and the patient is relatively comfortable in the intervals between the pains. Audible borborygmi are often noted by the patient simultaneously with the paroxysms of pain. The pain may become less severe as distention progresses, probably because motility is impaired in the edematous intestine. When strangulation is present, the pain is usually more localized and may be steady and severe without a colicky component, a fact that often causes delay in diagnosis of obstruction. Vomiting is almost invariable, and it is earlier and more profuse the higher the obstruction. The vomitus initially contains bile and mucus and remains as such if the obstruction is high in the intestine. With low ileal obstruction, the vomitus becomes feculent, i.e., orange-brown in color with a foul odor, which results from the overgrowth of bacteria proximal to the obstruction. Hiccups (singultus) are common. Obstipation and failure to pass gas by rectum are invariably present when the obstruction is complete, although some stool and gas may be passed spontaneously or after an enema shortly after onset of the complete obstruction. Diarrhea is occasionally observed in partial obstruction. Blood in the stool is

rare but does occur in cases of intussusception. Other than some minor but inconsistent differences in pain patterns noted above, the symptoms of strangulating obstructions cannot be distinguished from those of nonstrangulating obstructions.

Mechanical colonic obstruction produces colicky abdominal pain similar in quality to that of small-intestinal obstruction but of much lower intensity. Complaints of pain are occasionally absent in stoic elderly patients. Vomiting occurs late, if at all, particularly if the ileocecal valve is competent. Paradoxically, feculent vomitus is very rare. A history of recent alterations in bowel habits and blood in the stool is common because carcinoma and diverticulitis are the most frequent causes. Constipation becomes progressive, and obstipation with failure to pass gas ensues. Acute symptoms may develop over a period of a week. Cecal volvulus more closely resembles obstruction of the small intestine clinically, whereas patients with sigmoid volvulus more typically have the picture of colonic obstruction in which marked distention predominates, with relatively less pain.

In *adynamic ileus*, colicky pain is absent, and only discomfort from distention is evident. Vomiting may be frequent but is rarely profuse. It usually consists of gastric contents and bile and is almost never feculent. Complete obstipation may or may not occur. Singultus (hiccups) is common.

PHYSICAL FINDINGS

Abdominal distention is the hallmark of all forms of intestinal obstruction. It is least marked in cases of obstruction high in the small intestine and most marked in colonic obstruction. Early, especially in closed-loop strangulating small-bowel obstruction, distention may be barely perceptible or absent. Tenderness and rigidity are usually minimal; the temperature is rarely above 37.8°C (100°F) in nonstrangulating obstruction of the small and large intestine. Contrary to popular belief, the same is true of strangulating obstruction until very late, a fact that has often resulted in unfortunate delay in treatment. Signs and symptoms of shock also occur *very late* in strangulating obstruction. The appearance of shock, tenderness, rigidity, and fever often means that contamination of the peritoneum with infected intestinal content has occurred. Hernial orifices should always be carefully examined for the presence of a mass. The presence of a palpable abdominal mass usually signifies a closed-loop strangulating small-bowel obstruction because the tense fluid-filled loop is the palpable lesion. Auscultation may reveal loud, high-pitched borborygmi coincident with the colicky pain, but this finding is often absent late in strangulating or nonstrangulating obstruction. A quiet abdomen does not eliminate the possibility of obstruction, nor does it necessarily establish the diagnosis of adynamic ileus.

LABORATORY AND X-RAY FINDINGS

Leukocytosis, with shift to the left, usually occurs when strangulation is present, but a normal white blood cell count does not exclude strangulation. Elevation of the serum amylase level is encountered occasionally in all forms of intestinal obstruction, especially the strangulating variety.

The x-ray is extremely valuable but under certain circumstances may also be

misleading. In nonstrangulating complete small-bowel obstruction, x-rays are almost completely reliable. Distention of fluid- and gas-filled loops of small intestine usually arranged in a "stepladder" pattern with air-fluid levels and an absence or paucity of colonic gas are pathognomonic (Fig. 290-1). These findings, however, are absent in slightly over half the cases of strangulating small-bowel obstruction, especially early in the disease. A general haze due to peritoneal fluid and sometimes a "coffee bean"-shaped mass are seen in strangulating obstruction. Occasionally, the films are normal, but when symptoms are consistent with obstruction of the small intestine, a normal film should suggest strangulation. In these circumstances, computed tomography may be very useful. Roentgenographic differentiation of partial mechanical small-bowel obstruction from adynamic ileus may be impossible because gas is present in both the small and large intestines; however, colonic distention is usually more prominent in adynamic ileus. A radiopaque dye given by mouth is useful in making this distinction.

Colonic obstruction with a competent ileocecal valve is easily recognized because distention with gas is mainly confined to the colon. Barium enema, sigmoidoscopy, or colonoscopy, depending on the suspected site of obstruction, is usually advisable to determine the nature of the lesion, except when concomitant perforation is suspected, a rare occurrence. Sigmoidoscopy may be therapeutic in cases of sigmoid volvulus. When the ileocecal valve is incompetent, the films resemble those of partial small-bowel obstruction or adynamic ileus, and barium enema or colonoscopy is necessary to establish the correct diagnosis. Barium given by mouth is perfectly safe when obstruction is in the small intestine, since the barium sulfate does not become inspissated in this location. *Barium should never be given by mouth to a patient with possible colonic obstruction* until that possibility has been excluded by barium enema.

TREATMENT

Small-Intestinal Obstruction The overall mortality rate for obstruction of the small intestine is about 10%, even under the most optimal conditions. While the mortality rate for nonstrangulating obstruction is as low as 5 to 8%, that for strangulating obstruction has been reported to be between 20 and 75%. Well over half the deaths from small-bowel obstruction occur in those with strangulation; however, the latter constitute only one-fourth to one-third of the cases. Careful studies indicate that the clinical, laboratory, and x-ray findings are not reliable in distinguishing strangulating from nonstrangulating obstruction when obstruction is complete. Complete obstruction is suggested when passage of gas or stool per rectum has ceased and when gas is absent in the distal intestine by x-ray. Since strangulating small-bowel obstruction is always complete, operation should always be undertaken in such patients after suitable preparation. Before operation, fluid and electrolyte balance should be restored and decompression instituted by means of a nasogastric tube. Replacement of potassium is especially important because intake is nil and losses in vomitus are large. >From 6 to 8 h of preparation may be necessary. During this period, broad-spectrum antibiotics are indicated if strangulation is felt to be likely, but operation should not be delayed unless there is unequivocal clinical and roentgenographic evidence of resolution of the obstruction during the period of preparation. Attempts to pass a long tube into the small intestine usually fail while putting the patient through uncomfortable, unproductive manipulations that delay appropriate fluid replacement and decompression. *There are*

few, if any, indications for the use of a long intestinal tube. Procrastination of operation because of improvement in well-being of the patient during resuscitation and gastric decompression usually leads to unnecessary and hazardous delay in proper treatment. Purely nonoperative therapy is safe only in the presence of incomplete obstruction and is best utilized in patients with (1) repeated episodes of partial obstruction, (2) recent postoperative partial obstruction, and (3) partial obstruction following a recent episode of diffuse peritonitis.

Colonic Obstruction The mortality rate for colonic obstruction is about 20%. As in small-bowel obstruction, nonoperative treatment is contraindicated unless the obstruction is incomplete. Occasionally, but not always, when the obstruction is incomplete, nonoperative therapy may result in sufficient decompression that a definitive operative procedure can be undertaken at a later date. This can usually be accomplished by discontinuation of all oral intake and perhaps by nasogastric suction, although attempts to decompress a *completely* obstructed colon by intubation are almost invariably futile. A long intestinal tube will not decompress an obstructed colon with a competent ileocecal valve. When obstruction is complete, early operation is mandatory, especially when the ileocecal valve is competent; cecal gangrene is likely if the cecal diameter exceeds 10 cm on plain abdominal film. For obstruction on the left side of the colon, the most common site, preliminary operative decompression by cecostomy or transverse colostomy followed by definitive resection of the primary lesion has been the treatment of choice. Recently, primary resection of obstructing left-sided lesions with on-table washout of the colon has been accomplished safely. For a lesion of the right or transverse colon, primary resection and anastomosis can be performed safely because distention of the ileum with consequent discrepancy in size and hazard in suture are not present.

Adynamic Ileus This type of ileus usually responds to nonoperative continuous decompression and adequate treatment of the primary disease. The prognosis is usually good. Successful decompression of severe colonic ileus has been accomplished by colonoscopy, but this should be avoided if tenderness in the right lower quadrant suggests possible cecal gangrene. Neostigmine is effective in cases of colonic ileus that have not responded to other conservative treatment. Rarely, adynamic colonic distention may become so great that cecostomy is required if cecal gangrene is feared. Spastic ileus usually responds to treatment of the primary disease.

291. ACUTE APPENDICITIS - *William Silen*

INCIDENCE AND EPIDEMIOLOGY

The peak incidence of acute appendicitis is in the second and third decades of life; it is relatively rare at the extremes of age. Males and females are equally affected, except between puberty and age 25, when males predominate in a 3:2 ratio. Perforation is more common in infancy and in the aged, during which periods mortality rates are highest. The mortality rate has decreased steadily in Europe and the United States from 8.1 per 100,000 of the population in 1941 to less than 1 per 100,000 in 1970 and subsequently. The absolute incidence of the disease also decreased by about 40% between 1940 and 1960 but since then has remained unchanged. Although various factors such as changing dietary habits, altered intestinal flora, and better nutrition and intake of vitamins have been suggested to explain the reduced incidence, the exact reasons have not been elucidated. The overall incidence of appendicitis is much lower in underdeveloped countries, especially parts of Africa, and in lower socioeconomic groups.

PATHOGENESIS

Luminal obstruction has long been considered the pathogenetic hallmark. However, obstruction can be identified in only 30 to 40% of cases; ulceration of the mucosa is the initial event in the majority. The cause of the ulceration is unknown, although a viral etiology has been postulated. Infection with *Yersinia* organisms may cause the disease, since high complement fixation antibody titers have been found in up to 30% of cases of proven appendicitis. Whether the inflammatory reaction seen with ulceration is sufficient to obstruct the tiny appendiceal lumen even transiently is not clear. Obstruction, when present, is most commonly caused by a fecalith, which results from accumulation and inspissation of fecal matter around vegetable fibers. Enlarged lymphoid follicles associated with viral infections (e.g., measles), inspissated barium, worms (e.g., pinworms, *Ascaris*, and *Taenia*), and tumors (e.g., carcinoid or carcinoma) may also obstruct the lumen. Secretion of mucus distends the organ, which has a capacity of only 0.1 to 0.2 mL, and luminal pressures rise as high as 60 cmH_2O. Luminal bacteria multiply and invade the appendiceal wall as venous engorgement and subsequent arterial compromise result from the high intraluminal pressures. Finally, gangrene and perforation occur. If the process evolves slowly, adjacent organs such as the terminal ileum, cecum, and omentum may wall off the appendiceal area so that a localized abscess will develop, whereas rapid progression of vascular impairment may cause perforation with free access to the peritoneal cavity. Subsequent rupture of primary appendiceal abscesses may produce fistulas between the appendix and bladder, small intestine, sigmoid, or cecum. Occasionally, acute appendicitis may be the first manifestation of Crohn's disease.

While chronic infection of the appendix with tuberculosis, amebiasis, and actinomycosis may occur, a useful clinical aphorism states that *chronic appendiceal inflammation is not usually the cause of prolonged abdominal pain of weeks' or months' duration*. In contrast, recurrent acute appendicitis does occur, often with complete resolution of inflammation and symptoms between attacks. Recurrent acute appendicitis may become more frequent as antibiotics are dispensed more freely and if a long

appendiceal stump is left after laparoscopic appendectomy.

CLINICAL MANIFESTATIONS

The history and sequence of symptoms are important diagnostic features of appendicitis. The initial symptom is almost invariably *abdominal pain* of the visceral type, resulting from appendiceal contractions or distention of the lumen. It is usually poorly localized in the periumbilical or epigastric region with an accompanying urge to defecate or pass flatus, neither of which relieves the distress. This visceral pain is mild, often cramping, and rarely catastrophic in nature, usually lasting 4 to 6 h, but it may not be noted by stoic individuals or by some patients during sleep. As inflammation spreads to the parietal peritoneal surfaces, the pain becomes somatic, steady, and more severe, aggravated by motion or cough, and usually located in the *right lower quadrant*. *Anorexia* is nearly universal; a hungry patient does not have acute appendicitis. *Nausea* and *vomiting* occur in 50 to 60% of cases, but vomiting is usually self-limited. The development of nausea and vomiting before the onset of pain is extremely rare. Change in bowel habit is of little diagnostic value, since any or no alteration may be observed, although the presence of diarrhea caused by an inflamed appendix in juxtaposition to the sigmoid may cause serious diagnostic difficulties. Urinary frequency and dysuria occur if the appendix lies adjacent to the bladder. The typical sequence of symptoms (poorly localized periumbilical pain followed by nausea and vomiting with subsequent shift of pain to the right lower quadrant) occurs in only 50 to 60% of patients.

Physical findings vary with time after onset of the illness and according to the location of the appendix, which may be situated deep in the pelvic cul-de-sac; in the right lower quadrant in any relation to the peritoneum, cecum, and small intestine; in the right upper quadrant (especially during pregnancy); or even in the left lower quadrant. *The diagnosis cannot be established unless tenderness can be elicited*. While tenderness is sometimes absent in the early visceral stage of the disease, it ultimately always develops and is found in any location corresponding to the position of the appendix. Abdominal tenderness may be completely absent if a retrocecal or pelvic appendix is present, in which case the sole physical finding may be tenderness in the flank or on rectal or pelvic examination. Percussion, rebound tenderness, and referred rebound tenderness are often, but not invariably, present; they are most likely to be absent early in the illness. Flexion of the right hip and guarded movement by the patient are due to parietal peritoneal involvement. Hyperesthesia of the skin of the right lower quadrant and a positive psoas or obturator sign are often late findings and are rarely of diagnostic value. When the inflamed appendix is in close proximity to the anterior parietal peritoneum, muscular rigidity is present yet is often minimal early.

The temperature is usually normal or slightly elevated [37.2 to 38°C (99 to 100.5°F)], but a temperature> 38.3°C (101°F) should suggest perforation. Tachycardia is commensurate with the elevation of the temperature. Rigidity and tenderness become more marked as the disease progresses to perforation and localized or diffuse peritonitis. Distention is rare unless severe diffuse peritonitis has developed. The disappearance of pain and tenderness just before perforation is extremely unusual. A mass may develop if localized perforation has occurred but usually will not be detectable before 3 days after onset. Earlier presence of a mass suggests carcinoma of the cecum or Crohn's disease. Perforation is rare before 24 h after onset of symptoms,

but the rate may be as high as 80% after 48 h.

Diagnosis is based primarily on clinical grounds. Although moderate leukocytosis of 10,000 to 18,000 cells/uL is frequent (with a concomitant left shift), the absence of leukocytosis does not rule out acute appendicitis. Leukocytosis of >20,000 cells/uL suggests probable perforation. Anemia and blood in the stool suggest a primary diagnosis of carcinoma of the cecum, especially in elderly individuals. The urine may contain a few white or red blood cells without bacteria if the appendix lies close to the right ureter or bladder. Urinalysis is most useful in excluding genitourinary conditions that may mimic acute appendicitis.

Radiographs are rarely of value except when an opaque fecalith (5% of patients) is observed in the right lower quadrant (especially in children). Consequently, abdominal films are not routinely obtained unless other conditions such as intestinal obstruction or ureteral calculus may be present. In some patients with recurrent or prolonged symptoms, a careful barium enema or computed tomography (CT) scan may reveal an extrinsic defect on the medial wall of the cecum or a calcified fecalith. The value of CT scan in acute appendicitis is being evaluated. The diagnosis may also be established by the ultrasonic demonstration of an enlarged and thick-walled appendix. Ultrasound is most useful to exclude ovarian cysts, ectopic pregnancy, or tuboovarian abscess.

While the typical historic sequence and physical findings are present in 50 to 60% of cases, a wide variety of atypical patterns of disease are encountered, especially at the age extremes and during pregnancy. Infants under 2 years of age have a 70 to 80% incidence of perforation and generalized peritonitis. Any infant or child with diarrhea, vomiting, and abdominal pain is highly suspect. Fever is much more common in this age group, and abdominal distention is often the only physical finding. In the elderly, pain and tenderness are often blunted, and thus the diagnosis is frequently delayed and leads to a 30% incidence of perforation in patients over 70. Elderly patients often present initially with a slightly painful mass (a primary appendiceal abscess) or with adhesive intestinal obstruction 5 or 6 days after a previously undetected perforated appendix.

Appendicitis occurs about once in every 1000 pregnancies and is the most common extrauterine condition requiring abdominal operation. The diagnosis may be missed or delayed because of the frequent occurrence of mild abdominal discomfort and nausea and vomiting during pregnancy. During the last trimester, when the mortality rate from appendicitis is highest, uterine displacement of the appendix to the right upper quadrant and laterally leads to confusion in diagnosis because pain and tenderness are similarly displaced.

DIFFERENTIAL DIAGNOSIS

Appendicitis can be confused with any condition that causes abdominal pain. Diagnostic accuracy is about 75 to 80% for experienced clinicians and must be based solely on the clinical criteria outlined. It is probably better to err slightly in the direction of overdiagnosis, since delay is associated with perforation and increased morbidity and mortality. In unperforated appendicitis, the mortality rate is 0.1%, little more than that associated with general anesthesia; for perforated appendicitis, overall mortality is 3%,

(15% in the elderly). In doubtful cases, 4 to 6 h of observation is always more beneficial than harmful. The most common conditions discovered at operation when acute appendicitis is erroneously diagnosed are, in order of frequency, mesenteric lymphadenitis, no organic disease, acute pelvic inflammatory disease, ruptured graafian follicle or corpus luteum cyst, and acute gastroenteritis. In addition, acute cholecystitis, perforated ulcer, acute pancreatitis, acute diverticulitis, strangulating intestinal obstruction, ureteral calculus, and pyelonephritis may present diagnostic difficulties.

Differentiation of *pelvic inflammatory disease* from acute appendicitis on clinical grounds may be virtually impossible. Gram-negative intracellular diplococci on cervical smear are not pathognomonic unless *Neisseria gonorrhoeae* can be cultured. Pain on movement of the cervix is not specific and may occur in appendicitis if perforation has occurred or if the appendix lies adjacent to the uterus or adnexa. *Rupture of a graafian follicle* (mittelschmerz) occurs at midcycle and will spill off blood and fluid to produce pain and tenderness more diffuse and usually of a less severe degree than in appendicitis. Fever and leukocytosis are usually absent. *Rupture of a corpus luteum cyst* is identical clinically to rupture of a graafian follicle but develops about the time of menstruation. The presence of an adnexal mass, evidence of blood loss, and a positive pregnancy test help differentiate *ruptured tubal pregnancy*, but a negative pregnancy test is present when tubal abortion has occurred. *Twisted ovarian cyst* and *endometriosis* are occasionally difficult to distinguish from appendicitis. In all these female conditions, ultrasonography, laparoscopy, and occasionallyCT may be of great value.

Acute mesenteric lymphadenitis is the diagnosis usually given when enlarged, slightly reddened lymph nodes at the root of the mesentery and a normal appendix are encountered at operation in a patient who usually has right lower quadrant tenderness. Whether this is a single, discrete entity is unclear, since the causative factor is not known. Some of these patients have infection with *Y. pseudotuberculosis* or *Y. enterocolytica*, in which case the diagnosis can be established by culture of the mesenteric nodes or by serologic titers (Chap. 162). The diagnosis is essentially impossible clinically, although retrospectively these patients may have a higher temperature and more diffuse pain and tenderness. Children seem to be affected more frequently than adults. *Acute gastroenteritis* usually causes profuse watery diarrhea, often with nausea and vomiting, but without localized findings. Between cramps, the abdomen is completely relaxed. In *Salmonella* gastroenteritis, the abdominal findings are similar, although the pain may be more severe and more localized, and fever and chills are common. The occurrence of similar symptoms among other members of the family may be helpful. When the diagnosis of acute pelvic appendicitis with perforation has been missed, gastroenteritis is the most common previous working diagnosis. Persistent abdominal or rectal tenderness should eliminate the diagnosis of gastroenteritis. *Regional enteritis* (Crohn's disease) is usually associated with a more prolonged history, often with previous exacerbations regarded as episodes of gastroenteritis unless the diagnosis has been established previously. *Meckel's diverticulitis* usually cannot be distinguished from acute appendicitis but is very rare.

TREATMENT

Cathartics and enemas should be avoided if appendicitis is under consideration, and antibiotics should not be administered when the diagnosis is in question, since they will

only mask the perforation. The treatment is early operation and appendectomy as soon as the patient can be prepared. Appendectomy is increasingly accomplished laparoscopically and may have some benefits over the open technique. Preparation for operation rarely takes more than 1 to 2 h in early appendicitis but may require 6 to 8 h in cases of severe sepsis and dehydration associated with late perforation. The *only* circumstance in which operation is *not* indicated is the presence of a palpable mass 3 to 5 days after the onset of symptoms. Should operation be undertaken at that time, a phlegmon rather than a definitive abscess will be found, and complications from its dissection are frequent. Such patients treated with broad-spectrum antibiotics, parenteral fluids, and rest usually show resolution of the mass and symptoms within 1 week. *Interval appendectomy* should be done safely 3 months later. Should the mass enlarge or the patient become more toxic, drainage of the abscess is necessary. The complications of subphrenic, pelvic, or other intraabdominal abscesses usually follow perforation with generalized peritonitis and can be avoided by early diagnosis of the disease.

SECTION 2 -LIVER AND BILIARY TRACT DISEASE

292. APPROACH TO THE PATIENT WITH LIVER DISEASE - *Marc Ghany, Jay H. Hoofnagle*

In most instances, a diagnosis of liver disease can be made accurately by a careful history, physical examination, and application of a few laboratory tests. In some instances, radiologic examinations are helpful or, indeed, diagnostic. Liver biopsy is considered the "gold standard" in evaluation of liver disease but is now needed less for diagnosis than for grading and staging disease. This chapter provides an introduction to diagnosis and management of liver disease, briefly reviewing the structure and function of the liver; the major clinical manifestations of liver disease; and the use of clinical history, physical examination, laboratory tests, imaging studies, and liver biopsy.

LIVER STRUCTURE AND FUNCTION

The liver is the largest organ of the body, weighing 1 to 1.5 kg and representing 1.5 to 2.5% of the lean body mass. The size and shape of the liver vary and generally match the general body shape -- long and lean or squat and square. The liver is located in the right upper quadrant of the abdomen under the right lower rib cage against the diaphragm and projects for a variable extent into the left upper quadrant. The liver is held in place by ligamentous attachments to the diaphragm, peritoneum, great vessels, and upper gastrointestinal organs. It receives a dual blood supply; approximately 20% of the blood flow is oxygen-rich blood from the hepatic artery, and 80% is nutrient-rich blood from the portal vein arising from the stomach, intestines, and spleen.

The majority of cells in the liver are hepatocytes, which constitute two-thirds of the mass of the liver. The remaining cell types are Kupffer cells (members of the reticuloendothelial system), stellate (Ito or fat-storing) cells, endothelial cells and blood vessels, bile ductular cells, and supporting structures. Viewed by light microscopy, the liver appears to be organized in lobules, with portal areas at the periphery and central veins in the center of each lobule. However, from a functional point of view, the liver is organized into acini, with both hepatic arterial and portal venous blood entering the acinus from the portal areas and then flowing through the sinusoids to the terminal hepatic veins. The advantage of viewing the acinus as the physiologic unit of the liver is that it helps to explain the morphologic patterns of many vascular and biliary diseases not explained by the lobular arrangement.

Portal areas of the liver consist of small veins, arteries, bile ducts, and lymphatics organized in a loose stroma of supporting matrix and small amounts of collagen. Blood flowing into the portal areas is distributed through the sinusoids, passing from zone 1 to zone 3 of the acinus and draining into the terminal hepatic veins ("central veins"). The sinusoids are lined by unique endothelial cells that have prominent fenestrae of variable size, allowing the free flow of plasma but not cellular elements. The plasma is thus in direct contact with hepatocytes in the subendothelial space of Disse.

Hepatocytes have distinct polarity. The basolateral side of the hepatocyte lines the space of Disse and is richly lined with microvilli; it demonstrates endocytotic and pinocytotic activity, with passive and active uptake of nutrients, proteins, and other

molecules. The apical pole of the hepatocyte forms the cannicular membranes through which bile components are secreted. The canniculi of hepatocytes form a fine network, which fuses into the bile ductular elements near the portal areas. Kupffer cells usually lie within the sinusoidal vascular space and represent the largest group of fixed macrophages in the body. The stellate cells are located in the space of Disse but are not usually prominent unless activated, when they produce collagen and matrix. Red blood cells stay in the sinusoidal space as blood flows through the lobules, but white blood cells can migrate through or around endothelial cells into the space of Disse and from there to portal areas, where they can return to the circulation through lymphatics.

Hepatocytes perform numerous and vital roles in maintaining homeostasis and health. These functions include the synthesis of most essential serum proteins (albumin, carrier proteins, coagulation factors, many hormonal and growth factors), the production of bile and its carriers (bile acids, cholesterol, lecithin, phospholipids), the regulation of nutrients (glucose, glycogen, lipids, cholesterol, amino acids), and metabolism and conjugation of lipophilic compounds (bilirubin, cations, drugs) for excretion in the bile or urine. Measurement of these activities to assess liver function is complicated by the multiplicity and variability of these functions. The most commonly used liver "function" tests are measurements of serum bilirubin, albumin, and prothrombin time. The serum bilirubin level is a measure of hepatic conjugation and excretion, and the serum albumin level and prothrombin time are measures of protein synthesis. Abnormalities of bilirubin, albumin, and prothrombin time are typical of hepatic dysfunction. Frank liver failure is incompatible with life, and the functions of the liver are too complex and diverse to be subserved by a mechanical pump; dialysis membrane; or concoction of infused hormones, proteins, and growth factors.

LIVER DISEASES

While there are many causes of liver disease (Table 292-1), they generally present clinically in a few distinct patterns, usually classified as either hepatocellular or cholestatic (obstructive). In *hepatocellular diseases* (such as viral hepatitis or alcoholic liver disease), features of liver injury, inflammation, and necrosis predominate. In *cholestatic diseases* (such as gall stone or malignant obstruction, primary biliary cirrhosis, many drug-induced liver diseases), features of inhibition of bile flow predominate. The pattern of onset and prominence of symptoms can rapidly suggest a diagnosis, particularly if major risk factors are considered, such as the age and sex of the patient and a history of exposure or risk behaviors.

Typical presenting symptoms of liver disease include jaundice, fatigue, itching, right upper quadrant pain, abdominal distention, and intestinal bleeding. At present, however, many patients are diagnosed with liver disease who have no symptoms and who have been found to have abnormalities in biochemical liver tests as a part of a routine physical examination or screening for blood donation or for insurance or employment. The wide availability of batteries of liver tests makes it relatively simple to demonstrate the presence of liver injury as well as to rule it out in someone suspected of liver disease.

Evaluation of patients with liver disease should be directed at (1) establishing the etiologic diagnosis, (2) estimating the disease severity (grading), and (3) establishing

the disease stage (staging). *Diagnosis* should focus on the category of disease, such as hepatocellular versus cholestatic injury, as well as on the specific etiologic diagnosis. *Grading* refers to assessing the severity or activity of disease -- active or inactive, and mild, moderate, or severe. *Staging* refers to estimating the place in the course of the natural history of the disease, whether acute or chronic; early or late; precirrhotic, cirrhotic, or end-stage.

The goal of this chapter is to introduce general, salient concepts in the evaluation of patients with liver disease that help lead to the diagnoses discussed in subsequent chapters.

CLINICAL HISTORY

The clinical history should focus on the symptoms of liver disease -- their nature, pattern of onset, and progression -- and on potential risk factors for liver disease. The symptoms of liver disease include constitutional symptoms such as fatigue, weakness, nausea, poor appetite, and malaise and the more liver-specific symptoms of jaundice, dark urine, light stools, itching, abdominal pain, and bloating. Symptoms can also suggest the presence of cirrhosis, end-stage liver disease, or complications of cirrhosis such as portal hypertension. Generally, the constellation of symptoms and their pattern of onset rather than a specific symptom points to an etiology.

Fatigue is the most common and most characteristic symptom of liver disease. It is variously described as lethargy, weakness, listlessness, malaise, increased need for sleep, lack of stamina, and poor energy. The fatigue of liver disease typically arises after activity or exercise and is rarely present or severe in the morning after adequate rest (afternoon versus morning fatigue). Fatigue in liver disease is often intermittent and variable in severity from hour to hour and day to day. In some patients, it may not be clear whether fatigue is due to the liver disease or to other problems such as stress, anxiety, sleep disturbance, or a concurrent illness.

Nausea occurs with more severe liver disease and may accompany fatigue or be provoked by odors of food or eating fatty foods. Vomiting can occur but is rarely persistent or prominent. Poor appetite with weight loss occurs commonly in acute liver diseases but is rare in chronic disease, except when cirrhosis is present and advanced. Diarrhea is uncommon in liver disease, except with severe jaundice, in which case lack of bile acids reaching the intestine can lead to steatorrhea.

Right upper quadrant discomfort or ache ("liver pain") occurs in many liver diseases and is usually marked by tenderness over the liver area. The pain arises from stretching or irritation of Glisson's capsule, which surrounds the liver and is rich in nerve endings. Severe pain is most typical of gall bladder disease, liver abscess, and severe venoocclusive disease but is an occasional accompaniment of acute hepatitis.

Itching occurs with acute liver disease, appearing early in obstructive jaundice (from biliary obstruction or drug-induced cholestasis) and somewhat later in hepatocellular disease (acute hepatitis). Itching also occurs in chronic liver diseases, typically the cholestatic forms such as primary biliary cirrhosis and sclerosing cholangitis where it is often the presenting symptom, occurring before the onset of jaundice. However, itching

can occur in any liver disease, particularly once cirrhosis is present.

Jaundice is the hallmark symptom of liver disease and perhaps the most reliable marker of severity. Patients usually report darkening of the urine before they notice scleral icterus. Jaundice is rarely detectable with a bilirubin level less than 43 umol/L (2.5 mg/dL). With severe cholestasis there will also be lightening of the color of the stools and steatorrhea. Jaundice without dark urine usually indicates indirect (unconjugated) hyperbilirubinemia and is typical of hemolytic anemia and the genetic disorders of bilirubin conjugation, the common and benign form being Gilbert's syndrome and the rare and severe form being Crigler-Najjar syndrome. Gilbert's syndrome affects up to 5% of the population; the jaundice is more noticeable after fasting and with stress.

Major risk factors for liver disease that should be sought in the clinical history include details of alcohol use, medications (including herbal compounds, birth control pills, and over-the-counter medications), personal habits, sexual activity, travel, exposure to jaundiced or other high-risk persons, injection drug use, recent surgery, remote or recent transfusion with blood and blood products, occupation, accidental exposure to blood or needlestick, and familial history of liver disease.

For assessing the risk of viral hepatitis, a careful history of sexual activity is of particular importance and should include life-time number of sexual partners and, for men, a history of having sex with men. Sexual exposure is a common mode of spread of hepatitis B but is rare for hepatitis C. Maternal-infant transmission occurs with both hepatitis B and C. Vertical spread of hepatitis B can now be prevented by passive and active immunization of the infant at birth. Vertical spread of hepatitis C is uncommon, but there are no known means of prevention. A history of injection drug use, even in the remote past, is of great importance in assessing the risk for hepatitis B and C. Injection drug use is now the single most common risk factor for hepatitis C. Transfusion with blood or blood products is no longer an important risk factor for acute viral hepatitis. However, blood transfusions received before the introduction of sensitive enzyme immunoassays for antibody to hepatitis C virus (anti-HCV) in 1992 is an important risk factor for chronic hepatitis C. Blood transfusion before 1986, when screening for antibody to hepatitis B core antigen (anti-HBc) was introduced, is also a risk factor for hepatitis B. Travel to an underdeveloped area of the world, exposure to persons with jaundice, and exposure to young children in day-care centers are risk factors for hepatitis A. Tattooing and body piercing (for hepatitis B and C) and eating shellfish (for hepatitis A) are frequently mentioned but actually quite rate types of exposure for acquiring hepatitis.

A history of alcohol intake is important in assessing the cause of liver disease and also in planning management and recommendations. In the United States, for example, at least 70% of adults drink alcohol to some degree, but significant alcohol intake is less common; in population-based surveys, only 5% have more than two drinks per day, the average drink representing 11 to 15 g alcohol. Alcohol consumption associated with an increased rate of alcoholic liver disease is probably more than two drinks (22 to 30 g) per day in women and three drinks (33 to 45 g) in men. Most patients with alcoholic cirrhosis have a much higher daily intake and have drunk excessively for 10 years or more before onset of liver disease. In assessing alcohol intake, the history should also focus upon whether alcohol abuse or dependence is present. Alcoholism is usually

defined on the behavioral patterns and consequences of alcohol intake, not on the basis of the amount of alcohol intake. *Abuse* is defined by a repetitive pattern of drinking alcohol that has adverse effects on social, family, occupational, or health status. *Dependence* is defined by alcohol-seeking behavior, despite its adverse effects. Many alcoholics demonstrate both dependence and abuse, and dependence is considered the more serious and advanced form of alcoholism. A clinically helpful approach to diagnosis of alcohol dependence and abuse is the use of the CAGE questionnaire (Table 292-2), which is recommended in all medical history taking.

Family history can be helpful in assessing liver disease. Familial causes of liver disease include Wilson's disease; hemochromatosis and a_1-antitrypsin (a_1AT) deficiency; and the more uncommon inherited pediatric liver diseases of familial intrahepatic cholestasis (FIC), benign recurrent intrahepatic cholestasis (BRIC), and Alagille's syndrome. Onset of severe liver disease in childhood or adolescence with a family history of liver disease or neuropsychiatric disturbance should lead to investigation for Wilson's disease. A family history of cirrhosis, diabetes, or endocrine failure and the appearance of liver disease in adulthood should suggest hemochromatosis and lead to investigation of iron status. Patients with abnormal iron studies warrant genotyping of the HFE gene for the C282Y and H63D mutations typical of genetic hemochromatosis. A family history of emphysema should provoke investigation of a_1AT levels and, if low, for Pi genotype.

PHYSICAL EXAMINATION

The physical examination rarely demonstrates evidence of liver dysfunction in a patient without symptoms or laboratory findings, nor are most signs of liver disease specific to one diagnosis. Thus, the physical examination usually complements rather than replaces the need for other diagnostic approaches. In many patients, the physical examination is normal unless the disease is acute or severe and advanced. Nevertheless, the physical examination is important in that it can be the first evidence for the presence of hepatic failure, portal hypertension, and liver decompensation. In addition, the physical examination can reveal signs that point to a specific diagnosis, either in risk factors or in associated diseases or findings.

Typical physical findings in liver disease are icterus, hepatomegaly, hepatic tenderness, splenomegaly, spider angiomata, palmar erythema, and excoriations. Signs of advanced disease include muscle-wasting, ascites, edema, dilated abdominal veins, hepatic fetor, asterixis, mental confusion, stupor, and coma.

Icterus is best appreciated by inspecting the sclera under natural light. In fair-skinned individuals, a yellow color of the skin may be obvious. In dark-skinned individuals, the mucous membranes below the tongue can demonstrate jaundice. Jaundice is rarely detectable if the serum bilirubin level is <43 umol/L (2.5 ug/dL) but may remain detectable below this level during recovery from jaundice (because of protein and tissue binding of conjugated bilirubin).

Spider angiomata and palmar erythema occur in both acute and chronic liver disease and may be especially prominent in persons with cirrhosis, but they can occur in normal individuals and are frequently present during pregnancy. Spider angiomata are superficial, tortuous arterioles and, unlike simple telangiectases, typically fill from the

center outwards. Spider angiomata occur only on the arms, face, and upper torso; they can be pulsatile and may be difficult to detect in dark-skinned individuals.

Hepatomegaly is not a very reliable sign of liver disease, because of the variability of the size and shape of the liver and the physical impediments to assessing liver size by percussion and palpation. Marked hepatomegaly is typical of cirrhosis, venoocclusive disease, metastatic or primary cancers of the liver, and alcoholic hepatitis. Careful assessment of the liver edge may also demonstrate unusual firmness, irregularity of the surface, or frank nodules. Perhaps the most reliable physical finding in examining the liver is hepatic tenderness. Discomfort on touching or pressing on the liver should be carefully sought with percussive comparison of the right and left upper quadrants.

Splenomegaly occurs in many medical conditions but can be a subtle but significant physical finding in liver disease. The availability of ultrasound (US) assessment of the spleen allows for confirmation of the physical finding.

Signs of advanced liver disease include muscle-wasting and weight loss as well as hepatomegaly, bruising, ascites, and edema. Ascites is best appreciated by attempts to detect shifting dullness by careful percussion.US examination will confirm the finding of ascites in equivocal cases. Peripheral edema can occur with or without ascites. In patients with advanced liver disease, other factors frequently contribute to edema formation, including hypoalbuminemia, venous insufficiency, heart failure, and medications.

Hepatic failure is defined as the occurrence of signs or symptoms of hepatic encephalopathy in a person with severe acute or chronic liver disease. The first signs of hepatic encephalopathy can be subtle and nonspecific -- change in sleep patterns, change in personality, irritability, and mental dullness. Thereafter, confusion, disorientation, stupor, and eventually coma supervene. Physical findings include asterixis and flapping tremors of the body and tongue. *Fetor hepaticus* refers to the slightly sweet, ammoniacal odor that is common in patients with liver failure, particularly if there is portal-venous shunting of blood around the liver. Other causes of coma and confusion should be excluded, mainly electrolyte imbalances, sedative use, and renal or respiratory failure. A helpful measure of hepatic encephalopathy is a careful mental status examination and use of the trail-making test, which consists of a series of 20 numbered circles that the patient is asked to connect as rapidly as possible using a pencil. The normal range for the connect-the-dot test is 15 to 30 s; it is considerably delayed in patients with early hepatic encephalopathy. Other tests include drawing abstract objects or comparison of a signature to previous examples.

Other signs of advanced liver disease include umbilical hernia from ascites, prominent veins over the abdomen, and *caput medusa*, which consists of collateral veins seen radiating from the umbilicus and resulting from the recanulation of the umbilical vein. Widened pulse pressure and signs of a hyperdynamic circulation can occur in patients with cirrhosis as a result of fluid and sodium retention, increased cardiac output, and reduced peripheral resistance. Patients with long-standing cirrhosis are prone to develop the hepatopulmonary syndrome with hypoxemia due to pulmonary arteriovenous shunting, characterized by hypoxia that worsens when lying flat.

Several skin disorders and changes occur commonly in liver disease. Hyperpigmentation is typical of advanced chronic cholestatic diseases such as primary biliary cirrhosis and sclerosing cholangitis. In these same conditions, xanthelasma and tendon xanthomata occur as a result of retention and high serum levels of lipids and cholesterol. A slate-gray pigmentation to the skin also occurs with hemochromatosis if iron levels are high for a prolonged period. Mucocutaneous vasculitis with palpable purpura, especially on the lower extremities, is typical of cryoglobulinemia of chronic hepatitis C but can also occur in chronic hepatitis B.

Some physical signs point to specific liver diseases. Kayser-Fleischer rings occur in Wilson's disease and consist of a golden-brown copper pigment deposited at the periphery of the cornea; they are best seen by slit-lamp examination. In metastatic liver disease or primary hepatocellular carcinoma, signs of cachexia and wasting may be prominent, as well as firm hepatomegaly and a hepatic bruit.

LABORATORY TESTING

Diagnosis in liver disease is greatly aided by the availability of reliable and sensitive tests of liver injury and function. Use and interpretation of liver function tests is summarized in Chap. 293. A typical battery of blood tests used for initial assessment of liver disease includes measuring levels of serum alanine and aspartate aminotransferases (ALT and AST), alkaline phosphatase, direct and total serum bilirubin, and albumin and assessing prothrombin time. The pattern of abnormalities generally points to hepatocellular versus cholestatic liver disease and will help to decide whether the disease is acute or chronic and whether cirrhosis and hepatic failure are present. Based on these results, further testing over time may be necessary. Other laboratory tests may be helpful, such as g-glutamyl transpeptidase (GGT) to define whether alkaline phosphatase elevations are due to liver disease; hepatitis serology to define the type of viral hepatitis; and autoimmune markers to diagnose primary biliary cirrhosis (antimitochondrial antibody; AMA), sclerosing cholangitis (peripheral antineutrophil cytoplasmic antibody; pANCA), autoimmune hepatitis (antinuclear, smooth-muscle, and liver-kidney microsomal antibody). A simple delineation of laboratory abnormalities and common liver diseases is given in Table 292-3.

DIAGNOSTIC IMAGING

There have been great advances made in hepatic imaging, although no method is suitably accurate in demonstrating underlying cirrhosis. There are many modalities available for imaging the liver.US, computed tomography (CT), and magnetic resonance imaging (MRI) are the most commonly employed and are complementary to each other. In general, US and CT have a high sensitivity for detecting biliary duct dilatation and are the first-line options for investigating the patient with suspected obstructive jaundice. Both US and CT can detect a fatty liver, which appears bright on both studies. Endoscopic retrograde cholangiopancreatography (ERCP) is the procedure of choice for visualization of the biliary tree. ERCP also provides several therapeutic options in patients with obstructive jaundice, such as sphincterotomy, stone extraction, and placement of nasobiliary catheters and biliary stents. Doppler US and MRI are used to assess hepatic vasculature and hemodynamics and to monitor surgically or radiologically placed vascular shunts such as transjugular intrahepatic portosystemic

shunts (TIPS). CT and MRI are indicated for the identification and evaluation of hepatic masses, staging of liver tumors, and preoperative assessment. With regard to mass lesions, sensitivity of hepatic imaging continues to increase; unfortunately, specificity remains a problem, and often two and sometimes three studies are needed before a diagnosis can be reached. Finally, interventional radiologic techniques allow the biopsy of solitary lesions, insertion of drains into hepatic abscesses, and creation of vascular shunts in patients with portal hypertension. Which modality to use depends on factors such as availability, cost, and experience of the radiologist with each technique.

LIVER BIOPSY

Liver biopsy remains the gold standard in the evaluation of patients with liver disease, particularly in patients with chronic liver diseases. In selected instances, liver biopsy is necessary for diagnosis but is more often useful in assessing the severity (grade) and stage of liver damage, in predicting prognosis, and in monitoring response to treatment.

Diagnosis of Liver Disease The major causes of liver disease and key diagnostic features are outlined in Table 292-3 (specifics of diagnosis are discussed in later chapters). The most common causes of acute liver disease are viral hepatitis (particularly hepatitis A, B, and C), drug-induced liver injury, cholangitis, and alcoholic liver disease. Liver biopsy is usually not needed in the diagnosis and management of acute liver disease, exceptions being situations where the diagnosis remains unclear despite thorough clinical and laboratory investigation. Liver biopsy can be helpful in the diagnosis of drug-induced liver disease and in establishing the diagnosis of acute alcoholic hepatitis.

The most common causes of chronic liver disease in general order of frequency are chronic hepatitis C, alcoholic liver disease, nonalcoholic steatohepatitis, chronic hepatitis B, autoimmune hepatitis, sclerosing cholangitis, primary biliary cirrhosis, hemochromatosis, and Wilson's disease. Strict diagnostic criteria have not been developed for most liver diseases, but liver biopsy plays an important role in the diagnosis of autoimmune hepatitis, primary biliary cirrhosis, nonalcoholic and alcoholic steatohepatitis, and Wilson's disease (with a quantitative hepatic copper level).

Grading and Staging of Liver Disease Grading refers to an assessment of the severity or activity of liver disease, whether acute or chronic; active or inactive; and mild, moderate, or severe. Liver biopsy is the most accurate means of assessing severity, particularly in chronic liver disease. Serum aminotransferase levels are used as a convenient and noninvasive means to follow disease activity, but aminotransferases are not always reliable in reflecting disease severity. Thus, normal serum aminotransferases in patients with hepatitis B surface antigen (HBsAg) in serum may indicate the inactive HBsAg carrier state or may reflect mild chronic hepatitis B or hepatitis B with fluctuating disease activity. Serum testing for hepatitis B e antigen and hepatitis B virus DNA can help resolve these different patterns, but these markers can also fluctuate and change over time. Similarly, in chronic hepatitis C, serum aminotransferases can be normal despite moderate activity of disease. Finally, in both alcoholic and nonalcoholic steatohepatitis, aminotransferases are quite unreliable in reflecting severity. In these conditions, liver biopsy is helpful in guiding management and recommending therapy, particularly if therapy is difficult, prolonged, and expensive as is often the case in

chronic viral hepatitis. There are several well-verified numerical scales for grading activity in chronic liver disease, the most common being the histology activity index and the Ishak histology scale.

Liver biopsy is also the most accurate means of assessing stage of disease as early or advanced, precirrhotic, and cirrhotic. Staging of disease pertains largely to chronic liver diseases in which progression to cirrhosis and end-stage liver disease can occur, but which may require years or decades to develop. Clinical features, biochemical tests, and hepatic imaging studies are helpful in assessing stage but generally become abnormal only in the middle to late stages of cirrhosis. Early stages of cirrhosis are generally detectable only by liver biopsy. In assessing stage, the degree of fibrosis is usually used as its quantitative measure. The amount of fibrosis is generally staged on a 0 to 4+ (histology activity index) or 0 to 6+ scale (Ishak scale).

Cirrhosis can also be staged clinically. A reliable staging system is the modified Child-Pugh classification with a scoring system of 5 to 15: scores of 5 and 6 being Child-Pugh class A (consistent with "compensated cirrhosis"), scores of 7 to 9 indicating class B, and 10 to 15 class C (Table 292-4). This scoring system was initially devised to stratify patients into risk groups prior to undergoing portal decompressive surgery. It is now used to assess prognosis in cirrhosis and provides the standard criteria for listing for liver transplantation (Child-Pugh class B). The Child-Pugh score is a reasonably reliable predictor of survival in many liver diseases and predicts the likelihood of major complications of cirrhosis such as bleeding from varices and spontaneous bacterial peritonitis. Other means of assessing stage and survival have been developed for primary biliary cirrhosis and sclerosing cholangitis (Mayo Risk scores), which are somewhat more accurate but which actually rely mostly on the same measurements as the Child-Pugh score.

Thus, liver biopsy is helpful not only in diagnosis but also in management of chronic liver disease and assessment of prognosis. Because liver biopsy is an invasive procedure and not without complications, it should be used only when it will contribute materially to management and therapeutic decisions.

293. EVALUATION OF LIVER FUNCTION - *Daniel S. Pratt*, *Marshall M. Kaplan*

Several biochemical tests are useful in the evaluation and management of patients with hepatic dysfunction. These tests can be used to (1) detect the presence of liver disease; (2) distinguish among different types of liver disorders; (3) gauge the extent of known liver damage; and (4) follow the response to treatment.

Liver tests have shortcomings. They can be normal in patients with serious liver disease and abnormal in patients with diseases that do not affect the liver. Liver tests rarely suggest a specific diagnosis; rather, they suggest a general category of liver disease, such as hepatocellular or cholestatic, which then further directs the evaluation.

The liver carries out thousands of biochemical functions, most of which cannot be easily measured by blood tests. Laboratory tests measure only a limited number of these functions. In fact, many tests, such as the aminotransferases or alkaline phosphatase, do not measure liver function at all. Rather, they detect liver cell damage or interference with bile flow. Thus, no one test enables the clinician to accurately assess the liver's total functional capacity.

To increase both the sensitivity and the specificity of laboratory tests in the detection of liver disease, it is best to use them as a battery. Those tests usually employed in clinical practice include the bilirubin, aminotransferases, alkaline phosphatase, albumin, and prothrombin time tests. When more than one of these tests provide abnormal findings, or the findings are persistently abnormal on serial determinations, the probability of liver disease is high. When all test results are normal, the probability of missing occult liver disease is low.

When evaluating patients with liver disorders, it is helpful to group these tests into general categories. The classification we have found most useful is given below.

TESTS BASED ON DETOXIFICATION AND EXCRETORY FUNCTIONS

Serum Bilirubin Bilirubin, a breakdown product of the porphyrin ring of heme-containing proteins, is found in the blood in two fractions -- conjugated and unconjugated. The *van den Bergh assay*, or a variation of it, is still used in most clinical chemistry laboratories to determine the total serum bilirubin level and what amount is conjugated or unconjugated bilirubin. In this assay, the direct fraction provides an approximate determination of the conjugated bilirubin in serum. The total serum bilirubin is the amount that reacts after the addition of alcohol. The indirect fraction is the difference between the total and the direct bilirubin and provides an estimate of the unconjugated bilirubin in serum. The unconjugated fraction, also termed the indirect fraction, is insoluble in water and is bound to albumin in the blood. The conjugated (direct) bilirubin fraction is water soluble and can therefore be excreted by the kidney. When measured by the original van den Bergh method, the normal total serum bilirubin concentration is less than 1 mg/dL. Up to 30%, or 0.3 mg/dL, of the total is direct-reacting (or conjugated) bilirubin.

Elevation of the unconjugated fraction of bilirubin is rarely due to liver disease. An isolated elevation of unconjugated bilirubin is seen primarily in hemolytic disorders and

in a number of genetic conditions such as Crigler-Najjar and Gilbert's syndromes. *Gilbert's syndrome* is a common, benign condition with a reported incidence in 3 to 7% of the population. It is marked by the impaired conjugation of bilirubin due to reduced bilirubin uridine diphosphate (UDP) glucuronosyltransferase activity. This results in mild unconjugated hyperbilirubinemia, which is marked by considerable fluctuations and is sometimes only identified during periods of fasting. One molecular defect that has been identified in patients with Gilbert's syndrome is in the TATAA element in the 5¢ promoter region of the bilirubin UDP-glucuronosyltransferase gene upstream of exon 1. This defect alone is not necessarily sufficient for producing the clinical syndrome of Gilbert's, as there are patients who are homozygous for this defect yet do not have the levels of hyperbilirubinemia typically seen in Gilbert's syndrome. Isolated unconjugated hyperbilirubinemia (bilirubin elevated, but less than 15% direct) should prompt a workup for hemolysis (Fig. 293-1). In the absence of hemolysis, an isolated unconjugated hyperbilirubinemia can be attributed to Gilbert's syndrome and no further evaluation is required.

In contrast, conjugated hyperbilirubinemia almost always implies liver or biliary tract disease. The rate-limiting step in bilirubin metabolism is not conjugation of bilirubin, but rather the transport of conjugated bilirubin into the bile canaliculi. Thus, elevation of the conjugated fraction may be seen in any type of liver disease. In most liver diseases, both conjugated and unconjugated fractions of the bilirubin tend to be elevated. Except in the presence of a purely unconjugated hyperbilirubinemia, fractionation of the bilirubin is rarely helpful in determining the cause of jaundice.

Concern may be generated by a slower than expected decline of the serum bilirubin during convalescence from certain liver diseases. This can be attributed to the covalent binding of conjugated bilirubin to serum albumin that occurs when there is a prolonged episode of conjugated hyperbilirubinemia. The serum half-life of the albumin-bilirubin complex (15 days) is much longer than that of conjugated bilirubin and closer to that of albumin.

Urine Bilirubin Unconjugated bilirubin always binds to albumin in the serum and is not filtered by the kidney. Therefore, any bilirubin found in the urine is conjugated bilirubin; the presence of bilirubinuria implies the presence of liver disease. A urine dipstick test can theoretically give the same information as fractionation of the serum bilirubin. This test is almost 100% accurate. Phenothiazines may give a false positive reading with the Ictotest tablet.

Blood Ammonia Ammonia is produced in the body during normal protein metabolism and by intestinal bacteria, primarily those in the colon. The liver plays a role in the detoxification of ammonia by converting it to urea, which is excreted by the kidneys. Striated muscle also plays a role in detoxification of ammonia, which is combined with glutamic acid to form glutamine. Patients with advanced liver disease typically have significant muscle wasting, which likely contributes to hyperammonemia in these patients. Some physicians use the blood ammonia for detecting encephalopathy or for monitoring hepatic synthetic function, although its use for either of these indications has problems. There is very poor correlation between either the presence or the degree of acute encephalopathy and elevation of blood ammonia; it can be occasionally useful for identifying the occult liver disease in patients with mental status changes. There is also

a poor correlation of the blood serum ammonia and hepatic function. The ammonia can be elevated in patients with severe portal hypertension and portal blood shunting around the liver even in the presence of normal or near normal hepatic function.

Serum Enzymes The liver contains thousands of enzymes, some of which are also present in the serum in very low concentrations. These enzymes have no known function in the serum and behave like other serum proteins. They are distributed in the plasma and in interstitial fluid and have characteristic half-lives, usually measured in days. Very little is known about the catabolism of serum enzymes, although they are probably cleared by cells in the reticuloendothelial system. The elevation of a given enzyme activity in the serum is thought to primarily reflect its increased rate of entrance into serum from damaged liver cells.

Serum enzyme tests can be grouped into three categories: (1) enzymes whose elevation in serum reflects damage to hepatocytes; (2) enzymes whose elevation in serum reflects cholestasis; and (3) enzyme tests that do not fit precisely into either pattern.

Enzymes that Reflect Damage to Hepatocytes The aminotransferases (transaminases) are sensitive indicators of liver cell injury and are most helpful in recognizing acute hepatocellular diseases such as hepatitis. They include the aspartate aminotransferase (AST) and the alanine aminotransferase (ALT). AST is found in the liver, cardiac muscle, skeletal muscle, kidneys, brain, pancreas, lungs, leukocytes, and erythrocytes in decreasing order of concentration. ALT is found primarily in the liver. The aminotransferases are normally present in the serum in low concentrations. These enzymes are released into the blood in greater amounts when there is damage to the liver cell membrane resulting in increased permeability. Liver cell necrosis is not required for the release of the aminotransferases and there is a poor correlation between the degree of liver cell damage and the level of the aminotransferases. Thus, the absolute elevation of the aminotransferases is of no prognostic significance in acute hepatocellular disorders.

Any type of liver cell injury can cause modest elevations in the serum aminotransferases. Levels of up to 300 U/L are nonspecific and may be found in any type of liver disorder. Striking elevations -- i.e., aminotransferases>1000 U/L -- occur almost exclusively in disorders associated with extensive hepatocellular injury such as (1) viral hepatitis, (2) ischemic liver injury (prolonged hypotension or acute heart failure), or (3) toxin or drug-induced liver injury.

The pattern of the aminotransferase elevation can be helpful diagnostically. In most acute hepatocellular disorders, the ALTis higher than or equal to theAST. An AST:ALT ratio >2:1 is suggestive while a ratio>3:1 is highly suggestive of alcoholic liver disease. The AST in alcoholic liver disease is rarely>300 U/L and the ALT is often normal. A low level of ALT in the serum is due to an alcohol-induced deficiency of pyridoxal phosphate.

The aminotransferases are usually not greatly elevated in obstructive jaundice. One notable exception occurs during the acute phase of biliary obstruction caused by the passage of a gallstone into the common bile duct. In this setting, the aminotransferases

can briefly be in the 1,000 to 2,000 U/L range. However, aminotransferase levels decrease quickly and the liver function tests rapidly evolve into one typical of cholestasis.

Enzymes that Reflect Cholestasis The activities of three enzymes -- alkaline phosphatase, 5¢-nucleotidase, and gamma glutamyl transpeptidase (GGT) -- are usually elevated in cholestasis. Alkaline phosphatase and 5¢-nucleotidase are found in or near the bile canalicular membrane of hepatocytes, while GGT is located in the endoplasmic reticulum and in bile duct epithelial cells. Reflecting its more diffuse localization in the liver, GGT elevation in serum is less specific for cholestasis than are elevations of alkaline phosphatase or 5¢-nucleotidase. Some have advocated the use of GGT to identify patients with occult alcohol use. Its lack of specificity makes its use in this setting questionable.

The normal serum alkaline phosphatase consists of many distinct isoenzymes found in the liver, bone, placenta, and, less commonly, small intestine. Patients over age 60 can have a mildly elevated alkaline phosphatase (1 to 1$_1$/$_2$times normal), while individuals with blood types O and B can have an elevation of the serum alkaline phosphatase after eating a fatty meal due to the influx of intestinal alkaline phosphatase into the blood. It is also nonpathologically elevated in children and adolescents undergoing rapid bone growth because of bone alkaline phosphatase, and late in normal pregnancies due to the influx of placental alkaline phosphatase.

Elevation of liver-derived alkaline phosphatase is not totally specific for cholestasis and a less than threefold elevation can be seen in almost any type of liver disease. Alkaline phosphatase elevations greater than four times normal occur primarily in patients with cholestatic liver disorders, infiltrative liver diseases such as cancer, and bone conditions characterized by rapid bone turnover (e.g., Paget's disease). In bone diseases, the elevation is due to increased amounts of the bone isoenzymes. In liver diseases, the elevation is almost always due to increased amounts of the liver isoenzyme.

If an elevated serum alkaline phosphatase is the only abnormal finding in an apparently healthy person, or if the degree of elevation is higher than expected in the clinical setting, identification of the source of elevated isoenzymes is helpful (Fig. 293-1). This problem can be approached in several ways. First, and most precise, is the fractionation of the alkaline phosphatase by electrophoresis. The second approach is based on the observation that alkaline phosphatases from individual tissues differ in susceptibility to inactivation by heat. The finding of an elevated serum alkaline phosphatase level in a patient with a heat-stable fraction strongly suggests that the placenta or a tumor is the source of the elevated enzyme in serum. Susceptibility to inactivation by heat increases, respectively, for the intestinal, liver, and bone alkaline phosphatases, bone being by far the most sensitive. The third, best substantiated, and most available approach involves the measurement of serum 5¢-nucleotidase orGGT. These enzymes are rarely elevated in conditions other than liver disease.

In the absence of jaundice or elevated aminotransferases, an elevated alkaline phosphatase of liver origin often, but not always, suggests early cholestasis and, less often, hepatic infiltration by tumor or granulomata. Other conditions that cause isolated elevations of the alkaline phosphatase include Hodgkin's disease, diabetes,

hyperthyroidism, congestive heart failure, and inflammatory bowel disease.

The level of serum alkaline phosphatase elevation is not helpful in distinguishing between intrahepatic and extrahepatic cholestasis. There is essentially no difference among the values found in obstructive jaundice due to cancer, common duct stone, sclerosing cholangitis, or bile duct stricture. Values are similarly increased in patients with intrahepatic cholestasis due to drug-induced hepatitis, primary biliary cirrhosis, rejection of transplanted livers, and, rarely, alcohol-induced steatonecrosis. Values are also greatly elevated in hepatobiliary disorders seen in patients with AIDS (e.g., AIDS cholangiopathy due to cytomegalovirus or cryptosporidial infection and tuberculosis with hepatic involvement).

TESTS THAT MEASURE BIOSYNTHETIC FUNCTION OF THE LIVER

Serum Albumin Serum albumin is synthesized exclusively by hepatocytes. Serum albumin has a long half-life: 15 to 20 days, with approximately 4% degraded per day. Because of this slow turnover, the serum albumin is not a good indicator of acute or mild hepatic dysfunction; only minimal changes in the serum albumin are seen in acute liver conditions such as viral hepatitis, drug-related hepatoxicity, and obstructive jaundice. In hepatitis, albumin levels below 3 g/dL should raise the possibility of chronic liver disease. Hypoalbuminemia is more common in chronic liver disorders such as cirrhosis and usually reflects severe liver damage and decreased albumin synthesis. One exception is the patient with ascites in whom synthesis may be normal or even increased, but levels are low because of the increased volume of distribution. However, hypoalbuminemia is not specific for liver disease and may occur in protein malnutrition of any cause, as well as protein-losing enteropathies, nephrotic syndrome, and chronic infections that are associated with prolonged increases in serum interleukin-1 and/or tumor necrosis factor levels that inhibit albumin synthesis. Serum albumin should not be measured for screening in patients in whom there is no suspicion of liver disease. A general medical clinic study of consecutive patients in whom no indications were present for albumin measurement showed that while 12% of patients had abnormal test results, the finding was of clinical importance in only 0.4%.

Serum Globulins Serum globulins are a group of proteins made up of gamma globulins (immunoglobulins) produced by B lymphocytes and alpha and beta globulins produced primarily in hepatocytes. Gamma globulins are increased in chronic liver disease, such as chronic hepatitis and cirrhosis. In cirrhosis, the increased serum gamma globulin concentration is due to the increased synthesis of antibodies, some of which are directed against intestinal bacteria. This occurs because the cirrhotic liver fails to clear bacterial antigens that normally reach the liver through the hepatic circulation.

Increases in the concentration of specific isotypes of gamma globulins are often helpful in the recognition of certain chronic liver diseases. Diffuse polyclonal increases in IgG levels are common in autoimmune hepatitis; increases greater than 100% should alert the clinician to this possibility. Increases in the IgM levels are common in primary biliary cirrhosis, while increases in the IgA levels occur in alcoholic liver disease.

Coagulation Factors With the exception of factor VIII, the blood clotting factors are made exclusively in hepatocytes. Their serum half-lives are much shorter than albumin,

ranging from 6 hours for factor VII to 5 days for fibrinogen. Because of their rapid turnover, measurement of the clotting factors is the single best acute measure of hepatic synthetic function and helpful in both the diagnosis and assessing the prognosis of acute parenchymal liver disease. Useful for this purpose is the *serum prothrombin time*, which collectively measures factors II, V, VII, and X. Biosynthesis of factors II, VII, IX, and X depends on vitamin K. The prothrombin time may be elevated in hepatitis and cirrhosis as well as in disorders that lead to vitamin K deficiency such as obstructive jaundice or fat malabsorption of any kind. Marked prolongation of the prothrombin time,>5 s above control and not corrected by parenteral vitamin K administration, is a poor prognostic sign in acute viral hepatitis and other acute and chronic liver diseases.

OTHER DIAGNOSTIC TESTS

While tests may direct the physician to a category of liver disease, additional radiologic testing and procedures are often necessary to make the proper diagnosis, as shown inFig. 293-1. The two most commonly-used ancillary tests are reviewed here.

Percutaneous Liver Biopsy Percutaneous biopsy of the liver is a safe procedure that can be easily performed at the bedside with local anesthesia. Liver biopsy is of proven value in the following situations: (1) hepatocellular disease of uncertain cause; (2) prolonged hepatitis with the possibility of chronic active hepatitis; (3) unexplained hepatomegaly; (4) unexplained splenomegaly; (5) hepatic filling defects by radiologic imaging; (6) fever of unknown origin; (7) staging of malignant lymphoma. Liver biopsy is most accurate in disorders causing diffuse changes throughout the liver and is subject to sampling error in focal infiltrative disorders such as hepatic metastases. Liver biopsy should not be the initial procedure in the diagnosis of cholestasis. The biliary tree should first be assessed for signs of obstruction.

Ultrasonography Ultrasonography is the first diagnostic test to use in patients whose liver tests suggest cholestasis, to look for the presence of a dilated intrahepatic or extrahepatic biliary tree, or to identify gallstones. In addition, it shows space-occupying lesions within the liver, enables the clinician to distinguish between cystic and solid masses, and helps direct percutaneous biopsies. Ultrasound with Doppler imaging can detect the patency of the portal vein, hepatic artery, and hepatic veins and determine the direction of blood flow. This is the first test ordered in patients suspected of having Budd-Chiari syndrome.

USE OF LIVER TESTS

As previously noted, the best way to increase the sensitivity and specificity of laboratory tests in the detection of liver disease is to employ a battery of tests that include the aminotransferases, alkaline phosphatase, bilirubin, albumin, and prothrombin time along with the judicious use of the other tests described in this chapter.Table 293-1 shows how patterns of liver tests can lead the clinician to a category of disease which will direct further evaluation. However, it is important to remember that no single set of liver tests will necessarily provide a diagnosis. It is often necessary to repeat these tests on several occasions over days to weeks for a diagnostic pattern to emerge.Figure 293-1 is an algorithm for the evaluation of chronically abnormal liver tests.

294. BILIRUBIN METABOLISM AND THE HYPERBILIRUBINEMIAS - *Paul D. Berk*, *Allan W. Wolkoff*

BILIRUBIN METABOLISM

SOURCES OF BILIRUBIN

Bilirubin is the end-product of the metabolic degradation of heme, the prosthetic group of hemoglobin, myoglobin, the cytochrome P450s, and various other hemoproteins. The first step in the conversion of heme to bilirubin is the stereospecific oxidative opening of the heme molecule at its a-bridge carbon by the microsomal enzyme *heme oxygenase*, resulting in the formation of equimolar quantities of carbon monoxide and of the green tetrapyrrole biliverdin. Biliverdin is then reduced by a second enzyme, biliverdin reductase, to bilirubin. Between 70 and 90% of bilirubin is derived from degradation of the hemoglobin of senescent or injured circulating red blood cells. The remainder has several sources, including hemoglobin produced during the process of ineffective erythropoiesis within the bone marrow and the turnover of nonhemoglobin hemoproteins in cells throughout the body. Degradation of red-cell hemoglobin occurs principally in the spleen but also throughout the rest of the peripheral reticuloendothelial system, including the Kupffer cells within the liver. Bilirubin produced in the periphery is transported to the liver within the plasma, where, due to its insolubility in aqueous solutions, it is tightly bound to albumin.

The anatomy of the hepatic acinus is highly specialized to facilitate the extraction of such tightly protein-bound compounds (Fig. 294-1). Cuboidal hepatocytes within the hepatic cell plates are immediately adjacent to sinusoids on two surfaces. The endothelial cells of the sinusoids are fenestrated, allowing ready exchange of plasma between the sinusoidal blood and the extracellular space of Disse and affording direct access of the bilirubin-albumin complex to the surface of the hepatocyte, which is greatly expanded by the elaboration of microvilli.

HEPATIC DISPOSITION OF BILIRUBIN

Since bilirubin is a potentially toxic waste product, hepatic handling is designed to eliminate it from the body via the biliary tract. Transfer of bilirubin from blood to bile involves four distinct but interrelated steps, described below (Fig. 294-1).

Hepatocellular Uptake Bilirubin most likely enters the hepatocyte both by a facilitated transport mechanism and by passive diffusion. While kinetic data suggest that facilitated transport is the predominant process and several putative bilirubin transporters have been identified, none has been cloned successfully. Cloned transporters such as *organic anion transport protein* (OATP) and *sodium taurocholate co-transporting polypeptide* (NTCP), which are responsible for the hepatocellular uptake of other organic substrates, including sulfobromophthalein and bile acids, specifically do not transport bilirubin. Therefore, the precise mechanism of bilirubin uptake remains to be determined.

Intracellular Binding Having crossed the plasma membrane to enter the cell, bilirubin partitions between the lipid environment of intracellular membranes and the aqueous

cytosol, in which it is kept in solution by binding as a nonsubstrate ligand to several of the glutathione-S-transferases, formerly called ligandins.

Conjugation The aqueous insolubility of bilirubin reflects a rigid, highly ordered molecular structure in which internal hydrogen bonding involving the propionic acid carboxyl groups of one dipyrrolic half of the molecule and the imino and lactam groups of the opposite half blocks solvent access to these polar residues. When the carboxyl groups are esterified by conjugation with glucuronic acid residues, the internal hydrogen bonding is disrupted, rendering the resulting mono- and diglucuronide conjugates highly soluble in aqueous solution.

Bilirubin glucuronidation is catalyzed by a specific UDP-glucuronosyltransferase. The UDP-glucuronosyltransferases have been classified into gene families based on the degree of homology between the various protein isoforms. Those that conjugate bilirubin and certain other substrates have been designated the *UGT1* family and have been shown to be expressed from a single gene complex by alternative splicing. This gene complex contains multiple substrate-specific first exons, designated A1, A2, . . . (Fig. 294-2), each with its own promoter and each encoding the amino-terminal end of a specific isoform, as well as four common exons (exons 2 to 5) that encode the shared carboxyl-terminal end of all of the *UGT1* isoforms. The various first exons encode the specific substrate-binding sites for each isoform, while the shared exons encode common glycosylation, UDP-glucuronic acid-binding, transmembrane, and stop transfer domains. Exon A1 and the four common exons, collectively designated the *UGT1A1* gene (Fig. 294-2), encode the physiologically critical enzyme bilirubin-UDP-glucuronosyltransferase (UGT1A1). A critical corollary of the organization of the *UGT1* gene is that a mutation in one of the first exons will affect only a single enzyme isoform. By contrast, a mutation in exons 2 to 5 will alter all isoforms encoded by the *UGT1* gene complex.

Biliary Excretion Normal bile typically contains less than 5% unconjugated bilirubin, an average of 7% bilirubin monoconjugates, and 90% bilirubin diconjugates. The proportion of monoconjugates increases in the presence of an increased bilirubin load (hemolysis) or a reduced bilirubin-conjugating capacity. Bilirubin mono- and diglucuronides are excreted across the canalicular plasma membrane into the canaliculus by an ATP-dependent transport process mediated by a canalicular membrane protein called *multidrug resistance-associated protein 2* (MRP2). MRP2 is a member of the MRP gene family, other members of which pump certain types of drug conjugates, as well as unmodified anticancer drugs, out of cells. It is also a member of the ATP-binding cassette (ABC) superfamily. Mutations in the rat homologue of MRP2 result in conjugated hyperbilirubinemia in several jaundiced strains that serve as models of the Dubin-Johnson syndrome. It has recently been established that the Dubin-Johnson syndrome in humans also results from mutations in MRP2 (see below).

BILIRUBIN IN PLASMA

Although physicians equate the direct-reacting fraction of bilirubin in plasma with conjugated bilirubin and the indirect fraction with unconjugated bilirubin, modern analytical methods document that normal plasma contains virtually no bilirubin conjugates. The 10 to 20% of bilirubin in normal plasma that gives a prompt (direct)

diazo reaction is an artifact of the kinetics of the van den Bergh reaction, which, along with various modifications, is the method most commonly used to quantitate bilirubin in clinical laboratories. Indeed, when the direct-reacting fraction is less than 15% of total bilirubin at virtually any total bilirubin concentration, the bilirubin in the sample can be considered as essentially all unconjugated. The canalicular transport mechanism for excretion of bilirubin conjugates is very sensitive to injury. Accordingly, in hepatocellular disease, as well as with either cholestasis or mechanical obstruction to the bile ducts, bilirubin conjugates within the hepatocyte, prevented from taking their normal path into the canaliculi and down the bile ducts, may reflux into the bloodstream, resulting in a mixed or, less often, a truly conjugated hyperbilirubinemia.

EXTRAHEPATIC ASPECTS OF BILIRUBIN DISPOSITION

Bilirubin in the Gut Following secretion into bile, conjugated bilirubin reaches the duodenum and passes down the gastrointestinal tract without reabsorption by the intestinal mucosa. Although some reaches the feces unaltered, an appreciable fraction is converted to urobilinogen and related compounds by bacterial metabolism within the ileum and colon. Urobilinogen is reabsorbed from these sites, reaches the liver via the portal circulation, and is reexcreted into bile, undergoing an enterohepatic circulation. Urobilinogen not taken up by the liver reaches the systemic circulation, from which some is cleared by the kidneys. Urinary urobilinogen excretion normally does not exceed 4 mg/d. In the presence of hemolysis, which increases the amount of bilirubin entering the gut (and hence the amount of urobilinogen formed and reabsorbed), or in the presence of hepatic disease, which decreases hepatic extraction of urobilinogen, plasma urobilinogen levels rise, as does the amount excreted in the urine. Severe cholestasis, bile duct obstruction, or administration of broad-spectrum antibiotics that eliminate the enteric flora required for the conversion of bilirubin to urobilinogens, markedly decrease formation of urobilinogen and its urinary excretion.

Unconjugated bilirubin ordinarily does not reach the gut except in neonates or, by ill-defined alternative pathways, in the presence of severe unconjugated hyperbilirubinemia (e.g., Crigler-Najjar syndrome type I). In these circumstances, however, unconjugated bilirubin is readily reabsorbed from the gut lumen, amplifying the underlying hyperbilirubinemia.

Renal Excretion of Bilirubin Conjugates Unconjugated bilirubin is not excreted in urine no matter how high its plasma concentration, since it is too tightly bound to albumin for effective glomerular filtration and there is no tubular mechanism for its renal secretion. By contrast, the polar bilirubin conjugates are far less tightly bound to albumin and are readily filtered at the glomerulus. Bilirubin conjugates are not secreted by the renal tubules but may be minimally reabsorbed. Since normal plasma contains virtually exclusively unconjugated bilirubin, no bilirubin normally appears in the urine. Indeed, bilirubinuria indicates the presence of conjugated bilirubin in plasma and, therefore, hepatobiliary dysfunction.

CLINICAL PHYSIOLOGY

The plasma concentration of unconjugated bilirubin ([Br]) is determined by the rate at which newly synthesized bilirubin enters the plasma (plasma bilirubin turnover, BrT) and

hepatic bilirubin clearance (C_{Br}), according to the following relationship:

where k is a constant related to the different units of time employed in the conventional expression of BrTand C_{Br}. BrT closely reflects total bilirubin production; C_{Br}, analogous to the creatinine clearance test widely used to assess kidney function, is a measure of the rate at which bilirubin is extracted from plasma and is a true quantitative test of liver function. While not easily quantified in routine clinical settings, investigative measurements of BrT and C_{Br} have yielded useful pathophysiologic insights into the unconjugated hyperbilirubinemias.

Equation (1) indicates that the unconjugated bilirubin concentration will increase in the presence of either an increase inBrT or a reduction in hepatic C_{Br}. This equation therefore provides a basis for classifying unconjugated hyperbilirubinemias according to pathogenesis. Furthermore, for an individual with a given value for C_{Br}, or for a population in which C_{Br}varies within a narrow range, [Br] will increase as a linear function of BrT, with a slope relating increases in the plasma [Br] to increased BrT equal to k/C_{Br}. For individuals or populations with reduced bilirubin clearance (e.g., in Gilbert's syndrome, see below), this slope will be steeper than in normal individuals. Conversely, for a given BrT, the relationship between [Br] and C_{Br} is hyperbolic, like the relation between serum creatinine concentration and creatinine clearance. In any patient, if C_{Br} is reduced from its baseline value, [Br] will be increased in consequence, in direct proportion to the extent of the decrease in C_{Br}.

DISORDERS OF BILIRUBIN METABOLISM LEADING TO UNCONJUGATED HYPERBILIRUBINEMIA

INCREASED BILIRUBIN PRODUCTION

Hemolysis Increased destruction of erythrocytes leads to increased bilirubin turnover and unconjugated hyperbilirubinemia. With normal liver function, the hyperbilirubinemia is usually modest. In particular, since the bone marrow is only capable of a sustained eightfold increase in erythrocyte production in response to a hemolytic stress, hemolysis alone cannot result in a sustained hyperbilirubinemia of more than approximately 68 umol/L (4 mg/dL). Higher values imply concomitant hepatic dysfunction.

The causes of hemolysis are numerous. Besides specific hemolytic disorders, mild hemolytic processes accompany many acquired systemic diseases. When hemolysis is the only abnormality in an otherwise healthy individual, the result is a purely unconjugated hyperbilirubinemia, with the direct-reacting fraction as measured in a typical clinical laboratory being £15% of the total serum bilirubin. In the presence of systemic disease, which may include a degree of hepatic dysfunction, hemolysis may produce a component of conjugated hyperbilirubinemia in addition to an elevated unconjugated bilirubin concentration.

Prolonged hemolysis may lead to the precipitation of bilirubin salts within the gall bladder or biliary tree, resulting in the formation of gallstones in which bilirubin, rather than cholesterol, is the major component. Such pigment stones may lead to acute or

chronic cholecystitis, biliary obstruction, or any other biliary tract consequence of calculous disease.

Ineffective Erythropoiesis During erythroid maturation, small amounts of hemoglobin may be lost during nuclear extrusion, and a fraction of developing erythroid cells is destroyed within the marrow. These processes normally account for 10 to 15% of bilirubin produced. In various disorders, including thalassemia major, frankly megaloblastic anemias due to folate or vitamin B_{12}deficiency, congenital erythropoietic porphyria, lead poisoning, and various congenital and acquired dyserythropoietic anemias, the fraction of total bilirubin production derived from ineffective erythropoiesis is increased, reaching as much as 70% of the total, and may be sufficient to produce modest degrees of unconjugated hyperbilirubinemia.

Miscellaneous Degradation of the hemoglobin of extravascular collections of erythrocytes, such as those seen in massive tissue infarctions or large hematomas, may lead transiently to unconjugated hyperbilirubinemia.

DECREASED HEPATIC BILIRUBIN CLEARANCE

Decreased Hepatic Uptake As noted above, the mechanisms by which bilirubin enters hepatocytes are not fully defined but probably include both diffusion and facilitated transport. Decreased hepatic bilirubin uptake is believed to contribute to the unconjugated hyperbilirubinemia of Gilbert's syndrome (GS), although the molecular basis for this finding remains unclear (see below). Several drugs, including flavispidic acid, novobiocin, and various cholecystographic contrast agents, have been reported to inhibit bilirubin uptake. The resulting unconjugated hyperbilirubinemia resolves with cessation of the medication.

Impaired Conjugation

Physiologic Neonatal Jaundice Bilirubin produced by the fetus is cleared by the placenta and eliminated by the maternal liver. Consequently, bilirubin concentrations in normal neonates at birth are low. The presence of jaundice at birth is pathologic and requires investigation. Immediately after birth, the neonatal liver must assume responsibility for bilirubin clearance and excretion. However, many aspects of hepatic physiology are incompletely developed at birth. Levels of UGT1A1 are low, and alternative pathways allow passage of unconjugated bilirubin into the gut. Since the intestinal flora that converts bilirubin to urobilinogen is also undeveloped, an enterohepatic circulation of unconjugated bilirubin ensues. In consequence, most neonates develop mild unconjugated hyperbilirubinemia between days 2 and 5 after birth. Peak levels are typically less than 85 to 170 umol/L (5 to 10 mg/dL) and decline to normal adult concentrations within 2 weeks, as mechanisms required for bilirubin disposition mature.

Prematurity, with more profound immaturity of hepatic function, or hemolysis, such as occurs with erythroblastosis fetalis, results in higher levels of unconjugated hyperbilirubinemia. A rapidly rising unconjugated bilirubin concentration, or absolute levels in excess of 340 umol/L (20 mg/dL), puts the infant at risk for bilirubin encephalopathy, or *kernicterus*, in which bilirubin crosses an immature blood-brain barrier and precipitates in the basal ganglia and other areas of the brain. The

consequences range from appreciable neurologic deficits to death. Principal treatment options include phototherapy, which converts bilirubin into photoisomers that are soluble in aqueous media and readily excretable in bile without conjugation, and exchange transfusion.

The canalicular mechanisms responsible for bilirubin excretion are also immature at birth, and their maturation may, on occasion, lag behind that of UGT1A1. This may lead to transient conjugated neonatal hyperbilirubinemia, especially in infants with hemolysis.

Acquired Conjugation Defects A modest reduction in bilirubin-conjugating capacity may be observed in advanced hepatitis or cirrhosis. However, in this setting, conjugation is better preserved than other aspects of bilirubin disposition, such as canalicular excretion. Various drugs, including pregnanediol, novobiocin, chloramphenicol, and gentamicin, may produce unconjugated hyperbilirubinemia by inhibiting UGT1A1 activity. Finally, certain fatty acids and the progestational steroid 3a,20b-pregnanediol, identified in the breast milk but not the serum of mothers whose infants have excessive neonatal hyperbilirubinemia (*breast milk jaundice*), inhibit bilirubin conjugation. The pathogenesis of breast milk jaundice appears to differ from that of transient familial neonatal hyperbilirubinemia (Lucey-Driscoll syndrome), in which a UGT1A1 inhibitor is found in maternal serum.

HEREDITARY DEFECTS IN BILIRUBIN CONJUGATION

Three familial disorders characterized by differing degrees of unconjugated hyperbilirubinemia have long been recognized. The defining clinical features of each are described below (Table 294-1). While these disorders have been recognized for decades to reflect differing degrees of deficiency in the ability to conjugate bilirubin, recent advances in the molecular biology of the *UGT1* gene complex have elucidated their interrelationships and clarified previously puzzling features.

Crigler-Najjar Syndrome, Type I (CN-I) This disorder is characterized by striking unconjugated hyperbilirubinemia of about 340 to 765 umol/L (20 to 45 mg/dL) that appears in the neonatal period and persists for life. Other conventional hepatic biochemical tests such as serum aminotransferases and alkaline phosphatase are normal, and there is no evidence of hemolysis. Hepatic histology is also essentially normal except for the occasional presence of bile plugs within canaliculi.

Bilirubin glucuronides are markedly reduced or absent from the nearly colorless bile, and there is no detectable constitutive expression of UGT1A1 activity in hepatic tissue. Neither UGT1A1 activity nor the serum bilirubin concentration responds to administration of phenobarbital or other enzyme inducers. In the absence of conjugation, unconjugated bilirubin accumulates in plasma, from which it is eliminated very slowly by alternative pathways that include direct passage into the bile and small intestine. These account for the small amounts of urobilinogen found in feces. No bilirubin is found in the urine.

First described in 1952, the disorder is rare (estimated prevalence of 0.6 to 1.0 per million). Many patients are from geographically or socially isolated communities in which consanguinity is common, and pedigree analyses suggest an autosomal recessive

pattern of inheritance. The majority of patients (type IA) exhibit defects in the glucuronide conjugation of a spectrum of substrates in addition to bilirubin, including various drugs and other xenobiotics. These individuals have mutations in one of the common exons (2 to 5) of the *UGT1* gene (Fig. 294-2). In a smaller subset (type IB), the defect is limited largely to bilirubin conjugation, and the causative mutation is in the bilirubin-specific exon A1. More than 30 different *UGT1A1* mutations responsible forCN-Ihave been identified, including deletions, frameshifts, alterations in intronic splice donor and acceptor sites, and point mutations that introduce premature stop codons or alter critical aminoacids. Their common feature is that they all encode proteins with absent or, at most, traces of bilirubin-UDP-glucuronosyltransferase enzymatic activity.

Prior to the availability of phototherapy, most patients withCN-Idied of bilirubin encephalopathy (kernicterus) in infancy or early childhood. A few lived as long as early adult life without overt neurologic damage, although more subtle testing usually indicated mild but progressive brain damage. In all such cases, in the absence of liver transplantation, death eventually supervened from late-onset bilirubin encephalopathy, which often followed a nonspecific febrile illness. Recent data suggest that the best hope for survival of a neurologically intact patient involves the following regimen: (1) about 12 h/d of phototherapy from birth throughout childhood, perhaps supplemented by exchange transfusion in the immediate neonatal period; (2) use of tin-protoporphyrin to blunt transient episodes of increased hyperbilirubinemia; and (3) early liver transplantation, prior to the onset of brain damage. In a single patient, transplantation with isolated allogeneic hepatocytes produced a clinically significant reduction in serum bilirubin concentration.

Crigler-Najjar Syndrome, Type II (CN-II) Characterized by marked unconjugated hyperbilirubinemia in the absence of abnormalities of other conventional hepatic biochemical tests, hepatic histology, or hemolysis, this condition was recognized as a distinct entity in 1962. It differs fromCN-I in several specific ways (Table 294-1). (1) Although there is considerable overlap, average bilirubin concentrations are lower in CN-II; (2) accordingly, CN-II is only infrequently associated with kernicterus; (3) bile is deeply colored and bilirubin glucuronides are present, with a striking, characteristic increase in monoglucuronides; (4) UGT1A1 in liver is usually present at reduced levels (typically £10% of normal) but may be undetectable by less sensitive older assays; (5) while typically detected in infancy, hyperbilirubinemia was not recognized in some cases until later in life, and in one instance, until age 34. As with CN-I, most CN-II cases exhibit abnormalities in the conjugation of other compounds, such as salicylamide and menthol, but in some instances the defect appears limited to bilirubin.

Reduction of serum bilirubin concentrations by more than 25% in response to enzyme inducers such as phenobarbital distinguishesCN-IIfromCN-I, although this response may not be elicited in early infancy and often is not accompanied by measurable UGT1A1 induction. Bilirubin concentrations during phenobarbital administration do not return to normal but are typically in the range of 51 to 86 umol/L (3 to 5 mg/dL). Although the incidence of kernicterus in CN-II is low, instances have occurred, not only in infants but in adolescents and adults, often in the setting of an intercurrent illness, fasting, or any other factor that temporarily raises the serum bilirubin concentration above baseline. For this reason, phenobarbital therapy is widely recommended, a single bedtime dose often sufficing to maintain clinically safe plasma bilirubin concentrations.

At least 10 different mutations of *UGT1* associated withCN-IIhave been identified. Their common feature is that they encode for a bilirubin-UDP-glucuronosyltransferase with markedly reduced but detectable enzymatic activity. The spectrum of residual enzyme activity explains the spectrum of phenotypic severity of the resulting hyperbilirubinemia. Molecular analysis has established that a large majority of CN-II patients are either homozygotes or compound heterozygotes for CN-II mutations and that individuals carrying one mutated and one entirely normal allele have normal bilirubin concentrations. Possible inheritance in one case as a dominant negative mutation remains to be confirmed.

Gilbert's Syndrome This syndrome is characterized by mild unconjugated hyperbilirubinemia, normal values for standard hepatic biochemical tests, and normal hepatic histology other than a modest increase of lipofuscin pigment in some patients. Serum bilirubin concentrations are most often<51 umol/L (<3 mg/dL), although both higher and lower values are frequent. The spectrum of hyperbilirubinemia fades into that ofCN-II at serum bilirubin concentrations of 86 to 136 umol/L (5 to 8 mg/dL). At the other end of the scale, the distinction between mild cases ofGS and a normal state is often blurred. Bilirubin concentrations may fluctuate substantially in any given individual, and at least 25% of patients will exhibit temporarily normal values during prolonged follow-up. More elevated values are associated with stress, fatigue, alcohol use, reduced caloric intake, and intercurrent illness, while increased caloric intake or administration of enzyme-inducing agents produce lower bilirubin levels. GS is most often diagnosed at or shortly after puberty or in adult life during routine examinations that include multichannel biochemical analyses.

UGT1A1 activity is typically reduced to 10 to 35% of normal, and bile pigments in bile exhibit a characteristic increase in bilirubin monoglucuronides. Studies of radiobilirubin kinetics indicate that hepatic bilirubin clearance is reduced to an average of one-third of normal. Administration of phenobarbital normalizes both the serum bilirubin concentration and hepatic bilirubin clearance. However, failure of UGT1A1 activity to improve in many such instances suggests the possible coexistence of an additional defect. Compartmental analysis of bilirubin kinetic data suggests that GSpatients have a defect in bilirubin uptake as well as in conjugation. Defect(s) in the hepatic uptake of other organic anions that at least partially share an uptake mechanism with bilirubin, such as sulfobromophthalein and indocyanine green, are observed in some, but not all, patients. The disposition of bile acids, which do not utilize the bilirubin uptake mechanism, is normal.

The magnitude of changes in the plasma bilirubin concentration induced by provocation tests such as 48 h of fasting or the intravenous administration of nicotinic acid have been reported to be of help in separatingGSpatients from normal individuals. Other studies dispute this assertion. Moreover, on theoretical grounds, the results of such studies should provide no more information than simple measurements of the baseline plasma bilirubin concentration.

Family studies indicate thatGS and hereditary hemolytic anemias such as hereditary spherocytosis, glucose-6-phosphate dehydrogenase deficiency, andb-thalassemia trait sort independently. Reports of hemolysis in up to 50% of GS patients are believed to

reflect better case finding, since patients with both GS and hemolysis have higher bilirubin concentrations, and are more likely to be jaundiced, than patients with either defect alone.

GSis common, with many series placing its prevalence at 8% or more. Males predominate over females by reported ratios ranging from 1.5:1 to more than 7:1. However, these ratios may have a large artifactual component since normal males have higher mean bilirubin levels than normal females, but the diagnosis of GS is often based on comparison to normal ranges established in men. The high prevalence of GS in the general population may explain the reported frequency of mild unconjugated hyperbilirubinemia in liver transplant recipients.

The disposition of most xenobiotics metabolized by glucuronidation appears to be normal inGS, as is oxidative drug metabolism in the majority of reported studies. The principal exception is the metabolism of the anti-tumor agent irinotecan (CPT-11). Its active metabolite (SN-38) is glucuronidated specifically by bilirubin-UDP-glucuronosyltransferase. Administration of CPT-11 to patients with GS has resulted in several toxicities, including intractable diarrhea and myelosuppression. Some reports also suggest abnormal disposition of menthol, estradiol benzoate, acetaminophen, tolbutamide, and rifamycin SV. Although some of these studies have been disputed, and there have been no reports of clinical complications from use of these agents in GS, prudence should be exercised in prescribing them, or any agents metabolized primarily by glucuronidation, in this condition.

Most older pedigree studies ofGS were consistent with autosomal dominant inheritance with variable expressivity. However, studies of the *UGT1* gene in GS have indicated a variety of molecular genetic bases for the phenotypic picture and several different patterns of inheritance. Studies in European and U.S. patients found that the majority of GS patients had normal coding regions for UGT1A1 but were homozygous for an abnormality consisting of an extra TA (i.e., A[TA]$_7$TAA rather than A[TA]$_6$TAA) in the promoter region of the first exon. This appeared to be a necessary but not a sufficient genetic basis for clinically expressed GS, since 15% of normal controls were also homozygous for this variant. While normal by standard criteria, these individuals had somewhat higher bilirubin concentrations than the rest of the controls studied. Heterozygotes for this abnormality had bilirubin concentrations identical to those homozygous for the A[TA]$_6$TAA allele. The prevalence of the A[TA]$_7$TAA allele in a general western population is 30%, in which case 9% would be homozygotes. This is slightly higher than the prevalence of GS based on purely phenotypic parameters. It was suggested that additional variables, such as mild hemolysis or a defect in bilirubin uptake, might be among the factors enhancing phenotypic expression of the defect. Phenotypic expression of GS due solely to the A[TA]$_7$TAA promoter abnormality is inherited as an autosomal recessive trait.

A number ofCN-IIkindreds have been identified in which there is also an allele containing a normal coding region but the A[TA]$_7$TAA promoter abnormality. CN-II heterozygotes who have the A[TA]$_6$TAA promoter are phenotypically normal, whereas those with the A[TA]$_7$TAA promoter express the phenotypic picture ofGS. GS in such kindreds may also result from homozygosity for the A[TA]$_7$TAA promoter abnormality.

Seven different missense mutations in the *UGT1* gene that reportedly causeGS with dominant inheritance have been found in Japanese individuals. Another Japanese patient with mild unconjugated hyperbilirubinemia was homozygous for a missense mutation in exon 5. GS in her family appeared to be recessive. Missense mutations causing GS have not been reported outside of Japan.

DISORDERS OF BILIRUBIN METABOLISM LEADING TO MIXED OR PREDOMINANTLY CONJUGATED HYPERBILIRUBINEMIA

In hyperbilirubinemia due to acquired liver disease (e.g., acute hepatitis, common bile duct stone), there are usually elevations in the serum concentrations of both conjugated and unconjugated bilirubin. Although biliary tract obstruction or hepatocellular cholestatic injury may present on occasion with a predominantly conjugated hyperbilirubinemia, it is generally not possible to differentiate intrahepatic from extrahepatic causes of jaundice based upon the serum levels or relative proportions of unconjugated and conjugated bilirubin. The major reason for determining the amounts of conjugated and unconjugated bilirubin in the serum is for the initial differentiation of hepatic parenchymal and obstructive disorders (mixed conjugated and unconjugated hyperbilirubinemia) from the inheritable and hemolytic disorders discussed above that are associated with unconjugated hyperbilirubinemia.

FAMILIAL DEFECTS IN HEPATIC EXCRETORY FUNCTION

Dubin-Johnson Syndrome This benign, relatively rare disorder is characterized by low-grade, predominantly conjugated hyperbilirubinemia. Total bilirubin concentrations are typically between 34 and 85 umol/L (2 and 5 mg/dL) but on occasion can be in the normal range or as high as 340 to 430 umol/L (20 to 25 mg/dL) and can fluctuate widely in any given patient. The degree of hyperbilirubinemia may be increased by intercurrent illness, oral contraceptive use, and pregnancy. As the hyperbilirubinemia is due to a predominant rise in conjugated bilirubin, bilirubinuria is characteristically present. Aside from elevated serum bilirubin levels, other routine laboratory tests are normal. Physical examination is usually normal except for jaundice, although an occasional patient may have hepatosplenomegaly.

Patients with Dubin-Johnson syndrome are usually asymptomatic, although some may have vague constitutional symptoms. These latter patients have usually undergone extensive and often unnecessary diagnostic examinations for unexplained jaundice and have high levels of anxiety. In women, the condition may be subclinical until the patient becomes pregnant or receives oral contraceptives, at which time chemical hyperbilirubinemia becomes frank jaundice. Even in these situations, other routine liver function tests, including serum alkaline phosphatase and transaminase activities, are normal.

A cardinal feature of Dubin-Johnson syndrome is the accumulation in the lysosomes of centrilobular hepatocytes of dark, coarsely granular pigment. As a result, the liver may be grossly black in appearance. This pigment is thought to be derived from epinephrine metabolites that are not excreted normally. The pigment may disappear during bouts of viral hepatitis, only to reaccumulate slowly after recovery.

Biliary excretion of a number of anionic compounds is compromised in Dubin-Johnson syndrome. These include various cholecystographic agents, as well as sulfobromophthalein (Bromsulphalein, BSP), a synthetic dye formerly used in a test of liver function. In this test, the rate of disappearance of BSP from plasma was determined following bolus intravenous administration. BSP is conjugated with glutathione in the hepatocyte; the resulting conjugate is normally excreted rapidly into the canaliculus. Patients with Dubin-Johnson syndrome exhibit a characteristic rise in its plasma concentration at 90 min after injection, due to reflux of conjugated BSP into the circulation from the hepatocyte. Dyes such as indocyanine green (ICG) that are taken up by hepatocytes but are not further metabolized prior to biliary excretion do not show this reflux phenomenon. Continuous BSP infusion studies suggest a reduction in the $t_{max}$for biliary excretion. Bile acid disposition, including hepatocellular uptake and biliary excretion, are normal in Dubin-Johnson syndrome. These patients have normal serum and biliary bile acid concentrations and do not have pruritus.

By analogy with findings in several mutant rat strains, the selective defect in biliary excretion of bilirubin conjugates and certain other classes of organic compounds, but not of bile acids, that characterizes the Dubin-Johnson syndrome was found to reflect defective expression of MRP2, an ATP-dependent canalicular membrane transporter. Several different mutations in the *MRP2* gene produce the Dubin-Johnson phenotype, which has an autosomal recessive pattern of inheritance. Although MRP2 is undoubtedly important in the biliary excretion of conjugated bilirubin, the fact that this pigment is still excreted in the absence of MRP2 suggests that other, as yet uncharacterized, transport proteins may serve in a secondary role in this process.

Patients with Dubin-Johnson syndrome also have a diagnostic abnormality in urinary coproporphyrin excretion. There are two naturally occurring coproporphyrin isomers, I and III. Normally, approximately 75% of the coproporphyrin in urine is isomer III. In urine from Dubin-Johnson syndrome patients, total coproporphyrin content is normal, but more than 80% is isomer I. Heterozygotes for the syndrome show an intermediate pattern. The molecular basis for this phenomenon remains unclear.

Rotor Syndrome This benign, autosomal recessive disorder is clinically similar to the Dubin-Johnson syndrome, although it is seen even less frequently. A major phenotypic difference is that the liver in patients with Rotor syndrome has no increased pigmentation and appears totally normal. The only abnormality in routine laboratory tests is an elevation of total serum bilirubin, due to a predominant rise in conjugated bilirubin. This is accompanied by bilirubinuria. Several additional features differentiate Rotor and Dubin-Johnson syndromes. In Rotor syndrome, the gallbladder is usually visualized on oral cholecystography, in contrast to the nonvisualization that is typical of Dubin-Johnson syndrome. The pattern of urinary coproporphyrin excretion also differs. The pattern in Rotor syndrome resembles that of many acquired disorders of hepatobiliary function, in which coproporphyrin I, the major coproporphyrin isomer in bile, refluxes from the hepatocyte back into the circulation and is excreted in urine. Thus, total urinary coproporphyrin excretion is substantially increased in Rotor syndrome, in contrast to the normal levels seen in Dubin-Johnson syndrome. Although the fraction of coproporphyrin I in urine is elevated, it is usually less than 70% of the total, as compared to 80% or more in Dubin-Johnson syndrome. The disorders also can be distinguished by their patterns ofBSPexcretion. Although clearance of BSP from

plasma is delayed in Rotor syndrome, there is no reflux of conjugated BSP back into the circulation as seen in Dubin-Johnson syndrome. Kinetic analysis of plasma BSP infusion studies suggests the presence of a defect in intrahepatocellular storage of this compound. This has never been demonstrated directly, and the molecular basis of Rotor syndrome remains unknown.

Benign Recurrent Intrahepatic Cholestasis (BRIC) This rare disorder is characterized by recurrent attacks of pruritus and jaundice. The typical episode begins with mild malaise and elevations in serum aminotransferase levels, followed rapidly by rises in alkaline phosphatase and bilirubin and onset of jaundice and itching. The first one or two episodes may be misdiagnosed as acute viral hepatitis. The cholestatic episodes, which may begin in childhood or adulthood, can vary in duration from several weeks to months, following which there is complete clinical and biochemical resolution. Intervals between attacks may vary from several months to years. Between episodes, physical examination is normal, as are serum levels of bile acids, bilirubin, transaminases, and alkaline phosphatase. The disorder is familial and has an autosomal recessive pattern of inheritance.BRIC is considered a benign disorder in that it does not lead to cirrhosis or end-stage liver disease. However, the episodes of jaundice and pruritus can be prolonged and debilitating, and some patients have undergone liver transplantation to relieve the intractable and disabling symptoms. Treatment during the cholestatic episodes is symptomatic; there is no specific treatment to prevent or shorten the occurrence of episodes.

A gene termed *FIC1* was recently identified and found to be mutated in patients withBRIC. Curiously, this gene is expressed strongly in the small intestine but only weakly in the liver. The protein encoded by *FIC1* shows little similarity to genes that have been shown to play a role in bile canalicular excretion of various compounds. Rather, it appears to be a member of a P-type ATPase family that transports aminophospholipids from the outer to the inner leaflet of a variety of cell membranes.

Progressive Familial Intrahepatic Cholestasis (FIC) This name is applied to three phenotypically related syndromes. Progressive FIC type 1 (Byler disease) presents in early infancy as cholestasis that may be initially episodic. However, in contrast toBRIC, Byler disease progresses to malnutrition, growth retardation, and end-stage liver disease during childhood. This disorder is also a consequence of an FIC1 mutation. The functional relationship of the *FIC1* protein to the pathogenesis of cholestasis in these disorders is unknown. Two other types of progressive FIC (types 2 and 3) have been described. Type 2 is associated with a mutation in the protein named *sister of p-glycoprotein*, which is the major bile canalicular exporter of bile acids. Type 3 has been associated with a mutation of MDR3, a protein that is essential for normal bile canalicular excretion of phospholipids. Although all three types of progressive FIC have similar clinical phenotypes, only type 3 is associated with high serum levels ofg-glutamyltransferase activity. In contrast, activity of this enzyme is normal or only mildly elevated in symptomatic BRIC and progressive FIC types 1 and 2.

295. ACUTE VIRAL HEPATITIS - *Jules L. Dienstag*, *Kurt J. Isselbacher*

Acute viral hepatitis is a systemic infection affecting the liver predominantly. Almost all cases of acute viral hepatitis are caused by one of five viral agents: hepatitis A virus (HAV), hepatitis B virus (HBV), hepatitis C virus (HCV), the HBV-associated delta agent or hepatitis D virus (HDV), and hepatitis E virus (HEV). Other transfusion-transmitted agents, e.g., "hepatitis G" virus and "TT" virus, have been identified but do not cause hepatitis. All these human hepatitis viruses are RNA viruses, except for hepatitis B, which is a DNA virus. Although these agents can be distinguished by their molecular and antigenic properties, all types of viral hepatitis produce clinically similar illnesses. These range from asymptomatic and inapparent to fulminant and fatal acute infections common to all types, on the one hand, and from subclinical persistent infections to rapidly progressive chronic liver disease with cirrhosis and even hepatocellular carcinoma, common to the bloodborne types (HBV, HCV, and HDV), on the other.

VIROLOGY AND ETIOLOGY

Hepatitis A Hepatitis A virus is a nonenveloped 27-nm, heat-, acid-, and ether-resistant RNA virus in the hepatovirus genus of the picornavirus family (Fig. 295-1). Its virion contains four capsid polypeptides, designated VP1 to VP4, which are cleaved posttranslationally from the polyprotein product of a 7500-nucleotide genome. Inactivation of viral activity can be achieved by boiling for 1 min, by contact with formaldehyde and chlorine, or by ultraviolet irradiation. Despite nucleotide sequence variation of up to 20% among isolates ofHAV, all strains of this virus are immunologically indistinguishable and belong to one serotype. Hepatitis A has an incubation period of approximately 4 weeks. Its replication is limited to the liver, but the virus is present in the liver, bile, stools, and blood during the late incubation period and acute preicteric phase of illness. Despite persistence of virus in the liver, viral shedding in feces, viremia, and infectivity diminish rapidly once jaundice becomes apparent. HAV is the only one of the human hepatitis viruses that can be cultivated reproducibly in vitro.

Antibodies toHAV(anti-HAV) can be detected during acute illness when serum aminotransferase activity is elevated and fecal HAV shedding is still occurring. This early antibody response is predominantly of the IgM class and persists for several months, rarely for 6 to 12 months. During convalescence, however, anti-HAV of the IgG class becomes the predominant antibody (Fig. 295-2). Therefore, the diagnosis of hepatitis A is made during acute illness by demonstrating anti-HAV of the IgM class. After acute illness, anti-HAV of the IgG class remains detectable indefinitely, and patients with serum anti-HAV are immune to reinfection. Neutralizing antibody activity parallels the appearance of anti-HAV, and the IgG anti-HAV present in immune globulin accounts for the protection it affords against HAV infection.

Hepatitis B Hepatitis B virus is a DNA virus with a remarkably compact genomic structure; despite its small, circular, 3200-basepair size,HBV DNA codes for four sets of viral products and has a complex, multiparticle structure. HBV achieves its genomic economy by relying on an efficient strategy of encoding proteins from four overlapping genes: S, C, P, and X (Fig. 295-3), as detailed below. Once thought to be unique among viruses, HBV is now recognized as one of a family of animal viruses, hepadnaviruses (hepatotropic DNA viruses), and is classified as hepadnavirus type 1. Similar viruses

infect certain species of woodchucks, ground and tree squirrels, and Pekin ducks, to mention the most carefully characterized. Like HBV, all have the same distinctive three morphologic forms, have counterparts to the envelope and nucleocapsid virus antigens of HBV, replicate in the liver but exist in extrahepatic sites, contain their own endogenous DNA polymerase, have partially double-stranded and partially single-stranded genomes, are associated with acute and chronic hepatitis and hepatocellular carcinoma, and rely on a replicative strategy unique among DNA viruses but typical of retroviruses. Instead of DNA replication directly from a DNA template, hepadnaviruses rely on reverse transcription (effected by the DNA polymerase) of minus-strand DNA from a "pregenomic" RNA intermediate. Then plus-strand DNA is transcribed from the minus-strand DNA template by the DNA-dependent DNA polymerase. Viral proteins are translated by the pregenomic RNA, and the proteins and genome are packaged into virions and secreted from the hepatocyte. Although HBV is difficult to cultivate in vitro in the conventional sense from clinical material, several cell lines have been transfected with HBV DNA. Such transfected cells support in vitro replication of the intact virus and its component proteins.

Viral proteins and particles Three particulate forms ofHBV(Table 295-1) can be demonstrated by electron microscopy (Fig. 295-1). The most numerous are the 22-nm particles, which appear as spherical or long filamentous forms; these are antigenically indistinguishable from the outer surface or envelope protein of HBV and are thought to represent excess viral envelope protein. Outnumbered in serum by a factor of 100 or 1000 to 1 compared with the spheres and tubules are large, 42-nm, double-shelled spherical particles, which represent the intact hepatitis B virion. The envelope protein expressed on the outer surface of the virion and on the smaller spherical and tubular structures is referred to as *hepatitis B surface antigen* (HBsAg). The concentration of HBsAg and virus particles in the blood may reach 500 ug/mL and 10 trillion particles per milliliter, respectively. The envelope protein, HBsAg, is the product of the S gene of HBV.

A number of differentHBsAgsubdeterminants have been identified. There is a common group-reactive antigen, *a*, shared by all HBsAg isolates. In addition, HBsAg may contain one of several subtype-specific antigens, namely, *d* or *y*, *w* or *r*, as well as other more recently characterized specificities. Hepatitis B isolates fall into one of at least eight subtypes and six genotypes (A-F); however, clinical course and outcome are independent of subtype and genotype [except for an increase in "precore" mutations (see below) in certain genotypes].

Upstream of the S gene are the pre-S genes (Fig. 295-3), which code for pre-S gene products, including receptors on theHBVsurface for polymerized human serum albumin and for hepatocyte membrane proteins. The pre-S region actually consists of both pre-S1 and pre-S2. Depending on where translation is initiated, three potentialHBsAggene products are synthesized. The protein product of the S gene is HBsAg (*major protein*), the product of the S region plus the adjacent pre-S2 region is the *middle protein*, and the product of the pre-S1 plus pre-S2 plus S regions is the *large protein*. Compared with the smaller spherical and tubular particles of HBV, complete 42-nm virions are enriched in the large protein. Both pre-S proteins and their respective antibodies can be detected during HBV infection, and the period of pre-S antigenemia appears to coincide with other markers of virus replication, as detailed below.

The intact 42-nm virion can be disrupted by mild detergents, and the 27-nm nucleocapsid core particle isolated. Nucleocapsid proteins are coded for by the C gene. The antigen expressed on the surface of the nucleocapsid core is referred to as *hepatitis B core antigen* (HBcAg), and its corresponding antibody is anti-HBc. A thirdHBVantigen is *hepatitis B e antigen* (HBeAg), a soluble, nonparticulate, nucleocapsid protein that is immunologically distinct from intact HBcAg but is a product of the same C gene. The C gene has two initiation codons, a precore and a core region (Fig. 295-3). If translation is initiated at the precore region, the protein product is HBeAg, which has a signal peptide that binds it to the smooth endoplasmic reticulum and leads to its secretion into the circulation. If translation begins with the core region, HBcAg is the protein product; it has no signal peptide, it is not secreted, but it assembles into nucleocapsid particles, which bind to and incorporate RNA and which, ultimately, contain HBV DNA. Also packaged within the nucleocapsid core is a DNA polymerase, which directs replication and repair of HBV DNA. When packaging within viral proteins is complete, synthesis of the incomplete plus strand stops; this accounts for the single-stranded gap and for differences in the size of the gap. HBcAg particles remain in the hepatocyte, where they are readily detectable by immunohistochemical staining, and are exported after encapsidation by an envelope ofHBsAg. Therefore, naked core particles do not circulate in the serum. The secreted nucleocapsid protein, HBeAg, provides a convenient, readily detectable, qualitative marker of HBV replication and relative infectivity.

HBsAg-positive serum containingHBeAg is more likely to be highly infectious and to be associated with the presence of hepatitis B virions (and detectableHBV DNA, see below) than HBeAg-negative or anti-HBe-positive serum. For example, HBsAg carrier mothers who are HBeAg-positive almost invariably (>90%) transmit hepatitis B infection to their offspring, whereas HBsAg carrier mothers with anti-HBe rarely (10 to 15%) infect their offspring.

Early during the course of acute hepatitis B,HBeAgappears transiently; its disappearance may be a harbinger of clinical improvement and resolution of infection. Persistence of HBeAg in serum beyond the first 3 months of acute infection may be predictive of the development of chronic infection, and the presence of HBeAg during chronic hepatitis B is associated with ongoing viral replication, infectivity, and inflammatory liver injury.

The third of theHBVgenes is the largest, the P gene (Fig. 295-3), which codes for the DNA polymerase; as noted above, this enzyme has both DNA-dependent DNA polymerase and RNA-dependent reverse transcriptase activities. The fourth gene, X, codes for a small, nonparticulate protein that is capable of transactivating the transcription of both viral and cellular genes (Fig. 295-3). Such transactivation may enhance the replication of HBV, leading to the clinical association observed between the expression of the product of the X gene, hepatitis B x antigen (HBxAg), and antibodies to it in patients with severe chronic hepatitis and hepatocellular carcinoma. The transactivating activity can enhance the transcription and replication of other viruses besides HBV, such as HIV. Cellular processes transactivated by X include the human interferon ggene and class I major histocompatibility genes; potentially, these effects could contribute to enhanced susceptibility of HBV-infected hepatocytes to cytolytic T

cells. The expression of X can also induce programmed cell death (apoptosis). The X gene and its protein product, however, are absent in nonmammalian hepadnaviruses; therefore, X is not essential for hepadnavirus replication.

Serologic and virologic markers After infection withHBV, the first virologic marker detectable in serum isHBsAg(Fig. 295-4). Circulating HBsAg precedes elevations of serum aminotransferase activity and clinical symptoms and remains detectable during the entire icteric or symptomatic phase of acute hepatitis B and beyond. In typical cases, HBsAg becomes undetectable 1 to 2 months after the onset of jaundice and rarely persists beyond 6 months. After HBsAg disappears, antibody to HBsAg (anti-HBs) becomes detectable in serum and remains detectable indefinitely thereafter. BecauseHBcAg is sequestered within an HBsAg coat, HBcAg is not detectable routinely in the serum of patients with HBV infection. By contrast, anti-HBc is readily demonstrable in serum, beginning within the first 1 to 2 weeks after the appearance of HBsAg and preceding detectable levels of anti-HBs by weeks to months. Because variability exists in the time of appearance of anti-HBs after HBV infection, occasionally a gap of several weeks or longer may separate the disappearance of HBsAg and the appearance of anti-HBs. During this "gap" or "window" period, anti-HBc may represent serologic evidence of current or recent HBV infection, and blood containing anti-HBc in the absence of HBsAg and anti-HBs has been implicated in the development of transfusion-associated hepatitis B. In part because the sensitivity of immunoassays for HBsAg and anti-HBs has increased, however, this window period is rarely encountered. In some persons, years after HBV infection, anti-HBc may persist in the circulation longer than anti-HBs. Therefore, isolated anti-HBc does not necessarily indicate active virus replication; most instances of isolated anti-HBc represent hepatitis B infection in the remote past. Rarely, however, isolated anti-HBc represents low-level hepatitis B viremia, with HBsAg below the detection threshold; occasionally, isolated anti-HBc represents a cross-reacting or false-positive immunologic specificity. Recent and remote HBV infections can be distinguished by determination of the immunoglobulin class of anti-HBc. Anti-HBc of the IgM class (IgM anti-HBc) predominates during the first 6 months after acute infection, whereas IgG anti-HBc is the predominant class of anti-HBc beyond 6 months. Therefore, patients with current or recent acute hepatitis B, including those in the anti-HBc window, have IgM anti-HBc in their serum. In patients who have recovered from hepatitis B in the remote past as well as those with chronic HBV infection, anti-HBc is predominantly of the IgG class. Infrequently, in no more than 1 to 5% of patients with acute HBV infection, levels of HBsAg are too low to be detected; in such cases, the presence of IgM anti-HBc establishes the diagnosis of acute hepatitis B. When isolated anti-HBc occurs in the rare patient with chronic hepatitis B whose HBsAg level is below the sensitivity threshold of contemporary immunoassays (a low-level carrier), the anti-HBc is of the IgG class. Generally, in persons who have recovered from hepatitis B, anti-HBs and anti-HBc persist indefinitely.

The temporal association between the appearance of anti-HBs and resolution ofHBVinfection as well as the observation that persons with anti-HBs in serum are protected against reinfection with HBV suggest that *anti-HBs is the protective antibody*. Therefore, strategies for prevention of HBV infection are based on providing susceptible persons with circulating anti-HBs (see below). Occasionally, in 10 to 20% of patients with chronic hepatitis B, low-level, low-affinity anti-HBs can be detected. This antibody is directed against a subtype determinant different from that represented by the

patient'sHBsAg; its presence is thought to reflect the stimulation of a related clone of antibody-forming cells, but it has no clinical relevance and does not signal imminent clearance of hepatitis B.

The other readily detectable serologic marker ofHBVinfection,HBeAg, appears concurrently with or shortly after HBsAg. Its appearance coincides temporally with high levels of virus replication and reflects the presence of circulating intact virions and detectable HBV DNA. Pre-S1 and pre-S2 proteins are also expressed during periods of peak replication, but assays for these gene products are not routinely available. In self-limited HBV infections, HBeAg becomes undetectable shortly after peak elevations in aminotransferase activity, before the disappearance of HBsAg, and anti-HBe then becomes detectable, coinciding with a period of relatively lower infectivity (Fig. 295-4). Because markers of HBV replication appear transiently during acute infection, testing for such markers is of little clinical utility in typical cases of acute HBV infection. In contrast, markers of HBV replication provide valuable information in patients with protracted infections.

Departing from the pattern typical of acute HBV infections, in chronic HBV infection, HBsAg remains detectable beyond 6 months, anti-HBc is primarily of the IgG class, and anti-HBs is either undetectable or detectable at low levels (see "Laboratory Features," below) (Fig. 295-5). During early chronic HBV infection, HBV DNA can be detected both in serum and in hepatocyte nuclei, where it is present in free or episomal form. This *replicative stage* of HBV infection is the time of maximal infectivity and liver injury; HBeAg is a qualitative marker and HBV DNA a quantitative marker of this replicative phase, during which all three forms of HBV circulate, including intact virions. Over time, the replicative phase of chronic HBV infection gives way to a relatively *nonreplicative phase*. This occurs at a rate of approximately 10% per year and is accompanied by seroconversion from HBeAg-positive to anti-HBe-positive. In most cases, this seroconversion coincides with a transient, acute hepatitis-like elevation in aminotransferase activity, believed to reflect cell-mediated clearance of virus-infected hepatocytes. In the nonreplicative phase of chronic infection, when HBV DNA is demonstrable in hepatocyte nuclei, it tends to be integrated into the host genome. In this phase, only spherical and tubular forms of HBV, *not intact virions*, circulate, and liver injury tends to subside. Most such patients would be characterized as asymptomatic HBV *carriers*. In reality, the designations *replicative* and *nonreplicative* are only relative; even in the so-called nonreplicative phase, HBV replication can be detected with highly sensitive amplification probes such as the polymerase chain reaction. Still, the distinctions are pathophysiologically and clinically meaningful. Occasionally, nonreplicative HBV infection converts back to replicative infection. Such spontaneous reactivations are accompanied by reexpression of HBeAg and HBV DNA, and sometimes of IgM anti-HBc, as well as by exacerbations of liver injury.

Molecular variants Variation occurs throughout theHBVgenome, and clinical isolates of HBV that do not express typical viral proteins have been attributed to mutations in individual or even multiple gene locations. For example, variants have been described that lack nucleocapsid proteins, envelope proteins, or both. Two categories of HBV have attracted the most attention. One of these was identified initially in Mediterranean countries among patients with an unusual serologic-clinical profile. They have severe chronic HBV infection and detectable HBV DNA but with anti-HBe instead ofHBeAg.

These patients were found to be infected with an HBV mutant that contained an alteration in the precore region rendering the virus incapable of encoding HBeAg. Although several potential mutation sites exist in the pre-C region, the region of the C gene necessary for the expression of HBeAg (see "Virology and Etiology," above), the most commonly encountered in such patients is a single base substitution, from G to A, which occurs in the second to last codon of the pre-C gene at nucleotide 1896. This substitution results in the replacement of the TGG tryptophan codon by a stop codon (T*A*G), which prevents the translation of HBeAg. Another mutation in the core promoter region prevents transcription of the coding region for HBeAg and yields an HBeAg-negative phenotype. Patients with such precore mutants that are unable to secrete HBeAg tend to have severe liver disease that progresses rapidly to cirrhosis and that does not respond readily to antiviral therapy. Both "wild-type" HBV and precore mutant HBV can coexist in the same patient, or mutant HBV may arise during wild-type HBV infection. In addition, clusters of fulminant hepatitis B in Israel and Japan have been attributed to common-source infection with a precore mutant. Fulminant hepatitis B in North America and western Europe, however, occurs in patients infected with wild-type HBV, in the absence of precore mutants, and both precore mutants and other mutations throughout the HBV genome occur commonly even in patients with typical, self-limited, milder forms of HBV infection. In areas where chronic HBV infection is common, precore mutations are more frequent and may reflect viral evolution driven by immune selection. Additional investigation is necessary to define the effect of precore mutants on the pathogenicity and natural history of HBV infection.

The second important category ofHBVmutants consists of *escape mutants*, in which a single amino acid substitution, from glycine to arginine, occurs at position 145 of the immunodominant *a* determinant common to all subtypes ofHBsAg. This change in HBsAg leads to a critical conformational change that results in a loss of neutralizing activity by anti-HBs. This specific HBV/*a* mutant has been observed in two situations, active and passive immunization, in which humoral immunologic pressure may favor evolutionary change ("escape") in the virus -- in a small number of hepatitis B vaccine recipients who acquired HBV infection despite the prior appearance of neutralizing anti-HBs and in liver transplant recipients who underwent the procedure for hepatitis B and who were treated with a high-potency human monoclonal anti-HBs preparation. Although such mutants have not been recognized frequently, their existence raises a concern that may complicate vaccination strategies and serologic diagnosis.

Extrahepatic sites Hepatitis B antigens andHBV DNA have been identified in extrahepatic sites, including lymph nodes, bone marrow, circulating lymphocytes, spleen, and pancreas. Although the virus does not appear to be associated with tissue injury in any of these extrahepatic sites, its presence in these "remote" reservoirs has been invoked to explain the recurrence of HBV infection after orthotopic liver transplantation. A more complete understanding of the clinical relevance of extrahepatic HBV remains to be defined.

Hepatitis D The delta hepatitis agent, orHDV, is a defective RNA virus that coinfects with and requires the helper function ofHBV (or other hepadnaviruses) for its replication and expression. Slightly smaller than HBV, delta is a formalin-sensitive, 35- to 37-nm virus with a hybrid structure. Its nucleocapsid expresses delta antigen, which bears no antigenic homology with any of the HBV antigens, and contains the virus genome. The

delta core is "encapsidated" by an outer envelope ofHBsAg, indistinguishable from that of HBV except in its relative compositions of major, middle, and large HBsAg component proteins. The genome is a small, 1700-nucleotide, circular, single-stranded RNA (minus strand) that is nonhomologous with HBV DNA (except for a small area of the polymerase gene) but that has features and the rolling circle model of replication common to genomes of plant satellite viruses or viroids. HDV RNA contains many areas of internal complementarity; therefore, it can fold on itself by internal base pairing to form an unusual, very stable, rodlike structure. HDV RNA replicates via RNA-directed RNA synthesis by transcription of genomic RNA to a complementary antigenomic (plus strand) RNA; the antigenomic RNA, in turn, serves as a template for subsequent genomic RNA synthesis. Between the genomic and antigenomic RNAs of HDV, there are coding regions for nine proteins. Delta antigen, which is a product of the antigenomic strand, exists in two forms, a small, 195-amino-acid species, which plays a role in facilitating HDV RNA replication, and a large, 214-amino-acid species, which appears to suppress replication but is required for assembly of the antigen into virions. Although complete hepatitis D virions and liver injury require the cooperative helper function of HBV, intracellular replication of HDV RNA can occur without HBV. Genomic heterogeneity among HDV isolates has been described; however, pathophysiologic and clinical consequences of this genetic diversity have not been recognized.

HDVcan either infect a person simultaneously withHBV(*coinfection*) or superinfect a person already infected with HBV (*superinfection*); when HDV infection is transmitted from a donor with oneHBsAgsubtype to an HBsAg-positive recipient with a different subtype, the HDV agent assumes the HBsAg subtype of the recipient, rather than the donor. Because HDV relies absolutely on HBV, the duration of HDV infection is determined by the duration of (and cannot outlast) HBV infection. HDV antigen is expressed primarily in hepatocyte nuclei and is occasionally detectable in serum. During acute HDV infection, anti-HDV of the IgM class predominates, and 30 to 40 days may elapse after symptoms appear before anti-HDV can be detected. In self-limited infection, anti-HDV is low titer and transient, rarely remaining detectable beyond the clearance of HBsAg and HDV antigen. In chronic HDV infection, anti-HDV circulates in high titer, and both IgM and IgG anti-HDV can be detected. HDV antigen in the liver and HDV RNA in serum and liver can be detected during HDV replication.

Hepatitis C Hepatitis C virus, which, before its identification was labeled "non-A, non-B hepatitis," is a linear, single-stranded, positive-sense, 9400-nucleotide RNA virus, the genome of which is similar in organization to that of flaviviruses and pestiviruses;HCVconstitutes its own genus in the family Flaviviridae. The HCV genome contains a single large open reading frame (gene) that codes for a virus polyprotein of approximately 3000 amino acids. The 5¢ end of the genome consists of an untranslated region adjacent to the genes for structural proteins, the nucleocapsid core protein and two envelope glycoproteins, E1 and E2/NS1. The 5¢ untranslated region and core gene are highly conserved among genotypes, but the envelope proteins are coded for by the hypervariable region, which varies from isolate to isolate and may allow the virus to evade host immunologic containment directed at accessible virus-envelope proteins. The 3¢ end of the genome contains the genes for nonstructural (NS) proteins. The first reported HCV clone, 5-1-1, and the nucleotide sequence coding for C100-3, the recombinant virus protein used in the first immunoassay for antibodies to HCV, reside within the NS4 gene, and the RNA-dependent RNA polymerase, through which HCV

replicates, is encoded by the NS5 region (Fig. 295-6). Because HCV does not replicate via a DNA intermediate, it does not integrate into the host genome. Because HCV tends to circulate in very low titer, visualization of virus particles, estimated to be 40 to 60 nm in diameter, has been difficult. Although in vitro HCV replication remains difficult to accomplish convincingly, the chimpanzee has proven to be an invaluable experimental animal model.

At least six distinct genotypes, as well as subtypes within genotypes, ofHCV have been identified by nucleotide sequencing. Genotypes differ one from another in sequence homology by ³30%. Because divergence of HCV isolates within a genotype or subtype, and within the same host, may vary insufficiently to define a distinct genotype, these intragenotypic differences are referred to as *quasispecies* and differ in sequence homology by only a few percent. The genotypic and quasispecies diversity of HCV, resulting from its high mutation rate, interferes with effective humoral immunity. Neutralizing antibodies to HCV have been demonstrated, but they tend to be short-lived; and HCV infection does not induce lasting immunity against reinfection with different virus isolates or even the same virus isolate. Thus, neither *heterologous* nor *homologous* immunity appears to develop after acute HCV infection. Some HCV genotypes are distributed worldwide, while others are more geographically confined. In addition, differences in pathogenicity and responsiveness to antiviral therapy have been reported among genotypes; however, the biologic impact of genotype and quasispecies differences remains incompletely defined.

As noted above, the first assay detected antibodies to C100-3, a recombinant polypeptide derived from theNS4 region of the genome. In most patients with acute hepatitis C, antibody detected with this assay appears between 1 to 3 months after the onset of acute hepatitis but sometimes not for a year or longer. Second-generation assays incorporate recombinant proteins from the nucleocapsid core region, C22-3, and the NS3 region, C33c (expressed in combination with C100-3 as C200); these assays are more sensitive (by approximately 20%) and detect anti-HCV30 to 90 days earlier, during the period of acute hepatitis. A third-generation immunoassay, which incorporates proteins from the NS5 region and replaces some recombinant proteins with synthetic peptides, may detect anti-HCV even earlier. Because nonspecificity has been encountered in clinical samples tested for anti-HCV, a supplementary recombinant immunoblot assay was introduced. Reactivity in an immunoassay is "confirmed" by incubation with a nitrocellulose strip that contains individual bands of recombinant or synthetic HCV proteins. This approach allows the demonstration of individual antibodies to nonstructural and structural viral proteins and identifies false-positive reactivity associated with nonviral specificities. It is useful to support the validity of anti-HCV-reactive samples, especially in patients with a low prior probability of true infection (e.g., blood donors) or in patients with confounding activity in serum (such as a rheumatoid factor) that may yield false-positive antibody reactivity. Still, detection of anti-HCV is insufficient to identify all persons infected with HCV. The most sensitive indicator is the presence of HCV RNA, which requires molecular amplification by polymerase chain reaction (PCR) (Fig. 295-7). An alternative method for detection of HCV RNA, more easily automated but one or two orders of magnitude less sensitive, is branched-chain complementary DNA hybridization. HCV RNA can be detected within a few days of exposure to HCV, well before the appearance of anti-HCV, and tends to persist for the duration of HCV infection; however, in patients with chronic HCV

infection, occasionally, HCV RNA may be detectable only intermittently. Application of sensitive molecular probes for HCV RNA has revealed the presence of replicative HCV in peripheral blood lymphocytes of infected persons; however, as is the case forHBV in lymphocytes, the clinical relevance of HCV lymphocyte infection is not known.

Hepatitis E Previously labeled *epidemic* or *enterically transmitted non-A, non-B hepatitis*,HEV is an enterically transmitted virus that occurs primarily in India, Asia, Africa, and Central America. This agent, with epidemiologic features resembling those of hepatitis A, is a 32- to 34-nm, nonenveloped,HAV-like virus with a 7600-nucleotide, single-stranded, positive-sense RNA genome. HEV has three open reading frames (genes), the largest of which encodes nonstructural proteins involved in virus replication. A middle-sized gene encodes the nucleocapsid protein, and the smallest, whose function is not known, encodes protein specificities to which antibodies appear in human serum. All HEV isolates appear to belong to a single serotype, despite genomic heterogeneity of up to 25%. There is no genomic or antigenic homology, however, between HEV and HAV or other picornaviruses; and HEV, although resembling calciviruses, appears to be sufficiently distinct from any known agent to merit a new classification of its own within the alphavirus group. The virus has been detected in stool, bile, and liver and is excreted in the stool during the late incubation period; immune responses to viral antigens occur very early during the course of acute infection. Both IgM anti-HEV and IgG anti-HEV can be detected, but both fall rapidly after acute infection, reaching low levels within 9 to 12 months. Currently, serologic testing for HEV infection is not available routinely.

PATHOGENESIS

Under ordinary circumstances, none of the hepatitis viruses is known to be directly cytopathic to hepatocytes. Evidence suggests that the clinical manifestations and outcomes after acute liver injury associated with viral hepatitis are determined by the immunologic responses of the host.

Hepatitis B Among the viral hepatitides, the immunopathogenesis of hepatitis B has been studied most extensively. Certainly for this agent, the existence of asymptomatic hepatitis B carriers with normal liver histology and function suggests that the virus is not directly cytopathic. The fact that patients with defects in cellular immune competence are more likely to remain chronically infected rather than to clear the virus is cited to support the role of cellular immune responses in the pathogenesis of hepatitis B-related liver injury. The model that has the most experimental support involves cytolytic T cells sensitized specifically to recognize host and hepatitis B viral antigens on the liver cell surface. Recent laboratory observations suggest that nucleocapsid proteins (HBcAgand possiblyHBeAg), present on the cell membrane in minute quantities, are the viral target antigens that, with host antigens, invite cytolytic T cells to destroyHBV-infected hepatocytes. Differences in the robustness of cytolytic T cell responsiveness and in the elaboration of antiviral cytokines by T cells have been invoked to explain differences in outcomes between those who recover after acute hepatitis and those who progress to chronic hepatitis or between those with mild and those with severe (fulminant) acute HBV infection.

A recent observation provides further insight into the mechanism of viral clearance in

acute hepatitis B. Although a robust cytolytic T cell response occurs and eliminates virus-infected liver cells during acute hepatitis B, more than 90% ofHBV DNA has been found in experimentally infected chimpanzees to disappear from the liver and blood before maximal T cell infiltration of the liver and before most of the biochemical and histologic evidence of liver injury. This observation suggests that inflammatory cytokines, independent of cytopathic antiviral mechanisms, participate in early viral clearance; this effect has been shown to represent elimination of HBV replicative intermediates from the cytoplasm and covalently closed circular viral DNA from the nucleus of infected hepatocytes.

Debate continues over the relative importance of viral and host factors in the pathogenesis ofHBV-associated liver injury and its outcome. As noted above, precore genetic mutants of HBV have been associated with the more severe outcomes of HBV infection (severe chronic and fulminant hepatitis), suggesting that, under certain circumstances, relative pathogenicity is a property of the virus, not the host. The fact that concomitantHDV and HBV infections are associated with more severe liver injury than HBV infection alone and the fact that cells transfected in vitro with the gene for HDV (delta) antigen express HDV antigen and then become necrotic in the absence of any immunologic influences are also consistent with a viral effect on pathogenicity. Similarly, in patients who undergo liver transplantation for end-stage chronic hepatitis B, occasionally, rapidly progressive liver injury appears in the new liver. This clinical pattern is associated with an unusual histologic pattern in the new liver, *fibrosing cholestatic hepatitis*, which, ultrastructurally, appears to represent a choking of the cell with overwhelming quantities ofHBsAg. This observation suggests that under the influence of the potent immunosuppressive agents required to prevent allograft rejection, HBV may have a direct cytopathic effect on liver cells, independent of the immune system.

Although the precise mechanism of liver injury inHBVinfection remains elusive, studies of nucleocapsid proteins have shed light on the profound immunologic tolerance to HBV of babies born to mothers with highly replicative (HBeAg-positive), chronic HBV infection. In HBeAg-expressing transgenic mice, in utero exposure to HBeAg, which is sufficiently small to traverse the placenta, induces T cell tolerance to both nucleocapsid proteins. This, in turn, may explain why, when infection occurs so early in life, immunologic clearance does not occur, and protracted, lifelong infection ensues.

Hepatitis C Undoubtedly, cell-mediated immune responses and elaboration by T cells of antiviral cytokines contribute to the containment of infection and pathogenesis of liver injury associated with hepatitis C. PerhapsHCVinfection of lymphoid cells plays a role in moderating immune responsiveness to the virus, as well. Intrahepatic HLA class-I-restricted cytolytic T cells directed at nucleocapsid, envelope, andNS viral protein antigens have been demonstrated in patients with chronic hepatitis C. Such virus-specific cytolytic T cell responses, however, do not correlate adequately with the degree of liver injury or with recovery. Several HLA alleles have been linked with self-limited hepatitis C, but such associations do not apply universally. Finally, cross-reactivity between viral and host autoantigens has been invoked to explain the association between hepatitis C and a subset of patients with autoimmune hepatitis and antibodies to liver kidney microsomal antigen (anti-LKM) (Chap. 297).

Extrahepatic Manifestations Immune complex-mediated tissue damage appears to play a pathogenetic role in the extrahepatic manifestations of acute hepatitis B. The occasional prodromal serum sickness-like syndrome observed in acute hepatitis B appears to be related to the deposition in tissue blood vessel walls of circulating immune complexes leading to activation of the complement system. The clinical consequences are urticarial rash, angioedema, fever, and arthritis. During the early prodrome ofHBVinfection in these patients,HBsAg in high titer in association with small amounts of anti-HBs leads to the formation of soluble, circulating immune complexes (in antigen excess). Complement components in the serum are depressed during the arthritic phase of the illness and are also detectable in the circulating immune complexes, which also contain HBsAg, anti-HBs, IgG, IgM, IgA, and fibrin.

In patients with chronic hepatitis B, other types of immune-complex disease may be seen. Glomerulonephritis with the nephrotic syndrome is occasionally observed;HBsAg, immunoglobulin, and C3 deposition has been found in the glomerular basement membrane. While polyarteritis nodosa develops in considerably fewer than 1% of patients withHBVinfection, 20 to 30% of patients with polyarteritis nodosa have HBsAg in serum (Chap. 317). In these patients, the affected small and medium-sized arterioles have been shown to contain HBsAg, immunoglobulins, and complement components. Another extrahepatic manifestation of viral hepatitis, essential mixed cryoglobulinemia (EMC), was reported initially to be associated with hepatitis B. The disorder is characterized clinically by arthritis and cutaneous vasculitis (palpable purpura) and serologically by the presence of circulating cryoprecipitable immune complexes of more than one immunoglobulin class (Chap. 275). Many patients with this syndrome have chronic liver disease, but the association with HBV infection is limited; instead, a substantial proportion have chronicHCVinfection. Their circulating immune complexes contain HCV RNA at a concentration that exceeds its serum concentration, favoring a primary role for the virus in the pathogenesis of EMC.

PATHOLOGY

The typical morphologic lesions of all types of viral hepatitis are similar and consist of panlobular infiltration with mononuclear cells, hepatic cell necrosis, hyperplasia of Kupffer cells, and variable degrees of cholestasis. Hepatic cell regeneration is present, as evidenced by numerous mitotic figures, multinucleated cells, and "rosette" or "pseudoacinar" formation. The mononuclear infiltration consists primarily of small lymphocytes, although plasma cells and eosinophils occasionally are present. Liver cell damage consists of hepatic cell degeneration and necrosis, cell dropout, ballooning of cells, and acidophilic degeneration of hepatocytes (forming so-called Councilman bodies). Large hepatocytes with a ground glass appearance of the cytoplasm may be seen in chronic but not in acuteHBVinfection; these cells containHBsAgand can be identified histochemically with orcein or aldehyde fuchsin. In uncomplicated viral hepatitis, the reticulin framework is preserved.

In hepatitis C, the histologic lesion is often remarkable for a relative paucity of inflammation, a marked increase in activation of sinusoidal lining cells, lymphoid aggregates, the presence of fat, and, occasionally, bile duct lesions in which biliary epithelial cells appear to be piled up without interruption of the basement membrane. Occasionally, microvesicular steatosis occurs in hepatitis D. In hepatitis E, a common

histologic feature is marked cholestasis. A cholestatic variant of slowly resolving acute hepatitis A also has been described.

A more severe histologic lesion, *bridging hepatic necrosis*, also termed *subacute* or *confluent necrosis*, is occasionally observed in some patients with acute hepatitis. "Bridging" between lobules results from large areas of hepatic cell dropout, with collapse of the reticulin framework. Characteristically, the bridge consists of condensed reticulum, inflammatory debris, and degenerating liver cells that span adjacent portal areas, portal to central veins, or central vein to central vein. This lesion had been thought to have prognostic significance; in many of the originally described patients with this lesion, a subacute course terminated in death within several weeks to months, or severe chronic hepatitis and postnecrotic cirrhosis developed. More recent investigations have failed to uphold the association between bridging necrosis and such a poor prognosis in patients with acute hepatitis. Although the frequency of bridging may be higher among hospitalized patients with severe acute hepatitis, and although cirrhosis, chronic hepatitis, and even death have occurred in this group, the frequency of bridging necrosis in uncomplicated acute viral hepatitis is probably on the order of 1 to 5%. Prospective studies have failed to demonstrate a difference in prognosis between patients with acute hepatitis who have bridging necrosis and those who do not. Therefore, although demonstration of this lesion in patients with chronic hepatitis has prognostic significance (Chap. 297), its demonstration during acute hepatitis is less meaningful, and liver biopsies to identify this lesion are no longer undertaken routinely in patients with acute hepatitis. In *massive hepatic necrosis* (fulminant hepatitis, acute yellow atrophy), the striking feature at postmortem examination is the finding of a small, shrunken, soft liver. Histologic examination reveals massive necrosis and dropout of liver cells of most lobules with extensive collapse and condensation of the reticulin framework.

Immunofluorescence and immunoperoxidase antibody studies have localizedHBsAg to the cytoplasm and plasma membrane of infected liver cells. In contrast,HBcAgpredominates in the nucleus, but occasionally, scant amounts are also seen in the cytoplasm and on the cell membrane. Electron-microscopic studies of liver biopsy material have demonstrated the presence of HBsAg particles in the cytoplasm and HBcAg particles in the nucleus of liver cells during hepatitis B infection. These morphologic observations suggest that DNA is synthesized and packaged within core particles in the nucleus, while the envelope is assembled in the cytoplasm, resulting in the formation of intact hepatitis B virus.HDVantigen is localized to the hepatocyte nucleus, whileHAV,HCV, andHEVantigens are localized to the cytoplasm.

EPIDEMIOLOGY

Before the availability of serologic tests for hepatitis viruses, all viral hepatitis cases were labeled either as "infectious" or "serum" hepatitis. Modes of transmission overlap, however, and *a clear distinction among the different types of viral hepatitis cannot be made solely on the basis of clinical or epidemiologic features* (Table 295-2). The most accurate means to distinguish the various types of viral hepatitis involves specific serologic testing.

Hepatitis A *This agent is transmitted almost exclusively by the fecal-oral route*.

Person-to-person spread ofHAV is enhanced by poor personal hygiene and overcrowding; large outbreaks as well as sporadic cases have been traced to contaminated food, water, milk, frozen raspberries and strawberries, and shellfish. Intrafamily and intrainstitutional spread are also common. Early epidemiologic observations suggested that there is a predilection for hepatitis A to occur in late fall and early winter. In temperate zones, epidemic waves have been recorded every 5 to 20 years as new segments of nonimmune population appeared; however, in developed countries, the incidence of type A hepatitis has been declining, presumably as a function of improved sanitation, and these cyclic patterns are no longer being observed. No HAV carrier state has been identified after acute type A hepatitis; perpetuation of the virus in nature depends presumably on nonepidemic, inapparent subclinical infection.

In the general population, anti-HAV, an excellent marker for previous HAV infection, increases in prevalence as a function of increasing age and of decreasing socioeconomic status. In the 1970s, serologic evidence of prior hepatitis A infection occurred in about 40% of urban populations in the United States, most of whose members never recalled having had a symptomatic case of hepatitis. In subsequent decades, however, the prevalence of anti-HAV has been declining in the United States. In developing countries, exposure, infection, and subsequent immunity are almost universal in childhood. As the frequency of subclinical childhood infections declines in developed countries, a susceptible cohort of adults emerges. Hepatitis A tends to be more symptomatic in adults; therefore, paradoxically, as the frequency of HAV infection declines, the likelihood of clinically apparent, even severe, HAV illnesses increases in the susceptible adult population. Travel to endemic areas is a common source of infection for adults from nonendemic areas. More recently recognized epidemiologic foci of HAV infection include child-care centers, neonatal intensive care units, promiscuous homosexual men, and injection drug users. Although hepatitis A is rarely bloodborne, several outbreaks have been recognized in recipients of clotting factor concentrates.

Hepatitis B Percutaneous inoculation has long been recognized as a major route of hepatitis B transmission, but the outmoded designation "serum hepatitis" is an inaccurate label for the epidemiologic spectrum ofHBVinfection recognized today. As detailed below, most of the hepatitis transmitted by blood transfusion is not caused by HBV; moreover, in approximately two-thirds of patients with acute type B hepatitis, there is no history of an identifiable percutaneous exposure. We now recognize that many cases of type B hepatitis result from less obvious modes of nonpercutaneous or covert percutaneous transmission.HBsAghas been identified in almost every body fluid from infected persons, and at least some of these body fluids -- most notably semen and saliva -- are infectious, albeit less so than serum, when administered percutaneously or nonpercutaneously to experimental animals. Among the nonpercutaneous modes of HBV transmission, oral ingestion has been documented as a potential but inefficient route of exposure. By contrast, the two nonpercutaneous routes considered to have the greatest impact are intimate (especially sexual) contact and perinatal transmission.

In sub-Saharan Africa, intimate contact among toddlers is considered instrumental in contributing to the maintenance of the high frequency of hepatitis B in the population. Perinatal transmission occurs primarily in infants born toHBsAgcarrier mothers or mothers with acute hepatitis B during the third trimester of pregnancy or during the early postpartum period. Perinatal transmission is uncommon in North America and western

Europe but occurs with great frequency and is the most important mode ofHBVperpetuation in the Far East and developing countries. Although the precise mode of perinatal transmission is unknown, and although approximately 10% of infections may be acquired in utero, epidemiologic evidence suggests that most infections occur approximately at the time of delivery and are not related to breast feeding. The likelihood of perinatal transmission of HBV correlates with the presence ofHBeAg; 90% of HBeAg-positive mothers but only 10 to 15% of anti-HBe-positive mothers transmit HBV infection to their offspring. In most cases, acute infection in the neonate is clinically asymptomatic, but the child is very likely to become anHBsAgcarrier.

The more than 350 millionHBsAgcarriers in the world constitute the main reservoir of hepatitis B in human beings. Serum HBsAg is infrequent (0.1 to 0.5%) in normal populations in the United States and western Europe. However, a prevalence of up to 5 to 20% has been found in the Far East and in some tropical countries; in persons with Down's syndrome, lepromatous leprosy, leukemia, Hodgkin's disease, polyarteritis nodosa; in patients with chronic renal disease on hemodialysis; and in injection drug users.

Other groups with high rates ofHBVinfection include spouses of acutely infected persons, sexually promiscuous persons (especially promiscuous homosexual men), health care workers exposed to blood, persons who require repeated transfusions especially with pooled blood product concentrates (e.g., hemophiliacs), residents and staff of custodial institutions for the mentally retarded, prisoners, and, to a lesser extent, family members of chronically infected patients. In volunteer blood donors, the prevalence of anti-HBs, a reflection of previous HBV infection, ranges from 5 to 10%, but the prevalence is higher in lower socioeconomic strata, older age groups, and persons -- including those mentioned above -- exposed to blood products.

Prevalence of infection, modes of transmission, and human behavior conspire to mold geographically different epidemiologic patterns ofHBVinfection. In the Far East and Africa, hepatitis B, a disease of the newborn and young children, is perpetuated by a cycle of maternal-neonatal spread. In North America and western Europe, hepatitis B is primarily a disease of adolescence and early adulthood, the time of life when intimate sexual contact as well as recreational and occupational percutaneous exposures tend to occur.

Hepatitis D Infection withHDV has a worldwide distribution, but two epidemiologic patterns exist. In Mediterranean countries (northern Africa, southern Europe, the Middle East), HDV infection is endemic among those with hepatitis B, and the disease is transmitted predominantly by nonpercutaneous means, especially close personal contact. In nonendemic areas, such as the United States and northern Europe, HDV infection is confined to persons exposed frequently to blood and blood products, primarily injection drug users and hemophiliacs. HDV infection can be introduced into a population through drug users or by migration of persons from endemic to nonendemic areas. Thus, patterns of population migration and human behavior facilitating percutaneous contact play important roles in the introduction and amplification of HDV infection. Occasionally, the migrating epidemiology of hepatitis D is expressed in explosive outbreaks of severe hepatitis, such as those that have occurred in remote

South American villages as well as in urban centers in the United States. Ultimately, such outbreaks of hepatitis D -- either of coinfections with acute hepatitis B or of superinfections in those already infected with HBV -- may blur the distinctions between endemic and nonendemic areas.

Hepatitis C Routine screening of blood donors forHBsAgand the elimination of commercial blood sources in the early 1970s reduced the frequency of, but did not eliminate, transfusion-associated hepatitis. During the 1970s, the likelihood of acquiring hepatitis after transfusion of voluntarily donated, HBsAg-screened blood was approximately 10% per patient (up to 0.9% per unit transfused); 90 to 95% of these cases were classified, based on serologic exclusion of hepatitis A and B, as "non-A, non-B" hepatitis. For patients requiring transfusion of pooled products, such as clotting factor concentrates, the risk was even higher, up to 20 to 30%, while for those receiving such products as albumin and immune globulin, because of prior treatment of these materials by heating to 60°C or cold ethanol fractionation, there was no risk of hepatitis.

During the 1980s, voluntary self-exclusion of blood donors with risk factors for AIDS and then the introduction of donor screening for anti-HIV reduced further the likelihood of transfusion-associated hepatitis to under 5%. During the late 1980s and early 1990s, the introduction first of "surrogate" screening tests for non-A, non-B hepatitis [alanine aminotransferase (ALT) and anti-HBc, both shown to identify blood donors with a higher likelihood of transmitting non-A, non-B hepatitis to recipients] and, subsequently, after the discovery ofHCV, first-generation immunoassays for anti-HCV reduced the frequency of transfusion-associated hepatitis even further. A prospective analysis of transfusion-associated hepatitis conducted between 1986 and 1990 showed that the incidence of transfusion-associated hepatitis at one urban university hospital fell from a baseline of 3.8% per patient (0.45% per unit transfused) to 1.5% per patient (0.19% per unit) after the introduction of surrogate testing and to 0.6% per patient (0.03% per unit) after the introduction of first-generation anti-HCV assays. The introduction of second-generation anti-HCV assays has reduced the frequency of transfusion-associated hepatitis C to almost imperceptible levels, 1 in 100,000.

In addition to being transmitted by transfusion, hepatitis C can be transmitted by other percutaneous routes, such as self-injection with intravenous drugs. In addition, this virus can be transmitted by occupational exposure to blood, and the likelihood of infection is increased in hemodialysis units. Although the frequency of transfusion-associated hepatitis C fell as a result of blood donor screening, the overall frequency of hepatitis C remained the same until the early 1990s, when the overall frequency fell by 80%, in parallel with a reduction in the number of new cases in injection drug users. After the exclusion of anti-HCV-positive plasma units from the donor pool, rare, sporadic instances have occurred of hepatitis C among recipients of immune globulin preparations for intravenous (but not intramuscular) use.

Serologic evidence for HCVinfection occurs in 90% of patients with a history of transfusion-associated hepatitis (almost all occurring before 1992, when second-generation HCV-screening tests were introduced), hemophiliacs and others treated with clotting factors, and injection-drug users; 60 to 70% of patients with sporadic "non-A, non-B" hepatitis who lack identifiable risk factors; 0.5% of volunteer blood donors; and 1.8% of the general population in the United States, which translates

into 4 million persons. Comparable frequencies of HCV infection occur in most countries around the world, but extraordinarily high prevalences of HCV infection occur in certain countries, such as Egypt, where more than 20% of the population in some cities is infected. In the United States, African Americans and Mexican Americans have higher frequencies of HCV infection than whites, and 30- to 49-year-old adult males have the highest frequencies of infection. Chronic hepatitis C accounts for 20% of sporadic acute hepatitis and 40% of chronic liver disease, is the most frequent indication for liver transplantation, and is estimated to account for 8000 to 10,000 deaths per year in the United States.

Most asymptomatic blood donors found to have anti-HCVand approximately 40% of persons with reported cases of acute hepatitis C do not fall into a recognized risk group; however, many such blood donors do recall risk-associated behaviors when questioned carefully, and most patients with acute hepatitis C in the absence of clear-cut risk factors tend to be of lower socioeconomic backgrounds. Thorough questioning of anti-HCV-reactive blood donors has identified nasal cocaine inhalation, with shared equipment, as a potential risk factor for acquiring HCV infection.

As a bloodborne infection,HCVpotentially can be transmitted sexually and perinatally; however, both of these modes of transmission are inefficient for hepatitis C. Although 10 to 15% of patients with acute hepatitis C report having potential sexual sources of infection, most studies have failed to identify sexual transmission of this agent. The chances of sexual and perinatal transmission have been estimated to be approximately 5%, well below comparable rates for HIV andHBVinfections. Moreover, sexual transmission appears to be confined to such subgroups as persons with multiple sexual partners and sexually transmitted diseases; transmission of HCV infection is rare between stable, monogamous sexual partners. Breast feeding does not increase the risk of HCV infection between an infected mother and her infant. Infection of health workers is not dramatically higher than among the general population; however, health workers are more likely to acquire HCV infection through accidental needle punctures, the efficiency of which ranges between 3 and 10%. Infection of household contacts is rare as well.

Other groups with an increased frequency ofHCVinfection include patients who require hemodialysis and organ transplantation and those who require transfusions in the setting of cancer chemotherapy. In immunosuppressed individuals, levels of anti-HCV may be undetectable, and a diagnosis may require testing for HCV RNA. Although new acute cases of hepatitis C are rare, newly diagnosed cases are common among otherwise healthy persons who experimented briefly with injection drugs two or three decades earlier. Such instances usually remain unrecognized for years, until unearthed by laboratory screening for routine medical examinations, insurance applications, and attempted blood donation.

Hepatitis E The enteric form of non-A, non-B hepatitis identified in India, Asia, Africa, and Central America resembles hepatitis A in its primarily enteric mode of spread. The commonly recognized cases occur after contamination of water supplies such as after monsoon flooding, but sporadic, isolated cases occur. An epidemiologic feature that distinguishesHEV from other enteric agents is the rarity of secondary person-to-person spread from infected persons to their close contacts. Infections arise in populations that

are immune toHAV and favor young adults. It is not known if hepatitis E occurs outside of recognized endemic areas, for example, in the United States, but preliminary studies suggest that HEV does not account for any of the sporadic "non-A, non-B" cases in nonendemic areas. Cases imported from endemic areas have been found in the United States.

CLINICAL AND LABORATORY FEATURES

Symptoms and Signs Acute viral hepatitis occurs after an incubation period that varies according to the responsible agent. Generally, incubation periods for hepatitis A range from 15 to 45 days (mean 4 weeks), for hepatitis B and D from 30 to 180 days (mean 4 to 12 weeks), for hepatitis C from 15 to 160 days (mean 7 weeks), and for hepatitis E from 14 to 60 days (mean 5 to 6 weeks). The *prodromal symptoms* of acute viral hepatitis are systemic and quite variable. Constitutional symptoms of anorexia, nausea and vomiting, fatigue, malaise, arthralgias, myalgias, headache, photophobia, pharyngitis, cough, and coryza may precede the onset of jaundice by 1 to 2 weeks. The nausea, vomiting, and anorexia are frequently associated with alterations in olfaction and taste. A low-grade fever between 38 and 39°C (100 to 102°F) is more often present in hepatitis A and E than in hepatitis B or C, except when hepatitis B is heralded by a serum sicknesslike syndrome; rarely, a fever of 39.5 to 40°C (103 to 104°F) may accompany the constitutional symptoms. Dark urine and clay-colored stools may be noticed by the patient from 1 to 5 days before the onset of clinical jaundice.

With the onset of *clinical jaundice*, the constitutional prodromal symptoms usually diminish, but in some patients mild weight loss (2.5 to 5 kg) is common and may continue during the entire icteric phase. The liver becomes enlarged and tender and may be associated with right upper quadrant pain and discomfort. Infrequently, patients present with a cholestatic picture, suggesting extrahepatic biliary obstruction. Splenomegaly and cervical adenopathy are present in 10 to 20% of patients with acute hepatitis. Rarely, a few spider angiomas appear during the icteric phase and disappear during convalescence. During the *recovery phase*, constitutional symptoms disappear, but usually some liver enlargement and abnormalities in liver biochemical tests are still evident. The duration of the posticteric phase is variable, ranging from 2 to 12 weeks, and usually is more prolonged in acute hepatitis B and C. Complete clinical and biochemical recovery is to be expected 1 to 2 months after all cases of hepatitis A and E and 3 to 4 months after the onset of jaundice in three-quarters of uncomplicated cases of hepatitis B and C. In the remainder, biochemical recovery may be delayed. A substantial proportion of patients with viral hepatitis never become icteric.

Infection withHDV can occur in the presence of acute or chronicHBVinfection; the duration of HBV infection determines the duration of HDV infection. When acute HDV and HBV infection occur simultaneously, clinical and biochemical features may be indistinguishable from those of HBV infection alone, although occasionally they are more severe. As opposed to patients with *acute* HBV infection, patients with *chronic* HBV infection can support HDV replication indefinitely. This can happen when acute HDV infection occurs in the presence of a nonresolving acute HBV infection. More commonly, acute HDV infection becomes chronic when it is superimposed on an underlying chronic HBV infection. In such cases, the HDV superinfection appears as a clinical exacerbation or an episode resembling acute viral hepatitis in someone already

chronically infected with HBV. Superinfection with HDV in a patient with chronic hepatitis B often leads to clinical deterioration (see below).

In addition to superinfections with other hepatitis agents, acute hepatitis-like clinical events in persons with chronic hepatitis B may accompany spontaneousHBeAg-to-anti-HBe seroconversion or spontaneous reactivation, i.e., reversion from nonreplicative to replicative infection. Such reactivations can occur as well in therapeutically immunosuppressed patients with chronicHBVinfection when cytotoxic-immunosuppressive drugs are withdrawn; in these cases, restoration of immune competence is thought to allow resumption of previously checked cell-mediated cytolysis of HBV-infected hepatocytes. Occasionally, acute clinical exacerbations of chronic hepatitis B may represent the emergence of a precore mutant (see "Virology and Etiology," above).

Laboratory Features The serum aminotransferases aspartate aminotransferase (AST) andALT(previously designated SGOT and SGPT) show a variable increase during the prodromal phase of acute viral hepatitis and precede the rise in bilirubin level (Figs. 295-2 and295-4). The acute level of these enzymes, however, does not correlate well with the degree of liver cell damage. Peak levels vary from 400 to 4000 IU or more; these levels are usually reached at the time the patient is clinically icteric and diminish progressively during the recovery phase of acute hepatitis. The diagnosis of anicteric hepatitis is difficult and requires a high index of suspicion; it is based on clinical features and on aminotransferase elevations, although mild increases in conjugated bilirubin also may be found.

Jaundice is usually visible in the sclera or skin when the serum bilirubin value exceeds 43 umol/L (2.5 mg/dL). When jaundice appears, the serum bilirubin typically rises to levels ranging from 85 to 340 umol/L (5 to 20 mg/dL). The serum bilirubin may continue to rise despite falling serum aminotransferase levels. In most instances, the total bilirubin is equally divided between the conjugated and unconjugated fractions. Bilirubin levels above 340 umol/L (20 mg/dL) extending and persisting late into the course of viral hepatitis are more likely to be associated with severe disease. In certain patients with underlying hemolytic anemia, however, such as glucose-6-phosphate dehydrogenase deficiency and sickle cell anemia, a high serum bilirubin level is common, resulting from superimposed hemolysis. In such patients, bilirubin levels greater than 513 umol/L (30 mg/dL) have been observed and are not necessarily associated with a poor prognosis.

Neutropenia and lymphopenia are transient and are followed by a relative lymphocytosis. Atypical lymphocytes (varying between 2 and 20%) are common during the acute phase. These atypical lymphocytes are indistinguishable from those seen in infectious mononucleosis. Measurement of the prothrombin time (PT) is important in patients with acute viral hepatitis, for a prolonged value may reflect a severe synthetic defect, signify extensive hepatocellular necrosis, and indicate a worse prognosis. Occasionally, a prolonged PT may occur with only mild increases in the serum bilirubin and aminotransferase levels. Prolonged nausea and vomiting, inadequate carbohydrate intake, and poor hepatic glycogen reserves may contribute to hypoglycemia noted occasionally in patients with severe viral hepatitis. Serum alkaline phosphatase may be normal or only mildly elevated, while a fall in serum albumin is uncommon in uncomplicated acute viral hepatitis. In some patients, mild and transient steatorrhea has

been noted as well as slight microscopic hematuria and minimal proteinuria.

A diffuse but mild elevation of the gamma globulin fraction is common during acute viral hepatitis. Serum IgG and IgM levels are elevated in about one-third of patients during the acute phase of viral hepatitis, but the serum IgM level is elevated more characteristically during acute hepatitis A. During the acute phase of viral hepatitis, antibodies to smooth muscle and other cell constituents may be present, and low titers of rheumatoid factor, nuclear antibody, and heterophil antibody also can be found occasionally. In hepatitis C and D, antibodies to liver-kidney microsomes (LKM) may occur; however, the species of LKM antibodies in the two types of hepatitis are different from each other as well as from the LKM antibody species characteristic of autoimmune chronic hepatitis type 2 (Chap. 297). The autoantibodies in viral hepatitis are nonspecific and also can be associated with other viral and systemic diseases. In contrast, virus-specific antibodies, which appear during and after hepatitis virus infection, are serologic markers of diagnostic importance.

As described above, serologic tests are available with which to establish a diagnosis of hepatitis A, B, D, and C. Tests for fecal or serum HAV are not routinely available. Therefore, a diagnosis of type A hepatitis is based on detection of IgM anti-HAV during acute illness (Fig. 295-2). Rheumatoid factor can give rise to false-positive results in this test.

A diagnosis of HBV infection can usually be made by detection of HBsAg in serum. Infrequently, levels of HBsAg are too low to be detected during acute HBV infection, even with the current generation of highly sensitive immunoassays. In such cases, the diagnosis can be established by the presence of IgM anti-HBc.

The titer of HBsAg bears little relation to the severity of clinical disease. Indeed, there may be an inverse correlation between the serum concentration of HBsAg and the degree of liver cell damage. For example, titers are highest in immunosuppressed patients, lower in patients with chronic liver disease (but higher in mild chronic than in severe chronic hepatitis), and very low in patients with acute fulminant hepatitis. These observations suggest that in hepatitis B the degree of liver cell damage and the clinical course are probably related to variations in the patient's immune response to HBV rather than to the amount of circulating HBsAg. In immunocompetent persons, however, there is a correlation between markers of HBV *replication* and liver injury (see below).

Another serologic marker that may be of value in patients with hepatitis B is HBeAg. Its principal clinical usefulness is as an indicator of relative infectivity. Because HBeAg is invariably present during early acute hepatitis B, HBeAg testing is indicated primarily during follow-up of chronic infection.

In patients with hepatitis B surface antigenemia of unknown duration, e.g., blood donors found to be HBsAg-positive and referred to a physician for evaluation, testing for IgM anti-HBc may be useful to distinguish between acute or recent infection (IgM anti-HBc-positive) and chronic HBV infection (IgM anti-HBc-negative, IgG anti-HBc-positive). A false-positive test for IgM anti-HBc may be encountered in patients with high-titer rheumatoid factor.

Anti-HBs is rarely detectable in the presence ofHBsAg in patients with *acute* hepatitis B, but 10 to 20% of persons with *chronic*HBVinfection may harbor low-level anti-HBs. This antibody is directed not against the common group determinant, *a*, but against the heterotypic subtype determinant (e.g., HBsAg of subtype *ad* with anti-HBs of subtype *y*). In most cases, this serologic pattern cannot be attributed to infection with two different HBV subtypes, and the presence of this antibody is not a harbinger of imminent HBsAg clearance. When such antibody is detected, its presence is of no recognized clinical significance (see "Virology and Etiology," above).

After immunization with hepatitis B vaccine, which consists ofHBsAgalone, anti-HBs is the only serologic marker to appear. The commonly encountered serologic patterns of hepatitis B and their interpretations are summarized inTable 295-3. Tests for the detection ofHBV DNA in liver and serum are now available. LikeHBeAg, serum HBV DNA is an indicator of HBV replication, but tests for HBV DNA are more sensitive and quantitative. Hybridization assays for HBV DNA have a sensitivity of approximately 10^5 to 10^6virions/mL, a relative threshold below which infectivity and liver injury are limited and HBeAg is usually undetectable. Currently, testing for HBV DNA has shifted from insensitive hybridization assays to amplification assays, e.g., the polymerase chain reaction-based assay, which can detect as few as 100 or 1000 virions/mL. With increased sensitivity, amplification assays remain reactive well below the threshold for infectivity and liver injury. These markers are useful in following the course of HBV replication in patients with chronic hepatitis B receiving antiviral chemotherapy, e.g., with interferon or lamivudine (Chap. 297). In immunocompetent persons, a general correlation does appear to exist between the level of HBV replication, as reflected by the level of HBV DNA in serum, and the degree of liver injury. High serum HBV DNA levels, increased expression of viral antigens, and necroinflammatory activity in the liver go hand in hand unless immunosuppression interferes with cytolytic T cell responses to virus-infected cells; reduction of HBV replication with antiviral drugs tends to be accompanied by an improvement in liver histology.

In patients with hepatitis C, an episodic pattern of aminotransferase elevation is common. A specific serologic diagnosis of hepatitis C can be made by demonstrating the presence in serum of anti-HCV. When a second- or third-generation immunoassay (that detects antibodies to nonstructural and nucleocapsid proteins) is used, anti-HCV can be detected in acute hepatitis C during the initial phase of elevated aminotransferase activity. This antibody may never become detectable in 5 to 10% of patients with acute hepatitis C, and levels of anti-HCV may become undetectable after recovery from acute hepatitis C. In patients with chronic hepatitis C, anti-HCV is detectable in >95% of cases. Nonspecificity can confound immunoassays for anti-HCV, especially in persons with a low prior probability of infection, such as volunteer blood donors, or in persons with circulating rheumatoid factor, which can bind nonspecifically to assay reagents. A supplementary recombinant immunoblot assay (RIBA), in which serum is incubated with a nitrocellulose strip containing viral protein bands, can be used to establish the specific viral proteins to which anti-HCV is directed (see "Virology and Etiology," above). Such RIBA determinations are used routinely to confirm anti-HCV reactivity in blood donors, but determinations of HCV RNA have supplanted RIBA in many clinical settings. Assays for HCV RNA are the most sensitive tests for HCV infection and represent the "gold standard" in establishing a diagnosis of hepatitis C. HCV RNA can be detected even before acute elevation of aminotransferase activity and

before the appearance of anti-HCV in patients with acute hepatitis C. In addition, HCV RNA remains detectable indefinitely, continuously in most but intermittently in some, in patients with chronic hepatitis C (even detectable in some persons with normal liver tests, i.e., asymptomatic carriers). In the small minority of patients with hepatitis C who lack anti-HCV, a diagnosis can be supported by detection of HCV RNA. If all these tests are negative and the patient has a well-characterized case of hepatitis after percutaneous exposure to blood or blood products, a diagnosis of hepatitis caused by another agent, as yet unidentified, can be entertained.

Amplification techniques are required to detectHCV RNA, and two are available. One is a branched-chain complementary DNA (bDNA) assay, in which the detection signal (a colorimetrically detectable enzyme bound to a complementary DNA probe) is amplified. The other is aPCRassay, in which the viral RNA is reverse transcribed to complementary DNA and then amplified by repeated cycles of DNA synthesis and polymerization. Both can be used as quantitative assays and a measurement of relative "viral load"; PCR, with a sensitivity of 10^2 to 10^3virions per milliliter is more sensitive than bDNA, with a sensitivity of $2´10^5$. Determination of viral load is not a reliable marker of disease severity or prognosis but is helpful in predicting relative responsiveness to antiviral therapy. The same is true for determinations of HCV genotype (Chap. 297).

A proportion of patients with hepatitis C have isolated anti-HBc in their blood, a reflection of a common risk in certain populations to multiple bloodborne hepatitis agents. The anti-HBc in such cases is almost invariably of the IgG class and usually representsHBVinfection in the remote past, rarely current HBV infection with low-level virus carriage.

The presence ofHDVinfection can be identified by demonstrating intrahepatic HDV antigen or, more practically, an anti-HDV seroconversion (a rise in titer of anti-HDV or de novo appearance of anti-HDV). Circulating HDV antigen, also diagnostic of acute infection, is detectable only briefly, if at all. Because anti-HDV is often undetectable onceHBsAgdisappears, retrospective serodiagnosis of acute self-limited, simultaneousHBV and HDV infection is difficult. Early diagnosis of acute infection may be hampered by a delay of up to 30 to 40 days in the appearance of anti-HDV.

When a patient presents with acute hepatitis and hasHBsAgand anti-HDVin serum, determination of the class of anti-HBc is helpful in establishing the relationship between infection withHBV and HDV. Although IgM anti-HBc does not distinguish *absolutely* between acute and chronic HBV infection, its presence is a reliable indicator of recent infection and its absence a reliable indicator of infection in the remote past. In simultaneous acute HBV and HDV infections, IgM anti-HBc will be detectable, while in acute HDV infection superimposed on chronic HBV infection, anti-HBc will be of the IgG class.

Tests for the presence ofHDV RNA are useful for determining the presence of ongoing HDV replication and relative infectivity. Currently, probes for this marker are restricted to a limited number of research laboratories. Similarly, diagnostic tests for hepatitis E are confined to a small number of research laboratories.

Liver biopsy is rarely necessary or indicated in acute viral hepatitis, except when there is

a question about the diagnosis or when there is clinical evidence suggesting a diagnosis of chronic hepatitis.

A diagnostic algorithm can be applied in the evaluation of cases of acute viral hepatitis. A patient with acute hepatitis should undergo four serologic tests,HBsAg, IgM anti-HAV, IgM anti-HBc, and anti-HCV(Table 295-4). The presence of HBsAg, with or without IgM anti-HBc, represents HBV infection. If IgM anti-HBc is present, the HBV infection is considered acute; if IgM anti-HBc is absent, theHBVinfection is considered chronic. A diagnosis of acute hepatitis B can be made in the absence of HBsAg when IgM anti-HBc is detectable. A diagnosis of acute hepatitis A is based on the presence of IgM anti-HAV. If IgM anti-HAV coexists with HBsAg, a diagnosis of simultaneous HAV and HBV infections can be made; if IgM anti-HBc (with or without HBsAg) is detectable, the patient has simultaneous acute hepatitis A and B, and if IgM anti-HBc is undetectable, the patient has acute hepatitis A superimposed on chronic HBV infection. The presence of anti-HCV, if confirmable, supports a diagnosis of acute hepatitis C. Occasionally, testing for HCV RNA or repeat anti-HCV testing later during the illness is necessary to establish the diagnosis. Absence of all serologic markers is consistent with a diagnosis of "non-A, non-B, non-C" hepatitis, if the epidemiologic setting is appropriate.

In patients with chronic hepatitis, initial testing should consist ofHBsAgand anti-HCV. Anti-HCV supports and HCV RNA testing establishes the diagnosis of chronic hepatitis C. If a serologic diagnosis of chronic hepatitis B is made, testing forHBeAgand anti-HBe is indicated to evaluate relative infectivity. Testing forHBV DNA in such patients provides a more quantitative and sensitive measure of the level of virus replication and, therefore, is very helpful during antiviral therapy (Chap. 297). In patients with hepatitis B, testing for anti-HDVis useful under the following circumstances: patients with severe and fulminant diseases, patients with severe chronic disease, patients with chronic hepatitis B who have acute hepatitis-like exacerbations, persons with frequent percutaneous exposures, and persons from areas where HDV infection is endemic.

PROGNOSIS

Virtually all previously healthy patients with hepatitis A recover completely from their illness with no clinical sequelae. Similarly, in acute hepatitis B, 95 to 99% of previously healthy adults have a favorable course and recover completely. There are, however, certain clinical and laboratory features that suggest a more complicated and protracted course. Patients of advanced age and with serious underlying medical disorders may have a prolonged course and are more likely to experience severe hepatitis. Initial presenting features such as ascites, peripheral edema, and symptoms of hepatic encephalopathy suggest a poorer prognosis. In addition, a prolongedPT, low serum albumin level, hypoglycemia, and very high serum bilirubin values suggest severe hepatocellular disease. Patients with these clinical and laboratory features deserve prompt hospital admission. The case-fatality rate in hepatitis A and B is very low (approximately 0.1%) but is increased by advanced age and underlying debilitating disorders. Among patients ill enough to be hospitalized for acute hepatitis B, the fatality rate is 1%. Hepatitis C occurring after transfusion is less severe during the acute phase than hepatitis B and is more likely to be anicteric; fatalities are rare, but the precise case-fatality rate is not known. In outbreaks of waterborne hepatitis E in India and Asia, the case-fatality rate is 1 to 2% and up to 10 to 20% in pregnant women. Patients with

simultaneous acute hepatitis B and hepatitis D do not necessarily experience a higher mortality rate than do patients with acute hepatitis B alone; however, in several recent outbreaks of acute simultaneousHBV andHDVinfection among injection drug users, the case-fatality rate has been approximately 5%. In the case of HDV superinfection of a person with chronic hepatitis B, the likelihood of fulminant hepatitis and death is increased substantially. Although the case-fatality rate for hepatitis D has not been defined adequately, in outbreaks of severe HDV superinfection in isolated populations with a high hepatitis B carrier rate, the mortality rate has been recorded in excess of 20%.

COMPLICATIONS AND SEQUELAE

A small proportion of patients with hepatitis A experience *relapsing hepatitis* weeks to months after apparent recovery from acute hepatitis. Relapses are characterized by recurrence of symptoms, aminotransferase elevations, occasionally jaundice, and fecal excretion ofHAV. Another unusual variant of acute hepatitis A is *cholestatic hepatitis*, characterized by protracted cholestatic jaundice and pruritus. Rarely, liver test abnormalities persist for many months, even up to a year. Even when these complications occur, hepatitis A remains self-limited and does not progress to chronic liver disease. During the prodromal phase of acute hepatitis B, a serum sickness-like syndrome characterized by arthralgia or arthritis, rash, angioedema, and rarely hematuria and proteinuria may develop in 5 to 10% of patients. This syndrome occurs before the onset of clinical jaundice, and these patients are often erroneously diagnosed as having rheumatologic diseases. The diagnosis can be established by measuring serum aminotransferase levels, which are almost invariably elevated, and serumHBsAg. As noted above,EMC is an immune-complex disease that can complicate hepatitis C. Attention has been drawn as well to associations between hepatitis C and such cutaneous disorders as porphyria cutanea tarda and lichen planus. A mechanism for these associations is unknown.

The most feared complication of viral hepatitis is *fulminant hepatitis* (massive hepatic necrosis); fortunately, this is a rare event. Fulminant hepatitis is primarily seen in hepatitis B and D, as well as hepatitis E, but rare fulminant cases of hepatitis A occur primarily in older adults and in persons with underlying chronic liver disease. Hepatitis B accounts for more than 50% of fulminant hepatitis cases, a sizable proportion of which are associated withHDVinfection. Participation of HDV can be documented in approximately one-third of patients with acute fulminant hepatitis B and two-thirds of patients with fulminant hepatitis superimposed on chronic hepatitis B. Fulminant hepatitis is seen rarely in hepatitis C, but hepatitis E, as noted above, can be complicated by fatal fulminant hepatitis in 1 to 2% of all cases and in up to 20% of cases occurring in pregnant women. Patients usually present with signs and symptoms of encephalopathy that may evolve to deep coma. The liver is usually small and thePTexcessively prolonged. The combination of rapidly shrinking liver size, rapidly rising bilirubin level, and marked prolongation of the PT, even as aminotransferase levels fall, together with clinical signs of confusion, disorientation, somnolence, ascites, and edema, indicates that the patient has hepatic failure with encephalopathy. Cerebral edema is common; brainstem compression, gastrointestinal bleeding, sepsis, respiratory failure, cardiovascular collapse, and renal failure are terminal events. The mortality rate is exceedingly high (greater than 80% in patients with deep coma), but

patients who survive may have a complete biochemical and histologic recovery. If a donor liver can be located in time, liver transplantation may be life-saving in patients with fulminant hepatitis.

It is particularly important to document the disappearance ofHBsAgafter apparent clinical recovery from acute hepatitis B. Before laboratory methods were available to distinguish between acute hepatitis and acute hepatitis-like exacerbations (*spontaneous reactivations*) of chronic hepatitis B, observations suggested that approximately 10% of patients remained HBsAg-positive for longer than 6 months after the onset of clinically apparent acute hepatitis B. Half these persons cleared the antigen from their circulations during the next several years, but the other 5% remained chronically HBsAg-positive. More recent observations suggest that the true rate of chronic infection after clinically apparent acute hepatitis B is as low as 1% in normal, immunocompetent, young adults. Earlier, higher estimates may have been biased by inadvertent inclusion of acute exacerbations in chronically infected patients; these patients, chronically HBsAg-positive before exacerbation, were unlikely to seroconvert to HBsAg-negative thereafter. Whether the rate of chronicity is 10 or 1%, such patients have anti-HBc in serum; anti-HBs is either undetected or detected at low titer against the opposite subtype specificity of the antigen (see "Laboratory Features," above). These patients may (1) be asymptomatic carriers, (2) have low-grade, mild chronic hepatitis, or (3) have moderate to severe chronic hepatitis with or without cirrhosis. The likelihood of becoming an HBsAg carrier after acuteHBVinfection is especially high among neonates, persons with Down's syndrome, chronically hemodialyzed patients, and immunosuppressed patients, including persons with HIV infection.

Chronic hepatitis is an important late complication of acute hepatitis B occurring in a small proportion of patients with acute disease but more common in those who present with chronic infection without having experienced an acute illness (Chap. 297). Certain clinical and laboratory features suggest progression of acute hepatitis to chronic hepatitis: (1) lack of complete resolution of clinical symptoms of anorexia, weight loss, and fatigue and the persistence of hepatomegaly; (2) the presence of bridging or multilobular hepatic necrosis on liver biopsy during protracted, severe acute viral hepatitis; (3) failure of the serum aminotransferase, bilirubin, and globulin levels to return to normal within 6 to 12 months after the acute illness; and (4) the persistence ofHBeAgbeyond 3 months orHBsAgbeyond 6 months after acute hepatitis.

Although acute hepatitis D infection does not increase the likelihood of chronicity of simultaneous acute hepatitis B, hepatitis D has the potential for contributing to the severity of chronic hepatitis B. Hepatitis D superinfection can transform asymptomatic or mild chronic hepatitis B into severe, progressive chronic hepatitis and cirrhosis; it also can accelerate the course of chronic hepatitis B. SomeHDVsuperinfections in patients with chronic hepatitis B lead to fulminant hepatitis. Although HDV andHBVinfections are associated with severe liver disease, mild hepatitis and even asymptomatic carriage have been identified in some patients, and the disease may become indolent beyond the early years of infection. After transfusion-associated acute hepatitis C, at least 50% of patients have abnormal biochemical liver tests for more than a year. In some experiences, the frequency of progression to chronicity after acute hepatitis C is as high as 70%. In most of these patients, liver histology is consistent with moderate to severe chronic hepatitis. Even among those who recover biochemically, the likelihood of

retaining circulatingHCV RNA is high. Thus, after acute HCV infection, the likelihood of remaining chronically *infected* approaches 85 to 90%. Although many patients with chronic hepatitis C have no symptoms, cirrhosis may develop in as many as 20% within 10 to 20 years of acute illness; in some series of cases, cirrhosis has been reported in as many as 50% of patients with chronic hepatitis C. Although chronic hepatitis C accounts for at least a quarter of cases of chronic liver disease and a quarter of patients undergoing liver transplantation for end-stage liver disease in the United States and Europe, in the majority of patients with chronic hepatitis C, morbidity and mortality are limited during the initial 20 years after the onset of infection. Progression of chronic hepatitis C may be influenced by hepatitis C genotype, age of acquisition, duration of infection, and immunosuppression, as well as by coexisting excessive alcohol use or other hepatitis virus infection. In contrast, neitherHAV norHEVcauses chronic liver disease.

Rare complications of viral hepatitis include pancreatitis, myocarditis, atypical pneumonia, aplastic anemia, transverse myelitis, and peripheral neuropathy. *Carriers* ofHBsAg, particularly those infected in infancy or early childhood, have an enhanced risk of hepatocellular carcinoma. The risk of hepatocellular carcinoma is increased as well in patients with chronic hepatitis C, almost exclusively in patients with cirrhosis, and almost always after at least several decades, usually after three decades of disease (see Chap. 91). In children, hepatitis B may present rarely with anicteric hepatitis, a nonpruritic papular rash of the face, buttocks, and limbs, and lymphadenopathy (papular acrodermatitis of childhood or Gianotti-Crosti syndrome).

DIFFERENTIAL DIAGNOSIS

Viral diseases such as infectious mononucleosis; those due to cytomegalovirus, herpes simplex, and coxsackieviruses; and toxoplasmosis may share certain clinical features with viral hepatitis and cause elevations in serum aminotransferase and less commonly in serum bilirubin levels. Tests such as the differential heterophile and serologic tests for these agents may be helpful in the differential diagnosis ifHBsAg, anti-HBc, IgM anti-HAV, and anti-HCVdeterminations are negative. Aminotransferase elevations can accompany almost any systemic viral infection; other rare causes of liver injury confused with viral hepatitis are infections with *Leptospira*, *Candida*, *Brucella*, *Mycobacteria*, and *Pneumocystis*. A complete drug history is particularly important, for many drugs and certain anesthetic agents can produce a picture of either acute hepatitis or cholestasis (Chap. 296). Equally important is a past history of unexplained "repeated episodes" of acute hepatitis. This history should alert the physician to the possibility that the underlying disorder is chronic hepatitis. Alcoholic hepatitis also must be considered, but usually the serum aminotransferase levels are not as markedly elevated and other stigmata of alcoholism may be present. The finding on liver biopsy of fatty infiltration, a neutrophilic inflammatory reaction, and "alcoholic hyaline" would be consistent with alcohol-induced rather than viral liver injury. Because acute hepatitis may present with right upper quadrant abdominal pain, nausea and vomiting, fever, and icterus, it is often confused with acute cholecystitis, common duct stone, or ascending cholangitis. Patients with acute viral hepatitis may tolerate surgery poorly; therefore, it is important to exclude this diagnosis, and in confusing cases, a percutaneous liver biopsy may be necessary before laparotomy. Viral hepatitis in the elderly is often misdiagnosed as obstructive jaundice resulting from a common duct stone or carcinoma of the

pancreas. Because acute hepatitis in the elderly may be quite severe and the operative mortality high, a thorough evaluation including biochemical tests, radiographic studies of the biliary tree, and even liver biopsy may be necessary to exclude primary parenchymal liver disease. Another clinical constellation that may mimic acute hepatitis is right ventricular failure with passive hepatic congestion or hypoperfusion syndromes, such as those associated with shock, severe hypotension, and severe left ventricular failure. Also included in this general category is any disorder that interferes with venous return to the heart, such as right atrial myxoma, constrictive pericarditis, hepatic vein occlusion (Budd-Chiari syndrome), or venoocclusive disease. Clinical features are usually sufficient to distinguish between these vascular disorders and viral hepatitis. Acute fatty liver of pregnancy, cholestasis of pregnancy, eclampsia, and the HELLP syndrome (hemolysis, elevated liver tests, and low platelets) can be confused with viral hepatitis during pregnancy. Very rarely, malignancies metastatic to the liver can mimic acute or even fulminant viral hepatitis. Occasionally, genetic or metabolic liver disorders (e.g., Wilson's disease,a_1-antitrypsin deficiency) are confused with viral hepatitis.

TREATMENT

Treatment of Acute Attack Although therapy has been developed for chronic hepatitis B and C (Chap. 297), opportunities for treating acute hepatitis caused byHBV orHCV are limited. In hepatitis B, among previously healthy adults who present with clinically apparent acute hepatitis, recovery occurs in approximately 99%; therefore, antiviral therapy is not likely to improve the rate of recovery and is not required. In rare instances of severe acute hepatitis B, treatment with a nucleoside analogue, such as lamivudine, at the 100-mg/d oral dose used to treat chronic hepatitis B (Chap. 297), has been attempted successfully. However, clinical trials have not been done to establish the efficacy of this approach, severe acute hepatitis B is not an approved indication for therapy, and the duration of therapy has not been determined. In typical cases of acute hepatitis C, recovery is rare, progression to chronic hepatitis is the rule, occurring in 85 to 90% of patients, and meta-analyses of small clinical trials suggest that antiviral therapy with interferon alpha (3 million units subcutaneously three times a week) is beneficial, reducing the rate of chronicity considerably by inducing sustained responses in 40% of patients. The duration of therapy and whether to add the nucleoside analogue ribavirin remain to be determined, but the most reasonable approach is to follow recommendations for treatment of chronic hepatitis C (Chap 297). Because of the marked reduction over the last two decades in the frequency of acute hepatitis C, opportunities to identify and treat patients with acute hepatitis C are rare indeed. Hospital epidemiologists, however, will encounter health workers who sustain hepatitis C-contaminated needle sticks; when monitoring forALTelevations and HCV RNA after these accidents identifies acute hepatitis C, therapy should be initiated.

Notwithstanding these specific therapeutic considerations, in most cases of typical acute viral hepatitis, specific treatment generally is not necessary. Although hospitalization may be required for clinically severe illness, most patients do not require hospital care. Forced and prolonged bed rest is not essential for full recovery, but many patients will feel better with restricted physical activity. A high-calorie diet is desirable, and because many patients may experience nausea late in the day, the major caloric intake is best tolerated in the morning. Intravenous feeding is necessary in the acute stage if the patient has persistent vomiting and cannot maintain oral intake. Drugs capable of

producing adverse reactions such as cholestasis and drugs metabolized by the liver should be avoided. If severe pruritus is present, the use of the bile salt-sequestering resin cholestyramine will usually alleviate this symptom. Glucocorticoid therapy has no value in acute viral hepatitis. Even in severe cases associated with *bridging necrosis*, controlled trials have failed to demonstrate the efficacy of steroids. In fact, such therapy may be hazardous.

Physical isolation of patients with hepatitis to a single room and bathroom is rarely necessary except in the case of fecal incontinence for hepatitis A and E or uncontrolled, voluminous bleeding for hepatitis B (with or without concomitant hepatitis D) and hepatitis C. Because most patients hospitalized with hepatitis A excrete little if anyHAV, the likelihood of HAV transmission from these patients during their hospitalization is low. Therefore, burdensome *enteric precautions are no longer recommended*. Although gloves should be worn when the bedpans or fecal material of patients with hepatitis A are handled, these precautions do not represent a departure from sensible procedure for all hospitalized patients. For patients with hepatitis B and hepatitis C, emphasis should be placed on blood precautions, i.e., avoiding direct, ungloved hand contact with blood and other body fluids. Enteric precautions are unnecessary. The importance of simple hygienic precautions, such as hand washing, cannot be overemphasized. Universal precautions that have been adopted for all patients apply to patients with viral hepatitis.

Hospitalized patients may be discharged when there is substantial symptomatic improvement, a significant downward trend in the serum aminotransferase and bilirubin values, and a return to normal of thePT. Mild aminotransferase elevations should not be considered contraindications to the gradual resumption of normal activity.

In *fulminant hepatitis*, the goal of therapy is to support the patient by maintenance of fluid balance, support of circulation and respiration, control of bleeding, correction of hypoglycemia, and treatment of other complications of the comatose state in anticipation of liver regeneration and repair. Protein intake should be restricted, and oral lactulose or neomycin administered. Glucocorticoid therapy has been shown in controlled trials to be ineffective. Likewise, exchange transfusion, plasmapheresis, human cross-circulation, porcine liver cross-perfusion, and hemoperfusion have not been proven to enhance survival. Meticulous intensive care is the one factor that does appear to improve survival. Orthotopic liver transplantation is resorted to with increasing frequency, with excellent results, in patients with fulminant hepatitis (Chap. 301).

PROPHYLAXIS

Because application of therapy for acute viral hepatitis is limited, and because antiviral therapy for chronic viral hepatitis is effective in only a proportion of patients (Chap. 297), emphasis is placed on prevention through immunization. The prophylactic approach differs for each of the types of viral hepatitis. In the past, immunoprophylaxis relied exclusively on passive immunization with antibody-containing globulin preparations purified by cold ethanol fractionation from the plasma of hundreds of normal donors. Currently, for hepatitis A and B, active immunization with vaccines is available as well.

Hepatitis A Both passive immunization with immune globulin (IG) and active

immunization with a killed vaccine are available. All preparations of IG contain anti-HAVconcentrations sufficient to be protective. When administered before exposure or during the early incubation period, IG is effective in preventing clinically apparent hepatitis A. In some cases, IG does not abort infection but, by attenuating it, renders it inapparent. As a result, long-lasting "passive-active" immunity occurs; however, this is now considered to be the exception rather than the rule. For postexposure prophylaxis of intimate contacts (household, institutional) of persons with hepatitis A, the administration of 0.02 mL/kg is recommended as early after exposure as possible; it may be effective even when administered as late as 2 weeks after exposure. Prophylaxis is not necessary for casual contacts (office, factory, school, or hospital), for most elderly persons, who are very likely to be immune, or for those known to have anti-HAV in their serum. In day-care centers, recognition of hepatitis A in children or staff should provide a stimulus for immunoprophylaxis in the center and in the children's family members. By the time most common-source outbreaks of hepatitis A are recognized, it is usually too late in the incubation period for IG to be effective; however, prophylaxis may limit the frequency of secondary cases. For travelers to tropical countries, developing countries, and other areas outside standard tourist routes, IG prophylaxis had been recommended, before a vaccine became available. When such travel lasted less than 3 months, 0.02 mL/kg was given; for longer travel or residence in these areas, a dose of 0.06 mL/kg every 4 to 6 months was recommended. Administration of plasma-derived globulin is safe; it has not been associated with transmission of AIDS to recipients, and the AIDS virus (HIV) is inactivated by 25% alcohol, to which plasma is subjected during the cold ethanol fractionation process.

Formalin-inactivated vaccines made from strains ofHAVattenuated in tissue culture have been shown to be safe, immunogenic, and effective in preventing hepatitis A. Hepatitis A vaccines are approved for use in persons who are at least 2 years old and appear to provide adequate protection 4 weeks after a primary inoculation. If it can be given within 4 weeks of an expected exposure, such as by travel to an endemic area, hepatitis A vaccine is the preferred approach to *preexposure* immunoprophylaxis. If travel is more imminent,IG (0.02 mL/kg) should be administered at a different injection site, along with the first dose of vaccine. Because vaccination provides long-lasting protection (protective levels of anti-HAV should last 20 years after vaccination), persons whose risk will be sustained (e.g., frequent travelers or those remaining in endemic areas for prolonged periods) should be vaccinated, and vaccine should supplant the need for repeated IG injections. Other groups who are candidates for hepatitis A vaccination include military personnel, populations with cyclic outbreaks of hepatitis A (e.g., Alaskan natives), employees of day-care centers, primate handlers, laboratory workers exposed to hepatitis A or fecal specimens, children in communities with a high frequency of hepatitis A, and patients with chronic liver disease. Because of an increased risk of fulminant hepatitis A -- observed in some experiences but not confirmed in others -- among patients with chronic hepatitis C, patients with chronic hepatitis C have been singled out as candidates for hepatitis A vaccination. Other populations whose recognized risk of hepatitis A is increased should be vaccinated, including men who have sex with men, injection drug users, and persons with clotting disorders who require frequent administration of clotting-factor concentrates. Recommendations for dose and frequency differ for the two approved vaccine preparations; all injections are intramuscular. For the hepatitis A vaccine manufactured by SmithKline Beecham (Havrix), adults (older than 18 years) should receive two

1.0-mL injections containing 1440 enzyme-linked immunoassay units (ELU) 6 to 12 months apart. Children age 2 to 18 years should receive three 0.5-mL injections containing 360 ELU at time zero, 6, and 12 months or two 0.5-mL injections containing 720 ELU 6 to 12 months apart. For the hepatitis A vaccine manufactured by Merck (Vaqta), adults (older than 17 years) should receive two 1.0-mL injections containing 50 units 6 months apart; children age 2 to 17 years should receive two 0.5-mL doses containing 25 units 6 to 18 months apart. Hepatitis A vaccine has been reported to be effective in preventing secondary household cases of acute hepatitis A, but its role in other instances of postexposure prophylaxis remains to be demonstrated.

Hepatitis B Until 1982, prevention of hepatitis B was based on *passive* immunoprophylaxis either with standardIG, containing modest levels of anti-HBs, or hepatitis B immune globulin (HBIG), containing high-titer anti-HBs. The efficacy of standard IG has never been established and remains questionable; even the efficacy of HBIG, demonstrated in several clinical trials, has been challenged, and its contribution appears to be in reducing the frequency of clinical *illness*, not in preventing *infection*. The first vaccine for *active* immunization, introduced in 1982, was prepared from purified, noninfectious 22-nm spherical forms ofHBsAgderived from the plasma of healthy HBsAg carriers. In 1987, the plasma-derived vaccine was supplanted by a genetically engineered vaccine derived from recombinant yeast. The latter vaccine consists of HBsAg particles that are nonglycosylated but are otherwise indistinguishable from natural HBsAg; two recombinant vaccines are licensed for use in the United States. Current recommendations can be divided into those for preexposure and postexposure prophylaxis.

For *preexposure* prophylaxis against hepatitis B in settings of frequent exposure (health workers exposed to blood, hemodialysis patients and staff, residents and staff of custodial institutions for the developmentally handicapped, injection drug users, inmates of long-term correctional facilities, promiscuous homosexual men as well as promiscuous heterosexual individuals, persons such as hemophiliacs who require long-term, high-volume therapy with blood derivatives, household and sexual contacts ofHBsAgcarriers, persons living in or traveling extensively in endemic areas, unvaccinated children under the age of 18, and unvaccinated children who are Alaskan natives, Pacific Islanders, or residents in households of first-generation immigrants from endemic countries), three intramuscular (deltoid, not gluteal) injections of hepatitis B vaccine are recommended at 0, 1, and 6 months. Pregnancy is *not* a contraindication to vaccination. In areas of lowHBVendemicity such as the United States, despite the availability of safe and effective hepatitis B vaccines, a strategy of vaccinating persons in high-risk groups has not been effective. The incidence of new hepatitis B cases continued to increase in the United States after introduction of vaccines; fewer than 10% of all targeted persons in high-risk groups have actually been vaccinated, and approximately 30% of persons with sporadic acute hepatitis B do not fall into any high-risk-group category. Therefore, to have an impact on the frequency of HBV infection in an area of low endemicity such as the United States, universal hepatitis B vaccination in childhood has been recommended. For unvaccinated children born after the implementation of universal infant vaccination, vaccination during early adolescence, at age 11 to 12 years, was recommended, and this recommendation has been extended to include all unvaccinated children age 0 to 18 years.

The two available recombinant hepatitis B vaccines are comparable, one containing 10 ug ofHBsAg(Recombivax-HB) and the other containing 20 ug of HBsAg (Engerix-B), and recommended doses for each injection vary for the two preparations. For Recombivax-HB, 2.5 ug is recommended for children<11 years of age born to HBsAg-negative mothers, 5 ug for infants born to HBsAg-positive mothers (see below) and for children and adolescents 11 to 19 years of age; 10 ug for immunocompetent adults; and 40 ug for dialysis patients and other immunosuppressed persons. For Engerix-B, 10 ug is recommended for children aged 10 and under, 20 ug for immunocompetent children older than 10 years of age and adults, and 40 ug for dialysis patients and other immunocompromised persons.

For unvaccinated persons sustaining an exposure toHBV, *postexposure* prophylaxis with a combination ofHBIG(for rapid achievement of high-titer circulating anti-HBs) and hepatitis B vaccine (for achievement of long-lasting immunity as well as its apparent efficacy in attenuating clinical illness after exposure) is recommended. For *perinatal* exposure of infants born toHBsAg-positive mothers, a single dose of HBIG, 0.5 mL, should be administered intramuscularly in the thigh *immediately after birth*, followed by a complete course of three injections of recombinant hepatitis B vaccine (see doses above) to be started within the first 12 h of life. For those experiencing a direct percutaneous inoculation or transmucosal exposure to HBsAg-positive blood or body fluids (e.g., accidental *needle stick*, other mucosal penetration, or ingestion), a single intramuscular dose of HBIG, 0.06 mL/kg, administered as soon after exposure as possible, is followed by a complete course of hepatitis B vaccine to begin within the first week. For those exposed by *sexual* contact to a patient with acute hepatitis B, a single intramuscular dose of HBIG, 0.06 mL/kg, should be given within 14 days of exposure, to be followed by a complete course of hepatitis B vaccine. When both HBIG and hepatitis B vaccine are recommended, they may be given at the same time but at separate sites.

The precise duration of protection afforded by hepatitis B vaccine is unknown; however, approximately 80 to 90% of immunocompetent vaccinees retain protective levels of anti-HBs for at least 5 years, and 60 to 80% for 10 years. Thereafter and even after anti-HBs becomes undetectable, protection persists against clinical hepatitis B, hepatitis B surface antigenemia, and chronicHBVinfection. Currently, *booster* immunizations are not recommended routinely, except in immunosuppressed persons who have lost detectable anti-HBs or immunocompetent persons who sustain percutaneousHBsAg-positive inoculations after losing detectable antibody. Specifically, for hemodialysis patients, annual anti-HBs testing is recommended after vaccination; booster doses are recommended when anti-HBs levels fall below 10 mIU/mL.

Hepatitis D Infection with hepatitis D can be prevented by vaccinating susceptible persons with hepatitis B vaccine. No product is available for immunoprophylaxis to preventHDVsuperinfection inHBsAgcarriers; for them, avoidance of percutaneous exposures and limitation of intimate contact with persons who have HDV infection are recommended.

Hepatitis C IG is ineffective in preventing hepatitis C and is no longer recommended for postexposure prophylaxis in cases of perinatal, needle stick, or sexual exposure. Although a prototype vaccine that induces antibodies toHCVenvelope protein has been developed, currently, hepatitis C vaccination is not feasible practically. Genotype and

quasispecies viral heterogeneity, as well as rapid evasion of neutralizing antibodies by this rapidly mutating virus, conspire to render HCV a difficult target for immunoprophylaxis with a vaccine. Prevention of transfusion-associated hepatitis C has been accomplished by the following successively introduced measures: Exclusion of commercial blood donors and reliance on a volunteer blood supply; screening donor blood with surrogate markers such asALT (no longer recommended) and anti-HBc, markers that identify segments of the blood donor population with an increased risk of bloodborne infections; exclusion of blood donors in high-risk groups for AIDS and the introduction of anti-HIV screening tests; and progressively sensitive serologic screening tests for anti-HCV. Chemical and heat treatment of blood products used for large-pool and concentrated blood derivates are being pursued.

In the absence of active or passive immunization, prevention of hepatitis C includes behavior changes and precautions to limit exposures to infected persons. Recommendations designed to identify patients with clinically inapparent hepatitis as candidates for medical management have as a secondary benefit the identification of persons whose contacts could be at risk of becoming infected. A so-called "look-back" program has been recommended to identify persons who were transfused before 1992 with blood from a donor found subsequently to have hepatitis C. In addition, anti-HCVtesting is recommended for anyone who received a blood transfusion or a transplanted organ before the introduction of second-generation screening tests in 1992, people who ever used injection drugs, chronically hemodialyzed patients, persons with clotting disorders who received clotting factors made before 1987 from pooled blood products, persons with elevated aminotransferase levels, health workers exposed to HCV-positive blood or contaminated needles, and children born to HCV-positive mothers.

For stable, monogamous sexual partners, sexual transmission of hepatitis C is unlikely, and sexual barrier precautions are not recommended. For persons with multiple sexual partners or with sexually transmitted diseases, the risk of sexual transmission of hepatitis C is increased, and barrier precautions (latex condoms) are recommended. A person with hepatitis C should avoid sharing such items as razors, toothbrushes, and nail clippers with sexual partners and family members. No special precautions are recommended for babies born to mothers with hepatitis C, and breast feeding does not have to be restricted.

Hepatitis E WhetherIGprevents hepatitis E remains undetermined. Development of a vaccine is in progress.

296. TOXIC AND DRUG-INDUCED HEPATITIS - *Jules L. Dienstag*, *Kurt J. Isselbacher*

Liver injury may follow the inhalation, ingestion, or parenteral administration of a number of pharmacologic and chemical agents. These include industrial toxins (e.g., carbon tetrachloride, trichloroethylene, and yellow phosphorus), the heat-stable toxic bicyclic octapeptides of certain species of *Amanita* and *Galerina* (hepatotoxic mushroom poisoning), and, more commonly, pharmacologic agents used in medical therapy. It is essential that any patient presenting with jaundice or altered biochemical liver tests be questioned carefully about exposure to chemicals used in work or at home and drugs taken by prescription or bought "over the counter." Hepatotoxic drugs can injure the hepatocyte directly, e.g., via a free-radical or metabolic intermediate that causes peroxidation of membrane lipids and that results in liver cell injury. Alternatively, the drug or its metabolite can distort cell membranes or other cellular molecules or block biochemical pathways or cellular integrity. Such injuries, in turn, may lead to necrosis of hepatocytes; injure bile ducts, producing cholestasis; or block pathways of lipid movement, inhibit protein synthesis, or impair mitochondrial oxidation of fatty acids, resulting in fat accumulation (steatosis). In general, two major types of chemical hepatotoxicity have been recognized: (1) direct toxic type and (2) idiosyncratic type.

Most drugs, which are water-insoluble, undergo a series of metabolic transformation steps, culminating in a water-soluble form appropriate for renal or biliary excretion. This process begins with oxidation or methylation initially mediated by the mixed-function oxygenases cytochrome P450 (phase I reaction), followed by glucuronidation or sulfation (phase II reaction) or inactivation by glutathione. Most drug hepatotoxicity is mediated by a phase I toxic metabolite, but glutathione depletion, precluding inactivation of harmful compounds by glutathione S-transferase, can contribute as well.

As shown in Table 296-1, direct toxic hepatitis occurs with predictable regularity in individuals exposed to the offending agent and is dose-dependent. The latent period between exposure and liver injury is usually short (often several hours), although clinical manifestations may be delayed for 24 to 48 h. Agents producing toxic hepatitis are generally systemic poisons or are converted in the liver to toxic metabolites. The direct hepatotoxins result in morphologic abnormalities that are reasonably characteristic and reproducible for each toxin. For example, carbon tetrachloride and trichloroethylene characteristically produce a centrilobular zonal necrosis, whereas yellow phosphorus poisoning typically results in periportal injury. The hepatotoxic octapeptides of *Amanita phalloides* usually produce massive hepatic necrosis. The lethal dose of the toxin is about 10 mg, the amount found in a single deathcap mushroom. Tetracycline, when administered in intravenous doses>1.5 g daily, leads to microvesicular fat deposits in the liver. Liver injury, which is often only one facet of the toxicity produced by the direct hepatotoxins, may go unrecognized until jaundice appears.

In idiosyncratic drug reactions the occurrence of hepatitis is usually infrequent and unpredictable, the response is not dose-dependent, and it may occur at any time during or shortly after exposure to the drug. Extrahepatic manifestations of hypersensitivity, such as rash, arthralgias, fever, leukocytosis, and eosinophilia, occur in about one-quarter of patients with idiosyncratic hepatotoxic drug reactions; this observation and the unpredictability of idiosyncratic drug hepatotoxicity contributed to the hypothesis

that this category of drug reactions is immunologically mediated. More recent evidence, however, suggests that, in most cases, even idiosyncratic reactions represent direct hepatotoxity but are caused by drug metabolites rather than by the intact compound. Even the prototype of idiosyncratic hepatoxicity reactions, halothane hepatitis, and isoniazid hepatotoxicity, associated frequently with hypersensitivity manifestations, are now recognized to be mediated by toxic metabolites that damage liver cells directly. Currently, most idiosyncratic reactions are thought to result from differences in metabolic reactivity to specific agents; host susceptibility is mediated by the kinetics of toxic metabolite generation, which differs among individuals. Occasionally, however, the clinical features of an allergic reaction (prominent tissue eosinophilia, autoantibodies, etc.) are difficult to ignore. In vitro models have been described in which lymphocyte cytotoxicity can be demonstrated against rabbit hepatocytes altered by incubation with the potential offending drug. Furthermore, several instances of drug hepatotoxicity are associated with the appearance of autoantibodies, including a class of antibodies to liver-kidney microsomes, anti-LKM2, directed against a cytochrome P450 enzyme. Similarly, in selected cases, a drug or its metabolite has been shown to bind to a host cellular component forming a hapten; the immune response to this "neoantigen" is postulated to play a role in the pathogenesis of liver injury. Therefore, some authorities subdivide idiosyncratic drug hepatotoxicity into hypersensitivity (allergic) and "metabolic" categories. Several unusual exceptions notwithstanding, true drug allergy is difficult to support in most cases of idiosyncratic drug-induced liver injury.

Idiosyncratic reactions lead to a morphologic pattern that is more variable than those produced by direct toxins; a single agent is often capable of causing a variety of lesions, although certain patterns tend to predominate. Depending on the agent involved, idiosyncratic hepatitis may result in a clinical and morphologic picture indistinguishable from that of viral hepatitis (e.g., halothane) or may simulate extrahepatic bile duct obstruction clinically with morphologic evidence of cholestasis. Drug-induced cholestasis ranges from mild to increasingly severe: (1) bland cholestasis with limited hepatocellular injury (e.g., estrogens, 17,a-substituted androgens); (2) inflammatory cholestasis (e.g., phenothiazines, amoxicillin-clavulanic acid, oxacillin, erythromcyin estolate); (3) sclerosing cholangitis (e.g., after intrahepatic infusion of the chemotherapeutic agent floxuridine for hepatic metastases from a primary colonic carcinoma); (4) disappearance of bile ducts, "ductopenic" cholestasis, similar to that observed in chronic rejection following liver transplantation (e.g., carbamazine, chlorpromazine, tricyclic antidepressant agents). Morphologic alterations may also include bridging hepatic necrosis (e.g., methyldopa), or, infrequently, hepatic granulomas (e.g., sulfonamides). Some drugs result in macrovesicular or microvesicular steatosis or steatohepatitis, which in some cases has been linked to mitochondrial dysfunciton and lipid peroxidation. Severe hepatotoxicity associated with steatohepatitis, most likely a result of mitochondrial toxicity, is being recognized with increasing frequency among patients receiving antiretroviral therapy with reverse transcriptase inhibitors (e.g., zidovudine, didanosine) or protease inhibitors (e.g., indinavir, ritonavir) for HIV infection.

Not all adverse hepatic drug reactions can be classified as either toxic or idiosyncratic in type. For example, oral contraceptives, which combine estrogenic and progestational compounds, may result in impairment of hepatic tests and occasionally in jaundice. However, they do not produce necrosis or fatty change, manifestations of hypersensitivity are generally absent, and susceptibility to the development of oral

contraceptive-induced cholestasis appears to be genetically determined. Other instances of genetically determined drug hepatotoxicity have been identified. For example, approximately 10% of the population have an autosomally recessive trait associated with the absence of cytochrome P450 enzyme 2D6 and have impaired debrisoquine-4-hydroxylase enzyme activity. As a result, they cannot metabolize, and are at increased risk of hepatotoxicity resulting from, certain compounds such as desipramine, propranolol, and quinidine.

Because drug-induced hepatitis is often a presumptive diagnosis and many other disorders produce a similar clinicopathologic picture, evidence of a causal relationship between the use of a drug and subsequent liver injury may be difficult to establish. The relationship is most convincing for the direct hepatotoxins, which lead to a high frequency of hepatic impairment after a short latent period. Idiosyncratic reactions may be reproduced, in some instances, when rechallenge, after an asymptomatic period, results in a recurrence of signs, symptoms, and morphologic and biochemical abnormalities. Rechallenge, however, is often ethically unfeasible, because severe reactions may occur.

TREATMENT

Treatment of toxic and drug-induced hepatic disease is largely supportive, except in acetaminophen hepatotoxicity (see below). In patients with fulminant hepatitis resulting from drug hepatotoxicity, liver transplantation may be life-saving (Chap. 301). Withdrawal of the suspected agent is indicated at the first sign of an adverse reaction. In the case of the direct toxins, liver involvement should not divert attention from renal or other organ involvement, which may also threaten survival.

InTable 296-2, several classes of chemical agents are listed, together with examples of the pattern of liver injury produced by them. Certain drugs appear to be responsible for the development of chronic as well as acute hepatic injury. For example, oxyphenisatin, methyldopa, and isoniazid have been associated with moderate to severe chronic hepatitis, and halothane and methotrexate have been implicated in the development of cirrhosis. A syndrome resembling primary biliary cirrhosis has been described following treatment with chlorpromazine, methyl testosterone, tolbutamide, and other drugs. Portal hypertension in the absence of cirrhosis may result from alterations in hepatic architecture produced by vitamin A or arsenic intoxication, industrial exposure to vinyl chloride, or administration of thorium dioxide. The latter three agents have also been associated with angiosarcoma of the liver. Oral contraceptives have been implicated in the development of hepatic adenoma and, rarely, hepatocellular carcinoma and occlusion of the hepatic vein (Budd-Chiari syndrome). Another unusual lesion, peliosis hepatis (blood cysts of the liver), has been observed in some patients treated with anabolic steroids. The existence of these hepatic disorders expands the spectrum of liver injury induced by chemical agents and emphasizes the need for a thorough drug history in all patients with liver dysfunction.

The following are the patterns of adverse hepatic reactions for some prototypic agents.

ACETAMINOPHEN HEPATOTOXICITY (DIRECT TOXIN)

Acetaminophen has caused severe centrilobular hepatic necrosis when ingested in large amounts in suicide attempts or accidentally by children. A single dose of 10 to 15 g, occasionally less, may produce clinical evidence of liver injury. Fatal fulminant disease is usually (although not invariably) associated with ingestion of 25 g or more. Blood levels of acetaminophen correlate with the severity of hepatic injury (levels >300 ug/mL 4 h after ingestion are predictive of the development of severe damage; levels<150 ug/mL suggest that hepatic injury is highly unlikely). Nausea, vomiting, diarrhea, abdominal pain, and shock are early manifestations occurring 4 to 12 h after ingestion. Then 24 to 48 h later, when these features are abating, hepatic injury becomes apparent. Maximal abnormalities and hepatic failure may not be evident until 4 to 6 days after ingestion, and aminotransferase levels approaching 10,000 units are not uncommon. Renal failure and myocardial injury may be present.

Acetaminophen is metabolized predominantly by a phase II reaction to innocuous sulfate and glucuronide metabolites; however, a small proportion of acetaminophen is metabolized by a phase I reaction to a hepatotoxic metabolite formed from the parent compound by the cytochrome P450 2E1. This metabolite, *N*-acetyl-benzoquinone-imide (NAPQI), is detoxified by binding to "hepatoprotective" glutathione to become harmless, water-soluble mercapturic acid, which undergoes renal excretion. When excessive amounts of NAPQI are formed, or when glutathione levels are low, glutathione levels are depleted and overwhelmed, permitting covalent binding to nucleophilic hepatocyte macromolecules. This process is believed to lead to hepatocyte necrosis; the precise sequence and mechanism are unknown. Hepatic injury may be potentiated by prior administration of alcohol or other drugs, by conditions that stimulate the mixed-function oxidase system, or by conditions such as starvation that reduce hepatic glutathione levels. Cimetidine, which inhibits P450 enzymes, has the potential to reduce generation of the toxic metabolite. Alcohol induces cytochrome P450 2E1; consequently, increased levels of the toxic metabolite NAPQI are produced in chronic alcoholics after acetaminophen ingestion. In addition, alcohol suppresses hepatic glutathione production. Therefore, in chronic alcoholics, the toxic dose of acetaminophen may be as low as 2 g, and alcoholic patients should be warned specifically about the dangers of even standard doses of this commonly used drug. Such "therapeutic misadventures" also occur occasionally in patients with severe, febrile illnesses or pain syndromes; in such a setting, several days of anorexia and near-fasting coupled with regular administration of extra-strength acetaminophen formulations result in a combination of glutathione depletion and relatively high NAPQI levels in the absence of a history of recognized acetaminophen overdose.

TREATMENT

Treatment of acetaminophen overdosage includes gastric lavage, supportive measures, and oral administration of activated charcoal or cholestyramine to prevent absorption of residual drug. Neither of these agents appears to be effective if given more than 30 min after acetaminophen ingestion; if they are used, the stomach lavage should be done before other agents are administered orally. The chances of possible-, probable-, and high-risk hepatotoxicity can be derived from a nomogram plot (see Fig. 396-2), readily available in emergency departments, of acetaminophen plasma levels as a function of hours after ingestion. In patients with high acetaminophen blood levels (>200 ug/mL measured at 4 h or>100 ug/mL at 8 h after ingestion), the administration of sulfhydryl

compounds (e.g., cysteamine, cysteine, or *N*-acetylcysteine) appears to reduce the severity of hepatic necrosis. These agents appear to act by providing a reservoir of sulfhydryl groups to bind the toxic metabolites or by stimulating synthesis and repletion of hepatic glutathione. Therapy should be begun within 8 h of ingestion but may be effective even if given as late as 24 to 36 h after overdose. Later administration of sulfhydryl compounds is of uncertain value. Routine use of *N*-acetylcysteine has reduced substantially the occurrence of fatal acetaminophen hepatotoxicity. When given orally, *N*-acetylcysteine is diluted to yield a 5% solution. A loading dose of 140 mg/kg is given, followed by 70 mg/kg every 4 h for 15 to 20 doses. Whenever a patient with potential acetaminophen hepatotoxicity is encountered, a local poison control center should be contacted. Treatment can be stopped when plasma acetominophen levels indicate that the risk of liver damage is low.

Survivors of acute acetaminophen overdose usually have no evidence of hepatic sequelae. In a few patients, prolonged or repeated administration of acetaminophen in therapeutic doses appears to have led to the development of chronic hepatitis and cirrhosis.

HALOTHANE HEPATOTOXICITY (IDIOSYNCRATIC REACTION)

Administration of halothane, a nonexplosive fluorinated hydrocarbon anesthetic agent that is structurally similar to chloroform, results in severe hepatic necrosis in a small number of individuals, many of whom have previously been exposed to this agent. The failure to produce similar hepatic lesions reliably in animals, the rarity of hepatic impairment in human beings, and the delayed appearance of hepatic injury suggest that halothane is not a direct hepatotoxin but rather a sensitizing agent. However, manifestations of hypersensitivity are seen in<25% of cases. A genetic predisposition leading to an idiosyncratic metabolic reactivity has been postulated and appears to be the most likely mechanism of halothane hepatotoxicity. Adults (rather than children), obese people, and women appear to be particularly susceptible. Fever, moderate leukocytosis, and eosinophilia may occur in the first week following halothane administration. Jaundice is usually noted 7 to 10 days after exposure but may occur earlier in previously exposed patients. Nausea and vomiting may precede the onset of jaundice. Hepatomegaly is often mild, but liver tenderness is common. The serum aminotransferase levels are elevated. The pathologic changes at autopsy are indistinguishable from massive hepatic necrosis resulting from viral hepatitis. The case-fatality rate of halothane hepatitis is not known but may vary from 20 to 40% in cases with severe liver involvement. It is strongly suggested that patients in whom unexplained spiking fever, especially delayed fever, or jaundice develops after halothane anesthesia not receive this agent again. Because cross-reactions between halothane and methoxyfluorane have been reported, the latter agent should not be used after halothane reactions. Later-generation halogenated hydrocarbon anesthetics, which have supplanted halothane except in rare instances, are felt to be associated with a lower risk of hepatotoxicity.

METHYLDOPA HEPATOTOXICITY (TOXIC AND IDIOSYNCRATIC REACTION)

Minor alterations in liver tests are reported in about 5% of patients treated with this antihypertensive agent. These trivial abnormalities typically resolve despite continued

drug administration. In <1% of patients, acute liver injury resembling viral or chronic hepatitis or, rarely, a cholestatic reaction is seen 1 to 20 weeks after methyldopa is started. In 50% of cases the interval is <4 weeks. A prodrome of fever, anorexia, and malaise may be noted for a few days before the onset of jaundice. Rash, lymphadenopathy, arthralgia, and eosinophilia are rare. Serologic markers of autoimmunity are detected infrequently, and<5% of patients have a Coombs-positive hemolytic anemia. In about 15% of patients with methyldopa hepatotoxicity, the clinical, biochemical, and histologic features are those of moderate to severe chronic hepatitis, with or without bridging necrosis and macronodular cirrhosis. With discontinuation of the drug, the disorder usually resolves.

ISONIAZID HEPATOTOXICITY (TOXIC AND IDIOSYNCRATIC REACTION)

In approximately 10% of adults treated with the antituberculosis agent isoniazid, elevated serum aminotransferase levels develop during the first few weeks of therapy; this appears to represent an adaptive response to a toxic metabolite of the drug. Whether or not isoniazid is continued, these values (usually<200 units) return to normal in a few weeks. In about 1% of treated patients, an illness develops that is indistinguishable from viral hepatitis; approximately half of these cases occur within the first 2 months of treatment, while in the remainder, clinical disease may be delayed for many months. Liver biopsy reveals morphologic changes similar to those of viral hepatitis or bridging hepatic necrosis. The disease may be severe, with a case-fatality rate of 10%. Important liver injury appears to be age-related, increasing substantially after age 35; the highest frequency is in patients over age 50, the lowest under the age of 20. Even for patients>50 years of age monitored carefully during therapy, hepatotoxicity occurs in only approximately 2%, well below the risk estimate derived from earlier experiences. Isoniazid hepatotoxicity is enhanced by alcohol and rifampicin. Fever, rash, eosinophilia, and other manifestations of drug allergy are distinctly unusual. A reactive metabolite of acetylhydrazine, a metabolite of isoniazid, may be responsible for liver injury, and patients who are rapid acetylators would be more prone to such injury. A picture resembling chronic hepatitis has been observed in a few patients.

SODIUM VALPROATE HEPATOTOXICITY (TOXIC AND IDIOSYNCRATIC REACTION)

Sodium valproate, an anticonvulsant useful in the treatment of petit mal and other seizure disorders, has been associated with the development of severe hepatic toxicity and, rarely, fatalities, predominantly in children but also in adults. Asymptomatic elevations of serum aminotransferase levels have been recognized in as many as 45% of treated patients. These "adaptive" changes, however, appear to have no clinical importance, for major hepatotoxicity is not seen in the majority of patients despite continuation of drug therapy. In those rare patients in whom jaundice, encephalopathy, and evidence of hepatic failure are found, examination of liver tissue reveals microvesicular fat and bridging hepatic necrosis, predominantly in the centrilobular zone. Bile duct injury may also be apparent. It seems likely that sodium valproate is not directly hepatotoxic but that its metabolite, 4-pentenoic acid, may be responsible for hepatic injury.

PHENYTOIN HEPATOTOXICITY (IDIOSYNCRATIC REACTION)

Phenytoin, formerly diphenylhydantoin, a mainstay in the treatment of seizure disorders, has been associated in rare instances with the development of severe hepatitis-like liver injury leading to fulminant hepatic failure. In many patients the hepatitis is associated with striking fever, lymphadenopathy, rash (Stevens-Johnson syndrome or exfoliative dermatitis), leukocytosis, and eosinophilia, suggesting an immunologically mediated hypersensitivity mechanism. Despite these observations, there is also evidence that metabolic idiosyncrasy may be responsible for hepatic injury. In the liver, phenytoin is converted by the cytochrome P450 system to metabolites, which include the highly reactive electrophilic arene oxides. These metabolites are normally metabolized further by epoxide hydrolases. A defect (genetic or acquired) in epoxide hydrolase activity could permit covalent binding of arene oxides to hepatic macromolecules, thereby leading to hepatic injury. Regardless of the mechanism, hepatic injury is usually manifest within the first 2 months after beginning phenytoin therapy. With the exception of an abundance of eosinophils in the liver, the clinical, biochemical, and histologic picture resembles that of viral hepatitis. In rare instances, bile duct injury may be the salient feature of phenytoin hepatotoxicity, with striking features of intrahepatic cholestasis. Asymptomatic elevations of aminotransferase and alkaline phosphatase levels have been observed in a sizable proportion of patients receiving long-term phenytoin therapy. These liver changes are believed by some authorities to represent the potent hepatic enzyme-inducing properties of phenytoin and are accompanied histologically by swelling of hepatocytes in the absence of necroinflammatory activity or evidence of chronic liver disease.

CHLORPROMAZINE HEPATOTOXICITY (CHOLESTATIC IDIOSYNCRATIC REACTION)

In about 1% of patients receiving chlorpromazine, intrahepatic cholestasis with jaundice develops after 1 to 4 weeks of treatment. In rare instances, jaundice has been reported after a single exposure. Anicteric reactions are frequent. The onset may be abrupt, with fever, rash, arthralgias, lymphadenopathy, nausea, vomiting, and epigastric or right upper quadrant pain. Pruritus may precede the appearance of jaundice, dark urine, and light stools. Eosinophilia with or without mild leukocytosis may be present, and conjugated hyperbilirubinemia, moderately elevated serum alkaline phosphatase, and mildly elevated serum aminotransferase levels (100 to 200 units) are noted. Liver biopsy reveals cholestasis, bile plugs in dilated bile canaliculi, and a dense portal infiltrate of polymorphonuclear, eosinophilic, and mononuclear leukocytes. Occasionally, scattered foci of hepatic parenchymal necrosis may be evident. Jaundice and pruritus usually subside within 4 to 8 weeks following cessation of therapy, without sequelae, and fatalities are rare. Cholestyramine may be of value in relieving severe pruritus. In a small number of patients, jaundice is prolonged for several months to years; rarely, a disorder resembling but distinct from primary biliary cirrhosis may develop.

AMIODARONE HEPATOTOXICITY (TOXIC AND IDIOSYNCRATIC REACTION)

Therapy with this potent antiarrhythmic drug is accompanied in 15 to 50% of patients by modest elevations of serum aminotransferase levels that may remain stable or diminish despite continuation of the drug. Such abnormalities may appear days to many months after beginning therapy. A proportion of those with elevated aminotransferase levels

have detectable hepatomegaly, and clinically important liver disease develops in <5% of patients. Features that represent a direct effect of the drug on the liver and that are common to the majority of long-term recipients are ultrastructural phospholipidosis, unaccompanied by clinical liver disease, and interference with hepatic mixed-function oxidase metabolism of other drugs. The cationic amphiphilic drug and its major metabolite desethylamiodarone accumulate in hepatocyte lysosomes and mitochondria and in bile duct epithelium. The relatively common elevations in aminotransferase levels are also considered a predictable, dose-dependent, direct hepatotoxic effect. On the other hand, in the rare patient with clinically apparent, symptomatic liver disease, liver injury resembling that seen in alcoholic liver disease is observed. The so-called pseudoalcoholic liver injury can range from steatosis, to alcoholic hepatitis-like neutrophilic infiltration and Mallory's hyaline, to cirrhosis. Electron-microscopic demonstration of phospholipid-laden lysosomal lamellar bodies can help to distinguish amiodarone hepatotoxicity from typical alcoholic hepatitis. This category of liver injury appears to be a metabolic idiosyncracy that allows hepatotoxic metabolites to be generated. Rarely, an acute idiosyncratic hepatocellular injury resembling viral hepatitis or cholestatic hepatitis occurs. Hepatic granulomas have occasionally been observed. Because amiodarone has a long half-life, liver injury may persist for months after the drug is stopped.

ERYTHROMYCIN HEPATOTOXICITY (CHOLESTATIC IDIOSYNCRATIC REACTION)

The most important adverse effect associated with erythromycin, more common in children than adults, is the infrequent occurrence of a cholestatic reaction. Although most of these reactions have been associated with erythromycin estolate, other erythromycins may also be responsible. The reaction usually begins during the first 2 or 3 weeks of therapy and includes nausea, vomiting, fever, right upper quadrant abdominal pain, jaundice, leukocytosis, and moderately elevated aminotransferase levels. The clinical picture can resemble acute cholecystitis or bacterial cholangitis. Liver biopsy reveals variable cholestasis; portal inflammation comprising lymphocytes, polymorphonuclear leukocytes, and eosinophils; and scattered foci of hepatocyte necrosis. Symptoms and laboratory findings usually subside within a few days of drug withdrawal, and evidence of chronic liver disease has not been found on follow-up. The precise mechanism remains ill-defined.

ORAL CONTRACEPTIVE HEPATOTOXICITY (CHOLESTATIC REACTION)

The administration of oral contraceptive combinations of estrogenic and progestational steroids leads to intrahepatic cholestasis with pruritus and jaundice in a small number of patients weeks to months after taking these agents. Especially susceptible seem to be patients with recurrent idiopathic jaundice of pregnancy, severe pruritus of pregnancy, or a family history of these disorders. With the exception of liver biochemical tests, laboratory studies are normal, and extrahepatic manifestations of hypersensitivity are absent. Liver biopsy reveals cholestasis with bile plugs in dilated canaliculi and striking bilirubin staining of liver cells. In contrast to chlorpromazine-induced cholestasis, portal inflammation is absent. The lesion is reversible on withdrawal of the agent. The two steroid components appear to act synergistically on hepatic function, although the estrogen may be primarily responsible. Oral contraceptives are contraindicated in patients with a history of recurrent jaundice of pregnancy. Primarily benign, but rarely

malignant, neoplasms of the liver, hepatic vein occlusion, and peripheral sinusoidal dilatation have also been associated with oral contraceptive therapy.

17,a-ALKYL-SUBSTITUTED ANABOLIC STEROIDS (CHOLESTATIC REACTION)

In the majority of patients receiving these agents, used therapeutically mainly in the treatment of bone marrow failure but used surreptitiously and without medical indication by athletes to improve their performance, mild hepatic dysfunction develops. Impaired excretory function is the predominant defect, but the precise mechanism is uncertain. Jaundice, which appears to be dose-related, develops in only a minority of patients and may be the sole clinical manifestation of hepatotoxicity, although anorexia, nausea, and malaise may occur. Pruritus is not a prominent feature. Serum aminotransferase levels are usually <100 units, and serum alkaline phosphatase levels are normal, mildly elevated, or, in <5% of patients, three or more times the upper limit of normal. Examination of liver tissue reveals cholestasis without inflammation or necrosis. Hepatic sinusoidal dilatation and peliosis hepatis have been found in a few patients. The cholestatic disorder is usually reversible on cessation of treatment, although fatalities have been linked to peliosis. An association with hepatic adenoma and hepatocellular carcinoma has been reported.

TRIMETHOPRIM-SULFAMETHOXAZOLE HEPATOTOXICITY (IDIOSYNCRATIC REACTION)

This antibiotic combination is used routinely for urinary tract infections in immunocompetent persons and for prophylaxis against and therapy of *Pneumocystis carinii* pneumonia in immunosuppressed persons (transplant recipients, patients with AIDS). With its increasing use, its occasional hepatotoxicity is being recognized with growing frequency. Its likelihood is unpredictable, but when it occurs, trimethoprim-sulfamethoxazole hepatotoxicity follows a relatively uniform latency period of several weeks and is often accompanied by eosinophilia, rash, and other features of a hypersensitivity reaction. Biochemically and histologically, acute hepatocellular necrosis predominates, but cholestatic features are quite frequent. Occasionally, cholestasis without necrosis occurs, and very rarely, a severe cholangiolytic pattern of liver injury is observed. In most cases, liver injury is self-limited, but rare fatalities have been recorded. The hepatotoxicity is attributable to the sulfamethoxazole component of the drug and is similar in features to that seen with other sulfonamides; tissue eosinophilia and granulomas may be seen.

HYDROXYMETHYLGLUTARYL-COENZYME (HMG-COA) REDUCTASE INHIBITORS ("STATINS") (IDIOSYNCRATIC MIXED HEPATOCELLULAR AND CHOLESTATIC REACTION)

Between 1 and 2% of patients taking lovastatin, simvastatin, pravastatin, fluvastatin, or one of the newer "statin" drugs for the treatment of hypercholesterolemia experience asymptomatic, reversible elevations (> threefold) of aminotransferase activity. Acute hepatitis-like histologic changes, centrilobular necrosis, and centrilobular cholestasis have been described in several cases. In a larger proportion, minor aminotrasferase elevations appear during the first several weeks of therapy. Careful laboratory monitoring can distinguish between patients with minor, transitory changes, who may

continue therapy, and those with more profound and sustained abnormalities, who should discontinue therapy.

TOTAL PARENTERAL NUTRITION (STEATOSIS, CHOLESTASIS)

Total parenteral nutrition (TPN) is often complicated by cholestatic hepatitis attributable to either steatosis, cholestasis, or gallstones (or gallbladder sludge). Steatosis or steatohepatitis may result from the excess carbohydrate calories in these nutritional supplements and is the predominant form of TPN-associated liver disorder in adults. The frequency of this complication has been reduced substantially by the introduction of balanced TPN formulas that rely on lipid as an alternative caloric source. Cholestasis and cholelithiasis, caused by the absence of stimulation of bile flow and secretion resulting from the lack of oral intake, is the predominant form of TPN-associated liver disease in infants, especially in premature neonates. Often, cholestasis in such neonates is multifactorial, contributed to by other factors such as sepsis, hypoxemia, and hypotension; occasionally, TPN-induced cholestasis in neonates culminates in chronic liver disease and liver failure. When TPN-associated liver test abnormalities occur in adults, balancing the TPN formula with more lipid is the intervention of first recourse. In infants with TPN-associated cholestasis, the addition of oral feeding may ameliorate the problem. Therapeutic interventions suggested, but not yet shown to be of proven benefit, include CCK, ursodeoxycholic acid, *S*-adenosyl methionine, and taurine.

"ALTERNATIVE MEDICINES" (IDIOSYNCRATIC HEPATITIS, STEATOSIS)

The misguided popularity of herbal medications that are of scientifically unproven efficacy and that lack prospective safety oversight by regulatory agencies has resulted in occasional instances of hepatotoxicity. Included among the herbal remedies associated with toxic hepatitis are jin bu huan (Chap. 11), xiao-chai-hu-tang, germander, chaparral, senna, mistletoe, skullcap, gentian, comfrey (containing pyrrolizidine alkaloids), and herbal teas. Recently well characterized are the acute hepatitis-like histologic lesions following jin bu huan use: focal hepatocellular necrosis, mixed mononuclear portal tract infiltration, coagulative necrosis, apoptotic hepatocyte degeneration, tissue eosinophilia, and microvesicular steatosis. Megadoses of vitamin A can injure the liver, as can pyrrolizidine alkaloids, which often contaminate Chinese herbal preparations and can cause a venoocclusive injury leading to sinusoidal hepatic vein obstruction. Given the widespread use of such poorly defined herbal preparations, hepatotoxicity is likely to be encountered with increasing frequency; therefore, a drug history in patients with acute and chronic liver disease should include use of "alternative medicines" and other nonprescription preparations sold in so-called health food stores.

297. CHRONIC HEPATITIS - *Jules L. Dienstag*, *Kurt J. Isselbacher*

Chronic hepatitis represents a series of liver disorders of varying causes and severity in which hepatic inflammation and necrosis continue for at least 6 months. Milder forms are nonprogressive or only slowly progressive, while more severe forms may be associated with scarring and architectural reorganization, which, when advanced, lead ultimately to cirrhosis. Several categories of chronic hepatitis have been recognized. These include chronic viral hepatitis (Chap. 295), drug-induced chronic hepatitis (Chap. 296), and autoimmune chronic hepatitis. In many cases, clinical and laboratory features are insufficient to allow assignment into one of these three categories; these "idiopathic" cases are also believed to represent autoimmune chronic hepatitis. Finally, clinical and laboratory features of chronic hepatitis are observed occasionally in patients with such hereditary/metabolic disorders as Wilson's disease (copper overload) and even occasionally in patients with alcoholic liver injury (Chap. 298). Although all types of chronic hepatitis share certain clinical, laboratory, and histopathologic features, chronic viral and chronic autoimmune hepatitis are sufficiently distinct to merit separate discussions.

CLASSIFICATION OF CHRONIC HEPATITIS

Common to all forms of chronic hepatitis are histopathologic distinctions based on localization and extent of liver injury. These vary from the milder forms, previously labeled chronic persistent hepatitis and chronic lobular hepatitis, to the more severe form, formerly called chronic active hepatitis. When first defined, these designations were felt to have prognostic implications, which have been challenged by more recent observations. Compared to the time more than two decades ago when the histologic designations chronic persistent, chronic lobular, and chronic active hepatitis were adopted, much more information is currently available about the causes, natural history, pathogenesis, serologic features, and therapy of chronic hepatitis. Therefore, categorization of chronic hepatitis based primarily upon histopathologic features has been replaced by a more informative classification based upon a combination of clinical, serologic, and histologic variables. Classification of chronic hepatitis is based upon (1) its *cause*, (2) its histologic activity, or *grade*, and (3) its degree of progression, or *stage*. Thus, neither clinical features alone nor histologic features -- requiring liver biopsy -- alone are sufficient to characterize and distinguish among the several categories of chronic hepatitis.

Classification by Cause Clinical and serologic features allow the establishment of a diagnosis of *chronic viral hepatitis*, caused by hepatitis B, hepatitis B plus D, hepatitis C, or potentially other unknown viruses; *autoimmune hepatitis*, including several subcategories, types 1, 2, and 3, based on serologic distinctions; *drug-associated chronic hepatitis*; and a category of unknown cause, or *cryptogenic* chronic hepatitis (Table 297-1). These are addressed in more detail below.

Classification by Grade Grade, a histologic assessment of necroinflammatory activity, is based upon examination of the liver biopsy. An assessment of important histologic features includes the degree of *periportal necrosis* and the disruption of the limiting plate of periportal hepatocytes by inflammatory cells (so-called *piecemeal necrosis* or *interface hepatitis*); the degree of confluent necrosis that links or forms bridges between

vascular structures -- between portal tract and portal tract or even more important bridges between portal tract and central vein -- referred to as *bridging necrosis*; the degree of hepatocyte degeneration and focal necrosis within the lobule; and the degree of *portal inflammation*. Several scoring systems that take these histologic features into account have been devised, and the most popular is the numerical histologic activity index (HAI), based on the work of Knodell and Ishak (Table 297-2). Technically, the HAI, which is primarily a measure of *grade*, also includes an assessment of fibrosis, which is currently used to categorize *stage* of the disease, as described below. Such precise HAI scoring tends to be used more in measuring disease activity before and after therapy in clinical studies. In clinical practice, more qualitative grading suffices. Based on the presence and degree of these features of histologic activity, chronic hepatitis can be graded as mild, moderate, or severe.

Classification by Stage The stage of chronic hepatitis, which reflects the level of progression of the disease, is based on the degree of fibrosis. When fibrosis is so extensive that fibrous septa surround parenchymal nodules and alter the normal architecture of the liver lobule, the histologic lesion is defined as cirrhosis. Staging is based on the degree of fibrosis as follows:

0= no fibrosis

1= mild fibrosis

2= moderate fibrosis

3= severe fibrosis, including bridging fibrosis

4 =cirrhosis

Reconciliation between Histologic Classification and New Classification For historical purposes, and to provide the basis for navigating several decades worth of literature on chronic hepatitis, the histologic categories of chronic persistent hepatitis, chronic lobular hepatitis, and chronic active hepatitis are worth reviewing and linking with their new-classification counterparts (Table 297-3).

In *chronic persistent hepatitis*, a mononuclear inflammatory infiltrate expands, but is localized to and contained within, portal tracts. The "limiting plate" of periportal hepatocytes is intact, and there is no extension of the necroinflammatory process into the liver lobule. A "cobblestone" arrangement of liver cells, indicative of hepatic regenerative activity, is a common feature, and although minimal periportal fibrosis may be present, *cirrhosis is absent.* As a general rule, patients with chronic persistent hepatitis are asymptomatic or have relatively mild constitutional symptoms (e.g., fatigue, anorexia, nausea); have normal physical findings, except perhaps for liver enlargement, without the usual stigmata of chronic liver disease (see below); and have modest elevations of aminotransferase activities. Progression to more severe lesions (chronic active hepatitis and cirrhosis) was felt to be very unlikely, especially in patients with autoimmune or idiopathic chronic persistent hepatitis; however, progressive disease occurs in patients with chronic persistent *viral* hepatitis and in those with chronic persistent hepatitis following spontaneous or therapeutic remission of autoimmune

hepatitis. In the new nomenclature, chronic persistent hepatitis would be classified by *grade* as minimal or mild chronic hepatitis and by *stage* as absent or mild fibrosis.

In patients with *chronic lobular hepatitis*, in addition to portal inflammation, histologic examination of the liver reveals foci of necrosis and inflammation in the liver lobule. Morphologically, chronic lobular hepatitis resembles slowly resolving acute hepatitis. The limiting plate remains intact, periportal fibrosis is absent or limited, lobular architecture is preserved, and progression to chronic active hepatitis and cirrhosis was felt to be rare. Thus chronic lobular hepatitis can be considered a variant of chronic persistent hepatitis with a lobular component, and clinical/laboratory features are comparable. Occasionally, the clinical activity of chronic lobular hepatitis may increase spontaneously; elevation of aminotransferase activity may resemble that seen in acute hepatitis, and transient histologic deterioration can be documented. The same qualifications in prognostic import mentioned above for chronic persistent hepatitis apply to chronic lobular hepatitis. Chronic lobular hepatitis corresponds in the new nomenclature to a mild or moderate *grade* and a *stage* of absent or minimal fibrosis.

Chronic active hepatitis is characterized clinically by continuing hepatic necrosis, portal/periportal and, to a lesser extent, lobular inflammation, and fibrosis. Varying in severity from mild to severe, chronic active hepatitis was recognized to be a progressive disorder that can lead to cirrhosis, liver failure, and death. Morphologic characteristics of chronic active hepatitis include (1) a dense mononuclear infiltrate of the portal tracts, which are substantially expanded into the liver lobule (in the autoimmune type, plasma cells represent a component of the infiltrate); (2) destruction of the hepatocytes at the periphery of the lobule, with erosion of the limiting plate of hepatocytes surrounding the portal triads (piecemeal necrosis or interface hepatitis); (3) connective tissue septa surrounding portal tracts and extending from the portal zones into the lobule, isolating parenchymal cells into clusters and enveloping bile ducts; and (4) evidence of hepatocellular regeneration -- "rosette" formation, thickened liver cell plates, and regenerative "pseudolobules." This process may be patchy, with individual liver lobules spared, or it may be diffuse. Histologic evidence of single-cell coagulative necrosis, Councilman or acidophilic bodies, appear in the periportal areas. Piecemeal necrosis is the minimal histologic requirement to establish a diagnosis of chronic active hepatitis, but this change is seen even in mild, relatively nonprogressive forms of chronic active hepatitis. A more severe lesion, *bridging hepatic necrosis* (originally termed *subacute hepatic necrosis*), characterizes a more severe and progressive form of chronic active hepatitis. Although bridging necrosis can be seen occasionally in patients with acute hepatitis, in whom it carries no prognostic importance, in chronic active hepatitis this lesion is associated with progression to cirrhosis. Bridging necrosis is characterized by hepatocellular dropout that spans lobules (i.e., between portal tracts -- the periphery of the lobule -- or between portal tracts and central veins -- the centrizonal part of the lobule). Collapse of the reticulin network is a hallmark of bridging necrosis, and bridging fibrosis follows, leading ultimately to architectural reorganization by nodular regeneration, i.e., cirrhosis. A more extensive and ominous variant of bridging necrosis is multilobular collapse, in which bridging necrosis is widespread throughout the liver and which is associated clinically with rapid deterioration and even acute liver failure.

Although progression to cirrhosis is difficult to demonstrate in patients with chronic active hepatitis who have isolated piecemeal necrosis, in more severe forms of chronic

active hepatitis, progression to cirrhosis is common. Among patients with chronic active hepatitis on liver biopsy, 20 to 50% also have cirrhosis, even early during the course of the disease. Ordinarily, chronic active hepatitis is more severe clinically than chronic persistent and lobular hepatitis. Although a sizable proportion of patients with chronic active hepatitis are asymptomatic, the majority tend to have mild to severe constitutional symptoms, especially fatigue. Generally, physical findings associated with chronic liver disease and portal hypertension are more common, aminotransferase levels tend to be higher, and jaundice and hyperbilirubinemia are more frequent in this form of chronic hepatitis.

In the new nomenclature for chronic hepatitis, what used to be called chronic active hepatitis spans the entire spectrum of activity *grade* from minimal, to mild, to severe chronic hepatitis, based on the degree of periportal and piecemeal necrosis, on the degree of lobular inflammation and injury, and on the degree of portal inflammation. Similarly, *stage* in chronic active hepatitis can translate to mild, moderate, or severe fibrosis as well as to cirrhosis.

CHRONIC VIRAL HEPATITIS

Both the enterically transmitted forms of viral hepatitis, hepatitis A and E, are self-limited and do not cause chronic hepatitis (rare reports notwithstanding in which acute hepatitis A serves as a trigger for the onset of autoimmune hepatitis in genetically susceptible patients). In contrast, the entire clinicopathologic spectrum of chronic hepatitis occurs in patients with chronic viral hepatitis B and C as well as in patients with chronic hepatitis D superimposed on chronic hepatitis B.

Chronic Hepatitis B The likelihood of chronicity after acute hepatitis B varies as a function of age. Infection at birth is associated with a clinically silent acute infection but a 90% chance of chronic infection, while infection in young adulthood in immunocompetent persons is typically associated with clinically apparent acute hepatitis but a risk of chronicity of only approximately 1%. Most cases of chronic hepatitis B among adults, however, occur in patients who never had a recognized episode of clinically apparent acute viral hepatitis. The degree of liver injury (grade) in patients with chronic hepatitis B is variable, ranging from none in asymptomatic carriers, to mild, to severe. Among adults with chronic hepatitis B, histologic features are of prognostic importance. In one long-term study of patients with chronic hepatitis B, investigators found a 5-year survival of 97% for patients with chronic persistent hepatitis (mild chronic hepatitis), of 86% for patients with chronic active hepatitis (moderate to severe chronic hepatitis), and of only 55% for patients with chronic active hepatitis and postnecrotic cirrhosis. The 15-year survival in these cohorts were 77, 66, and 40%, respectively. On the other hand, more recent observations do not allow us to be so sanguine about the prognosis in patients with mild chronic hepatitis; among patients with what used to be labeled chronic persistent hepatitis followed for 1 to 13 years, progression to more severe chronic hepatitis and cirrhosis has been observed in more than a quarter of cases.

Probably more important to consider than histology alone in patients with chronic hepatitis B is the degree of hepatitis B virus (HBV) replication. As reviewed inChap. 295, chronic hepatitis B can be divided into two phases based on the relative level of HBV

replication. The relatively *replicative phase* is characterized by the presence in the serum of markers of HBV replication [hepatitis B e antigen (HBeAg) HBV DNA], by the presence in the liver of detectable intrahepatocyte nucleocapsid antigens [primarily hepatitis B core antigen (HBcAg)], by high infectivity, and by accompanying liver injury; HBV DNA can be detected in the liver but is extrachromosomal. In contrast, the relatively *nonreplicative phase* is characterized by the absence of conventional markers of HBV replication (HBeAg and HBV DNA detectable by hybridization) but an association with anti-HBe, the absence of intrahepatocytic HBcAg, limited infectivity, and minimal liver injury; HBV DNA can be detected in the liver but is integrated into the host genome. Those in the replicative phase tend to have more severe chronic hepatitis, while those in the nonreplicative phase tend to have minimal or mild chronic hepatitis or to be asymptomatic hepatitis B carriers; however, distinctions in HBV replication and in histologic category do not always coincide. The likelihood of converting spontaneously from relatively replicative to nonreplicative chronic HBV infection is approximately 10 to 15% per year. As noted in Chap. 295, the conversion from replicative to nonreplicative chronic hepatitis B is associated with a transient elevation in aminotransferase activity resembling acute hepatitis; occasionally, spontaneous resumptions of replicative activity occur in nonreplicative infection; and occasionally, HBV variants occur in which serologic markers of replication (HBeAg) are absent, despite the presence of replicative infection. Chronic HBV infection, especially when acquired at birth or in early childhood, is associated with an increased risk of hepatocellular carcinoma (Chap. 91).*A discussion of the pathogenesis of liver injury in patients with chronic hepatitis B appears in Chap. 295.*

The spectrum of *clinical features* of chronic hepatitis B is broad, ranging from asymptomatic infection to debilitating disease or even end-stage, fatal hepatic failure. As noted above, the onset of the disease tends to be insidious in most patients, with the exception of the very few in whom chronic disease follows failure of resolution of clinically apparent acute hepatitis B. The clinical and laboratory features associated with progression from acute to chronic hepatitis B are discussed in Chap. 295. *Fatigue* is a common symptom, and persistent or intermittent *jaundice* is a common feature in severe or advanced cases. Intermittent deepening of jaundice and recurrence of malaise and anorexia, as well as worsening fatigue, are reminiscent of acute hepatitis; such exacerbations may occur spontaneously, often coinciding with evidence of virologic reactivation, may lead to progressive liver injury, and, when superimposed on well-established cirrhosis, may cause hepatic decompensation. Complications of cirrhosis occur in end-stage chronic hepatitis and include ascites, edema, bleeding gastroesophageal varices, hepatic encephalopathy, coagulopathy, or hypersplenism. Occasionally, these complications bring the patient to initial clinical attention. Extrahepatic complications of chronic hepatitis B, similar to those seen during the prodromal phase of acute hepatitis B, are associated with deposition of circulating hepatitis B antigen-antibody immune complexes. These include arthralgias and arthritis, which are common, and the more rare purpuric cutaneous lesions (leukocytoclastic vasculitis), immune-complex glomerulonephritis, and generalized vasculitis (polyarteritis nodosa) (Chaps. 295 and317).

Laboratory features of chronic hepatitis B do not distinguish adequately between histologically mild and severe hepatitis. Aminotransferase elevations tend to be modest for chronic hepatitis B but may fluctuate in the range of 100 to 1000 units. As is true for

acute viral hepatitis B, alanine aminotransferase (ALT, or SGPT) tends to be more elevated than aspartate aminotransferase (AST, or SGOT); however, once cirrhosis is established, AST tends to exceed ALT. Levels of alkaline phosphatase activity tend to be normal or only marginally elevated. In severe cases, moderate elevations in serum bilirubin [51.3 to 171 umol/L (3 to 10 mg/dL)] occur. Hypoalbuminemia and prolongation of the prothrombin time occur in severe or end-stage cases. Hyperglobulinemia and detectable circulating autoantibodies are distinctly absent in chronic hepatitis B (in contrast to autoimmune hepatitis).*Viral markers of chronic HBV infection are discussed in Chap. 295.*

TREATMENT

Management of chronic hepatitis B depends on the level of virus replication. Although progression to cirrhosis is more likely in severe chronic than in mild or moderate chronic hepatitis B, all forms of chronic viral hepatitis can be progressive. Interferon a(IFN-a) was the first approved therapy for chronic hepatitis B, but the recently approved dideoxynucleoside lamivudine expands the options for treatment. The most common indication for treatment is chronic "replicative" hepatitis B, with detectableHBeAgand HBVDNA (by hybridization assay), elevated ALT activity, and histologic evidence of chronic hepatitis on liver biopsy in an immunocompetent adult. A 16-week course of INF-a given by subcutaneous injection at a daily dose of 5 million units, or three times a week at a dose of 10 million units, results in seroconversion from "replicative" (detectable HBeAg and HBV DNA) to "nonreplicative" (undetectable HBeAg and HBV DNA by hybridization assay) HBV infection in approximately 35% of patients, with a concomitant improvement in liver histologic features. As a result of INF-atherapy, approximately 20% of patients acquire anti-HBe, and in early trials, approximately 8% lost hepatitis B surface antigen (HBsAg). Successful interferon therapy and seroconversion is often accompanied by an acute hepatitis-like elevation in aminotransferase activity, which has been postulated to result from enhanced cytolytic T cell clearance of HBV-infected hepatocytes. Relapse after successful therapy is rare (1 or 2%). The likelihood of responding to interferon is higher in patients with lower levels of HBV DNA and substantial elevations ofALT. Although children can respond as well as adults, interferon therapy has not been effective in very young children infected at birth. Similarly, interferon therapy has not been effective in immunosuppressed persons, Asian patients with minimal-to-mild ALT elevations, patients with pre-core mutant HBV infection (Chap. 295), or in patients with decompensated chronic hepatitis B (in whom such therapy can actually be detrimental, sometimes precipitating decompensation, often associated with severe adverse effects). Among patients with HBeAg loss during therapy, long-term follow-up has demonstrated that 80% experience eventual loss of HBsAg, i.e., all serologic markers of infection, and normalization of ALT over a 9-year posttreatment period. In addition, improved long-term and complication-free survival as well as a reduction in the frequency of hepatocellular carcinoma have been documented among interferon responders, supporting the conclusion that successful interferon therapy improves the natural history of chronic hepatitis B. Indications for interferon therapy in patients with chronic hepatitis B are summarized in Table 297-4.

Complications of interferon therapy include systemic "flulike" symptoms, marrow suppression, emotional lability (irritability commonly, depression rarely), autoimmune reactions (especially autoimmune thyroiditis), and miscellaneous side effects such as

alopecia, rashes, diarrhea, and numbness and tingling of the extremities. With the possible exception of autoimmune thyroiditis, all these side effects are reversible upon dose lowering or cessation of therapy.

In patients with chronic hepatitis B, long-term therapy with glucocorticoids is not only ineffective but also detrimental. Short-term glucocorticoid therapy, however, has been advocated as a potential antiviral approach. Glucocorticoids increaseHBVreplication and expression in hepatocytes and depress cytolytic T cells. When glucocorticoids are administered for a brief time and then withdrawn abruptly, cytolytic T cells, suppressed while HBV replication was enhanced by the drug, resume their presteroid function. These restored cytolytic T cells attack hepatocytes, the HBV expression of which had been enhanced by the brief pulse of glucocorticoid therapy. An acute hepatitis-like flare of aminotransferase activity follows and may be accompanied by a dramatic drop, or even loss of, HBV replication. Such glucocorticoid "priming" prior to interferon therapy has not been shown to be more effective than interferon alone and has been abandoned.

Several nucleoside analogues active againstHBV are being evaluated and developed. Famciclovir and ganciclovir have only limited activity against hepatitis B; however, lamivudine, which inhibits reverse transcriptase activity of both HIV and HBV, is a potent and effective agent for patients with chronic hepatitis B. Lamivudine suppresses HBV DNA by a median of four orders of magnitude at oral daily doses of 100 mg. In clinical trials conducted in Asia, North America, Europe, and Australia, lamivudine therapy for 12 months was associated with almost universal suppression of HBV DNA detectable by hybridization assays; loss ofHBeAg in 32 to 33%; HBeAg seroconversion (i.e., conversion from HBeAg-reactive to anti-HBe-reactive) in 16 to 20%; normalization ofALT in approximately 40%; improvement in histology in over 50%; and retardation in fibrosis in 20%. Among patients who experienced HBeAg responses during therapy, 70 to 80% maintained the response over longer than a year of follow-up monitoring. Because maintenance of the response to lamivudine occurs in almost all patients with an HBeAg response, the achievement of an HBeAg response may be a viable stopping point in therapy. If HBeAg is unaffected by lamivudine therapy, the current approach is to continue therapy until an HBeAg response occurs, but long-term therapy may be required to suppress HBV replication and, in turn, limit liver injury. Preliminary observations indicate that HBeAg seroconversions can increase to a level of 27% after 2 years and 44% after 3 years of therapy.

Losses ofHBsAghave been few during lamivudine therapy, and this observation had been cited as an advantage of interferon over lamivudine; however, in head-to-head comparisons between interferon and lamivudine monotherapy, HBsAg losses were rare in both groups. Trials in which lamivudine and interferon were administered in combination failed to show a benefit of combination therapy over lamivudine monotherapy for either treatment-naive patients or prior interferon nonresponders.

Among patients withHBeAgand HBVDNA but with normalALTactivity, lamivudine suppresses liver injury during therapy but rarely achieves an HBeAg response. In patients with pre-core HBV mutations, who lack HBeAg but who have detectable HBV DNA and liver injury, lamivudine suppresses HBV DNA and normalizes ALT in 65% and improves liver histology in 60%. When therapy is discontinued, reactivation is common,

and these patients require long-term therapy.

Clinical and laboratory side effects of lamivudine are negligible, indistinguishable from those observed in placebo recipients. During lamivudine therapy, transientALTelevations, resembling those seen during interferon therapy and during spontaneousHBeAg-to-anti-HBe seroconversions, occur in a quarter of patients. These ALT elevations may result from restored cytolytic T cell activation permitted by suppression of HBV replication. Similar ALT elevations, however, occur at an identical frequency in placebo recipients, but ALT elevations associated with HBeAg seroconversion are confined to lamivudine-treated patients. When therapy is stopped after a year of therapy, 2- to 3-fold ALT elevations occur in 20 to 30% of lamivudine-treated patients, representing renewed liver-cell injury as HBV replication returns. Although these posttreatment flares are almost always transient and mild, rare severe exacerbations have been observed, mandating close and careful clinical and virologic monitoring after discontinuation of treatment.

Long-term monotherapy with lamivudine is associated with methionine-to-valine or methionine-to-isoleucine mutations in the YMDD (tyrosine-methionine-aspartate-aspartate) motif ofHBV DNA polymerase, analogous to mutations that occur in patients with HIV infection treated with this drug. During a year of therapy, YMDD mutations occur in 15 to 30% of patients; the frequency increases at year two to 38% and at year three to almost 50%. Although transient elevations inALT and HBV DNA levels occur when such variants emerge, YMDD-variant HBV appears to be less replicatively competent and a less robust pathogen. Even after YMDD mutations occur, HBV DNA and ALT levels as well as histologic scores tend to remain lower than baseline levels in immunocompetent patients. In immunosuppressed patients, a proportion of patients with YMDD mutations experience hepatic decompensation. Until other antivirals are developed, the approach to YMDD variants emerging during lamivudine treatment is to continue therapy. Other antiviral drugs, such as the experimental agent adefovir dipivoxil, inhibit YMDD-variant HBV. In the future, combination antiviral therapy will almost invariably become the norm as new agents are introduced.

Because lamivudine monotherapy can result universally in the rapid emergence ofYMDDvariants in persons with HIV infection, patients with chronic hepatitis B should be tested for anti-HIV prior to therapy; if HIV infection is identified, lamivudine monotherapy at theHBVdaily dose of 100 mg is contraindicated. These patients should be treated with triple-drug antiretroviral therapy, including a lamivudine daily dose of 300 mg (Chap. 309). The safety of lamivudine during pregnancy has not been established.

No treatment is indicated or available for asymptomatic "nonreplicative" hepatitis B carriers. Whereas patients with decompensated chronic hepatitis B are not candidates for interferon therapy, they may respond to lamivudine, with reversal of the signs of decompensation.

Table 297-4 summarizes the indications in patients with chronic hepatitis B for antiviral therapy with lamivudine, as compared with interferon. Both drugs are quite comparable in efficacy as first-line therapy for chronic hepatitis B (Table 297-5). Interferon requires only brief-duration therapy, too limited in duration to support viral variants, but requires

subcutaneous injections and is associated with a high level of intolerability. Lamivudine requires long-term therapy in most patients and, when used alone, fosters the emergence of viral variants. On the other hand, lamivudine is taken orally, is very well tolerated, leads to improved histology even in the absence of HBeAgresponses, and is effective even in patients who fail to respond to interferon. Although some prefer to begin with interferon, most physicians and patients prefer lamivudine as first-line therapy.

For patients with end-stage chronic hepatitis B, liver transplantation is the only potential lifesaving intervention. Reinfection of the new liver is almost universal; however, the likelihood of liver injury associated with hepatitis B in the new liver is variable. The majority of patients become high-level viremic carriers with minimal liver injury. Unfortunately, an unpredictable proportion experience severe hepatitis B-related liver injury, sometimes a fulminant-like hepatitis, sometimes a rapid recapitulation of the original severe chronic hepatitis B (Chap. 301). Prevention of recurrent hepatitis B after liver transplantation has been achieved by *prophylaxis* with hepatitis B immune globulin and with nucleoside analogues such as lamivudine; in addition, nucleoside analogues have been used successfully to *reverse* posttransplantation liver injury associated with recurrent hepatitis B (Chap. 301).

Chronic Hepatitis D (Delta Hepatitis) The clinical and laboratory features of chronic hepatitis D virus (HDV) infection are summarized inChap. 295. Chronic hepatitis D may follow acute coinfection with HBV but at a rate no higher than the rate of chronicity of hepatitis B. That is, although HDV coinfection can increase the severity of acute hepatitis B,HDV does not increase the likelihood of progression to chronic hepatitis B. However, when HDV superinfection occurs in a person who is already chronically infected with HBV, long-term HDV infection is the rule and a worsening of the liver disease the expected consequence. Except for severity, chronic hepatitis B plus D has similar clinical and laboratory features to those seen in chronic hepatitis B alone. Relatively severe chronic hepatitis, with or without cirrhosis, is the rule, and mild chronic hepatitis the exception. A distinguishing serologic feature of chronic hepatitis D is the presence in the circulation of antibodies to liver-kidney microsomes (anti-LKM); however, the anti-LKM seen in hepatitis D are designated anti-LKM3, are directed against uridine diphosphate glucuronosyltransferase, and are distinct from anti-LKM1 seen in patients with autoimmune hepatitis and in a subset of patients with chronic hepatitis C (see below).

TREATMENT

Management is not well defined. Glucocorticoids are ineffective and are not used. Preliminary experimental trials of interferon asuggested that conventional doses and durations of therapy lower levels ofHDV RNA and aminotransferase activity only transiently during treatment but have no impact on the natural history of the disease. Although high-doseIFN-a(9 million units) three times a week for 12 months may be associated with a sustained loss of HDV replication and clinical improvement in up to 50% of patients, ultimately recurrent HDV replication becomes universal after cessation of therapy. Antiviral therapy for chronic hepatitis D remains the subject of experimental trials; early observations suggest that lamivudine is not effective. In patients with end-stage liver disease secondary to chronic hepatitis D, liver transplantation has been

effective. If hepatitis D recurs in the new liver without the expression of hepatitis B (an unusual serologic profile in immunocompetent persons, but common in transplant patients), liver injury is limited. In fact, the outcome of transplantation for chronic hepatitis D is superior to that for chronic hepatitis B (Chap. 301).

Chronic Hepatitis C Regardless of the epidemiologic mode of acquisition of hepatitis C virus (HCV) infection, chronic hepatitis follows acute hepatitis C in 50 to 70% of cases; even in those with a return to normal in aminotransferase levels after acute hepatitis C, chronic infection is common, adding up to an 85 to 90% likelihood of chronic HCV infection after acute hepatitis C. Furthermore, in patients with chronic transfusion-associated hepatitis followed for 10 to 20 years, progression to cirrhosis occurs in about 20%. Such is the case even for patients with relatively clinically mild chronic hepatitis, including those without symptoms, with only modest elevations of aminotransferase activity, and with mild chronic hepatitis on liver biopsy. Even in cohorts of well-compensated patients with chronic hepatitis C (no complications of chronic liver disease and with normal hepatic synthetic function), the prevalence of cirrhosis may be as high as 50%. Many cases of hepatitis C are identified in asymptomatic patients who have no history of acute hepatitis C, e.g., those discovered while attempting to donate blood or as a result of routine laboratory screening tests. The source of HCV infection in most of these cases is not defined, although a long-forgotten percutaneous exposure in the remote past can be elicited in a substantial proportion. The natural history of chronic hepatitis C identified under these circumstances remains to be determined. Among asymptomatic persons with anti-HCV, even when aminotransferase levels are normal, between a third and a half have been reported to have chronic hepatitis on liver biopsy, although mild in most cases. In these asymptomatic persons with normal aminotransferase levels, the presence of detectable circulatingHCV RNA appears to distinguish those with chronic hepatitis on biopsy from those with normal liver histology.

Despite this substantial rate of progression of chronic hepatitis C, and despite the fact that liver failure can result from end-stage chronic hepatitis C, the long-term prognosis for chronic hepatitis C in a majority of patients is relatively benign. Mortality over 10 to 20 years among patients with transfusion-associated chronic hepatitis C has been shown not to differ from mortality in a matched population of transfused patients in whom hepatitis C did not develop. Although death in the hepatitis group is more likely to result from liver failure, and although hepatic decompensation may occur in approximately 15% of such patients over the course of a decade, the majority (almost 60%) of patients remain asymptomatic and well compensated, with no clinical sequelae of chronic liver disease. Overall, then, chronic hepatitis C tends to be very slowly and insidiously progressive, if at all, in the vast majority of patients, while in approximately a quarter of cases, chronic hepatitis C will progress eventually to end-stage cirrhosis. Referral bias may account for the more severe outcomes described in cohorts of patients reported from tertiary-care centers versus the more benign outcomes in cohorts of patients monitored from initial blood-product-associated acute hepatitis. Still unexplained, however, are the wide ranges in reported progression to cirrhosis, from 2% over 17 years in a population of women with hepatitis C infection acquired from contaminated anti-D immune globulin to 30% over £11 years in recipients of contaminated intravenous immune globulin.

Progression of liver disease in patients with chronic hepatitis C has been reported to be more likely in patients with older age, longer duration of infection, advanced histologic stage and grade, genotype 1 (especially type 1b), more complex quasispecies diversity, and increased hepatic iron. Among these variables, however, duration of infection appears to be the most important, and many of the others probably reflect disease duration to some extent (e.g., quasispecies diversity, hepatic iron accumulation).

Perhaps the best prognostic indicator in chronic hepatitis C is liver histology. Patients with mild necrosis and inflammation as well as those with limited fibrosis have an excellent prognosis and limited progression to cirrhosis. In contrast, among patients with moderate to severe necroinflammatory activity or fibrosis, including septal or bridging fibrosis, progression to cirrhosis is highly likely over the course of 10 to 20 years. Among patients with compensated cirrhosis associated with hepatitis C, the 10-year survival is close to 80 percent; mortality occurs at a rate of 2 to 6% per year, decompensation at a rate of 4 to 5% per year, and hepatocellular carcinoma at a rate of 1 to 3% per year.

In addition, severity of chronic hepatitis is greater and progression of chronic liver disease is more accelerated in patients who have chronic hepatitis C as well as other liver processes, including alcoholic liver disease, chronic hepatitis B, hemochromatosis, and a_1-antitrypsin deficiency. No other epidemiologic or clinical features of chronic hepatitis C (e.g., severity of acute hepatitis, level of aminotransferase activity, level ofHCV RNA, presence or absence of jaundice) are predictive of eventual outcome. Despite the relative benignity of chronic hepatitis C over time, cirrhosis following chronic hepatitis C has been associated with the late development, after several decades, of hepatocellular carcinoma (HCC) (Chap. 91). As noted above, the annual rate of HCC in cirrhotic patients with hepatitis C is 1 to 3%.

Clinical features of chronic hepatitis C are similar to those described above for chronic hepatitis B. Generally, *fatigue* is the most common symptom; jaundice is rare. Immune-complex mediated extrahepatic complications of chronic hepatitis C are less common than in chronic hepatitis B, with the exception of essential mixed cryoglobulinemia (Chap. 295). This is the case despite the fact that assays for immune-complex-like activity are often positive in patients with chronic hepatitis C. In addition, chronic hepatitis C has been associated with extrahepatic complications unrelated to immune-complex injury. These include Sjogren's syndrome, lichen planus, and porphyria cutanea tarda. *Laboratory features* of chronic hepatitis C are similar to those in patients with chronic hepatitis B, but aminotransferase levels tend to fluctuate more (the characteristic episodic pattern of aminotransferase activity) and to be lower, especially in patients with long-standing disease. An interesting and occasionally confusing finding in patients with chronic hepatitis C is the presence of autoantibodies. Rarely, patients with autoimmune hepatitis (see below) and hyperglobulinemia have false-positive enzyme immunoassays for anti-HCV. On the other hand, some patients with serologically confirmable chronic hepatitis C have circulatinganti-LKM. These antibodies are anti-LKM1, as seen in patients with autoimmune hepatitis *type 2* (see below), and are directed against a 33-amino-acid sequence of P450 IID6. The occurrence of anti-LKM1 in some patients with chronic hepatitis C may result from the partial sequence homology between the epitope recognized by anti-LKM1 and two segments of the HCV polyprotein. In addition, the presence of this autoantibody in some

patients with chronic hepatitis C suggests that autoimmunity may be playing a role in the pathogenesis of chronic hepatitis C.*Histopathologic features of chronic hepatitis C, especially those that distinguish hepatitis C from hepatitis B, are described in Chap. 295.

TREATMENT

Two approaches to antiviral therapy of chronic hepatitis C have been approved: *monotherapy* with interferon and *combination therapy* with interferon plus ribavirin. According to a National Institutes of Health Consensus Development Conference in March 1997, responses measured at the end of treatment are referred to as end-treatment responses, and responses sustained for at least 6 months after discontinuation of therapy are referred to as sustained responses.

Interferon Monotherapy Interferon a, administered by subcutaneous injection three times a week for 6 months yields end-treatment biochemical responses (return to normal ofALTlevels) as high as approximately 50% and virologic responses (undetectableHCV RNA) by polymerase chain reaction (PCR) of approximately 30%. Unfortunately, because of a relapse rate as high as 90% in end-treatment responders, these responses are not maintained after discontinuation of therapy except in a small minority of patients; after 6 months of interferon monotherapy, the likelihood of a sustained biochemical and virologic response is only approximately 10%. Even in the absence of a biochemical/virologic response, however, end-treatment histologic responses -- primarily reductions in periportal and lobular activity -- occur in three-fourths of treated patients. Unlike the case in hepatitis B, in chronic hepatitis C successful responses to therapy are not accompanied by transient, acute-hepatitis-like elevations in aminotransferase activity; instead, ALT levels fall precipitously. Between 85 to 90% of responses occur within the first 3 months of therapy; responses thereafter are rare.

In a proportion of cases, markers ofHCVreplication can be eradicated by interferon therapy, and durable responses with normalALT, improved histology, and absence of HCV RNA in serum and liver have been documented many years after successful therapy. A small proportion of patients, approximately 10%, experience biochemical "breakthrough" *during* interferon therapy and are classified as nonresponders. In general, they remain refractory to retreatment thereafter; some such breakthroughs are associated with interferon antibodies, while others may reflect mutations in the HCV genome that render HCV nonresponsive to interferon.

Levels ofHCV RNA fall in tandem withALTlevels during interferon therapy, but loss of detectable HCV RNA does not preclude relapse. When a patient experiences an apparently sustained biochemical response after discontinuing interferon but continues to remain viremic, as reflected by the persistence of detectable HCV RNA, future biochemical relapse is likely. Patient variables that tend to correlate with *sustained* responsiveness to interferon include a low baseline level of HCV RNA and histologically mild hepatitis. Patients with cirrhosis can respond, but they are less likely to do so and especially unlikely to have a *sustained* response. Patients with HCV genotype 1 are less likely to respond than patients with other genotypes. Other variables reported to correlate with increased responsiveness include brief duration of infection, low HCV

quasispecies diversity, immunocompetence, and low liver iron levels. High levels of HCV RNA, more histologically advanced liver disease, and high quasispecies diversity all go hand in hand with advanced duration of infection, which may be the single most important variable determining interferon responsiveness. The ironic fact, then, is that patients whose disease is *least* likely to progress are the ones *most* likely to respond to interferon and vice versa. Finally, among patients with genotype 1b, responsiveness to interferon is enhanced in those with amino-acid-substitution mutations in the nonstructural protein 5A gene.

The most effective approach to increasing responsiveness to interferon monotherapy is to increase the duration of therapy to 12 months or longer, a regimen associated with a sustained biochemical and virologic response of approximately 20%. Higher doses of interferon (e.g., 5 to 10 million units) or daily injections increase response rates only marginally and at a substantial cost in intolerability. Thus, if interferon monotherapy is selected, the consensus is that 3 million units for at least 12 months is the preferred regimen. Currently, three types ofIFN-aare approved in the United States; for the two recombinant products, the recommended dose is 3 million units, and for the one synthetic consensus interferon (synthesized to represent the amino acids at each position that occur most frequently among the multiple, natural interferona subspecies), the dose is 9ug. Several other types of INF-a, including lymphoblastoid interferon, are available in Europe and Asia. A review of the different types of INF-a during the NIH Consensus Development Conference in 1997 led to the conclusion that they are all equivalent in efficacy.

Studies of viral kinetics have shown that despite a virion half life in serum of only 2 to 3 h, the level ofHCV is maintained by a high replication rate of 10_{12}hepatitis C virions per day. Interferon a blocks virion production or release with an efficacy that increases with increasing drug doses; moreover, the calculated death rate for infected cells during interferon therapy is inversely related to viral load; patients with the most rapid death rate of infected hepatocytes are more likely to achieve undetectable HCV RNA at 3 months; achieving this landmark is predictive of a subsequent sustained response. Therefore, to achieve rapid viral clearance from serum and the liver, *high-dose induction therapy* has been advocated. In practice, high-dose induction therapy has not yielded higher sustained response rates. Other approaches that have been suggested include tapering therapy slowly, rather than discontinuing therapy abruptly, and, because high liver iron levels are associated with nonresponsiveness, the addition of phlebotomy to interferon therapy. None of these approaches has been shown to be effective.

Long-acting interferons bound to polyethylene glycol (PEG) have several advantages. Such "pegylated" interferons, with elimination times seven-fold longer than standard interferons, achieve prolonged concentration peaks and can be administered once, rather than three times, a week. Instead of the frequent drug peaks and troughs associated with frequent administration of short-acting interferons, administration of pegylated interferons results in drug concentrations that are more stable and sustained over time. Preliminary studies suggest that once-a-week injections of pegylated interferons are at least as effective as standard interferons given three times a week and may result in sustained responses comparable to those achieved with combination interferon-ribavirin therapy (see below).

If a patient relapses after a course of interferon monotherapy, repeating a course of interferon monotherapy is unlikely to achieve a sustained response unless the dose or preferably the duration of therapy is increased. Under these circumstances, sustained response rates as high as 40% can be realized. Although a small proportion of interferon nonresponders can respond to a repeat course of interferon monotherapy, and although a 13% sustained response rate has been reported for prior interferon nonresponders treated with high-dose (15 ug) consensus interferon, the likelihood of responding is not increased substantially by retreating interferon nonresponders with interferon monotherapy.

Combination Interferon-Ribavirin Therapy The most effective way to increase the efficacy of interferon therapy is to add ribavirin, an oral guanoside nucleoside. When used as monotherapy, ribavirin is ineffective and does not reduceHCV RNA levels. In contrast, the combination of interferon at standard doses with ribavirin at doses of 1000 mg (for patients weighing<75 kg) to 1200 mg (for patients weighing³75 kg) per day increases both end-treatment responses and sustained responses in previously untreated patients. Large, international, multicenter trials have shown that end-treatment responses at 6 months or 12 months exceed 50% and sustained responses as high as 33% at 6 months and 41% at 12 months have been achieved. Thus, a full year of combination therapy is twice as effective as a year of interferon monotherapy. Sustained responses were more likely in patients with low viral loads (below 2 million copies/mL), genotypes other than 1, minimal fibrosis, age<40, and females. In patients with low viral loads and non-1 genotypes, sustained response rates can be as high as 95%, and combination therapy for 24 weeks suffices, achieving the same end as continuing therapy for a full year. Therefore, for patients with low viral loads and non-1 genotypes, therapy need last only 6 months. Unless contraindications to the use of combination therapy exist (see below), combination interferon-ribavirin is the treatment of choice for chronic hepatitis C (Table 297-6).

For those who relapse after a 6-month course of interferon monotherapy, a 6-month course of combination therapy results in a sustained response rate of 50%, and retreatment of relapsers is another approved indication for combination therapy. Unfortunately, combination therapy has been disappointing in interferon nonresponders.

Side effects of combination therapy are similar to those of interferon monotherapy; however, ribavirin causes hemolysis; a reduction in hemoglobin of up to 2 to 3 gm or in hematocrit of up 5 to 10% can be anticipated. A small, unpredictable proportion of patients will experience profound, brisk hemolysis, resulting in symptomatic anemia. Therefore, close monitoring of blood counts is crucial, and combination therapy should be avoided in patients with anemia or hemoglobinopathies and in patients with coronary artery disease or cerebrovascular disease, in whom anemia can precipitate an ischemic event. Ribavirin, which is renally excreted, should not be used by patients with renal insufficiency; the drug is teratogenic, precluding its use during pregnancy and mandating the use of efficient contraception during therapy.

Ribavirin therapy has also been characterized by nasal congestion, pruritus, and precipitation of gout; the combination is more difficult to tolerate than interferon monotherapy. In one large clinical trial of combination therapy versus monotherapy among patients treated for a year, 21% of the combination group (but only 14% of the

monotherapy group) had to discontinue treatment, while 26% of the combination group (but only 9% of the monotherapy group) required dose reductions.

Indications for Antiviral Therapy Patients with chronic hepatitis C who have elevatedALTlevels, detectableHCV RNA, and chronic hepatitis of at least moderate grade and stage are candidates for antiviral therapy with interferon and ribavirin, unless ribavirin is contraindicated (Table 297-6). Preliminary retrospective analyses have shown that interferon treatment improves survival and complication-free survival. One year of combination therapy is standard, but 6 months suffice for patients with non-1 genotypes and low viral loads. For patients treated with interferon monotherapy, 12 months is the standard duration in all cases, regardless of genotype and viral load. According to the NIH Consensus Development Conference in 1997, therapy should be discontinued in patients who have not achieved a normal ALT and an undetectable HCV RNA by month three. Although the vast majority of patients treated with combination therapy who become sustained responders will have achieved an early biochemical and virologic response, a proportion of sustained responders experienced late viral clearance. In addition, even in biochemical and virologic nonresponders, histologic improvement is common. Therefore, recommendations for early cessation of therapy based on interim assessments of biochemical and virologic responsiveness require reevaluation. Although response rates are lower in patients with certain pretreatment variables, selection for treatment should not be based on symptoms, genotype, viral load, or the mode of acquisition of infection.

Patients who have relapsed after an initial course of interferon monotherapy are candidates for a 6-month course of combination interferon-ribavirin therapy; if they cannot tolerate ribavirin, they should be retreated with interferon monotherapy, but the course should be longer. It remains to be determined whether long-term (even indefinite) maintenance therapy will be necessary or effective in patients who relapse repeatedly whenever therapy is discontinued. For interferon nonresponders, retreatment with interferon monotherapy or combination therapy is unlikely to achieve a sustained response. Clinical trials are in progress to determine whether long-term suppression of virus-induced liver injury with antiviral therapy will be of benefit in this population.

In patients with acute hepatitis C, a course of interferon has been shown to reduce the likelihood of chronicity by one-half (Chapter 295). In patients with normalALTlevels, long-term monitoring studies have shown absence of histologic progression, and clinical trials of antiviral therapy have shown no benefit; therefore, treatment of such patients is not recommended. Because hepatitis C can reactivate in patients with normal ALT levels, laboratory monitoring several times a year should be done, and therapy should be considered for sustained elevations in ALT levels. Patients with mild hepatitis on liver biopsy are not routine candidates for antiviral therapy, but treatment decisions should be individualized between physician and patient. Most authorities would recommend a pretreatment liver biopsy to help in the decision-making about therapy.

Patients with compensated cirrhosis can respond to therapy, although their likelihood of a sustained response is lower than in noncirrhotics. Combination therapy brings sustained response rates in cirrhotics up to the level achieved with interferon monotherapy in noncirrhotics. Retrospective analyses generally have not demonstrated an improvement in survival among interferon-treated cirrhotic patients. Similarly, several

studies have suggested that treatment of cirrhotics with hepatitis C reduces the frequency ofHCC; however, logistic regression analyses have shown that patient characteristics at the time of therapy (e.g., less advanced disease), not treatment itself, accounted for the reduced frequency of HCC observed in the treated cohort. Patients with decompensated cirrhosis are not candidates for antiviral therapy but should be referred for liver transplantation. After liver transplantation, recurrent hepatitis C is the rule. Most patients who undergo liver transplantation for chronic hepatitis C experience little, if any, morbidity, allograft loss, or mortality associated with recurrent hepatitis C during the early postoperative years (Chapter 301); studies are in progress to determine how best to treat hepatitis C after liver transplantation. The cutaneous and renal vasculitis ofHCV-associated essential mixed cryoglobulinemia (Chap. 295) may respond to interferon, but sustained responses are rare after discontinuation of therapy; therefore, prolonged, perhaps indefinite, therapy is recommended in this group.

Anecdotal reports suggest that antiviral therapy may be effective in porphyria cutanea tarda or lichen planus associated with hepatitis C. In patients with HIV infection, responses similar to those seen in other groups have been reported in patients with normal CD4 counts.

AUTOIMMUNE HEPATITIS

Definition Autoimmune hepatitis (formerly called autoimmune chronic active hepatitis) is a chronic disorder characterized by continuing hepatocellular necrosis and inflammation, usually with fibrosis, which tends to progress to cirrhosis and liver failure. When fulfilling criteria of severity, this type of chronic hepatitis may have a 6-month mortality of as high as 40%. The prominence of extrahepatic features of autoimmunity as well as seroimmunologic abnormalities in this disorder supports an autoimmune process in its pathogenesis; this concept is reflected in the labels "lupoid," plasma cell, or autoimmune hepatitis. Because autoantibodies and other typical features of autoimmunity do not occur in all cases, however, a broader, more appropriate designation for this type of chronic hepatitis is "idiopathic" or cryptogenic. Cases in which hepatotropic viruses, metabolic/genetic derangements, and hepatotoxic drugs have been excluded merit this designation and probably include a spectrum of heterogeneous liver disorders of unknown cause, a proportion of which have characteristic autoimmune features.

Immunopathogenesis The weight of evidence suggests that the progressive liver injury in patients with idiopathic/autoimmune hepatitis is the result of a cell-mediated immunologic attack directed against liver cells; in all likelihood, predisposition to autoimmunity is inherited, while the liver specificity of this injury is triggered by environmental (e.g., chemical or viral) factors. For example, patients have been described in whom apparently self-limited cases of acute hepatitis A or B led to autoimmune hepatitis, presumably because of genetic susceptibility or predisposition. Evidence to support an autoimmune pathogenesis in this type of hepatitis includes the following: (1) In the liver, the histopathologic lesions are composed predominantly of cytotoxic T cells and plasma cells; (2) circulating autoantibodies (nuclear, smooth muscle, thyroid, etc.; see below), rheumatoid factor, and hyperglobulinemia are common; (3) other autoimmune disorders -- such as thyroiditis, rheumatoid arthritis, autoimmune hemolytic anemia, ulcerative colitis, proliferative glomerulonephritis,

juvenile diabetes mellitus, and Sjogren's syndrome -- occur with increased frequency in patients who have autoimmune hepatitis and in their relatives; (4) histocompatibility haplotypes associated with autoimmune diseases, such as HLA-B1, -B8, -DR3, and -DR4, are common in patients with autoimmune hepatitis; and (5) this type of chronic hepatitis is responsive to glucocorticoid/immunosuppressive therapy, effective in a variety of autoimmune disorders.

Cellular immune mechanisms appear to be important in the pathogenesis of autoimmune hepatitis. In vitro studies have suggested that in patients with this disorder, lymphocytes are capable of becoming sensitized to hepatocyte membrane proteins and of destroying liver cells. Abnormalities of immunoregulatory control over cytotoxic lymphocytes (impaired suppressor cell influences) may play a role as well. Studies of genetic predisposition to autoimmune hepatitis demonstrate that certain haplotypes are associated with the disorder, as enumerated above. The precise triggering factors, genetic influences, and cytotoxic and immunoregulatory mechanisms involved in this type of liver injury remain poorly defined.

Intriguing clues into the pathogenesis of autoimmune hepatitis come from the observation that circulating autoantibodies are prevalent in patients with this disorder. Among the autoantibodies described in these patients are antibodies to nuclei [so-called antinuclear antibodies (ANA), primarily in a homogeneous pattern] and smooth muscle (so-called anti-smooth-muscle antibodies, directed at actin),anti-LKM(see below), antibodies to "soluble liver antigen" (directed at a member of the glutathione S-transferase gene family), as well as antibodies to the liver-specific asialoglycoprotein receptor (or "hepatic lectin") and other hepatocyte membrane proteins. Although some of these provide helpful diagnostic markers, their involvement in the pathogenesis of autoimmune hepatitis has not been established.

Humoral immune mechanisms have been shown to play a role in the extrahepatic manifestations of autoimmune/idiopathic hepatitis. Arthralgias, arthritis, cutaneous vasculitis, and glomerulonephritis occurring in patients with autoimmune hepatitis appear to be mediated by the deposition in affected tissue vessels of circulating immune complexes, followed by complement activation, inflammation, and tissue injury. While specific viral antigen-antibody complexes can be identified in acute and chronic viral hepatitis, the nature of the immune complexes in autoimmune hepatitis has not been defined.

Many of the *clinical features* of autoimmune hepatitis are similar to those described for chronic viral hepatitis. The onset of disease may be insidious or abrupt; the disease may present initially like, and be confused with, acute viral hepatitis; a history of recurrent bouts of what had been labeled acute hepatitis is not uncommon. A subset of patients with autoimmune hepatitis has distinct features. Such patients are predominantly young to middle-aged women with marked hyperglobulinemia and high-titer circulatingANA. This is the group with positive LE preparations (initially labeled "lupoid" hepatitis) in whom other autoimmune features are common. Fatigue, malaise, anorexia, amenorrhea, acne, arthralgias, and jaundice are common. Occasionally, arthritis, maculopapular eruptions (including cutaneous vasculitis), erythema nodosum, colitis, pleurisy, pericarditis, anemia, azotemia, and sicca syndrome (keratoconjunctivitis, xerostomia) occur. In some patients, complications of cirrhosis, such as ascites and

edema (associated with hypoalbuminemia), encephalopathy, hypersplenism, coagulopathy, or variceal bleeding may bring the patient to initial medical attention.

The course of autoimmune hepatitis may be variable. In those with mild disease or limited histologic lesions (e.g., piecemeal necrosis without bridging), progression to cirrhosis is limited. In those with severe symptomatic autoimmune hepatitis (aminotransferase levels >10 times normal, marked hyperglobulinemia, "aggressive" histologic lesions -- bridging necrosis or multilobular collapse, cirrhosis), the 6-month mortality without therapy may be as high as 40%. Such severe disease accounts for only 20% of cases; the natural history of milder disease is variable, often accentuated by spontaneous remissions and exacerbations. Especially poor prognostic signs include multilobular collapse at the time of initial presentation and failure of the bilirubin to improve after 2 weeks of therapy. Death may result from hepatic failure, hepatic coma, other complications of cirrhosis (e.g., variceal hemorrhage), and intercurrent infection. In patients with established cirrhosis, hepatocellular carcinoma may be a late complication (Chap. 91).

Laboratory features of autoimmune hepatitis are similar to those seen in chronic viral hepatitis. Liver biochemical tests are invariably abnormal but may not correlate with the clinical severity or histopathologic features in individual cases. Many patients with autoimmune hepatitis have normal serum bilirubin, alkaline phosphatase, and globulin levels with only minimal aminotransferase elevations. SerumAST andALTlevels are increased and fluctuate in the range of 100 to 1000 units. In severe cases, the serum bilirubin level is moderately elevated [51 to 171 umol/L (3 to 10 mg/dL)]. Hypoalbuminemia occurs in patients with very active or advanced disease. Serum alkaline phosphatase levels may be moderately elevated or near normal. In a small proportion of patients, marked elevations of alkaline phosphatase activity occur; in such patients, clinical and laboratory features overlap with those of primary biliary cirrhosis (Chap. 299). The prothrombin time is often prolonged, particularly late in the disease or during active phases.

Hypergammaglobulinemia (>2.5 g/dL) is common in autoimmune hepatitis. Rheumatoid factor is common as well. As noted above, circulating autoantibodies are also common. The most characteristic areANA in a homogeneous staining pattern. Smooth-muscle antibodies are less specific, seen just as frequently in chronic viral hepatitis. Because of the high levels of globulins achieved in the circulation of some patients with autoimmune hepatitis, occasionally the globulins may bind nonspecifically in solid-phase binding immunoassays for viral antibodies. This has been recognized most commonly in tests for antibodies to hepatitis C virus, as noted above. In fact, studies of autoantibodies in autoimmune hepatitis have led to the recognition of new categories of autoimmune hepatitis. *Type I autoimmune hepatitis* is the classic syndrome occurring in young women, associated with marked hyperglobulinemia, lupoid features, and circulating ANA. *Type II autoimmune hepatitis*, often seen in children and more common in Mediterranean populations, is associated not with ANA but withanti-LKM. Actually, anti-LKM represent a heterogeneous group of antibodies. In type II autoimmune hepatitis, the antibody is anti-LKM1, directed against P450 IID6. This is the same anti-LKM seen in some patients with chronic hepatitis C. Anti-LKM2 is seen in drug-induced hepatitis, and anti-LKM3 is seen in patients with chronic hepatitis D. Type II autoimmune hepatitis has been subdivided by some authorities into two categories,

one more typically autoimmune and the other associated with viral hepatitis type C. Autoimmune hepatitis type IIa is felt to be autoimmune, is more likely to occur in young women, is associated with hyperglobulinemia, is associated with high-titer anti-LKM1, responds to glucocorticoid therapy, and is seen commonly in western Europe and the United Kingdom. Type IIb autoimmune hepatitis is associated with hepatitis C virus infection, tends to occur in older men, is associated with normal globulin levels and low-titer anti-LKM1, responds to interferon, and occurs most commonly in Mediterranean countries. In addition, another type of autoimmune hepatitis has been recognized, *autoimmune hepatitis type III*. These patients lack ANA and anti-LKM1 and have circulating antibodies to soluble liver antigen, which are directed at hepatocyte cytoplasmic cytokeratins 8 and 18. Most of these patients are women and have clinical features similar to those of patients with type I autoimmune hepatitis.

TREATMENT

The mainstay of management in autoimmune or idiopathic (nonviral) hepatitis is glucocorticoid therapy. Several controlled clinical trials have documented that such therapy leads to symptomatic, clinical, biochemical, and histologic improvement as well as increased survival. A therapeutic response can be expected in up to 80% of patients. Unfortunately, therapy has not been shown to prevent ultimate progression to cirrhosis. Although some advocate the use of prednisolone (the hepatic metabolite of prednisone), prednisone is just as effective and is favored by most authorities. Therapy may be initiated at 20 mg/d, but a popular regimen in the United States relies on an initiation dose of 60 mg/d. This high dose is tapered successively over the course of a month down to a maintenance level of 20 mg/d. An alternative but equally effective approach is to begin with half the prednisone dose (30 mg/d) along with azathioprine (50 mg/d). With azathioprine maintained at 50 mg/d, the prednisone dose is tapered over the course of a month down to a maintenance level of 10 mg/d. The advantage of the combination approach is a reduction, over the span of an 18-month course of therapy, in serious, life-threatening complications of steroid therapy from 66% down to under 20%. Azathioprine alone, however, is not effective in achieving remission, nor is alternate-day glucocorticoid therapy. Although therapy has been shown to be effective for severe autoimmune hepatitis, therapy is not indicated for mild forms of chronic hepatitis (which used to be labeled chronic persistent hepatitis or chronic lobular hepatitis), and the efficacy of therapy in mild or asymptomatic autoimmune hepatitis has not been established.

Improvement of fatigue, anorexia, malaise, and jaundice tends to occur within days to several weeks; biochemical improvement occurs over the course of several weeks to months, with a fall in serum bilirubin and globulin levels and an increase in serum albumin. Serum aminotransferase levels usually drop promptly, but improvements inAST andALTalone do not appear to be a reliable marker of recovery in individual patients; histologic improvement, characterized by a decrease in mononuclear infiltration and in hepatocellular necrosis may be delayed for 6 to 24 months. Still, if interpreted cautiously, aminotransferase levels are valuable indicators of relative disease activity, and many authorities do *not* advocate serial liver biopsies to assess therapeutic success or to guide decisions to alter or stop therapy. Therapy should continue for at least 12 to 18 months. After tapering and cessation of therapy, the likelihood of relapse is at least 50%, even if posttreatment histology has improved to

show mild chronic hepatitis, and the majority of patients require therapy at maintenance doses indefinitely. Continuing azathioprine alone after cessation of prednisone therapy may reduce the frequency of relapse.

If medical therapy fails, or when chronic hepatitis progresses to cirrhosis and is associated with life-threatening complications of liver decompensation, liver transplantation is the only recourse (Chap. 301). Recurrence of autoimmune hepatitis in the new liver occurs rarely, if at all.

DIFFERENTIAL DIAGNOSIS

Early during the course of chronic hepatitis, the disease may resemble typical *acute viral hepatitis*. Without histologic assessment, severe chronic hepatitis cannot be readily distinguished based on clinical or biochemical criteria from mild chronic hepatitis. In adolescence, *Wilson's disease* may present with features of chronic hepatitis long before neurologic manifestations become apparent and before the formation of Kayser-Fleischer rings; in this age group, serum ceruloplasmin and serum and urinary copper determinations plus measurement of liver copper levels will establish the correct diagnosis. *Postnecrotic* or *cryptogenic cirrhosis* and *primary biliary cirrhosis* share clinical features with autoimmune hepatitis; biochemical, serologic, and histologic assessments are usually sufficient to allow these entities to be distinguished from autoimmune hepatitis. Of course, the distinction between autoimmune ("idiopathic") and chronic viral hepatitis is not always straightforward, especially when viral antibodies occur in patients with autoimmune disease or when autoantibodies occur in patients with viral disease. Finally, the presence of extrahepatic features such as arthritis, cutaneous vasculitis, or pleuritis -- not to mention the presence of circulating autoantibodies -- may cause confusion with *rheumatologic disorders* such as rheumatoid arthritis and systemic lupus erythematosus. The existence of clinical and biochemical features of progressive necroinflammatory liver disease distinguishes chronic hepatitis from these other disorders, which are not associated with severe liver disease.

298. ALCOHOLIC LIVER DISEASE - *Mark E. Mailliard*, *Michael F. Sorrell*

Chronic and excessive alcohol ingestion is one of the major causes of liver disease in the western world. Classically, alcoholic liver injury comprises three major forms: (1) fatty liver, (2) alcoholic hepatitis, and (3) cirrhosis. Although cirrhosis is discussed in Chap. 299, it is important to emphasize that rarely does a pure form of liver injury exist by itself. Fatty liver is present in over 90% of binge and heavy drinkers. A much smaller percentage of drinkers progress to alcoholic hepatitis, thought to be a precursor to cirrhosis. Although alcohol is considered a direct hepatotoxin, only 10 to 20% of alcoholics develop alcoholic hepatitis. The explanation for this apparent paradox is unclear but involves complex factors such as gender and heredity.

ETIOLOGY AND PATHOGENESIS

Quantity and duration of alcohol intake are the most important risk factors involved in the development of alcoholic liver disease (Table 298-1). The roles of beverage type and pattern of drinking are less clear. Progress of the hepatic injury beyond the fatty liver stage seems to require additional risk factors that remain incompletely defined. Women are more susceptible to alcoholic liver injury than men; they develop advanced liver disease with substantially less alcohol intake. In general, the time it takes to develop liver disease is directly related to the amount of alcohol consumed. It is useful in estimating alcohol consumption to understand that one beer, four ounces of wine, or one ounce of 80% spirits all contain approximately 12 g of alcohol. The threshold for developing severe alcoholic liver disease in men is an intake of >60 to 80 g/d of alcohol for 10 years, while women are at increased risk for developing similar degrees of liver injury by consuming 20 to 40 g/d. Gender-dependent differences in the gastric and hepatic metabolism of alcohol, in addition to poorly understood hormonal factors, likely contribute to the increased susceptibility of women to alcohol-induced liver injury. Social, nutritional, immunologic, and host factors have all been postulated to play a part in the development of the pathogenic process.

Chronic infection with hepatitis C (HCV) (Chap. 297) is an important risk factor in the progression and acceleration of alcoholic liver disease. The presence of HCV in patients with severe alcoholic liver disease is increased five- to tenfold above that in a matched control alcoholic population. Patients with both alcoholic liver injury and HCV develop decompensated liver disease at a younger age and have poorer overall survival rates. As a consequence of the overlapping injurious processes secondary to alcohol abuse and HCV infection, patients can develop an increased liver iron burden and rarely, porphyria cutanea tarda.

Our understanding of the pathogenesis of alcoholic liver injury is incomplete. Alcohol is a direct hepatotoxin, but ingestion of alcohol initiates a variety of metabolic responses that influence the final hepatotoxic response. The initial concept of malnutrition as the major pathogenic mechanism has given way to the present understanding that the metabolism of alcohol by the hepatocyte initiates a cascade of events involving production of protein-aldehyde adducts, lipid peroxidation, immunologic events, and cytokine release (Fig. 298-1). The production of cytokines is in large measure responsible for the systemic manifestations of alcoholic hepatitis, e.g., fever, leukocytosis, and anorexia. The degree of fibrosis stimulated by these complex events

determines the extent of architectural derangement of the liver after chronic alcohol ingestion.

PATHOLOGY

The liver has a limited repertoire in response to injury. Fatty liver is the initial and most common histologic response to increased alcohol ingestion. The accumulation of fat in the perivenular hepatocytes coincides with the location of alcohol dehydrogenase, the major enzyme responsible for alcohol metabolism. Continuing alcohol ingestion results in fat accumulation throughout the entire hepatic lobule. Despite extensive fatty changes and distortion of the hepatocytes with macrovesicular fat, the cessation of drinking results in normalization of hepatic architecture and fat content in the liver. Alcoholic fatty liver has traditionally been regarded as entirely benign; but similar to the spectrum of non-alcoholic steatohepatitis, certain pathologic features such as giant mitochondria, perivenular fibrosis, and macrovesicular fat may be associated with progressive liver injury.

The transition between fatty liver and the development of alcoholic hepatitis is blurred. The hallmark of alcoholic hepatitis is hepatocyte injury characterized by ballooning degeneration, spotty necrosis, polymorphonuclear infiltration, and fibrosis in the perivenular and perisinusoidal space of Disse. Mallory bodies are often present in florid cases but are neither specific nor necessary to establishing the diagnosis. Alcoholic hepatitis is thought to be a precursor to the development of cirrhosis. However, like fatty liver, it is potentially reversible with cessation of drinking. Cirrhosis is present in up to 50% of patients with biopsy-proven alcoholic hepatitis.

CLINICAL FEATURES

The clinical manifestations of alcoholic fatty liver are subtle and characteristically detected as a consequence of the patient's visit for a seemingly unrelated matter. Previously unsuspected hepatomegaly is often the only clinical finding. Occasionally, patients with fatty liver present with right upper quadrant discomfort, tender hepatomegaly, nausea, and jaundice. Differentiation of alcoholic fatty liver from non-alcoholic fatty liver is difficult unless an accurate drinking history is verified. Alcoholism does not respect social and economic class. In every instance where liver disease is present, a thoughtful and sensitive drinking history should be obtained. Alcoholic hepatitis is associated with a wide gamut of clinical features. Fever, spider nevi, jaundice, and abdominal pain simulating an acute abdomen represent the extreme end of the spectrum; but many patients are entirely asymptomatic. Recognition of the clinical features of alcoholic hepatitis is central to the initiation of an effective and appropriate diagnostic and therapeutic strategy.

LABORATORY FEATURES

Patients with alcoholic fatty liver are often identified through routine screening tests. The typical laboratory abnormalities are nonspecific and include modest elevations of the aspartate aminotransferase (AST) and alanine aminotransferase (ALT) accompanied by hypertriglyceridemia, hypercholesterolemia, and, occasionally, hyperbilirubinemia. In alcoholic hepatitis and in contrast to other causes of fatty liver, the AST and ALT are

usually elevated two- to sevenfold. They rarely are above 400 IU, and the AST/ALT ratio is >1 (Table 298-2). Hyperbilirubinemia is common and is accompanied by modest increases in the alkaline phosphatase. Derangement in hepatocyte synthetic function indicates more serious disease. Hypoalbuminemia and coagulopathy are common in advanced liver injury. The mean corpuscular volume (MCV) and uric acid level are commonly elevated in chronic alcohol abuse. Measurement of the carbohydrate-deficient transferrin (CDT) is superior to the measurement of the gamma-glutamyl transpeptidase (GGTP) or MCV in identifying excessive drinking. Ultrasonography is useful in detecting fatty infiltration of the liver and determining liver size. The demonstration by ultrasound of portal vein flow reversal, ascites, and intra-abdominal collaterals indicates serious liver injury with less potential for complete reversal of liver disease.

PROGNOSIS

Critically ill patients with alcoholic hepatitis have short-term mortality rates approaching 70%. Severe alcoholic hepatitis is heralded by coagulopathy (prothrombin time >5 s), anemia, serum albumin concentrations below 2.5 mg/dL, serum bilirubin levels>8 mg/dL, renal failure, and ascites. A discriminant function calculated as 4.6 ´[prothrombin time - control(seconds)] + serum bilirubin (mg/dL) can identify patients with a poor prognosis (discriminant function >32). The presence of ascites, variceal hemorrhage, deep encephalopathy, or hepatorenal syndrome predicts a dismal prognosis. The pathologic stage of the injury can be helpful in predicting prognosis. Liver biopsy should be performed whenever possible to confirm the diagnosis, to establish potential reversibility of the liver disease, and to guide the therapeutic decisions.

TREATMENT

Complete abstinence from alcohol is the cornerstone in the treatment of alcoholic liver disease. Improved survival rates and the potential for reversal of histologic injury regardless of the initial clinical presentation are associated with total avoidance of alcoholic ingestion. Referral of patients to experienced alcohol counselors and/or alcohol treatment programs should be routine in the management of patients with alcoholic liver disease. Attention should be directed to the nutritional and psychosocial states during the evaluation and treatment periods. Because of data suggesting that the pathogenic mechanisms in alcoholic hepatitis involve cytokine release and the perpetuation of injury by immunologic processes, glucocorticoids have been extensively evaluated in the treatment of alcoholic hepatitis. Patients with severe alcoholic hepatitis, defined as a discriminant function >32, were given prednisone, 40 mg/d, or prednisolone, 32 mg/d, for 4 weeks followed by a steroid taper (Fig. 298-2). Exclusion criteria included active gastrointestinal bleeding, sepsis, renal failure, or pancreatitis. Because of inordinate surgical mortality rates and the high rates of recidivism after transplantation, patients with alcoholic hepatitis are not candidates for immediate liver transplantation. The transplant candidacy of these patients should be reevaluated after a defined period of sobriety.

299. CIRRHOSIS AND ITS COMPLICATIONS - *Raymond T. Chung*, *Daniel K. Podolsky*

Cirrhosis is a pathologically defined entity that is associated with a spectrum of characteristic clinical manifestations. The cardinal pathologic features reflect irreversible chronic injury of the hepatic parenchyma and include extensive fibrosis in association with the formation of regenerative nodules. These features result from hepatocyte necrosis, collapse of the supporting reticulin network with subsequent connective tissue deposition, distortion of the vascular bed, and nodular regeneration of remaining liver parenchyma. The central event leading to hepatic fibrosis is activation of the hepatic stellate cell. Upon activation by factors released by hepatocytes and Kupffer cells, the stellate cell assumes a myofibroblast-like conformation and, under the influence of cytokines such as transforming growth factor b(TGF-b), produces fibril-forming type I collagen. The precise point at which fibrosis becomes irreversible is unclear. The pathologic process should be viewed as a final common pathway of many types of chronic liver injury. Clinical features of cirrhosis derive from the morphologic alterations and often reflect the severity of hepatic damage rather than the etiology of the underlying liver disease. Loss of functioning hepatocellular mass may lead to jaundice, edema, coagulopathy, and a variety of metabolic abnormalities; fibrosis and distorted vasculature lead to portal hypertension and its sequelae, including gastroesophageal varices and splenomegaly. Ascites and hepatic encephalopathy result from both hepatocellular insufficiency and portal hypertension.

Classification of the various types of cirrhosis based on either etiology or morphology alone is unsatisfactory. A single pathologic pattern may result from a variety of insults, while the same insult may produce several morphologic patterns. Nevertheless, most types of cirrhosis may be usefully classified by a mixture of etiologically and morphologically defined entities as follows: (1) alcoholic; (2) cryptogenic and posthepatitic; (3) biliary; (4) cardiac; and (5) metabolic, inherited, and drug-related. This chapter considers the various types of cirrhosis and their complications.

ALCOHOLIC CIRRHOSIS

Definition *Alcoholic cirrhosis* is only one of many consequences resulting from chronic alcohol ingestion, and it often accompanies other forms of alcohol-induced liver injury, including alcoholic fatty liver and alcoholic hepatitis (Chap. 298). Alcoholic cirrhosis, historically referred to as *Laennec's cirrhosis*, is the most common type of cirrhosis encountered in North America and many parts of western Europe and South America. It is characterized by diffuse fine scarring, fairly uniform loss of liver cells, and small regenerative nodules, and therefore it is sometimes referred to as *micronodular cirrhosis*. However, micronodular cirrhosis may also result from other types of liver injury (e.g., following jejunoileal bypass), and thus alcoholic cirrhosis and micronodular cirrhosis are not necessarily synonymous. Conversely, alcoholic cirrhosis may progress to macronodular cirrhosis with time.

Etiology SeeChap. 298, "Alcoholic Liver Disease."

Pathology and Pathogenesis With continued alcohol intake and destruction of hepatocytes, fibroblasts (including activated hepatic stellate cells that have transformed

into myofibroblasts with contractile properties) appear at the site of injury and deposit collagen. Weblike septa of connective tissue appear in periportal and pericentral zones and eventually connect portal triads and central veins. This fine connective tissue network surrounds small masses of remaining liver cells, which regenerate and form nodules. Although regeneration occurs within the small remnants of parenchyma, cell loss generally exceeds replacement. With continuing hepatocyte destruction and collagen deposition, the liver shrinks in size, acquires a nodular appearance, and becomes hard as "end-stage" cirrhosis develops. Although alcoholic cirrhosis is usually a progressive disease, appropriate therapy and strict avoidance of alcohol may arrest the disease at most stages and permit functional improvement. In addition, there is strong evidence that concomitant chronic hepatitis C virus (HCV) infection significantly accelerates development of alcoholic cirrhosis.

Clinical Features

Signs and Symptoms Alcoholic cirrhosis may be clinically silent, and many cases (10 to 40%) are discovered incidentally at laparotomy or autopsy. In many cases symptoms are insidious in onset, occurring usually after 10 or more years of excessive alcohol use and progressing slowly over subsequent weeks and months. Anorexia and malnutrition lead to weight loss and a reduction in skeletal muscle mass. The patient may experience easy bruising, increasing weakness, and fatigue. Eventually the clinical manifestations of hepatocellular dysfunction and portal hypertension ensue, including progressive jaundice, bleeding from gastroesophageal varices, ascites, and encephalopathy. The abrupt onset of one of these complications may be the first event prompting the patient to seek medical attention. In other cases, cirrhosis first becomes evident when the patient requires treatment of symptoms related to alcoholic hepatitis.

A firm, nodular liver may be an early sign of disease; the liver may be either enlarged, normal, or decreased in size. Other frequent findings include jaundice, palmar erythema, spider angiomas, parotid and lacrimal gland enlargement, clubbing of fingers, splenomegaly, muscle wasting, and ascites with or without peripheral edema. Men may have decreased body hair and/or gynecomastia and testicular atrophy, which, like the cutaneous findings, result from disturbances in hormonal metabolism, including increased peripheral formation of estrogen due to diminished hepatic clearance of the precursor androstenedione. Testicular atrophy may reflect hormonal abnormalities or the toxic effect of alcohol on the testes. In women, signs of virilization or menstrual irregularities may occasionally be encountered. Dupuytren's contractures resulting from fibrosis of the palmar fascia with resulting flexion contracture of the digits are associated with alcoholism but are not specifically related to cirrhosis.

Although the cirrhotic patient may stabilize if drinking is discontinued, over a period of years, the patient may become emaciated, weak, and chronically jaundiced. Ascites and other signs of portal hypertension may become increasingly prominent. Ultimately, most patients with advanced cirrhosis die in hepatic coma, commonly precipitated by hemorrhage from esophageal varices or intercurrent infection. Progressive renal dysfunction often complicates the terminal phase of the illness.

Laboratory Findings In advanced alcoholic liver disease, abnormalities of laboratory tests are more common. Anemia may result from acute and chronic gastrointestinal

blood loss, coexistent nutritional deficiency (notably of folic acid and vitamin B_{12}), hypersplenism, and a direct suppressive effect of alcohol on the bone marrow. Hemolytic anemia, presumably due to effects of hypercholesterolemia or erythrocyte membranes resulting in unusual spurlike projections (acanthocytosis), has been described in some alcoholics with cirrhosis. Mild or pronounced hyperbilirubinemia may be found, usually in association with varying elevations of serum alkaline phosphatase levels. Levels of serum AST (asparate aminotransferase) are frequently elevated, but levels>5ukat (300 units) are unusual and should prompt one to look for other coincident or complicating factors. In contrast to viral hepatitis, the serum AST is usually disproportionately elevated relative to ALT (alanine aminotransferase), i.e., AST/ALT ratio >2. This discrepancy in alcoholic liver disease may result from the proportionally greater inhibition of ALT synthesis by ethanol, which may be partially reversed by pyridoxal phosphate.

The serum prothrombin time is frequently prolonged, reflecting reduced synthesis of clotting proteins, most notably the vitamin K-dependent factors (see "Coagulopathy," below). The serum albumin level is usually depressed, while serum globulins are increased. Hypoalbuminemia reflects in part overall impairment in hepatic protein synthesis, while hyperglobulinemia is thought to result from nonspecific stimulation of the reticuloendothelial system. Elevated blood ammonia levels in patients with hepatic encephalopathy reflect diminished hepatic clearance because of impaired liver function and shunting of portal venous blood around the cirrhotic liver into the systemic circulation (see "Hepatic Encephalopathy," below).

A variety of metabolic disturbances may be detected. Glucose intolerance due to endogenous insulin resistance may be present; however, clinical diabetes is uncommon. Central hyperventilation may lead to respiratory alkalosis in patients with cirrhosis. Dietary deficiency and increased urinary losses lead to hypomagnesemia and hypophosphatemia. In patients with ascites and dilutional hyponatremia, hypokalemia may occur from increased urinary potassium losses due in part to hyperaldosteronism. Prerenal azotemia is also observed in such patients.

Diagnosis Alcoholic cirrhosis should be strongly suspected in patients with a history of prolonged or excessive alcohol intake and physical signs of chronic liver disease. However, since only 10 to 15% of individuals with excessive alcohol intake develop cirrhosis, other causes and types of liver disease may have to be excluded. The clinical features and laboratory findings are usually sufficient to provide reasonable indication of the presence and extent of hepatic injury. Although a percutaneous needle biopsy of the liver is not usually necessary to confirm the typical findings of alcoholic hepatitis or cirrhosis, it may be helpful in distinguishing patients with less advanced liver disease from those with cirrhosis and in excluding other forms of liver injury such as viral hepatitis. Biopsy may also be helpful as a diagnostic tool in evaluating patients with clinical findings suggestive of alcoholic liver disease who deny alcohol intake. In patients with features of cholestasis, ultrasonography may be appropriate to exclude the presence of extrahepatic biliary obstruction. When the clinical status of an otherwise stable cirrhotic patient deteriorates without an obvious explanation, complicating conditions, such as infection, portal vein thrombosis, and hepatocellular carcinoma, should be sought.

Prognosis Abstinence from alcohol as well as early and appropriate medical care can decrease long-term morbidity and mortality and delay or prevent the appearance of further complications. Patients who have had a major complication of cirrhosis and who continue to drink have a 5-year survival of less than 50%. However, those patients who remain abstinent have a substantially better prognosis. In general, the overall outlook in patients with advanced liver disease remains poor; most of these patients eventually die as a result of massive variceal hemorrhage and/or profound hepatic encephalopathy.

TREATMENT

Alcoholic cirrhosis is a serious illness that requires long-term medical supervision and careful management. Therapy of the underlying liver disease is largely supportive. Specific treatment is directed at particular complications such as variceal bleeding and ascites (see below). While some studies suggest that administration of glucocorticoids in moderately large doses for 4 weeks is helpful in patients with severe alcoholic hepatitis and encephalopathy, these drugs have no role in the treatment of established alcoholic cirrhosis. While one study suggested a mortality benefit for the antifibrotic agent colchicine in alcoholic cirrhosis, it has not yet been reproduced; thus colchicine cannot be routinely recommended.

The patient should be made to realize that there is no medication that will protect the liver against the effects of further alcohol ingestion. Therefore, alcohol should be absolutely forbidden. An important component of the complete care of such patients is encouragement to become involved in an appropriate alcohol counseling program.

All medicines must be administered with caution in the patient with cirrhosis, especially those eliminated or modified through hepatic metabolism or biliary pathways. In particular, care must be taken to avoid overzealous use of drugs that may directly or indirectly precipitate complications of cirrhosis. For example, vigorous treatment of ascites with diuretics may result in electrolyte abnormalities or hypovolemia, which can lead to coma. Similarly, even modest doses of sedatives can lead to deepening encephalopathy. Aspirin should be avoided in patients with cirrhosis because of its effects on coagulation and gastric mucosa. Acetaminophen should be used with caution and in doses of less than 2 g/day. Patients who drink alcohol are more sensitive to the hepatotoxic effects of acetaminophen, probably due to increased metabolism of the drug to toxic intermediates and decreased glutathione levels.

POSTHEPATITIC AND CRYPTOGENIC CIRRHOSIS

Definition Posthepatitic or postnecrotic cirrhosis represents the final common pathway of many types of chronic liver disease. *Coarsely nodular* and *multilobular cirrhosis* are terms synonymous with posthepatitic cirrhosis. The term *cryptogenic cirrhosis* has been used interchangeably with postpathepatitic cirrhosis, but this designation should be reserved for those cases in which the etiology of cirrhosis is unknown (approximately 10% of all patients with cirrhosis).

Etiology *Posthepatitic cirrhosis* is a morphologic term referring to a defined stage of advanced chronic liver injury of both specific and unknown (cryptogenic) causes. Epidemiologic and serologic evidence suggest that viral hepatitis (hepatitis B or hepatitis

C) may be an antecedent factor in from one-fourth to three-fourths of cases of apparently cryptogenic posthepatitic cirrhosis. In areas where hepatitis B virus (HBV) infection is endemic (e.g., Southeast Asia, sub-Saharan Africa), up to 15% of the population may acquire the infection in early childhood, and cirrhosis may ultimately develop in one-fourth of these chronic carriers. Although HBV infection is much less prevalent in the United States, it is relatively common among certain high-risk groups (e.g., persons with multiple sexual partners, especially men who have sex with men, injection drug users) and contributes to an increased incidence of cirrhosis. In the United States,HCVinfection accounts for many cases of cirrhosis following blood transfusions. Before routine screening of blood donors was introduced, hepatitis C occurred in 5 to 10% of blood recipients. Following infection, cirrhosis may ultimately develop in more than 20% of individuals after 20 years. More than half of patients who would previously have been designated as having cryptogenic chronic liver disease have evidence of HCV infection. Increasing recognition of the progressive nature of nonalcoholic steatohepatitis has revealed that a large portion of cases previously designated cryptogenic cirrhosis may be attributable to this disorder (Chap. 300). Posthepatitic cirrhosis may also develop in patients with autoimmune hepatitis (Chap. 297).

The most common causes of cirrhosis in the United States, which ultimately lead to liver transplantation, include chronicHCVinfection, alcohol, primary biliary cirrhosis, primary sclerosing cholangitis, and nonalcoholic steatohepatitis (NASH). Less common causes of posthepatitic cirrhosis, including drugs and toxins, are listed inTable 299-1.

Pathology The posthepatitic liver is typically shrunken in size, distorted in shape, and composed of nodules of liver cells separated by dense and broad bands of fibrosis. The microscopic picture is consistent with the gross impression. Posthepatitic cirrhosis is characterized morphologically by (1) extensive confluent loss of liver cells, (2) stromal collapse and fibrosis resulting in broad bands of connective tissue containing the remains of many portal triads, and (3) irregular nodules of regenerating hepatocytes, varying in size from microscopic to several centimeters in diameter.

Clinical Features In patients with cirrhosis of known etiology in whom there is progression to a posthepatitic stage, the clinical manifestations are an extension of those resulting from the initial disease process. Usually clinical symptoms are related to portal hypertension and its sequelae, such as ascites, splenomegaly, hypersplenism, encephalopathy, and bleeding gastroesophageal varices. The hematologic and liver function abnormalities resemble those seen with other types of cirrhosis. In a few patients with posthepatitic cirrhosis, the diagnosis may be made incidentally at operation, at postmortem, or by a needle biopsy of the liver performed to investigate abnormal liver function tests or hepatomegaly.

Diagnosis and Prognosis Posthepatitic cirrhosis should be suspected in patients with signs and symptoms of cirrhosis or portal hypertension. Needle or operative liver biopsies confirm the diagnosis, although nonuniformity of the pathologic process may result in sampling errors. The diagnosis of cryptogenic cirrhosis is reserved for those patients in whom no known etiology can be demonstrated. About 75% of patients have progressive disease despite supportive therapy and die within 1 to 5 years from complications, including variceal hemorrhage, hepatic encephalopathy, or

superimposed hepatocellular carcinoma.

TREATMENT

Management is usually limited to treatment of the complications of portal hypertension, including control of ascites, avoidance of drugs or excessive protein intake that may induce hepatic coma, and prompt treatment of infections (see below). In patients with asymptomatic cirrhosis, expectant management alone is appropriate. In those patients in whom posthepatitic cirrhosis has developed as a result of a treatable condition, therapy directed at the primary disorder may limit further progression (e.g., Wilson's disease, hemochromatosis).

BILIARY CIRRHOSIS

Biliary cirrhosis results from injury to or prolonged obstruction of either the intrahepatic or extrahepatic biliary system. It is associated with impaired biliary excretion, destruction of hepatic parenchyma, and progressive fibrosis. Primary biliary cirrhosis (PBC) is characterized by chronic inflammation and fibrous obliteration of intrahepatic bile ductules. Secondary biliary cirrhosis (SBC) is the result of long-standing obstruction of the larger extrahepatic ducts. Although primary and secondary biliary cirrhosis are separate pathophysiologic entities with respect to the initial insult, many clinical features are similar.

PRIMARY BILIARY CIRRHOSIS

Etiology and Pathogenesis The cause of PBC remains unknown. Several observations suggest that a disordered immune response may be involved. PBC is frequently associated with a variety of disorders presumed to be autoimmune in nature, such as the syndrome of *c*alcinosis, *R*aynaud's phenomenon, *e*sophageal dysmotility, *s*clerodactyly, *t*elangiectasia (CREST); the sicca syndrome (dry eyes and dry mouth); autoimmune thyroiditis; type 1 diabetes mellitus; and IgA deficiency.

Most important, a circulating IgG antimitochondrial antibody (AMA) is detected in more than 90% of patients with PBC and only rarely in other forms of liver disease. It has been demonstrated that these autoantibodies recognize three to five inner mitochondrial membrane proteins identified as enzymes of the pyruvate dehydrogenase complex (PDC), the branched chain-ketoacid dehydrogenase complex (BCKDC), and thea-ketoglutarate dehydrogenase complex (KGDC). The major autoantigen in PBC (found in 90% of patients) has been identified as the 74-kDa E2 component of the PDC, dihydrolipoamide acetyltransferase. The antibodies are directed to a region essential for binding of a lipoic acid cofactor and inhibit the overall enzymatic activity of the PDC. Other AMA autoantibodies in PNC patients are directed to similar constituents of BCKDC and KGDC and also inhibit their enzymatic function. It remains unclear whether these properties have a direct pathogenetic role in the development of PBC. In addition to AMA, elevated serum levels of IgM and cryoproteins consisting of immune complexes capable of activating the alternative complement pathway are found in 80 to 90% of patients. Aberrant expression of major histocompatibility complex class II molecules has been found on biliary epithelium in association with PBC, suggesting that these cells may serve as antigen-presenting cells in this setting. Lymphocytes are prominent in the

portal regions and surround damaged bile ducts. These histologic findings resemble those noted in graft-versus-host disease following bone marrow transplantation and suggest that damage to bile ducts may be immunologically mediated, perhaps reflecting a defect in a suppressor cell population.

Pathology PBC is divided into four stages based on morphologic findings. The earliest recognizable lesion (stage I), termed *chronic nonsuppurative destructive cholangitis*, is a necrotizing inflammatory process of the portal triads. It is characterized by destruction of medium and small bile ducts, a dense infiltrate of acute and chronic inflammatory cells, mild fibrosis, and occasionally, bile stasis. At times, periductal granulomas and lymph follicles are found adjacent to affected bile ducts. Subsequently, the inflammatory infiltrate becomes less prominent, the number of bile ducts is reduced, and smaller bile ductules proliferate (stage II). Progression over a period of months to years leads to a decrease in interlobular ducts, loss of liver cells, and expansion of periportal fibrosis into a network of connective tissue scars (stage III). Ultimately, cirrhosis, which may be micronodular or macronodular, develops (stage IV).

Clinical Features

Signs and Symptoms Many patients withPBC are asymptomatic, and the disease is initially detected on the basis of elevated serum alkaline phosphatase levels during routine screening. The majority of such patients remain asymptomatic for prolonged periods, although most ultimately develop progressive liver injury.

Among patients with symptomatic disease, 90% are women age 35 to 60. Often the earliest symptom is pruritus, which may be either generalized or limited initially to the palms and soles. In addition, fatigue is commonly a prominent early symptom. After several months or years, jaundice and gradual darkening of the exposed areas of the skin (melanosis) may ensue. Other early clinical manifestations ofPBCreflect impaired bile excretion. These include steatorrhea and the malabsorption of lipid-soluble vitamins. Protracted elevation of serum lipids, especially cholesterol, leads to subcutaneous lipid deposition around the eyes (xanthelasmas) and over joints and tendons (xanthomas). Over a period of months to years, the itching, jaundice, and hyperpigmentation slowly worsen. Eventually, signs of hepatocellular failure and portal hypertension develop and ascites appears. Progression may be quite variable. Whereas a proportion of asymptomatic patients may show no signs of progression for a decade or longer, in others, death due to hepatic insufficiency may occur within 5 to 10 years after the first signs of the illness. Such decompensation is often precipitated by uncontrolled variceal hemorrhage or infection.

Physical examination may be entirely normal in the early phase of the disease, when patients are asymptomatic or pruritus is the sole complaint. Later, there may be jaundice of varying intensity, hyperpigmentation of the exposed skin areas, xanthelasmas and tendinous and planar xanthomas, moderate to striking hepatomegaly, splenomegaly, and clubbing of the fingers. Bone tenderness, signs of vertebral compression, ecchymoses, glossitis, and dermatitis may all be noted. Clinical evidence of the sicca syndrome can be found in as many as 75% of patients, and serologic evidence of autoimmune thyroid disease in 25%. Other conditions encountered with increased frequency include rheumatoid arthritis,CRESTsyndrome, keratoconjunctivitis sicca, IgA

deficiency, type 1 diabetes mellitus, scleroderma, pernicious anemia, and renal tubular acidosis. Bone disease is often a significant problem encountered over the course of the disease. While osteomalacia occurs due to diminished vitamin D absorption, accelerated osteoporosis in this patient population (the majority of whom are postmenopausal women) is even more common.

Laboratory Findings PBC is increasingly diagnosed at a presymptomatic stage, prompted by the finding of a twofold or greater elevation of the serum alkaline phosphatase during routine screening. Serum 5¢-nucleotidase activity andg-glutamyl transpeptidase levels are also elevated. In this setting, serum bilirubin is usually normal and aminotransferase levels minimally increased. The diagnosis is supported by a positiveAMA test (titer > 1:40). The latter is both relatively specific and sensitive; a positive test is found in over 90% of symptomatic patients and is present in fewer than 5% of patients with other liver diseases. As the disease evolves, the serum bilirubin level rises progressively and may reach 510 umol/L (30 mg/dL) or more in the final stages. Serum aminotransferase values rarely exceed 2.5 to 3.3 ukat (150 to 200 units). Hyperlipidemia is common, and a striking increase of the serum unesterified cholesterol is often noted. An abnormal serum lipoprotein (lipoprotein X) may be present in PBC but is not specific and appears in other cholestatic conditions. A deficiency of bile salts in the intestine leads to moderate steatorrhea and impaired absorption of the fat-soluble vitamins and hypoprothrombinemia. Patients with PBC have elevated liver copper levels, but this finding is not specific and is found in all disorders in which there is prolonged cholestasis.

Diagnosis PBCshould be considered in middle-aged women with unexplained pruritus or an elevated serum alkaline phosphatase and in whom there may be other clinical or laboratory features of protracted impairment of biliary excretion. Although a positive serumAMAdetermination provides important diagnostic evidence, false-positive results do occur; therefore, liver biopsy should be performed to confirm the diagnosis. Rarely, the AMA test may be negative in patients with histologic features of PBC. Frequently, patients have antibodies to the E2 protein in tests using these specific antigens. In some cases with histologic features of PBC and a negative AMA, antinuclear or smooth-muscle antibodies are present (as in autoimmune hepatitis), and the designation *autoimmune cholangitis* is applied. The natural history of this entity, however, appears to resemble that of PBC. If the AMA test is negative, the biliary tract should be evaluated to exclude primary sclerosing cholangitis and remediable extrahepatic biliary tract obstruction, especially in view of the frequent presence of coexisting cholelithiasis.

TREATMENT

While there is no specific therapy for PBC, ursodiol has been shown to improve biochemical and histologic features and might improve survival, particularly liver transplantation-free survival (although this remains unproven). Ursodiol should be given in doses of 10 to 15 mg/kg per day, but lower doses are sometimes just as effective in reducing serum alkaline phosphatase and aminotransferase levels. Ursodiol should be given with food and can be taken in a single dose daily. Side effects are rare: gastrointestinal intolerance (bloating, indigestion) and skin rashes occur but are uncommon. Isolated instances of severe exacerbation of pruritus have been reported in

patients with advanced disease. Ursodiol probably works by replacing the endogenously produced hydrophobic bile acids with urosdeoxycholate, a hydrophilic and relatively nontoxic bile acid.

Unfortunately, ursodiol does not prevent ultimate progression ofPBC, and the only established "cure" is liver transplantation. Results of liver transplantation for PBC are excellent, survival exceeding that for patients receiving transplantation for most other forms of end-stage liver disease. Recurrence of PBC after liver transplantation has been reported but is uncommon, and the recurrent disease is only slowly progressive. Most patients remainAMApositive after transplantation, and as many as 25% will have histologic features of PBC on liver biopsy after 5 years. Other therapies such as glucocorticoids, colchicine, methotrexate, azathioprine, cyclosporine, and tacrolimus have been reported as effective in small cases series, but none have shown to be effective in adequately controlled trials.

Relief of symptoms is also an important part of management ofPBC. As noted, ursodiol may be helpful in controlling symptoms and improving the patient's sense of well-being. Although the mechanism of the protracted pruritus is not entirely clear, cholestyramine, an oral bile salt-sequestering resin, may be helpful in doses of 8 to 12 g/d to decrease both pruritus and hypercholesterolemia. Rifampin, opiate antagonists, ondansetron, plasmapheresis, and ultraviolet light have all been tried for control of pruritus, with varying results. Steatorrhea can be reduced by a low-fat diet and substituting medium-chain triglycerides for dietary long-chain triglycerides. Fat-soluble vitamins A and K should be given by parenteral injection at regular intervals to prevent or correct night blindness and hypoprothrombinemia, respectively. Zinc supplementation may be necessary if night blindness is refractory to vitamin A therapy. An important part of management of PBC and any cholestatic liver disease is assessment and treatment of osteoporosis and osteomalacia. Patients should be screened periodically by bone densitometry and treated as needed with calcium supplements, estrogen, and/or the newer bisphosphonate agents (e.g., alendronate). Progression of PBC leads to the typical complications of advanced liver disease (see below).

SECONDARY BILIARY CIRRHOSIS

Etiology SBCresults from prolonged partial or total obstruction of the common bile duct or its major branches. In adults, obstruction is most frequently caused by postoperative strictures or gallstones, usually with superimposed infectious cholangitis. Chronic pancreatitis may lead to biliary stricture and secondary cirrhosis. SBC is also an important complication of primary sclerosing cholangitis, a progressive immunologic disorder of the intrahepatic and extrahepatic biliary tree (Chap. 302). Patients with malignant tumors of the common bile duct or pancreas rarely survive long enough to develop SBC. In children, congenital biliary atresia and cystic fibrosis are common causes of SBC. Choledochal cysts, if unrecognized, may also be a rare cause of SBC.

Pathology and Pathogenesis Unrelieved obstruction of the extrahepatic bile ducts leads to (1) bile stasis and focal areas of centrilobular necrosis followed by periportal necrosis, (2) proliferation and dilatation of the portal bile ducts and ductules, (3) sterile or infected cholangitis with accumulation of polymorphonuclear infiltrates around bile ducts, and (4) progressive expansion of portal tracts by edema and fibrosis.

Extravasation of bile from ruptured interlobular bile ducts into areas of periportal necrosis leads to the formation of "bile lakes" surrounded by cholesterol-rich pseudoxanthomatous cells. As in other forms of cirrhosis, injury is accompanied by regeneration in residual parenchyma. These changes gradually lead to a finely nodular cirrhosis. In general, at least 3 to 12 months is required for biliary obstruction to result in cirrhosis. Relief of the obstruction is frequently accompanied by biochemical and morphologic improvement.

Clinical Features The symptoms, signs, and biochemical findings ofSBC are similar to those ofPBC. Jaundice and pruritus are usually the most prominent features. In addition, fever and/or right upper quadrant pain, reflecting bouts of cholangitis or biliary colic, are typical. The manifestations of portal hypertension are found only in advanced cases. SBC should be considered in any patient with clinical and laboratory evidence of prolonged obstruction to bile flow, especially when there is a history of previous biliary tract surgery or gallstones, bouts of ascending cholangitis, or right upper quadrant pain. Cholangiography (either percutaneous or endoscopic) usually demonstrates the underlying pathologic process. Liver biopsy, although not always necessary from a clinical standpoint, can document the development of cirrhosis.

TREATMENT

Relief of obstruction to bile flow, by either endoscopic or surgical means, is the most important step in the prevention and therapy ofSBC. Effective decompression of the biliary tract results in a significant improvement in both symptoms and survival, even in patients with established cirrhosis. When obstruction cannot be relieved, as in sclerosing cholangitis, antibiotics may be helpful acutely in controlling superimposed infection or, when administered on a chronic basis, as prophylactic therapy in suppressing recurring episodes of ascending cholangitis. Without relief of obstruction, there is a steady progression to end-stage cirrhosis and its terminal manifestations.

CARDIAC CIRRHOSIS

Definition Prolonged, severe right-sided congestive heart failure may lead to chronic liver injury and cardiac cirrhosis. The characteristic pathologic features of fibrosis and regenerative nodules distinguish cardiac cirrhosis from both reversible passive congestion of the liver due to acute heart failure and acute hepatocellular necrosis ("ischemic hepatitis" or "shock liver") resulting from systemic hypotension and hypoperfusion of the liver.

Etiology and Pathology In right-sided heart failure, retrograde transmission of elevated venous pressure via the inferior vena cava and hepatic veins leads to congestion of the liver. Hepatic sinusoids become dilated and engorged with blood, and the liver becomes tensely swollen. With prolonged passive congestion and ischemia from poor perfusion secondary to reduced cardiac output, necrosis of centrilobular hepatocytes ensues and leads to fibrosis in these central areas. Ultimately, centrilobular fibrosis develops, with collagen extending outward in a characteristic stellate pattern from the central vein. Gross examination of the liver shows alternating red (congested) and pale (fibrotic) areas, a pattern often referred to as "nutmeg liver." Improvement in management of cardiac disorders, particularly advances in surgical treatment, has reduced the

frequency of cardiac cirrhosis.

Clinical Features A range of abnormalities of liver function tests may be found, though none is uniformly present. The serum bilirubin is usually only mildly increased and may be predominantly either conjugated or unconjugated. Mild to moderate elevation in alkaline phosphatase level and prothrombin time prolongation are sometimes present. TheASTlevel is typically mildly elevated but may be transiently very high following a period of marked systemic hypotension (shock liver), when the clinical picture can mimic acute viral or drug-induced hepatitis. In cases of tricuspid insufficiency the liver may be pulsatile, but this finding disappears as cirrhosis develops. With prolonged right-sided heart failure the liver becomes enlarged, firm, and usually nontender. The signs and symptoms of heart failure usually overshadow the liver disease. Bleeding from esophageal varices is rare, but chronic encephalopathy may be prominent, with a waxing and waning course reflecting variations in the severity of right-sided heart failure. Ascites and peripheral edema, often primarily related to the underlying cardiac dysfunction, may be worsened by the superimposed liver disease.

Diagnosis The presence of a firm, enlarged liver with signs of chronic liver disease in a patient with valvular heart disease, constrictive pericarditis, or cor pulmonale of long duration (>10 years) should suggest cardiac cirrhosis. Liver biopsy can confirm the diagnosis but is usually contraindicated because of coagulopathy or ascites. Coexistent chronic heart and liver disease should also raise the possibility of hemochromatosis (Chap. 345), amyloidosis (Chap. 319), or other infiltrative diseases.

Budd-Chiari syndrome resulting from the occlusion of the hepatic veins or inferior vena cava may be confused with acute congestive hepatomegaly. In this condition the liver is grossly enlarged and tender, and severe intractable ascites is present. However, signs and symptoms of heart failure are notably absent. The most common cause is thrombosis of the hepatic veins, often in the setting of polycythemia rubra vera, myeloproliferative syndromes, paroxysmal nocturnal hemoglobinuria, oral contraceptive use, or other hypercoagulable states; it may also result from invasion of the inferior vena cava by tumor, such as renal cell or hepatocellular carcinoma. Idiopathic membranous obstruction of the inferior vena cava is the most common cause of this syndrome in Japan. Hepatic venography or liver biopsy showing centrilobular congestion and sinusoidal dilatation in the absence of right-sided heart failure establishes the diagnosis of Budd-Chiari syndrome. Venocclusive disease affecting the sublobular branches of the hepatic veins and the hepatic venues may result from hepatic irradiation, treatment with certain antineoplastic agents, or ingestion of pyrrolidizine alkaloids present in some herbal teas ("bush tea disease") and can mimic congestive hepatomegaly.

TREATMENT

Prevention or treatment of cardiac cirrhosis depends on the diagnosis and therapy of the underlying cardiovascular disorder. Improvement in cardiac function frequently results in improvement of liver function and stabilization of the liver disease.

METABOLIC, HEREDITARY, DRUG-RELATED, AND OTHER TYPES OF CIRRHOSIS (See Table 299-1)

Cirrhosis or hepatitis may result from a wide variety of other processes encompassing the spectrum of etiologic factors listed in Table 299-2. Although some of these disorders have distinctive clinical or morphologic features, the manifestations of cirrhosis are largely independent of the underlying pathogenic mechanism.

NONCIRRHOTIC FIBROSIS OF THE LIVER

Several diseases, either congenital or acquired, may be associated with localized or generalized hepatic fibrosis. They are distinguished from cirrhosis by the absence of hepatocellular damage and the lack of nodular regenerative activity. The clinical manifestations in such cases are largely secondary to portal hypertension. The different types of these disorders are indicated inTable 299-2; with the exception of schistosomiasis in some regions of the world, all these conditions are relatively rare.

MAJOR COMPLICATIONS OF CIRRHOSIS

The clinical course of patients with advanced cirrhosis is often complicated by a number of important sequelae that are independent of the etiology of the underlying liver disease. These include portal hypertension and its consequences (e.g., gastroesophageal varices and splenomegaly), ascites, hepatic encephalopathy, spontaneous bacterial peritonitis, hepatorenal syndrome, and hepatocellular carcinoma.

PORTAL HYPERTENSION

Definition and Pathogenesis Normal pressure in the portal vein is low (5 to 10 mmHg) because vascular resistance in the hepatic sinusoids is minimal. Portal hypertension (>10 mmHg) most commonly results from increased resistance to portal blood flow. Because the portal venous system lacks valves, resistance at any level between the right side of the heart and splanchnic vessels results in retrograde transmission of an elevated pressure. Increased resistance can occur at three levels relative to the hepatic sinusoids: (1) presinusoidal, (2) sinusoidal, and (3) postsinudoidal. Obstruction in the *presinusoidal* venous compartment may be anatomically outside the liver (e.g., portal vein thrombosis) or within the liver itself but at a functional level proximal to the hepatic sinusoids so that the liver parenchyma is not exposed to the elevated venous pressure (e.g., schistosomiasis).

Postsinusoidal obstruction may also occur outside the liver at the level of the hepatic veins (e.g., Budd-Chiari syndrome), the inferior vena cava, or, less commonly, within the liver (e.g., venocclusive disease). When cirrhosis is complicated by portal hypertension, the increased resistance is usually *sinusoidal*. While distinctions between pre-, post-, and sinusoidal processes are conceptually appealing, functional resistance to portal flow in a given patient may occur at more than one level. Portal hypertension may also arise from increased blood flow (e.g., massive splenomegaly or arteriovenous fistulas), but the low outflow resistance of the normal liver makes this a rare clinical problem.

Cirrhosis is the most common cause of portal hypertension in the United States. Clinically significant portal hypertension is present in >60% of patients with cirrhosis. *Portal vein obstruction* is the second most common cause; it may be idiopathic or occur in association with cirrhosis, infection, pancreatitis, or abdominal trauma. Portal vein

thrombosis may develop in a variety of hypercoagulable states including polycythemia vera; essential thrombocythemia; deficiencies of protein C, protein S, or antithrombin III; resistance to activated protein C (factor V Leiden); and a mutation of the prothrombin gene (G20210A). Portal vein thrombosis may be idiopathic, though some of these patients may have a subclinical myeloproliferative disorder. Hepatic vein thrombosis (Budd-Chiari syndrome) and hepatic venoocclusive disease are relatively infrequent causes of portal hypertension (see above). Portal vein occlusion may result in massive hematemesis from gastroesophageal varices, but ascites is usually found only when cirrhosis is present. Noncirrhotic portal fibrosis (Table 299-2) accounts for only a few cases of portal hypertension.

Clinical Features The major clinical manifestations of portal hypertension include hemorrhage from gastroesophageal varices, splenomegaly with hypersplenism, ascites, and acute and chronic hepatic encephalopathy. These are related, at least in part, to the development of portal-systemic collateral channels. The absence of valves in the portal venous system facilitates retrograde (hepatofugal) blood flow from the high-pressure portal venous system to the lower-pressure systemic venous circulation. Major sites of collateral flow involve the veins around cardioesophageal junction (esophagogastric varices), the rectum (hemorrhoids), retroperitoneal space, and the falciform ligament of the liver (periumbilical or abdominal wall collaterals). Abdominal wall collaterals appear as tortuous epigastric vessels that radiate from the umbilicus toward the xiphoid and rib margins (caput medusae).

A frequent marker of the presence of cirrhosis in a patient being followed for chronic liver disease is a progressive decrease in platelet count. A low-normal platelet count can be the first clue to progression to cirrhosis. Ultimately, a marked decrease in platelets (to 30,000 to 60,000/uL) and white blood cells can occur.

Diagnosis In patients with known liver disease, the development of portal hypertension is usually revealed by the appearance of splenomegaly, ascites, encephalopathy, and/or esophageal varices. Conversely, the finding of any of these features should prompt evaluation of the patient for the presence of underlying portal hypertension and liver disease. Varices are most reliably documented by fiberoptic esophagoscopy; their presence lends indirect support to the diagnosis of portal hypertension. Although rarely necessary, portal venous pressure may be measured directly by percutaneous transhepatic "skinny needle" catheterization or indirectly through transjugular cannulation of the hepatic veins. Both free and wedged hepatic vein pressure should be measured. While the latter is elevated in sinusoidal and postsinusoidal portal hypertension, including cirrhosis, this measurement is usually normal in presinusoidal portal hypertension. In patients in whom additional information is necessary (e.g., preoperative evaluation before portal-systemic shunt surgery) or when percutaneous catheterization is not feasible, mesenteric and hepatic angiography may be helpful. Particular attention should be directed to the venous phase to assess the patency of the portal vein and the direction of portal blood flow.

TREATMENT

Although treatment is usually directed toward a specific complication of portal hypertension, attempts are sometimes made to reduce the pressure in the portal venous

system. Surgical decompression procedures have been used for many years to lower portal pressure in patients with bleeding esophageal varices (see below). However, portal-systemic shunt surgery does not result in improved survival rates in patients with cirrhosis. Decompression can now be accomplished without surgery through the percutaneous placement of a portal-systemic shunt, termed a *transjugular intrahepatic portosystemic shunt* (TIPS).b-Adrenergic blockade with propranolol or nadolol reduces portal pressure through vasodilatory effects on both the splanchnic arterial bed and the portal venous system in combination with reduced cardiac output. Such therapy has been shown to be effective in preventing both a first variceal bleed and subsequent episodes after an initial bleed. Treatment of patients with clinically significant sequelae of portal hypertension, especially variceal bleeding, with doses of propranolol titrated to reduce the resting pulse by 25% is reasonable if no contraindications exist.

Vigorous treatment of patients with alcoholic hepatitis and cirrhosis, chronic active hepatitis, or other liver diseases may lead to a fall in portal pressure and to a reduction in variceal size. In general, however, portal hypertension due to cirrhosis is not reversible. In appropriately selected patients, hepatic transplantation will be beneficial.

VARICEAL BLEEDING

Pathogenesis While vigorous hemorrhage may arise from any portal-systemic venous collaterals, bleeding is most common from varices in the region of the gastroesophageal junction. The factors contributing to bleeding from gastroesophageal varices are not entirely understood but include the degree of portal hypertension (>12 mmHg) and the size of the varices.

Clinical Features and Diagnosis Variceal bleeding often occurs without obvious precipitating factors and usually presents with painless but massive hematemesis with or without melena. Associated signs range from mild postural tachycardia to profound shock, depending on the extent of blood loss and degree of hypovolemia. Because patients with varices may bleed just as frequently from other gastrointestinal lesions (e.g., peptic ulcer, gastritis), exclusion of other bleeding sources is important even in patients with prior variceal hemorrhage. Endoscopy is the best approach to evaluate upper gastrointestinal hemorrhage in patients with known or suspected portal hypertension.

TREATMENT

(SeeFig. 299-1) Variceal bleeding is a life-threatening emergency. Prompt estimation and vigorous replacement of blood loss to maintain intravascular volume are essential and take precedence over diagnostic studies and more specific intervention to stop the bleeding. However, excessive fluid administration can increase portal pressure with resultant further bleeding and should therefore be avoided. Replacement of clotting factors with fresh-frozen plasma is important in patients with coagulopathy. Patients are best managed in an intensive care unit and require close monitoring of central venous or pulmonary capillary wedge pressures, urine output, and mental status. Only when the patient is hemodynamically stable should attention be directed toward specific diagnostic studies (especially endoscopy) and other therapeutic modalities to prevent further or recurrent bleeding.

About half of all episodes of variceal hemorrhage cease without intervention, although the risk of rebleeding is very high. The medical management of acute variceal hemorrhage includes the use of vasoconstrictors (somatostatin/octreotide or vasopressin), balloon tamponade, and endoscopic banding of varices or endoscopic sclerosis of varices (sclerotherapy). Intravenous infusion of *vasopressin* at a rate of 0.1 to 0.4 U/min results in generalized vasoconstriction leading to diminished blood flow in the portal venous system. Intravenous infusion of vasopressin is as effective as selective intraarterial administration. Control of bleeding can be achieved in up to 80% of cases, but bleeding recurs in more than half after the vasopressin is tapered and discontinued. Furthermore, a number of serious side effects, including cardiac and gastrointestinal tract ischemia, acute renal failure, and hyponatremia, may be associated with vasopressin therapy. Concurrent use of venodilators such as nitroglycerin as an intravenous infusion or isosorbide dinitrate sublingually may enhance the effectiveness of vasopressin and reduce complications. *Somatostatin* and its analogue, *octreotide*, are direct splanchnic vasoconstrictors. In some studies somatostatin, given as an initial 250-ug bolus followed by constant infusion (250 ug/h), has been found to be as effective as vasopressin. Octreotide at doses of 50 to 100 ug/h is also effective. These agents are preferable to vasopressin, offering equivalent efficacy with fewer complications. If bleeding is too vigorous or endoscopy is not available, *balloon tamponade* of the bleeding varices may be accomplished with a triple-lumen (Sengstaken-Blakemore) or four-lumen (Minnesota) tube with esophageal and gastric balloons. Because of the high risk of aspiration, endotracheal intubation should be performed prior to placing one of these tubes. After the tube is introduced into the stomach, the gastric balloon is inflated and pulled back into the cardia of the stomach. If bleeding does not stop, the esophageal balloon is inflated for additional tamponade. Complications occur in 15% or more of patients and include aspiration pneumonitis as well as esophageal rupture.

Where available, *endoscopic intervention* should be employed as the first line of treatment to control bleeding acutely (Chaps. 44 and283). Over the past 18 years, endoscopic sclerosis of esophageal varices has been extensively employed. In this procedure, the varices are injected with one of several sclerosing agents via a needle-tipped catheter passed through the endoscope. After endoscopic identification of varices as the presumed source of bleeding, sclerotherapy controls acute bleeding in up to 90% of cases. In addition, repeated sclerotherapy can be performed until obliteration of all varices is accomplished in an effort to prevent recurrent bleeding. While available data support the efficacy of sclerotherapy in controlling bleeding acutely and in decreasing rebleeding rates, repeated sclerotherapy has not been documented to prolong survival. Mucosal ulceration resulting from injection of the caustic sclerosant may occur and result in further hemorrhage or stenosis. More recently, endoscopic band ligation, in which esophageal varices are ligated and strangulated with endoscopically placed small elastic O-rings, has gained favor. Band ligation has proven to be at least as effective as sclerotherapy in controlling acute variceal bleeding and preventing rebleeding. Because it has been associated with fewer treatment-related complications, band ligation is recommended for long-term obliteration of varices that have bled. Although prophylactic sclerosis or banding of esophageal varices in the absence of proven bleeding cannot yet be recommended, one report suggests that banding may be more effective than beta-blockade in primary prevention of variceal bleeding in high-risk

patients.

The effectiveness of *nonselective b-adrenergic blocking agents* (e.g., propranolol) in the management of acute variceal bleeding is limited due to concomitant hypotension resulting from hypovolemia. However, a number of studies suggest they may be of value in secondary prevention of recurrent variceal hemorrhage. Moreover, prophylactic treatment with nonselective beta blockers (propranolol or nadolol) in patients with large ("high-risk") varices that have never bled appears to decrease the incidence of bleeding and prolong survival. Thus, endoscopic screening for varices in patients with cirrhosis is desirable; some have suggested this should be repeated every other year. Patients with portal hypertension without specific contraindications should be given propranolol in doses that produce a 25% reduction in the resting heart rate or the hepatic venous pressure gradient (HVPG), where available. Propranolol may also prevent recurrent bleeding from severe portal hypertensive gastropathy in patients with cirrhosis. The optimal combination of endoscopic and pharmacologic therapy for prevention of recurrent hemorrhage remains to be established and is the subject of ongoing trials.

Surgical treatment of portal hypertension and variceal bleeding involves the creation of a portal-systemic shunt to permit decompression of the portal system. Two types of portal systemic shunts have been used: *nonselective shunts*, to decompress the entire portal system, and *selective shunts*, intended to decompress only the varices while maintaining blood flow to the liver itself. Nonselective shunts include end-to-side or side-to-side portacaval and proximal splenorenal anastomoses; selective shunts include the distal splenorenal shunt. Nonselective shunts are more likely to be complicated by encephalopathy than selective shunts. Emergency portal-systemic nonselective shunts may control acute hemorrhage, but such surgery is usually used only as a last resort because early operative mortality can be high. The role of portal-systemic shunt surgery after initial control of bleeding by nonoperative means is also uncertain. Surgically created shunts effectively reduce the risk of recurrent hemorrhage, but the overall mortality of patients undergoing such surgery is comparable to that of unoperated patients. Although patients who have undergone portal-systemic surgery succumb to recurrent bleeding less commonly than unoperated patients, this improvement is counterbalanced by increased morbidity from encephalopathy and death from progressive liver failure. Increasingly, therapeutic portal-systemic shunts have been reserved for patients who experience further bleeding despite serial endoscopic sclerotherapy or band ligation.

InTIPS, a technique developed to create a portal-systemic shunt by a percutaneous approach, an expandable metal stent is advanced to the hepatic veins under angiographic guidance and then through the substance of the liver to create a direct portacaval channel. This technique offers an alternative to surgery for refractory bleeding due to portal hypertension. However, stents frequently undergo stenosis or occlude over a period of months, prompting the need for a second TIPS or an alternative approach. Encephalopathy may be encountered after TIPS just as in the surgical shunts and is especially problematic in the elderly and those patients with preexisting encephalopathy. TIPS should be reserved for those individuals who fail endoscopic or medical management and are poor surgical risks. TIPS may have a useful role as a "bridge" for those patients with end-stage cirrhosis awaiting liver transplantation. Procedures such as esophageal transection have also been advocated

for the management of acute variceal bleeding, but their efficacy remains unproven. Even though recent trials found that esophageal transection was as effective as endoscopic sclerotherapy, transection is usually considered a last resort.

The management of bleeding gastric fundal varices, either alone or in conjunction with esophageal varices, is more problematic, since sclerotherapy and banding are generally not effective. Vasoactive pharmacologic therapy should be instituted, butTIPS or shunt surgery should be considered because of high failure and rebleeding rates. For isolated gastric varices, splenic vein thrombosis should be specifically sought, since splenectomy is curative.

Portal Hypertensive Gastropathy Although variceal hemorrhage is the most commonly encountered bleeding complication of portal hypertension, many patients will develop a congestive gastropathy due to the venous hypertension. In this condition, identified by endoscopic examination, the mucosa appears engorged and friable. Indolent mucosal bleeding occurs rather than the brisk hemorrhage typical of a variceal source. b-Adrenergic blockade with propranolol (reducing splanchnic arterial pressure as well as portal pressure) is sometimes effective in ameliorating this condition. H_2receptor antagonists or other agents useful in the treatment of peptic disease are usually not helpful.

SPLENOMEGALY

Definition and Pathogenesis Congestive splenomegaly is common in patients with severe portal hypertension. Rarely, massive splenomegaly from nonhepatic disease leads to portal hypertension due to increased blood flow in the splenic vein.

Clinical Features Although usually asymptomatic, splenomegaly may be massive and contribute to the thrombocytopenia or pancytopenia of cirrhosis. In the absence of cirrhosis, splenomegaly in association with variceal hemorrhage should suggest the possibility of splenic vein thrombosis.

TREATMENT

Splenomegaly usually requires no specific treatment, although massive enlargement of the spleen may occasionally necessitate splenectomy at the time of shunt surgery. However, it should be noted that splenectomy without an accompanying shunt may actually increase portal pressure, and portal vein thrombosis may result from splenectomy. Splenectomy may also be indicated if splenomegaly is the cause rather than the result of portal hypertension (as in splenic vein thrombosis). Thrombcytopenia alone is rarely severe enough to necessitate removal of the spleen. Splenectomy should be avoided in a patient eligible for liver transplantation.

ASCITES

Definition Ascites is the accumulation of excess fluid within the peritoneal cavity. It is most frequently encountered in patients with cirrhosis and other forms of severe liver disease, but a number of other disorders may lead to either transudative or exudative ascites (Chap. 46).

Pathogenesis The accumulation of ascitic fluid represents a state of total-body sodium and water excess, but the event that initiates this imbalance is unclear. Three theories have been proposed (Fig. 299-2). The "underfilling" theory suggests that the primary abnormality is inappropriate sequestration of fluid within the splanchnic vascular bed due to portal hypertension and a consequent decrease in effective circulating blood volume. According to this theory, an apparent decrease in intravascular volume (underfilling) is sensed by the kidney, which responds by retaining salt and water. The "overflow" theory suggests that the primary abnormality is inappropriate renal retention of salt and water in the absence of volume depletion. A third and more recent theory, the peripheral arterial vasodilation hypothesis, may unify the earlier theories and accounts for the constellation of arterial hypotension and increased cardiac output in association with high levels of vasoconstrictor substances that are routinely found in patients with cirrhosis and ascites. Again, sodium retention is considered secondary to arterial vascular underfilling and the result of a disproportionate increase of the vascular compartment due to arteriolar vasodilation rather than from decreased intravascular volume. According to this theory, portal hypertension results in splanchnic arteriolar vasodilation, mediated by nitric oxide, and leading to underfilling of the arterial vascular space and baroreceptor-mediated stimulation of renin-angiotensin, sympathetic output, and antidiuretic hormone release.

Regardless of the initiating event, a number of factors contribute to accumulation of fluid in the abdominal cavity (Fig. 299-2). Elevated levels of serum epinephrine and norepinephrine have been well documented. *Increased central sympathetic outflow* is found in patients with cirrhosis and ascites but not in those with cirrhosis alone. Increased sympathetic output results in diminished natriuresis by activation of the renin-angiotensin system and diminished sensitivity to atrial natriuretic peptide. *Portal hypertension* plays an important role in the formation of ascites by raising hydrostatic pressure within the splanchnic capillary bed. *Hypoalbuminemia* and *reduced plasma oncotic pressure* also favor the extravasation of fluid from plasma to the peritoneal cavity, and thus ascites is infrequent in patients with cirrhosis unless both portal hypertension and hypoalbuminemia are present. Hepatic lymph may weep freely from the surface of the cirrhotic liver due to distortion and obstruction of hepatic sinusoids and lymphatics and contributes to ascites formation. In contrast to the contribution of transudative fluid from the portal vascular bed, hepatic lymph may weep into the peritoneal cavity even in the absence of marked hypoproteinemia because the endothelial lining of the hepatic sinusoids is discontinuous. This mechanism may account for the high protein concentration present in the ascitic fluid of some patients with venoocclusive disease or the Budd-Chiari syndrome.

Renal factors also play an important role in perpetuating ascites. Patients with ascites fail to excrete a water load in a normal fashion. They have increased renal sodium reabsorption by both proximal and distal tubules, the latter due largely to increased plasma renin activity and secondary hyperaldosteronism. Insensitivity to circulating atrial natriuretic peptide, often present in elevated concentrations in patients with cirrhosis and ascites, may be an important contributory factor in many patients. This insensitivity has been documented in those patients with the most severely impaired sodium excretion, who typically also exhibit low arterial pressure and marked overactivity of the renin-aldosterone axis. Renal vasoconstriction, perhaps resulting from increased serum

prostaglandin or catecholamine levels, may also contribute to sodium retention. Recently a role for endothelin, a potent vasoconstrictor peptide, has been proposed. While elevated levels have been reported by some, this has not been observed by others.

As discussed inChap. 46, ascites may arise in a number of clinical settings in addition to cirrhosis and portal hypertension. Although historically ascites was classified as either transudative or exudative, similar to the characterization of pleural fluids, this schema has limitations. Instead, the serum-ascites albumin gradient (SAAG) provides a better classification than total protein content or other parameters. In cirrhosis, the serum albumin concentration is usually at least 10 g/L (1 g/dL) higher than that of the ascitic fluid, thus yielding a high SAAG [³11 g/L (³1.1 g/dL)], reflecting indirectly the abnormally high hydrostatic pressure gradient between the portal bed and the ascitic compartment. Conversely, the presence of a low SAAG [<11 g/L (<1.1 g/dL)] will usually exclude cirrhosis and portal hypertension.

Clinical Features and Diagnosis Usually ascites is first noticed by the patient because of increasing abdominal girth. More pronounced accumulation of fluid may cause shortness of breath because of elevation of the diaphragm. When peritoneal fluid accumulation exceeds 500 mL, ascites may be demonstrated on physical examination by the presence of shifting dullness, a fluid wave, or bulging flanks. Ultrasound examination, preferably with a Doppler study, can detect smaller quantities of ascites and should be performed when physical examination is equivocal or when the cause of the recent onset of ascites is not clear (e.g., exclude Budd-Chiari syndrome or portal vein thrombosis).

TREATMENT

(SeeFig. 299-3) A thorough search should be made for precipitating factors in the patient with recent onset of or worsening ascites, e.g., excessive salt intake, medication noncompliance, superimposed infection, worsening liver disease, portal vein thrombosis, or development of hepatocellular carcinoma. When ascites develops in the setting of severe, acute liver disease, resolution of ascites is likely to follow improvement in liver function. More commonly, ascites develops in patients with stable or steadily worsening liver function. Paracentesis should usually be performed with a small-gauge needle at the time of initial evaluation or at the time of any clinical deterioration of a cirrhotic patient with ascites. A small amount of fluid (<200 mL) should be obtained and examined for evidence of infection, tumor, or other possible causes and complications of ascites. Therapeutic intervention is indicated both to prevent potential complications and to control progressive increase in ascites, which may become pronounced enough to cause physical discomfort. For the patient with a modest accumulation, therapy can be undertaken as an outpatient and should be gentle and incremental (see below). The goal is the loss of no more than 1.0 kg/d if both ascites and peripheral edema are present and no more than 0.5 kg/d in patients with ascites alone. In some patients, particularly those with a large accumulation of fluid, it may be desirable to hospitalize the patient so that daily weights and frequent serum electrolyte levels can be monitored and compliance ensured. Although abdominal girth measurements are frequently used as an index of fluid loss, they tend to be unreliable.

Salt restriction is the cornerstone of therapy. A diet containing 800 mg sodium (2 g NaCl) is often adequate to induce a negative sodium balance and permit diuresis. Response to salt restriction alone is more likely to occur if the ascites is of recent onset, the underlying liver disease is reversible, a precipitating factor can be corrected, or the patient has a high urinary sodium excretion (>25 mmol/d) and normal renal function. Fluid restriction of approximately 1000 mL/d does little to enhance diuresis but may be necessary to correct hyponatremia. If sodium restriction alone fails to result in diuresis and weight loss, diuretics should be prescribed. Because of the role of hyperaldosteronism in sustaining salt retention, spironolactone or other distal tubule-acting diuretics (triamterene, amiloride) are the drugs of choice. These agents are also preferred because of their gentle action and specific potassium-sparing properties. Spironolactone is initially given in a dose of 100 mg a day and is increased as needed by 100 mg/d every several days to a maximum dose that should rarely exceed 400 mg/d. An indication of the minimum effective dose of spironolactone may be obtained by monitoring urinary electrolyte concentrations for a rise in sodium and fall in potassium levels, reflecting effective competitive inhibition of aldosterone. Conversely, the development of azotemia or hyperkalemia may be dose-limiting or even warrant a reduction in the amount of this medication. In some patients, diuresis cannot be initiated despite maximal doses of distal tubule-acting agents (e.g., 400 mg spironolactone) because of avid proximal tubular sodium absorption. More potent and proximally acting diuretics (furosemide, thiazide, or ethacrynic acid) may then be added cautiously to the regimen. Spironolactone plus furosemide, 40 or 80 mg/d, is usually sufficient to initiate a diuresis in most patients. However, such aggressive therapy must be used with great caution to avoid plasma volume depletion, azotemia, and hypokalemia, which may lead to encephalopathy.

In patients with pronounced ascites, particularly those requiring hospitalization, large-volume paracentesis has proven to be an effective and less costly approach to initial management than prolonged bed rest and conventional diuretic treatment. In this approach, ascitic fluid is removed by peritoneal cannula using strict aseptic techniques and monitoring hemodynamic and renal function. This can be safely accomplished in a single session. The need for concomitant albumin replacement by intravenous infusion remains controversial but may be prudent in the patient without peripheral edema, to avoid depleting the intravascular space and precipitating hypotension. Maintenance diuretic therapy in conjunction with sodium restriction may then be instituted to avoid recurrent ascites.

A minority of patients with advanced cirrhosis has "refractory ascites" or rapidly reaccumulate fluid after control by paracentesis. In some patients, a side-to-side *portacaval shunt* may result in improvement in ascites, although generally these patients are extremely poor surgical risks. In the past, intractable ascites has also been treated with the surgical implantation of a plastic *peritoneovenous shunt*, which has a pressure-sensitive, one-way valve allowing ascitic fluid to flow from the abdominal cavity to the superior vena cava. However, the usefulness of this technique is limited by a high rate of complications such as infection, disseminated intravascular coagulation, and thrombosis of the shunt. More recently, in selected patientsTIPS has been used effectively to control refractory ascites, although portal decompression, while mobilizing ascitic fluid, has precipitated severe hepatic encephalopathy in some patients. TIPS remains a promising but unproven treatment for refractory ascites. None of these shunts

has been shown to extend life expectancy.

SPONTANEOUS BACTERIAL PERITONITIS (SBP)

Patients with ascites and cirrhosis may develop acute bacterial peritonitis without an obvious primary source of infection. Patients with very advanced liver disease are particularly susceptible to SBP. The ascitic fluid in these patients typically has especially low concentrations of albumin and other so-called opsonic proteins, which normally may provide some protection against bacteria. Although key steps in the pathogenesis of SBP remain to be elucidated, it is clear that most bacteria contributing to SBP derive from the bowel and eventually are spread to ascitic fluid by the hematogenous route after transmigration through the bowel wall and transversing the lymphatics. Clinical features can include abrupt onset of fever, chills, generalized abdominal pain, and, rarely, rebound abdominal tenderness. However, the clinical symptoms *may be minimal*, and some patients manifest only worsening jaundice or encephalopathy in the absence of localizing abdominal complaints. The diagnosis is based on careful examination of the ascitic fluid. An ascitic fluid leukocyte count of>500 cells/L (with a proportion of polymorphonuclear leukocytes of ³50%) or more than 250 polymorphonuclear leukocytes should suggest the possibility of bacterial peritonitis while results of bacterial cultures of ascitic fluid are pending. Other measurements such as fluid pH or determination of gradients between serum and fluid pH or lactate are generally not necessary. The presence of more than 10,000 leukocytes per liter, multiple organisms, or failure to improve after standard therapy for 48 h suggest that the peritonitis may be secondary to an infection elsewhere in the body.

A variant ofSBP, designated *monomicrobial nonneutrocytic bacterascites*, is sometimes seen. In these patients, culture of ascitic fluid yields bacteria, but the neutrophil count is less than 250/L. These patients often have less severe liver disease than those found initially to have typical SBP. While many patients with this variant have cleared the bacterascites at the time of a subsequent paracentesis, nearly 40% will develop typical SBP; thus follow-up paracentesis is usually warranted in this setting.

TREATMENT

Empirical therapy with cefotaxime or ampicillin and an aminoglycoside should be initiated when the diagnosis is first suspected because enteric gram-negative bacilli are found in the majority of cases; less frequently, the infection is caused by pneumococci and other gram-positive bacteria. Cefotaxime is preferable due to the lower rate of renal toxicity. Specific antibiotic therapy can be selected once the specific organism is identified. Therapy is usually administered for 10 to 14 days, although one controlled study has suggested that a 5-day course of intravenous antibiotics may be as effective when repeat paracentesis at 48 h demonstrates a decline in the ascitic polymorphonuclear leukocytes count by more than 50% and negative cultures.

While appropriate antibiotic therapy is usually effective in the treatment of an episode ofSBP, recurrent episodes are relatively common; as many as 70% of patients will experience at least one recurrence within a year of the first episode. The risk of recurrence likely reflects the predisposing role of the underlying advanced liver disease that contributed to the development of the first episode of SBP. Recent trials have

demonstrated that prophylactic maintenance therapy with norfloxacin (400 mg/d) can reduce the frequency of recurrent SBP. This agent presumably causes selective decontamination of the intestine, eliminating many aerobic gram-negative bacilli. Trimethoprim-sulfamethoxazole given for 5 days a week has also proven effective. Antibiotics may be administered as infrequently as once a week (e.g., ciprofoxacin, 750 mg once weekly). While maintenance therapy reduces the frequency of SBP and need for hospitalization, it is unclear whether this is associated with prolonged survival. Primary prevention of SBP in a subset of high-risk cirrhotic patients [ascitic fluid protein<10 g/L (<1.0 g/dL)] also appears to be warranted, as is prophylaxis for SBP during variceal hemorrhage.

HEPATORENAL SYNDROME

Definition and Pathogenesis Hepatorenal syndrome is a serious complication in the patient with cirrhosis and ascites and is characterized by worsening azotemia with avid sodium retention and oliguria in the absence of identifiable specific causes of renal dysfunction. The exact basis for this syndrome is not clear, but altered renal hemodynamics appear to be involved. The kidneys are structurally intact; urinalysis and pyelography are usually normal. Renal biopsy, although rarely needed, is also normal, and in fact, kidneys from such patients have been used successfully for renal transplantation. There are indications that an imbalance in certain metabolites of arachidonic acid (prostaglandins and thromboxane) may play a pathogenetic role.

Clinical Features and Diagnosis Worsening azotemia, hyponatremia, progressive oliguria, and hypotension are the hallmarks of the hepatorenal syndrome. This syndrome, which is distinct from prerenal azotemia, may be precipitated by severe gastrointestinal bleeding, sepsis, or overly vigorous attempts at diuresis or paracentesis; it may also occur without an obvious cause. It is essential to exclude other causes of renal impairment often seen in these patients. These include prerenal azotemia or acute tubular necrosis due to hypovolemia (e.g., secondary to gastrointestinal bleeding or diuretic therapy) or an increased nitrogen load such as that seen as a result of bleeding. Drug nephrotoxicity is also often a consideration, particularly in the patient who has received agents such as aminoglycosides or contrast dye. The diagnosis rests on the finding of an elevated serum creatinine level [>133 umol/L (>1.5 g/dL)] that fails to improve with volume expansion or withdrawal of diuretics, together with an unremarkable urine sediment. The diagnosis is supported by the demonstration of avid urinary sodium retention. Typically, the urine sodium concentration is<5 mmol/L, a concentration lower than that generally found in uncomplicated prerenal azotemia.

TREATMENT

Treatment is usually unsuccessful. Although some patients with hypotension and decreased plasma volume may respond to infusions of salt-poor albumin, volume expansion must be undertaken with caution to avoid precipitating variceal bleeding. Vasodilator therapy, including intravenous infusions of low dose dopamine, is not effective. WhileTIPS has been reported to improve renal function in some patients, its use can not be recommended. In appropriate candidates, the treatment of choice for hepatorenal syndrome is liver transplantation.

HEPATIC ENCEPHALOPATHY

Definition Hepatic (portal-systemic) encephalopathy is a complex neuropsychiatric syndrome characterized by disturbances in consciousness and behavior, personality changes, fluctuating neurologic signs, asterixis or "flapping tremor," and distinctive electroencephalographic changes. Encephalopathy may be *acute* and reversible or *chronic* and progressive. In severe cases, irreversible coma and death may occur. Acute episodes may recur with variable frequency.

Pathogenesis The specific cause of hepatic encephalopathy is unknown. The most important factors in the pathogenesis are severe hepatocellular dysfunction and/or intrahepatic and extrahepatic shunting of portal venous blood into the systemic circulation so that the liver is largely bypassed. As a result of these processes, various toxic substances absorbed from the intestine are not detoxified by the liver and lead to metabolic abnormalities in the central nervous system (CNS). *Ammonia* is the substance most often incriminated in the pathogenesis of encephalopathy. Many, but not all, patients with hepatic encephalopathy have elevated blood ammonia levels, and recovery from encephalopathy is often accompanied by declining blood ammonia levels. Other compounds and metabolites that may contribute to the development of encephalopathy include mercaptans (derived from intestinal metabolism of methionine), short-chain fatty acids, and phenol. *False neurochemical transmitters* (e.g., octopamine), resulting in part from alterations in plasma levels of aromatic and branched-chain amino acids, may also play a role. An increase in the permeability of the blood-brain barrier to some of these substances may be an additional factor involved in the pathogenesis of hepatic encephalopathy. Several observations suggest that excessive concentrations of g-aminobutyric acid (GABA), an inhibitory neurotransmitter, in theCNS are important in the reduced levels of consciousness seen in hepatic encephalopathy. Increased CNS GABA may reflect failure of the liver to extract precursor amino acids efficiently or to remove GABA produced in the intestine. In support of this, there is also evidence to suggest that endogenous benzodiazepines, which act through the GABA receptor, may contribute to the development of hepatic encephalopathy. This evidence includes isolation of 1,4-benzodiazepines from brain tissue of patients with fulminant hepatic failure as well as the partial response observed in some patients and experimental animals after administration of flumazenil, a benzodiazepine antagonist. However, the inconsistent effect of flumazenil in patients with encephalopathy, as well as potential methodologic pitfalls in the measurement of endogenous benzodiazepines, preclude definitive attribution of a role to these substances in the pathogenesis of hepatic encephalopathy. The finding of direct enhancement of GABA receptor activation by ammonia suggests that several of the factors described above may be operating via a final common pathway to produce the neuronal depression of hepatic encephalopathy. Finally, the observation of hyperintensity in the basal ganglia by magnetic resonance imaging in cirrhotic patients suggests that excessive *manganese* deposition may also contribute to the pathogenesis of hepatic encephalopathy. Further studies are needed to determine whether chelation therapy exerts long-term benefit.

In the patient with otherwise stable cirrhosis, hepatic encephalopathy often follows a clearly identifiable precipitating event (Table 299-3). Perhaps the most common predisposing factor is *gastrointestinal bleeding*, which leads to an increase in the

production of ammonia and other nitrogenous substances, which are then absorbed. Similarly, *increased dietary protein* may precipitate encephalopathy as a result of increased production of nitrogenous substances by colonic bacteria. *Electrolyte disturbances*, particularly hypokalemic alkalosis secondary to overzealous use of diuretics, vigorous paracentesis, or vomiting, may precipitate hepatic encephalopathy. Systemic alkalosis causes an increase in the amount of nonionic ammonia (NH_3) relative to ammonium ions NH_4^+). Only nonionic (uncharged) ammonia readily crosses the blood-brain barrier and accumulates in theCNS. Hypokalemia also directly stimulates renal ammonia production. Injudicious use of CNS-depressing drugs (e.g., barbiturates, benzodiazepines) and acute infection may trigger or aggravate hepatic encephalopathy, although the mechanisms involved are not clear. Other potential precipitating factors include superimposed acute viral hepatitis, alcoholic hepatitis, extrahepatic bile duct obstruction, constipation, surgery, and other coincidental medical complications.

Hepatic encephalopathy has protean manifestations, and any neurologic abnormality, including focal deficits, may be encountered. In patients with acute encephalopathy, neurologic deficits are completely reversible upon correction of underlying precipitating factors and/or improvement in liver function, but in patients with chronic encephalopathy, the deficits may be irreversible and progressive. Cerebral edema is frequently present and contributes to the clinical picture and overall mortality in patients with both acute and chronic encephalopathy.

The diagnosis of hepatic encephalopathy should be considered when four major factors are present: (1) acute or chronic hepatocellular disease and/or extensive portal-systemic collateral shunts (the latter may be either spontaneous, e.g., secondary to portal hypertension, or surgically created, e.g., portacaval anastomosis); (2) disturbances of awareness and mentation, which may progress from forgetfulness and confusion to stupor and finally coma; (3) shifting combinations of neurologic signs, including asterixis, rigidity, hyperreflexia, extensor plantar signs, and rarely, seizures; and (4) a characteristic (but nonspecific) symmetric, high-voltage, triphasic slow-wave (2 to 5 per second) pattern on the electroencephalogram. Asterixis ("liver flap," "flapping tremor") is a nonrhythmic asymmetric lapse in voluntary sustained position of the extremities, head, and trunk. It is best demonstrated by having the patient extend the arms and dorsiflex the hands. Because elicitation of asterixis depends on sustained voluntary muscle contraction, it is not present in the comatose patient. Asterixis is nonspecific and also occurs in patients with other forms of metabolic brain disease. Disturbances of sleep with reversal of sleep/wake cycles are among the earliest signs of encephalopathy. Alterations in personality, mood disturbances, confusion, deterioration in self-care and handwriting, and daytime somnolence are additional clinical features of encephalopathy. *Fetor hepaticus*, a unique musty odor of the breath and urine believed to be due to mercaptans, may be noted in patients with varying stages of hepatic encephalopathy.

Grading or classifying the stages of hepatic encephalopathy is often helpful in following the course of the illness and assessing response to therapy. One useful classification is shown in Table 299-4.

The diagnosis of hepatic encephalopathy is usually one of exclusion. There are no

diagnostic liver function test abnormalities, although an elevated serum ammonia level in the appropriate clinical setting is highly suggestive of the diagnosis. Examination of the cerebrospinal fluid is unremarkable, and computed tomography of the brain shows no characteristic abnormalities until late in stage IV when cerebral edema may supervene. A number of conditions, particularly disorders related to acute and chronic alcoholism, can mimic the clinical features of hepatic encephalopathy. These include acute alcohol intoxication, sedative overdose, delirium tremens, Wernicke's encephalopathy, and Korsakoff's psychosis (Chap. 373). Subdural hematoma, meningitis, and hypoglycemia or other metabolic encephalopathies must also be considered, especially in patients with alcoholic cirrhosis. In young patients with liver disease and neurologic abnormalities, Wilson's disease should be excluded.

TREATMENT

(SeeFig. 299-4) Early recognition and prompt treatment of hepatic encephalopathy are essential. Patients with acute, severe hepatic encephalopathy (stage IV) require the usual supportive measures for the comatose patient. Specific treatment of hepatic encephalopathy is aimed at (1) elimination or treatment of precipitating factors and (2) lowering of blood ammonia (and other toxin) levels by decreasing the absorption of protein and nitrogenous products from the intestine. In the setting of acute gastrointestinal bleeding, blood in the bowel should be promptly evacuated with laxatives (and enemas if necessary) in order to reduce the nitrogen load. Protein should be excluded from the diet, and constipation should be avoided. Ammonia absorption can be decreased by the administration of lactulose, a nonabsorbable disaccharide that acts as an osmotic laxative. Metabolism of lactulose by colonic bacteria may also result in an acid pH that favors conversion of ammonia to the poorly absorbed ammonium ion. In addition, lactulose may actually diminish ammonia production through its direct effects on bacterial metabolism. Acutely, lactulose syrup can be administered in a dose of 30 to 60 mL every hour until diarrhea occurs; thereafter the dose is adjusted (usually 15 to 30 mL three times daily) so that the patient has two to four soft stools daily. Intestinal ammonia production by bacteria can also be decreased by oral administration of a "nonabsorbable" antibiotic such as neomycin (0.5 to 1.0 g every 6 h). However, despite poor absorption, neomycin may reach sufficient concentrations in the bloodstream to cause renal toxicity. Equal benefits may be achieved with broad-spectrum antibiotics such as metronidazole. The use of agents such as levodopa, bromocriptine, keto analogues of essential amino acids, and intravenous amino acid formulations rich in branched-chain amino acids in the treatment of acute hepatic encephalopathy remains of unproven benefit. Flumazenil, a short-acting benzodiazepine antagonist, may have a role in management of hepatic encephalopathy precipitated by use of benzodiazepines, if there is a need for urgent therapy. Hemoperfusion to remove toxic substances and therapy directed primarily toward coincident cerebral edema in acute encephalopathy are also of unproven value. The efficacy of extracorporeal liver assist devices employing hepatocytes of porcine or human origin to bridge patients to recovery or transplantation is as yet unproven but is currently being studied.

Chronic encephalopathy may be effectively controlled by administration of lactulose. Management of patients with chronic encephalopathy should include dietary protein restriction (usually to 60 g/d) in combination with low doses of lactulose or neomycin. Nephrotoxicity or ototoxicity may be limiting in prolonged usage of neomycin. There are

suggestions that vegetable protein may be preferable to animal protein.

OTHER SEQUELAE OF CIRRHOSIS

Coagulopathy Patients with cirrhosis often demonstrate a variety of abnormalities in both cellular and humoral clotting function. Thrombocytopenia may result from hypersplenism. In the alcoholic patient, there may be direct bone marrow suppression by ethanol. Diminished protein synthesis may lead to reduced production of fibrinogen (factor I), prothrombin (factor II), and factors V, VII, IX, and X. Reduction in levels of all factors except factor V may be worsened by the coincident malabsorption of the fat-soluble cofactor vitamin K due to cholestasis (Chap. 286). Of these, factor VII appears to be pivotal. In cirrhosis, it is the first of the factors to become depleted and, because of its short half-life, replacement with plasma often fails to correct an elevated prothrombin time. Preliminary studies suggest that selective replacement of factor VII can correct the prothrombin time in patients with cirrhosis.

Hepatocellular Carcinoma SeeChap. 91.

HYPOXEMIA AND HEPATOPULMONARY SYNDROME

Definition and Pathogenesis Mild hypoxemia occurs in approximately one-third of patients with chronic liver disease. The hepatopulmonary syndrome is typically manifest by hypoxemia, platypnea, and orthodeoxia. Hypoxemia usually results from right-to-left intrapulmonary shunts through dilatations in intrapulmonary vessels that can be detected by contrast-enhanced echocardiography or a macroaggregated albumin lung perfusion scan. The mechanisms of shunt formation are unclear, but one animal model suggests that endothelin-1 levels and pulmonary nitric oxide, raised in cirrhosis, correlate with degree of shunting.

TREATMENT

No specific treatment is consistently effective, though large arteriovenous shunts may be embolized. It is now increasingly recognized that liver transplantation may eventually lead to amelioration of the hepatopulmonary syndrome in cases that have not yet been complicated by advanced pulmonary hypertension.

300. INFILTRATIVE, GENETIC, AND METABOLIC DISEASES AFFECTING THE LIVER - *Daniel K. Podolsky*

Many disseminated, systemic, or metabolic diseases involve the liver in a diffuse manner by the infiltration of abnormal cells or the accumulation of chemical substances or metabolites. Chemical accumulation may be extracellular or intracellular and may involve hepatocytes, Kupffer cells, or other elements of the reticuloendothelial system. Although infiltrative diseases may vary widely in cause and extrahepatic manifestations, the findings in the liver may be quite similar. Generalized enlargement and firmness of the liver, gradual and nonspecific deterioration of liver function, and, less often, signs of portal hypertension or ascites are typical features of this group of diseases. Differential diagnosis by clinical means may be difficult on occasion, but in patients in whom ancillary clinical findings do not establish the diagnosis, the diffusely infiltrated liver provides an excellent source of tissue for diagnostic purposes.

HEPATIC STEATOSIS (FATTY LIVER) AND NONALCOHOLIC STEATOHEPATITIS

Slight to moderate enlargement of the liver due to a diffuse accumulation of neutral fat (triglycerides) in hepatocytes is an important clinical and pathologic finding. Imaging techniques such as computed tomography (CT), ultrasound, and magnetic resonance imaging (MRI) may each yield alterations suggesting increased fat in the liver. Several mechanisms can contribute to lipid accumulation in the liver. Fatty liver can be separated into two categories based on whether the fat droplets in the hepatocytes are macrovesicular or microvesicular (Table 300-1). In addition, fatty infiltration may be accompanied by necroinflammatory activity, a condition designated *nonalcoholic steatohepatitis (NASH)*.

MACROVESICULAR FATTY LIVER

This is the most common type of fatty liver and is seen most frequently in alcoholism or alcoholic liver disease, diabetes mellitus, obesity, and prolonged parenteral nutrition. Hematoxylin and eosin-stained liver sections show hepatocytes with large, empty vacuoles with the nucleus "pushed" to the periphery of the cell. In general, fat in the liver is not damaging per se, and the fat will disappear with improvement or elimination of the predisposing condition.

Etiology The major causes of fatty liver with macrovesicular fat depend on the age, geographic location, and metabolic-nutritional status of the patient population. *Chronic alcoholism* is the most common cause of hepatic steatosis in this country and in other countries with a high alcohol intake. The severity of fatty involvement is roughly proportional to the duration and degree of alcoholic excess. In addition, in western countriesNASH is associated with obesity. Many of these patients (up to one-third) have type 2 diabetes and/or hyperlipidemia. Inflammatory activity when present may reflect the combined effects of oxidative stress, subsequent lipid peroxidation and abnormal cytokine expression, especially increased tumor necrosis factor (TNF).

Protein malnutrition, especially in infancy and early childhood, accounts for most cases of severe fatty liver in the tropical zones of Africa, South America, and Asia. The hepatic changes may be associated with other clinical and pathologic features of kwashiorkor.

Jejunoileal bypass for surgical treatment of morbid obesity was sometimes associated with severe fatty liver and hepatic failure that could be fatal. In patients with Cushing's syndrome and in those receiving large doses of glucocorticoids, fatty infiltration of the liver may occur. In many *chronic illnesses*, especially those complicated by impaired nutrition or malabsorption, increased fat is found in liver cells. For example, patients with severe ulcerative colitis, chronic pancreatitis, or protracted heart failure frequently have moderate hepatic steatosis at the time of death. Patients maintained on prolonged *total parenteral nutrition* also may develop a fatty liver. In some cases, fatty infiltration and steatohepatitis may occur in the absence of an identifiable cause.

Acute fatty liver is caused by a number of hepatotoxins and is frequently accompanied by signs and symptoms of liver failure. Carbon tetrachloride intoxication, DDT poisoning, and ingestion of substances containing yellow phosphorus result in severe hepatic steatosis. Acute and prolonged alcohol ingestion may also be considered in this category and may be associated with a rapidly enlarging and fat-laden liver.

Clinical Features The signs and symptoms of hepatic steatosis are related to the degree of fat infiltration, the time course of its accumulation, and the underlying cause. The obese or diabetic patient with a chronic fatty liver is usually asymptomatic and has only mild tenderness over the enlarged liver. The liver function tests are normal or show mild elevations of alkaline phosphatase or aminotransferases. In contrast, the rapid accumulation of fat seen in the setting of hyperalimentation may lead to marked tenderness, presumably resulting from stretching of Glisson's capsule. Similarly, alcoholic patients with acute fatty liver following a bout of heavy drinking may have right upper quadrant pain and tenderness, often with laboratory evidence of cholestasis. The clinical presentation of fatty liver from hepatotoxins is similar to that of fulminant hepatic failure arising from any cause, with evidence of hepatic encephalopathy, marked elevations of prothrombin time and aminotransferases, and variable degrees of jaundice. Although steatohepatitis is generally thought to have a benign clinical course with improvement following elimination of the associated precipitant, in some individuals it may result in significant fibrosis and even cirrhosis. Recent studies indicate that substantial fibrosis or cirrhosis may be present in 15 to 50% of patients withNASH. In the only long-term follow-up study, 30% of patients with fibrosis had cirrhosis after 10 years. It is possible that some cases of "cryptogenic" cirrhosis are due to longstanding NASH and that the fat leaves the liver as endstage liver disease develops.

Diagnosis The findings of a firm, nontender, and generally enlarged liver with minimal hepatic dysfunction in a patient with chronic alcoholism, malnutrition, poorly controlled diabetes mellitus, or obesity should suggest hepatic steatosis. This can usually be detected byCT,MRI, or ultrasound. Modest elevations of aminotransferases are often found in association with hepatic steatohepatitis. A disproportional elevation in AST leading to an AST/ALT ratio greater than 2 is generally associated with alcoholic hepatitis. When diagnostic uncertainty exists, needle biopsy of the liver will demonstrate the increased fat content, the presence of any fibrosis, and possibly the underlying primary disorder.

TREATMENT

Adequate nutritional intake, removal of alcohol or offending toxins, and correction of any

associated metabolic disorders usually result in recovery. There is no clinical rationale for the use of lipotropic agents such as choline. When indicated, attention should be directed to abstinence from alcohol, careful control of diabetes, weight loss, or correction of intestinal absorptive defects. In the alcoholic fatty liver, there is gradual disappearance of fat from the liver after 4 to 8 weeks of adequate diet and abstinence from alcohol. Similarly, fatty infiltration usually resolves within 2 weeks after discontinuation of parenteral hyperalimentation. Pilot studies in patients withNASHhave suggested benefits from vitamin E and phlebotomy. Troglitazone has shown some benefit in those patients with concomitant insulin resistance.

MICROVESICULAR FATTY LIVER

This is the less common form of fatty liver. On microscopic examination, the fat is present in many small vacuoles. Although the droplets consist of triglycerides in both the macrovesicular and microvesicular forms, the reason for this difference in morphologic appearance is not clear.

Acute fatty liver of pregnancy (AFLP) is a syndrome that occurs late in pregnancy and is often associated with jaundice and hepatic failure. The liver is typically small. AFLP is more common when the mother is carrying a male fetus and may be associated with a deficiency of long-chain-3-hydroxy acyl COH dehydrogenase. Preeclampsia or the HELLP syndrome, which may complicate eclampsia, presents in a similar fashion and progresses to severe liver dysfunction, though typically with a normal size liver. Aminotransferase elevations are typically modest in all of these conditions (generally <500). If diagnosed in time, the disease usually resolves with termination of the pregnancy. Recurrence in subsequent pregnancies is rare.

Microvesicular fat accumulation also may be seen as a toxic reaction to *valproic acid* and with excessive doses of *tetracycline*. It is a typical finding in *Jamaican vomiting sickness*, which is caused by hypoglycin A present in unripened ackee fruit. Lactic acidosis and severe liver injury with microvesicular fat has been described as a complication of nucleoside analogue therapy.

REYE'S SYNDROME (FATTY LIVER WITH ENCEPHALOPATHY)

This acute illness is encountered exclusively in children below 15 years of age. It is characterized clinically by vomiting and signs of progressive central nervous system damage, signs of hepatic injury, and hypoglycemia. Morphologically, there is extensive fatty vacuolization of the liver and renal tubules. There is mitochondrial dysfunction with decreased activity of hepatic mitochondrial enzymes. The cause is unknown, although viral agents and drugs, especially salicylates, have been implicated. Increased aspirin use and much higher serum salicylate levels in children with this illness than in the general population have been described during outbreaks of Reye's syndrome. Recognition of this relationship and reduced aspirin use in this setting may account for the decreasing incidence of Reye's syndrome. However, this illness may occur in the absence of exposure to salicylates. In fatal cases, the liver is enlarged and yellow with striking diffuse fatty microvacuolization of cells. Peripheral zonal hepatic necrosis also has been present in some cases. Fatty changes of the renal tubular cells, cerebral edema, and neuronal degeneration of the brain are the major extrahepatic changes.

Electron-microscopic studies show structural alterations of mitochondria in liver, brain, and muscle.

The onset usually follows an upper respiratory tract infection, especially influenza or chickenpox. Within 1 to 3 days, persistent vomiting occurs, together with stupor, which usually progresses rapidly to generalized convulsions and coma. The liver is enlarged, but *jaundice is characteristically absent or minimal*. Elevations in serum aminotransferases and prothrombin time, hypoglycemia, metabolic acidosis, and elevated serum ammonia levels are the major laboratory findings. The mortality rate in Reye's syndrome is approximately 50%. Therapy consists of infusions of 20% glucose and fresh frozen plasma, as well as intravenous mannitol to reduce the cerebral edema. Chronic liver disease has not been reported in survivors.

STORAGE DISEASES

Lipid storage diseases include the hereditary disorders of Gaucher's and Niemann-Pick disease. Other rare diseases associated with increased fat in the liver include abetalipoproteinemia, Tangier disease, Fabry's disease, and types I and V hyperlipoproteinemia (see Chap. 344 for details). Hepatic enlargement caused by distention of liver cells with glycogen is present in some poorly controlled diabetics and frequently in juvenile diabetes. More often, however, hepatomegaly is due to fatty infiltration (see above). Ketoacidosis and vigorous insulin therapy may further enhance hepatic enlargement.

HEPATIC MINERAL ACCUMULATION

WILSON'S DISEASE

This is an uncommon inherited disorder of copper metabolism. Wilson's disease presents clinically in adolescence or young adulthood by which time there is excess copper accumulation in the liver and other tissues. Deficiency of the plasma copper protein ceruloplasmin is a characteristic feature. The accumulation appears to result from impaired copper excretion due to a mutation in a gene that encodes a P-type ATPase copper transporter. Clinically, patients may present in teenage or early adult years with chronic hepatitis, cirrhosis, or their complications. A small number of patients will present with fulminant hepatitis. Liver disease is often accompanied by softening and degeneration of the basal ganglia (hepatolenticular degeneration) due to copper deposition, which results in extrapyramidal neurologic and psychiatric symptoms. Brownish pigmentation of Descemet's membrane in the cornea (Kayser-Fleischer rings) is frequently present. Hemolytic anemia is also common, especially with fulminant disease. Liver biopsy may reveal findings ranging from fulminant hepatitis to chronic hepatitis and macronodular cirrhosis, in addition to excess copper levels. Typically, liver cells are ballooned and show increased glycogen with glycogen vacuolization in the nuclei. All patients under age 40 with unexplained chronic hepatitis or cirrhosis should be evaluated for possible Wilson's disease. Prompt diagnosis is important; treatment, which must be continued throughout life, can prevent progression of end-organ damage.**For further discussion, see Chap. 348.*

HEMOCHROMATOSIS

Hemochromatosis may be the most common genetic disorder of humans; it involves accumulation of abnormal amounts of iron due to inappropriate absorption from the intestine. Between 85 and 95% of patients with genetic hemochromatosis are homozygous for a point mutation (cystine to tyrosine at codon 282:C282). The liver, as a primary site of iron storage, is affected most directly. There is diffuse deposition of excess iron in hepatocytes, in contrast to the characteristic accumulation of iron in the reticuloendothelial compartment typical of secondary iron overload and hemosiderosis. Excess hepatic iron commonly results in hepatomegaly. Although liver function is initially well preserved, if the disease is untreated, progressive impairment is followed by the development of cirrhosis. Prompt diagnosis can permit the institution of effective lifelong therapy to reduce the iron load and halt progression of the disease.**For further discussion, see Chap. 345.*

OTHER INFILTRATIVE AND METABOLIC DISEASES

a_1-ANTITRYPSIN DEFICIENCY

Patients with homozygous deficiency of seruma_1-antitrypsin (a_1AT) are prone to develop emphysema in adult life. The disease is suggested by the absence of alpha$_1$globulin on serum electrophoresis (a_1AT makes up 90% of this fraction normally) and confirmed by direct measurement ofa_1AT. The exact phenotype can then be determined by starch electrophoresis. Although there are approximately 75 recognized alleles, only PiZ and PiS are associated with clinical disease. The molecular bases of these altered products have been related to single nucleic acid substitutions -- e.g., PiZ is caused by a G (guanine) to A (adenine) transposition, which results in a substitution of a glutamic acid for lysine at residue 292 in thea_1AT protein. Hepatocytes of some patients with this deficiency contain globules positive with the periodic acid Schiff reaction. Approximately 10% of children with homozygous deficiency (PiZZ phenotype) ofa_1AT will develop significant liver disease, including neonatal hepatitis and progressive cirrhosis. It has been suggested that 15 to 20 percent of all chronic liver disease in infancy may be attributed toa_1AT deficiency. In adults, the most common manifestation ofa_1AT deficiency is asymptomatic cirrhosis, which may progress from a micronodular to a macronodular state and may be complicated by the development of hepatocellular carcinoma. The occurrence of liver disease in these patients is not dependent on the development of lung disease.**For further discussion, see Chap. 258.*

HURLER'S SYNDROME

This is an uncommon hereditary disease that is characterized by the widespread tissue deposition of mucopolysaccharide (chondroitin sulfate B and heparan sulfate) in many tissues. The liver is frequently enlarged and firm. Microscopically, Kupffer cells and other macrophages are enlarged and filled with metachromatic granular material. Cirrhosis may be a late complication.**For further discussion, see Chap. 349.*

PORPHYRIAS SeeChap. 346.

RETICULOENDOTHELIAL DISORDERS (See also Chaps. 61 and 113)

Moderate to massive hepatomegaly and splenomegaly occur frequently in the various types of *leukemia* and *lymphoma*. Jaundice, when present, is usually slight and results from hemolysis, although cholestasis may occasionally be associated with lymphoma as a paraneoplastic syndrome. Deep and protracted jaundice is distinctly rare and is caused by obstruction of the intrahepatic or extrahepatic bile ducts by tumor. Liver biopsy specimens reveal portal and sinusoidal infiltrates in most cases of leukemia, but the cellular pattern may be mixed and nonspecific. Liver biopsy is diagnostic in only 5% of patients with *Hodgkin's disease*. This percentage is increased in those with advanced disease or splenomegaly. Directed biopsy at laparoscopy or laparotomy is more likely to be positive than "blind" needle biopsy. Nonspecific histologic changes in the liver have been described in patients with lymphoma and may contribute to the abnormal liver function tests.

Myeloid metaplasia and other myeloproliferative disorders associated with extramedullary hematopoiesis produce hepatomegaly which may reach huge proportions, especially following splenectomy. Serum alkaline phosphatase elevations are often found. Ascites and portal hypertension, resulting from diffuse involvement of portal venules and lymphatics, are rare complications.

GRANULOMATOUS INFILTRATIONS

Perhaps as a result of the large population of mononuclear phagocytes, a number of systemic granulomatous diseases involve the liver, including sarcoidosis, miliary tuberculosis, histoplasmosis, brucellosis, schistosomiasis, berylliosis, and drug reactions (Table 300-2). In addition, isolated granulomas of no diagnostic importance may be found occasionally in patients with various forms of cirrhosis and hepatitis. The liver infiltrated by granulomas may be slightly enlarged and firm, but hepatic dysfunction is usually limited. Increases in serum alkaline phosphatase are common and may range from mild to marked. Occasionally, mild serum elevations in aminotransferases are also present. In a few patients with sarcoidosis or brucellosis, portal hypertension may develop, and extensive postnecrotic scarring or postnecrotic cirrhosis may follow healing of the granulomatous lesions, as in schistosomiasis.

Needle biopsy of the liver often provides the first definite evidence of a systemic or disseminated granulomatous disease. In patients with sarcoidosis who have neither clinical nor laboratory evidence of hepatic involvement, needle biopsy shows sarcoid granulomas in about 80% of cases. In cases of suspected miliary tuberculosis, a portion of the biopsy should be cultured and stained for mycobacteria. The organism can be detected in the majority of cases, particularly when caseating granulomas are present. Serial sections of the biopsy specimen should be examined if granulomas are not apparent. Individual granulomas are rarely specific in their microscopic appearance, and final diagnosis usually requires other clinical, laboratory, or histologic data.

In approximately 20% of patients, it is not possible to identify a cause for the granulomatous infiltration. When these infiltrates are accompanied by fever of unknown origin, the diagnosis of *granulomatous hepatitis* should be considered. This is an uncommon disorder of unknown cause and is diagnosed by exclusion. While granulomatous hepatitis invariably responds to moderate doses of glucocorticoids, relapses are frequent, and such therapy should never be undertaken unless tuberculous

disease or other causes of granulomatous infiltration have been excluded. This may include an initial empiric trial of antituberculous therapy.

AMYLOIDOSIS (See alsoChap. 319)

Systemic amyloidosis, whether primary and idiopathic, familial, or secondary to chronic inflammatory or neoplastic diseases, often involves the liver. Grossly, the liver infiltrated with amyloid is enlarged and pale and rubbery in consistency. Microscopically, the birefringent amyloid deposits appear as homogeneous waxy material within the space of Disse, often being concentrated in the periportal areas and associated with atrophy of adjacent liver cell plates. Selective involvement of the walls of blood vessels, especially of the hepatic arterioles, may be a striking feature of primary amyloidosis. With this possible exception, however, the hepatic lesions are the same in all forms of amyloidosis and are present in 60 to 90% of cases.

An enlarged and firm liver is found in about 60% of patients, and ascites occurs in advanced stages of the disease in about 20%. Jaundice, portal hypertension, and other signs of chronic liver disease are usually absent. Liver function changes, although frequent, correlate poorly with the extent of liver infiltration. Hypoalbuminemia and elevated serum alkaline phosphatase are common. Hypoalbuminemia, however, may be related to the presence of nephrosis; the prothrombin time is usually normal. The diagnosis is established by biopsy of rectum, skin, liver, or other involved organs and demonstration of the characteristic Congo red-staining deposits by polarizing microscopy.

AIDS-RELATED LIVER DISEASE

In AIDS, evidence of liver disease is quite common but is usually mild with minimal morbidity. In these patients, hepatic granulomatous disease is often present and may be caused by opportunistic infections, with *Mycobacterium avium-intracellulare* being the most frequent pathogen. Cytomegalovirus hepatitis and hepatic mycoses are less common. These patients are frequently being treated for *Pneumocystis carinii* infections with sulfonamides, which also may cause hepatic granulomatous disease. AIDS cholangiopathy has become a well recognized entity. It exhibits features similar to those found in primary sclerosing cholangitis and is typically associated with cryptosporidia, microsporidia, and/or cytomegalovirus infection in the biliary tract. Papillary stenosis is frequently present. In addition, AIDS patients are vulnerable to hepatic injury resulting from drugs used to treat HIV, most notably nucleoside analogues.

ACKNOWLEDGEMENT

This chapter represents a revised version of a chapter by Dr. Kurt J. Isselbacher and Dr. Daniel K. Podolsky that has appeared in previous editions of this textbook.

301. LIVER TRANSPLANTATION - *Jules L. Dienstag*

Liver transplantation -- the replacement of the native, diseased liver by a normal organ (allograft) recovered from a brain-dead donor -- has matured from an experimental procedure reserved for desperately ill patients to an accepted, lifesaving operation applied much earlier in the natural history of end-stage liver disease. The preferred and technically most advanced approach is *orthotopic transplantation*, in which the native organ is removed and the donor organ is inserted in the same anatomic location. Pioneered in the 1960s by Starzl at the University of Colorado and, later, at the University of Pittsburgh and by Calne in Cambridge, England, liver transplantation is now performed routinely by dozens of centers throughout North America and western Europe. Success and survival have improved from approximately 30% in the 1970s to>80% today. These improved prospects for prolonged survival, dating back to the early 1980s, resulted from refinements in operative technique (including the introduction of venovenous bypass to allow venous return from the extremities and visceral circulation during clamping of the inferior vena cava), improvements in organ procurement and preservation, advances in immunosuppressive therapy, and, perhaps most influentially, more enlightened patient selection and timing. Despite the perioperative morbidity and mortality, the technical and management challenges of the procedure, and its costs, liver transplantation has become the approach of choice for selected patients whose chronic or acute liver disease is progressive, life-threatening, and unresponsive to medical therapy. Based on the current level of success, the number of liver transplants has continued to grow each year; in 1999,>4000 patients received liver allografts in the United States. Still, the demand for new livers continues to outpace availability; in 1999, >6000 patients in the United States were on a waiting list for a donor liver.

INDICATIONS

Potential candidates for liver transplantation are children and adults who, in the absence of contraindications (see below), suffer from severe, irreversible liver disease for which alternative medical or surgical treatments have been exhausted or are unavailable. *Timing of the operation is of critical importance*. Indeed, improved timing and better patient selection are felt to have contributed more to the increased success of liver transplantation in the 1980s and beyond than all the impressive technical and immunologic advances combined. Although the disease should be advanced, and although opportunities for spontaneous or medically induced stabilization or recovery should be allowed, the procedure should be done sufficiently early to give the surgical procedure a fair chance for success. Ideally, transplantation should be considered in patients with end-stage liver disease who are experiencing or have experienced a life-threatening complication of hepatic decompensation, whose quality of life has deteriorated to unacceptable levels, or whose liver disease will result predictably in irreversible damage to the central nervous system (CNS). If this is done sufficiently early, the patient will not have developed any contraindications or extrahepatic systemic deterioration. Although patients with well-compensated cirrhosis can survive for many years, many patients with quasi-stable chronic liver disease have much more advanced disease than may be apparent. As discussed below, the better the status of the patient prior to transplantation, the higher will be the anticipated success rate of transplantation. The decision about *when* to transplant is complex and requires the combined judgment

of an experienced team of hepatologists, transplant surgeons, anesthesiologists, and specialists in support services, not to mention the well-informed consent of the patient and the patient's family.

Transplantation in Children Indications for transplantation in children are listed inTable 301-1. The most common is *biliary atresia*. *Inherited or genetic disorders of metabolism* associated with liver failure constitute another major indication for transplantation in children and adolescents. In Crigler-Najjar disease type I and in certain hereditary disorders of the urea cycle and of amino acid or lactate-pyruvate metabolism, transplantation may be the only way to prevent impending deterioration ofCNSfunction, despite the fact that the native liver is structurally normal. Combined heart and liver transplantation has yielded dramatic improvement in cardiac function and in cholesterol levels in children with homozygous familial hypercholesterolemia; combined liver and kidney transplantation has been successful in patients with hereditary oxalosis. In hemophiliacs with transfusion-associated hepatitis and liver failure, liver transplantation has been associated with recovery of normal factor VIII synthesis.

Transplantation in Adults Liver transplantation is indicated for end-stage *cirrhosis* of all causes (Table 301-1). In sclerosing cholangitis and *Caroli's disease* (multiple cystic dilatations of the intrahepatic biliary tree), recurrent infections and sepsis associated with inflammatory and fibrotic obstruction of the biliary tree may be an indication for transplantation. Because prior biliary surgery complicates, and is a relative contraindication for, liver transplantation, surgical diversion of the biliary tree has been all but abandoned for patients with sclerosing cholangitis. In patients who undergo transplantation for *hepatic vein thrombosis (Budd-Chiari syndrome)*, postoperative anticoagulation is essential; underlying myeloproliferative disorders may have to be treated but are not a contraindication to liver transplantation. If a donor organ can be located quickly, before life-threatening complications -- including cerebral edema -- set in, patients with *fulminant hepatitis* are candidates for liver transplantation. More controversial as candidates for liver transplantation are patients with *alcoholic cirrhosis*, *chronic viral hepatitis*, and *primary hepatocellular malignancies*. Although all three of these categories are considered to be high risk, liver transplantation can be offered to carefully selected patients. Patients with alcoholic cirrhosis can be considered as candidates for transplantation if they meet strict criteria for abstinence and reform. Patients with chronic hepatitis C have done as well as any other subset of patients after transplantation, despite the fact that recurrent infection in the donor organ is the rule. In patients with chronic hepatitis B, in the absence of measures to prevent recurrent hepatitis B, survival after transplantation is reduced by approximately 10 to 20%; however, prophylactic use of hepatitis B immune globulin (HBIG) during and after transplantation increases the success of transplantation to a level comparable to that seen in patients with nonviral causes of liver decompensation. Specific antiviral drugs, such as lamivudine, that can be used for both prophylaxis against and treatment of recurrent hepatitis B will facilitate further the management of patients undergoing liver transplantation for end-stage hepatitis B. Issues of disease recurrence are discussed in more detail below. Patients with nonmetastatic primary hepatobiliary tumors -- primary hepatocellular carcinoma, cholangiocarcinoma, hepatoblastoma, angiosarcoma, epithelioid hemangioendothelioma, and multiple or massive hepatic adenomata -- have undergone liver transplantation; however, for hepatobiliary malignancies, overall survival

is significantly lower than that for other categories of liver disease. To minimize the very high likelihood of recurrent tumor after transplantation, some centers are evaluating experimental adjuvant chemotherapy protocols. Some transplantation centers have reported excellent long-term, recurrence-free survival in patients with unresectable hepatocellular carcinoma for single tumors<5 cm in diameter or for three or fewer lesions all<3 cm. Consequently, most centers restrict liver transplanation to patients whose hepatic malignancies are confined to these limits. Because the likelihood of recurrent cholangiocarcinoma is almost universal, this tumor is no longer considered an indication for transplantation.

CONTRAINDICATIONS

Absolute contraindications for transplantation include life-threatening systemic diseases, uncontrolled extrahepatic bacterial or fungal infections, preexisting advanced cardiovascular or pulmonary disease, multiple uncorrectable life-threatening congenital anomalies, metastatic malignancy, active drug or alcohol abuse, and HIV infection (Table 301-2). Because carefully selected patients in their sixties and even seventies have undergone transplantation successfully, advanced age per se is no longer considered an absolute contraindication; however, in older patients, a more thorough preoperative evaluation should be undertaken to exclude ischemic cardiac disease. Advanced age (>70 years), however, may be considered a *relative contraindication* -- that is, a factor to be taken into account with other relative contraindications. Other relative contraindications include highly replicative hepatitis B, portal vein thrombosis, preexisting renal disease not associated with liver disease, intrahepatic or biliary sepsis, severe hypoxemia resulting from right-to-left intrapulmonary shunts, previous extensive hepatobiliary surgery, and any uncontrolled serious psychiatric disorder. Any one of these relative contraindications is insufficient in and of itself to preclude transplantation. For example, the problem of portal vein thrombosis can be overcome by constructing a graft from the donor liver portal vein to the recipient's superior mesenteric vein.

TECHNICAL CONSIDERATIONS

Donor Selection Donor livers for transplantation are procured primarily from victims of head trauma. Organs from brain-dead donors up to age 60 are acceptable if the following criteria are met: hemodynamic stability; adequate oxygenation; absence of bacterial or fungal infection; serologic exclusion of hepatitis B and C viruses and HIV; absence of abdominal trauma; and absence of hepatic dysfunction. Cardiovascular and respiratory functions are maintained artificially until the liver can be removed. Compatibility in ABO blood group and organ size between donor and recipient are important considerations in donor selection; however, ABO-incompatible or reduced-donor-organ transplants can be performed in emergency or marked donor-scarcity situations. Tissue typing for HLA matching is not required, and preformed cytotoxic HLA antibodies do not preclude liver transplantation. Following perfusion with cold electrolyte solution, the donor liver is removed and packed in ice. The use of University of Wisconsin (UW) solution, rich in lactobionate and raffinose, has permitted the extension of cold ischemic time up to 20 h; however, 12 h may be a more reasonable limit. Improved techniques for harvesting multiple organs from the same donor have increased the availability of donor livers, but the availability of donor livers is far outstripped by the demand. Currently, in the United States, all donor livers are

distributed through a nationwide organ-sharing network (United Network of Organ Sharing) designed to allocate available organs based on regional considerations and recipient acuity. Recipients who require the highest level of care (intensive care) have the highest priority, as outlined in Table 301-3.

Surgical Technique Removal of the recipient's native liver is technically difficult, particularly in the presence of portal hypertension with its associated collateral circulation and extensive varices, and even more so in the presence of scarring from previous abdominal operations. The combination of portal hypertension and coagulopathy (elevated prothrombin time and thrombocytopenia) translates into large blood product transfusion requirements. After the portal vein and infrahepatic and suprahepatic inferior vena cavae are dissected, a pump-driven venovenous bypass system is applied to reroute blood from the portal vein and inferior vena cava, preventing congestion of visceral organs. After the hepatic artery and common bile duct are dissected, the native liver is removed and the donor organ inserted. During the anhepatic phase, coagulopathy, hypoglycemia, hypocalcemia, and hypothermia are encountered and must be managed by the anesthesiology team. Caval, portal vein, hepatic artery, and bile duct anastomoses are performed in succession, the last by end-to-end suturing of the donor and recipient common bile ducts or by choledochojejunostomy to a Roux en Y loop if the recipient common bile duct cannot be used for reconstruction (e.g., in sclerosing cholangitis). A typical transplant operation lasts 8 h, with a range of 6 to 18 h. Because of excessive bleeding, large volumes of blood, blood products, and volume expanders may be required during surgery.

Emerging alternatives to orthotopic liver transplantation include split-liver grafts, in which one donor organ is divided and inserted into two recipients; and living-related-donor procedures, in which the left lobe of the liver is harvested from a living-related donor for transplantation into the recipient. Heterotopic liver transplantation, in which the donor liver is inserted without removal of the native liver, has met with very limited success and acceptance, except in a very small number of centers. To support desperately ill patients until a suitable donor organ can be identified, several transplantation centers are studying extracorporeal perfusion with bioartificial liver cartridges constructed from hepatocytes bound to hollow fiber systems and used as temporary hepatic-assist devices, but their efficacy remains to be established. Areas of research with the potential to overcome the shortage of donor organs include hepatocyte transplantation and xenotransplantation with genetically modified organs of nonhuman origin (e.g., swine).

POSTOPERATIVE COURSE AND MANAGEMENT

Immunosuppressive Therapy The introduction in 1980 of cyclosporine as an immunosuppressive agent contributed substantially to the improvement in survival after liver transplantation. Cyclosporine inhibits early activation of T cells and is specific for T cell functions that result from the interaction of the T cell with its receptor and that involve the calcium-dependent signal transduction pathway. As a result, the activity of cyclosporine leads to inhibition of lymphokine gene activation, blocking interleukins 2, 3, and 4, tumor necrosis factor a, as well as other lymphokines. Cyclosporine also inhibits B cell functions. This process occurs without affecting rapidly dividing cells in the bone marrow, which may account for the reduced frequency of posttransplantation systemic

infections. The most common and important side effect of cyclosporine therapy is nephrotoxicity. Cyclosporine causes dose-dependent renal tubular injury and direct renal artery vasospasm. Following renal function, therefore, is important in monitoring cyclosporine therapy, perhaps even a more reliable indicator than blood levels of the drug. Nephrotoxicity is reversible and can be managed by dose reduction. Other adverse effects of cyclosporine therapy include hypertension, hyperkalemia, tremor, hirsutism, glucose intolerance, and gum hyperplasia.

Tacrolimus (originally labeled FK 506) is a macrolide lactone antibiotic isolated from a Japanese soil fungus, *Streptomyces tsukubaensis*. It has the same mechanism of action as cyclosporine but is 10 to 100 times more potent. Initially applied as "rescue" therapy for patients in whom rejection occurred despite the use of cyclosporine, tacrolimus has been shown in two large, multicenter, randomized trials to be associated with a reduced frequency of acute rejection, refractory rejection, and chronic rejection. Although patient and graft survival are the same with these two drugs, the advantage of tacrolimus in minimizing episodes of rejection, reducing the need for additional glucocorticoid doses, and reducing the likelihood of bacterial and cytomegalovirus infection has simplified the management of patients undergoing liver transplantation. In addition, the oral absorption of tacrolimus is more predictable than that of cyclosporine, especially during the early postoperative period when T-tube drainage interferes with the enterohepatic circulation of cyclosporine. As a result, in most transplantation centers, tacrolimus has now supplanted cyclosporine for primary immunosuppression, and many centers rely on oral, rather than intravenous, administration from the outset. For transplantation centers that prefer cyclosporine, a new, better-absorbed, microemulsion preparation is now available.

Although tacrolimus is more potent than cyclosporine, it is also more toxic and more likely to be discontinued for adverse events. The toxicity of tacrolimus is similar to that of cyclosporine; nephrotoxicity and neurotoxicity are the most commonly encountered adverse effects, and neurotoxicity (tremor, seizures, hallucinations, psychoses, coma) is more likely and more severe in tacrolimus-treated patients. Both drugs can cause diabetes mellitus, but tacrolimus does not cause hirsutism or gingival hyperplasia. Because of overlapping toxicity between cyclosporine and tacrolimus, especially nephrotoxicity, and because tacrolimus reduces cyclosporine clearance, these two drugs should not be used together. Because 99% of tacrolimus is metabolized by the liver, hepatic dysfunction reduces its clearance; in primary graft nonfunction (when, for technical reasons or because of ischemic damage prior to its insertion, the allograft is defective and does not function normally from the outset) tacrolimus doses have to be reduced substantially, especially in children. Both cyclosporine and tacrolimus are metabolized by the cytochrome P450 IIIA system, and, therefore, drugs that induce cytochrome P450 (e.g., phenytoin, phenobarbital, carbamazepine, rifampin) reduce available levels of cyclosporine and tacrolimus; drugs that inhibit cytochrome P450 (e.g., erythromycin, fluconazole, ketoconazole, clotrimazole, itraconazole, verapamil, diltiazem, nicardipine, cimetidine, danazol, metoclopramide, bromocriptine) increase cyclosporine and tacrolimus blood levels. Like azathioprine, cyclosporine and tacrolimus appear to be associated with a risk of lymphoproliferative malignancies (see below), which may occur earlier after cyclosporine or tacrolimus than after azathioprine therapy. Because of these side effects, combinations of cyclosporine or tacrolimus with prednisone and azathioprine -- all at reduced doses -- are preferable regimens for

immunosuppressive therapy.

In patients with pretransplant renal dysfunction or renal deterioration that occurs intraoperatively or immediately postoperatively, tacrolimus or cyclosporine therapy may not be practical; under these circumstances, induction or maintenance of immunosuppression with monoclonal antibodies to T cells, OKT3, may be appropriate. Therapy with OKT3 has been especially effective in reversing acute rejection in the posttransplant period and is the standard treatment for acute rejection that fails to respond to methylprednisolone boluses. Intravenous infusions of OKT3 may be complicated by transient fever, chills, and diarrhea. When this drug is used to induce immunosuppression initially or to provide "rescue" in those who reject despite "conventional" therapy, the incidence of bacterial, fungal, and especially cytomegalovirus infections is increased during and after such therapy. In some centers, ganciclovir antiviral therapy is initiated prophylactically as a routine along with OKT3. Another immunosuppressive drug that is likely to be used in the future for patients undergoing liver transplantation is mycophenolic acid, a nonnucleoside purine metabolism inhibitor derived as a fermentation product from several *Penicillium* species. Mycophenolate has been shown to be better than azathioprine, when used with other standard immunosuppressive drugs, in preventing rejection after renal transplantation and has been approved for use in renal transplantation. Rapamycin, an inhibitor of later events in T cell activation, is yet another drug undergoing experimental evaluation as an immunosuppressive agent.

The most important principle of immunosuppression is that the ideal approach strikes a balance between immunosuppression and immunologic competence. Given sufficient immunosuppression, acute liver allograft rejection is always reversible; however, if the cumulative dose of immunosuppressive therapy is too large, the patient will succumb to opportunistic infection. Therefore, immunosuppressive drugs must be used judiciously, with strict attention to the infectious consequences of such therapy.

Postoperative Complications Complications of liver transplantation can be divided into hepatic and nonhepatic categories (Tables 301-4 and301-5). In addition, both immediately postoperative and late complications are encountered. Patients who undergo liver transplantation as a rule have been chronically ill for protracted periods and may be malnourished and wasted. The impact of such chronic illness and the multisystem failure that accompanies liver failure continues to require attention in the postoperative period. Because of the massive fluid losses and fluid shifts that occur during the operation, patients may remain fluid overloaded during the immediate postoperative period, straining cardiovascular reserve; this effect can be amplified in the face of transient renal dysfunction and pulmonary capillary vascular permeability. Continuous monitoring of cardiovascular and pulmonary function, measures to maintain the integrity of the intravascular compartment and to treat extravascular volume overload, and scrupulous attention to potential sources of and sites of infection are of paramount importance. Cardiovascular instability may also result from the electrolyte imbalance that may accompany reperfusion of the donor liver. Pulmonary function may be compromised further by paralysis of the right hemidiaphragm associated with phrenic nerve injury. The hyperdynamic state with increased cardiac output that is characteristic of patients with liver failure reverses rapidly after successful liver transplantation.

Other immediate management issues include renal dysfunction; prerenal azotemia, acute kidney injury associated with hypoperfusion (acute tubular necrosis), and renal toxicity caused by antibiotics, tacrolimus, or cyclosporine are frequently encountered in the postoperative period, sometimes necessitating dialysis. Occasionally, postoperative intraperitoneal bleeding may be sufficient to increase intraabdominal pressure, which, in turn, may reduce renal blood flow; this effect is rapidly reversible when abdominal distention is relieved by exploratory laparotomy to identify and ligate the bleeding site and to remove intraperitoneal clot. Anemia also may result from acute upper gastrointestinal bleeding or from transient hemolytic anemia, which may be autoimmune, especially when blood group O livers are transplanted into blood group A or B recipients. This autoimmune hemolytic anemia is mediated by donor intrahepatic lymphocytes that recognize red blood cell A or B antigens on recipient erythrocytes. Transient in nature, this process resolves once the donor liver is repopulated by recipient bone marrow-derived lymphocytes; the hemolysis can be treated by transfusing blood group O red blood cells and/or by administering higher doses of glucocorticoids. Transient thrombocytopenia is also commonly encountered. Aplastic anemia, a late occurrence, is rare but has been reported in almost 30% of patients who underwent liver transplantation for acute, severe hepatitis of unknown cause.

Bacterial, fungal, or viral infections are common and may be life-threatening postoperatively. Early after transplant surgery, common postoperative infections predominate -- pneumonia, wound infections, infected intraabdominal collections, urinary tract infections, and intravenous line infections -- rather than opportunistic infections; these infections may involve the biliary tree and liver as well. Beyond the first postoperative month, the toll of immunosuppression becomes evident, and opportunistic infections -- cytomegalovirus, herpes viruses, fungal infections (*Aspergillus*, *Candida*, cryptococcal disease), mycobacterial infections, parasitic infections (*Pneumocystis*, *Toxoplasma*), bacterial infections (*Nocardia*, *Legionella*, and *Listeria*) -- predominate. Rarely, early infections represent those transmitted with the donor liver, either infections present in the donor or infections acquired during procurement processing. De novo viral hepatitis infections acquired from the donor organ or from transfused blood products occur after typical incubation periods for these agents (well beyond the first month). Obviously, infections in an immunosuppressed host demand early recognition and prompt management; prophylactic antibiotic therapy is administered routinely in the immediate postoperative period. Use of sulfamethoxazole with trimethoprim reduces the incidence of postoperative *Pneumocystis carinii* pneumonia.

Neuropsychiatric complications include seizures (commonly associated with cyclosporine and tacrolimus toxicity), encephalopathy, depression, and difficult psychosocial adjustment. Rarely, diseases are transmitted by the allograft from the donor to the recipient. In addition to viral and bacterial infections, malignancies of donor origin have occurred. Lymphoproliferative malignancies, especially B cell lymphoma, are a recognized complication associated with immunosuppressive drugs such as azathioprine, tacrolimus, and cyclosporine (see above). Epstein-Barr virus has been shown to play a contributory role in some of these tumors, which may regress when immunosuppressive therapy is reduced.

Hepatic Complications Hepatic dysfunction after liver transplantation is similar to the hepatic complications encountered after major abdominal and cardiothoracic surgery;

however, in addition, there may be complications such as primary graft failure, vascular compromise, failure or obstruction of the biliary anastomoses, and rejection. As in nontransplant surgery, postoperative jaundice may result from prehepatic, intrahepatic, and posthepatic sources. *Prehepatic* sources represent the massive hemoglobin pigment load from transfusions, hemolysis, hematomas, ecchymoses, and other collections of blood. *Early intrahepatic* liver injury includes effects of hepatotoxic drugs and anesthesia; hypoperfusion injury associated with hypotension, sepsis, and shock; and benign postoperative cholestasis. *Late intrahepatic* sources of liver injury include posttransfusion hepatitis and exacerbation of primary disease. *Posthepatic* sources of hepatic dysfunction include biliary obstruction and reduced renal clearance of conjugated bilirubin. Hepatic complications unique to liver transplantation include primary graft failure associated with ischemic injury to the organ during harvesting; vascular compromise associated with thrombosis or stenosis of the portal vein or hepatic artery anastomoses; vascular anastomotic leak; stenosis, obstruction, or leakage of the anastomosed common bile duct; recurrence of primary hepatic disorder (see below); and rejection.

Transplant Rejection Despite the use of immunosuppressive drugs, rejection of the transplanted liver still occurs in a majority of patients, beginning 1 to 2 weeks after surgery. Clinical signs suggesting rejection are fever, right upper quadrant pain, and reduced bile pigment and volume. Leukocytosis may occur, but the most reliable indicators are increases in serum bilirubin and aminotransferase levels. Because these tests lack specificity, distinguishing among rejection and biliary obstruction, primary graft nonfunction, vascular compromise, viral hepatitis, cytomegalovirus infection, drug hepatotoxicity, and recurrent primary disease may be difficult. Radiographic visualization of the biliary tree and/or percutaneous liver biopsy often help to establish the correct diagnosis. Morphologic features of acute rejection include portal infiltration, bile duct injury, and/or endothelial inflammation ("endothelialitis"); some of these findings are reminiscent of graft-versus-host disease and primary biliary cirrhosis. As soon as transplant rejection is suspected, treatment consists of intravenous methylprednisolone in repeated boluses; if this fails to abort rejection, many centers use antibodies to lymphocytes, such as OKT3, or polyclonal antilymphocyte globulin.

Chronic rejection is a relatively rare outcome that may follow repeated bouts of acute rejection or that occurs unrelated to preceding rejection episodes. Morphologically, chronic rejection is characterized by progressive cholestasis, focal parenchymal necrosis, mononuclear infiltration, vascular lesions (intimal fibrosis, subintimal foam cells, fibrinoid necrosis), and fibrosis. This process may be reflected as ductopenia -- the vanishing bile duct syndrome. Some of the histologic hallmarks of chronic rejection may be so similar to those of chronic viral hepatitis that differentiation between the two may be difficult. Reversibility of chronic rejection is limited; in patients with therapy-resistant chronic rejection, retransplantation has yielded encouraging results.

OUTCOME

Survival The survival rate for patients undergoing liver transplantation has improved steadily since 1983. One-year survival rates have increased from approximately 70% in the early 1980s to 80 to 90% in the late 1990s. Currently, the 5-year survival rate exceeds 60%. An important observation is the relation between clinical status before

transplantation and outcome. For patients who undergo liver transplantation when their level of compensation is high (e.g., still working or only partially disabled), a 1-year survival rate of 85% is common. For those whose level of decompensation mandates continuous in-hospital care prior to transplantation, the 1-year survival rate is about 70%, while for those who are so decompensated that they require life support in an intensive care unit, the 1-year survival rate is approximately 50%. Indeed, the trend toward transplantation earlier in the natural history of end-stage liver disease is a major factor in the increased success of liver transplantation during the 1980s and 1990s. Another important distinction in survival has been drawn between high-risk and low-risk patient categories. For patients who do not fit any "high-risk" designations, 1-year and 5-year survival rates of 85 and 80%, respectively, have been recorded. In contrast, among patients in high-risk categories -- cancer, fulminant hepatitis, hepatitis B, age >65, concurrent renal failure, respirator dependence, portal vein thrombosis, and history of a portacaval shunt or multiple right upper quadrant operations -- survival statistics fall into the range of 60% at 1 year and 35% at 5 years. Survival after retransplantation for primary graft nonfunction is approximately 50%. Causes of failure of liver transplantation vary with time. Failures within the first 3 months result primarily from technical complications, postoperative infections, and hemorrhage. Transplant failures after the first 3 months are more likely to result from infection, rejection, or recurrent disease (such as malignancy or viral hepatitis).

Recurrence of Primary Disease The recurrence of autoimmune hepatitis or primary sclerosing cholangitis has not been reported. There have been reports of recurrent primary biliary cirrhosis after liver transplantation; however, the histologic features of primary biliary cirrhosis and acute rejection are virtually indistinguishable and occur as frequently in patients with primary biliary cirrhosis as in patients undergoing transplantation for other reasons. Hereditary disorders such as Wilson's disease anda_1-antitrypsin deficiency have not recurred after liver transplantation; however, recurrence of disordered iron metabolism has been observed in some patients with hemochromatosis. Hepatic vein thrombosis (Budd-Chiari syndrome) may recur; this can be minimized by treating underlying lymphoproliferative disorders and by anticoagulation. Cholangiocarcinoma recurs almost invariably; therefore, few centers now transplant such patients. In patients with hepatocellular carcinoma, tumor recurrence in the liver is common after approximately 1 year, although better success has been reported in patients with an unresectable isolated lesion <5 cm or with three or fewer lesions all<3 cm. Trials are underway to assess the benefit of adjuvant chemotherapy.

Hepatitis A can recur after transplantation for fulminant hepatitis A, but such acute reinfection has no serious clinical sequelae. In fulminant hepatitis B, recurrence is not the rule; however, in the absence of any prophylactic measures, hepatitis B usually recurs after transplantation for end-stage chronic hepatitis B. With sufficient immunosuppressive therapy to prevent allograft rejection, levels of hepatitis B viremia increase markedly, regardless of pretransplantation values. A majority of patients undergoing transplantation for chronic hepatitis B become carriers of hepatitis B virus (HBV) with high levels of virus replication but without liver injury; however, some patients experience a rapid recapitulation of severe injury -- severe chronic hepatitis or even fulminant hepatitis -- after transplantation. *Fibrosing cholestatic hepatitis* is a histologic feature linked to rapidly progressive liver injury in approximately 10% of

patients who undergo liver transplantation for hepatitis B. These patients experience marked hyperbilirubinemia, substantial prolongation of the prothrombin time (both out of proportion to relatively modest elevations of aminotransferase activity), and rapidly progressive liver failure. This lesion has been suggested to represent a "choking off" of the hepatocyte by an overwhelming density of HBV proteins. Complications such as sepsis and pancreatitis have also been observed more frequently in patients undergoing liver transplantation for hepatitis B. Although the risk of recurrent hepatitis B is approximately 20% higher in patients with pretransplantation markers of HBV replication (hepatitis B e antigen and HBV DNA), recurrent hepatitis B occurs in at least 60% of patients whose replicative markers were undetectable prior to transplantation, probably because of the enhancing impact of immunosuppressive drugs on HBV replication. Most transplantation centers will not undertake liver transplantation in patients with hepatitis B unless immunoprophylaxis withHBIG is used. Neither preoperative hepatitis B vaccination, preoperative or postoperative interferon therapy, nor short-term (£2 months) HBIG prophylaxis has been shown to be effective, but a retrospective analysis of data from several hundred European patients followed for 3 years after transplantation has shown that long-term (³6 months) prophylaxis with HBIG is associated with a lowering of the risk of HBV reinfection from approximately 75% to 35% and a reduction in mortality from approximately 50 percent to 20%.

As a result of long-termHBIG use following liver transplantation for chronic hepatitis B, similar improvements in outcome have been observed in the United States, with 1-year survival rates between 75 and 90%. Currently, with HBIG prophylaxis, the outcome of liver transplantation for chronic hepatitis B is indistinguishable from that for chronic liver disease unassociated with chronic hepatitis B; essentially, medical concerns regarding liver transplantation for chronic hepatitis B have been eliminated. Passive immunoprophylaxis with HBIG is begun during the anhepatic stage of surgery, repeated daily for the first 6 postoperative days, then continued with infusions that are given either at regular intervals of 4 to 6 weeks or, alternatively, when anti-HBs levels fall below a threshold of 100 mIU/mL. In all likelihood, indefinite HBIG infusions will be required, and, occasionally "breakthrough"HBVinfection occurs. This approach is very expensive, approximately $20,000 per year, and involves the intravenous administration of a globulin preparation designed for intramuscular injection. Although this approach is now practiced universally, it has not been approved officially by the U.S. Food and Drug Administration; clinical trials of HBIG preparations produced specifically for intravenous administration are in progress.

An alternative and promising but still experimental approach to the prophylaxis of patients with chronic hepatitis B undergoing liver transplantation is the use of nucleoside analogues such as lamivudine (Chap. 297). Limited evidence available to date suggests that lamivudine can be used to prevent recurrence ofHBVinfection when administered *prior* to transplantation, to treat hepatitis B that recurs *after* transplantation, including in patients who break throughHBIGprophylaxis, and to reverse the course of otherwise fatal fibrosing cholestatic hepatitis. Clinical trials have shown that lamivudine monotherapy reduces the level of HBV replication substantially, sometimes even resulting in clearance of HBsAg; reduces ALT levels; and improves histologic features of necrosis and inflammation. Long-term use of lamivudine is safe and effective, but, after several months, a proportion of patients become resistant to lamivudine, resulting from "YMDD" mutations in the HBV polymerase motif (Chap. 297). In approximately half of

such resistant patients, hepatic deterioration may ensue. Perhaps the best results with currently available antiviral approaches can be achieved by combining HBIG and lamivudine. In addition, new nucleoside analogues and related drugs are being assessed as antiviral agents against HBV infection. Some of these are effective against lamivudine-associated YMDD variants of HBV; these novel agents also are likely to be used in patients undergoing liver transplantation. Clinical trials are underway to define the optimal application of these antiviral agents in the management of patients undergoing liver transplantation for chronic hepatitis B.

Patients who undergo liver transplantation for chronic hepatitis B plus D have a better survival rate than patients undergoing transplantation for hepatitis B alone. Accounting for up to 40% of all liver transplantation procedures, the most common indication for liver transplantation is end-stage liver disease resulting from chronic hepatitis C. Recurrence of hepatitis C virus (HCV) after liver transplantation can be documented in almost every patient, if sufficiently sensitive virus markers are used. Although acute and chronic liver injury occur after transplantation in patients with chronic hepatitis C, clinical consequences of recurrent hepatitis C are limited during the first 5 years after transplantation. Nonetheless, despite the relative clinical benignity of recurrent hepatitis C in the early years after liver transplantation, and despite the negligible impact on patient survival during these early years, histologic studies have documented the presence of moderate to severe chronic hepatitis in more than half of all patients and bridging fibrosis or cirrhosis in approximately 10%. Ultimately, such histologic evidence of chronic hepatitis and cirrhosis will be expressed clinically as well, and the expectation is that the 10-year outcome will not be as favorable as the 5-year statistics suggest. In a proportion of patients, even during the early posttransplantation period, recurrent hepatitis C may be sufficiently severe biochemically and histologically to merit antiviral therapy. Treatment with interferon monotherapy, which can *suppress* HCV-associated liver injury in approximately half of patients but rarely leads to *sustained* benefit, has been disappointing. The addition of the nucleoside analogue ribavirin to interferon has resulted in improved responses to antiviral therapy, and many centers have adopted some form of combination therapy for their patients with recurrent chronic hepatitis C; however, the efficacy of such combination therapy remains the subject of clinical trials. Of interest is the preliminary observation that the immunosuppressive agent mycophenolate may have a suppressive effect on HCV. A small number succumb to early HCV-associated liver injury, and a syndrome reminiscent of fibrosing cholestatic hepatitis (see above) has been observed rarely. Because patients with more episodes of rejection receive more immunosuppressive therapy, and because immunosuppressive therapy enhances HCV replication, patients with severe or multiple episodes of rejection are more likely to experience early recurrence of hepatitis C after transplantation. Both HCV genotype 1b and high viral load have been linked to recurrent HCV-induced liver disease and to earlier disease recurrence after transplantation; however, the association between genotype and recurrence of HCV-associated liver injury has not been supported by more recent reports.

Patients who undergo liver transplantation for end-stage alcoholic cirrhosis are at risk of resorting to drinking again after transplantation, a potential source of recurrent alcoholic liver injury. Currently, alcoholic liver disease is one of the more common indications for liver transplantation, accounting for 20 to 25% of all liver transplantation procedures, and most transplantation centers screen candidates carefully for predictors of continued

abstinence. Recidivism is more likely in patients whose sobriety prior to transplantation was shorter than 6 months. For abstinent patients with alcoholic cirrhosis, liver transplantation can be undertaken successfully, with outcomes comparable to those for other categories of patients with chronic liver disease, when coordinated by a team approach that includes substance abuse counseling.

Posttransplantation Quality of Life Full rehabilitation is achieved in the majority of patients who survive the early postoperative months and escape chronic rejection or unmanageable infection. Psychosocial maladjustment interferes with medical compliance in a small number of patients, but most manage to adhere to immunosuppressive regimens, which must be continued indefinitely. In one study, 85% of patients who survived their transplants returned to gainful activities. In fact, some women have conceived and carried pregnancies to term after transplantation without demonstrable injury to their infants.

302. DISEASES OF THE GALLBLADDER AND BILE DUCTS - *Norton J. Greenberger*, *Gustav Paumgartner*

PHYSIOLOGY OF BILE PRODUCTION AND FLOW

Bile Secretion and Composition Bile formed in the hepatic lobules is secreted into a complex network of canaliculi, small bile ductules, and larger bile ducts that run with lymphatics and branches of the portal vein and hepatic artery in portal tracts situated between hepatic lobules. These interlobular bile ducts coalesce to form larger septal bile ducts that join to form the right and left hepatic ducts, which in turn unite to form the common hepatic duct. The common hepatic duct is joined by the cystic duct of the gallbladder to form the common bile duct (CBD), which enters the duodenum (often after joining the main pancreatic duct) through the ampulla of Vater.

Hepatic bile is an isotonic fluid with an electrolyte composition resembling blood plasma. The electrolyte composition of gallbladder bile differs from that of hepatic bile because most of the inorganic anions, chloride and bicarbonate, have been removed by reabsorption across the gallbladder epithelium.

Major components of bile by weight include water (82%), bile acids (12%), lecithin and other phospholipids (4%), and unesterified cholesterol (0.7%). Other constituents include conjugated bilirubin, proteins (IgA, metabolites of hormones, and other proteins metabolized in the liver), electrolytes, mucus, and, often, drugs and their metabolites.

The total daily basal secretion of hepatic bile is approximately 500 to 600 mL. Many substances taken up or synthesized by the hepatocyte are secreted into the bile canalculi. The canalicular membrane forms microvilli and is associated with microfilaments of actin, microtubules, and other contractile elements. Prior to their secretion into the bile, many substances that are taken up into the hepatocyte are conjugated, while others such as phospholipids, a portion of primary bile acids, and some cholesterol are synthesized de novo in the hepatocyte. Three mechanisms are important in regulating bile flow: (1) active transport of bile acids from hepatocytes into the bile canaliculi, (2) active transport of other organic anions, and (3) cholangiocellular secretion. The last is a secretin-mediated and cyclic AMP-dependent mechanism that ultimately results in the secretion of a sodium- and bicarbonate-rich fluid into the bile ducts.

Active vectorial secretion of biliary constituents from the portal blood into the bile canaliculi is driven by a distinct set of polarized transport systems at the basolateral (sinusoidal) and the canalicular plasma membrane domains of the hepatocyte. Two sinusoidal bile salt uptake systems have been cloned in humans, the Na^+/taurocholate cotransporter and the organic anion transporting protein, which also transports a large variety of non-bile salt organic anions. Four ATP-dependent canalicular transport systems ("export pumps") have been identified: a bile salt export pump (BSEP), which was formerly called "sister of P-glycoprotein"; a conjugate export pump (MRP2), also called the canalicular multispecific organic anion transporter, which mediates the canalicular excretion of various amphiphilic conjugates formed by phase II conjugation (e.g., bilirubin diglucuronide); a multidrug export pump (MDR1) for hydrophobic cationic compounds; and a phospholipid export pump (MDR3). The canalicular membrane also

contains ATP-independent transport systems such as the Cl^-/HCO_3^--anion exchanger isoform 2 for canalicular bicarbonate secretion. For some of these transporters, genetic defects have been identified that are associated with various forms of cholestasis or defects of biliary excretion. BSEP is defective in progressive familial intrahepatic cholestasis (PFIC) type 2. Mutations of MRP2 cause the Dubin-Johnson syndrome, an inherited form of conjugated hyperbilirubinemia. A defective MDR3 results in PFIC-3. The cystic fibrosis transmembrane regulator located on bile duct epithelial cells is defective in cystic fibrosis, which may be associated with impaired cholangiocellular bile formation and chronic cholestatic liver disease.

The Bile Acids The primary bile acids, cholic acid and chenodeoxycholic acid (CDCA), are synthesized from cholesterol in the liver, conjugated with glycine or taurine, and excreted into the bile. Secondary bile acids, including deoxycholate and lithocholate, are formed in the colon as bacterial metabolites of the primary bile acids. However, lithocholic acid is much less efficiently absorbed from the colon than deoxycholic acid. Another secondary bile acid, found in low concentration is ursodeoxycholic acid (UDCA), a stereoisomer of CDCA. In normal bile, the ratio of glycine to taurine conjugates is about 3:1.

Bile acids are detergents that in aqueous solutions and above a critical concentration of about 2 m*M* form molecular aggregates called *micelles*. Cholesterol alone is poorly soluble in aqueous environments, and its solubility in bile depends on both the total lipid concentration and the relative molar percentages of bile acids and lecithin. Normal ratios of these constituents favor the formation of solubilizing *mixed micelles*, while abnormal ratios promote the precipitation of cholesterol crystals in bile.

In addition to facilitating the biliary excretion of cholesterol, bile acids are necessary for the normal intestinal absorption of dietary fats via a micellar transport mechanism (Chap. 286). Bile acids also serve as a major physiologic driving force for hepatic bile flow and aid in water and electrolyte transport in the small bowel and colon.

Enterohepatic Circulation Bile acids are efficiently conserved under normal conditions. Unconjugated, and to a lesser degree also conjugated, bile acids are absorbed by *passive diffusion* along the entire gut. Quantitatively much more important for bile salt recirculation, however, is the *active transport* mechanism for conjugated bile acids in the distal ileum (Chap. 286). The reabsorbed bile acids enter the portal bloodstream and are taken up rapidly by hepatocytes, reconjugated, and resecreted into bile (enterohepatic circulation).

The normal bile acid pool size is approximately 2 to 4 g. During digestion of a meal, the bile acid pool undergoes at least one or more enterohepatic cycles, depending on the size and composition of the meal. Normally, the bile acid pool circulates approximately 5 to 10 times daily. Intestinal absorption of the pool is about 95% efficient, so fecal loss of bile acids is in the range of 0.3 to 0.6 g/d. This fecal loss is compensated by an equal daily synthesis of bile acids by the liver, and thus the size of the bile acid pool is maintained. Bile acids returning to the liver suppress de novo hepatic synthesis of primary bile acids from cholesterol by inhibiting the rate-limiting enzyme cholesterol 7a-hydroxylase. While the loss of bile salts in stool is usually matched by increased hepatic synthesis, the maximum rate of synthesis is approximately 5 g/d, which may be

insufficient to replete the bile acid pool size when there is pronounced impairment of intestinal bile salt reabsorption.

Gallbladder and Sphincteric Functions In the fasting state, the sphincter of Oddi offers a high-pressure zone of resistance to bile flow from the common bile duct into the duodenum. This tonic contraction serves to (1) prevent reflux of duodenal contents into the pancreatic and bile ducts and (2) promote bile filling of the gallbladder. The major factor controlling the evacuation of the gallbladder is the peptide hormone cholecystokinin (CCK), which is released from the duodenal mucosa in response to the ingestion of fats and amino acids.CCKproduces (1) powerful contraction of the gallbladder, (2) decreased resistance of the sphincter of Oddi, (3) increased hepatic secretion of bile, and thus (4) enhanced flow of biliary contents into the duodenum.

Hepatic bile is "concentrated" within the gallbladder by energy-dependent transmucosal absorption of water and electrolytes. Almost the entire bile acid pool may be sequestered in the gallbladder following an overnight fast for delivery into the duodenum with the first meal of the day. The normal capacity of the gallbladder is 30 to 50 mL of bile.

DISEASES OF THE GALLBLADDER

CONGENITAL ANOMALIES

Anomalies of the biliary tract may be found in 10 to 20% of the population, including abnormalities in number, size, and shape (e.g., agenesis of the gallbladder, duplications, rudimentary or oversized "giant" gallbladders, and diverticula). Phrygian cap is a clinically innocuous entity in which a partial or complete septum (or fold) separates the fundus from the body. Anomalies of position or suspension are not uncommon and include left-sided gallbladder, intrahepatic gallbladder, retrodisplacement of the gallbladder, and "floating" gallbladder. The latter condition predisposes to acute torsion, volvulus, or herniation of the gallbladder.

GALLSTONES

Pathogenesis Gallstones are quite prevalent in most western countries. In the United States, autopsy series have shown gallstones in at least 20% of women and in 8% of men over the age of 40. It is estimated that 16 to 20 million persons in the United States have gallstones and that approximately 1 million new cases of cholelithiasis develop each year.

Gallstones are formed by concretion or accretion of normal or abnormal bile constituents. They are divided into three major types; cholesterol and mixed stones account for 80% of the total, with pigment stones comprising the remaining 20%. Mixed and cholesterol gallstones usually contain more than 50% cholesterol monohydrate plus an admixture of calcium salts, bile pigments, proteins, and fatty acids. Pigment stones are composed primarily of calcium bilirubinate; they contain less than 20% cholesterol.

Cholesterol and Mixed Stones and Biliary Sludge Cholesterol is essentially water insoluble and requires aqueous dispersion into either micelles or vesicles, both of which

require the presence of a second lipid to "liquefy" the cholesterol. Cholesterol and phospholipids are secreted into bile as unilamellar bilayered vesicles, which are converted into mixed micelles consisting of bile acids, phospholipids, and cholesterol by the action of bile acids. If there is an excess of cholesterol in relation to phospholipids and bile acids, unstable cholesterol-rich vesicles remain, which aggregate into large multilamellar vesicles from which cholesterol crystals precipitate (Fig. 302-1).

There are several important mechanisms in the formation of lithogenic (stone-forming) bile. The most important is increased biliary secretion of cholesterol. This may occur in association with obesity, high-caloric and cholesterol-rich diets, or drugs (e.g., clofibrate) and may result from increased activity of HMG-CoA reductase, the rate-limiting enzyme of hepatic cholesterol synthesis, and increased hepatic uptake of cholesterol from blood. In patients with gallstones, dietary cholesterol *increases* biliary cholesterol secretion. This does not occur in non-gallstone patients on high-cholesterol diets. In addition to environmental factors such as high-caloric and cholesterol-rich diets, genetic factors play an important role in cholesterol hypersecretion and gallstone formation. A high prevalence of gallstones is found among first-degree relatives of gallstone carriers and in certain ethnic populations such as American Indians as well as Chilean Indians and Chilean Hispanics. A common genetic trait has been identified for some of these populations by mitochondrial DNA analysis. A genetic defect in the control of cholesterol secretion also exists in certain strains of inbred mice who develop gallstones under a lithogenic diet. In some patients, impaired hepatic conversion of cholesterol to bile acids may also occur, resulting in an increase of the lithogenic cholesterol/bile acid ratio. Lithogenic bile may also result from conditions affecting the enterohepatic circulation of bile acids (e.g., prolonged parenteral alimentation or ileal disease or resection). In addition, most patients with gallstones may have reduced activity of hepatic cholesterol 7a-hydroxylase, the rate-limiting enzyme for primary bile acid synthesis.

Thus an excess of biliary cholesterol in relation to bile acids and phospholipids is primarily due to hypersecretion of cholesterol, but hyposecretion of bile acids may contribute. Two additional disturbances of bile acid metabolism that are likely to contribute to supersaturation of bile with cholesterol are (1) reduction of the bile acid pool and (2) enhanced conversion of cholic acid to deoxycholic acid, with replacement of the cholic acid pool by an expanded deoxycholic acid pool. The first disorder may be caused by more rapid loss of primary bile acid from the small intestine into the colon. The second disturbance may result from enhanced dehydroxylation of cholic acid and increased absorption of newly formed deoxycholic acid. An increased deoxycholate secretion is associated with hypersecretion of cholesterol into bile. While supersaturation of bile with cholesterol is an important prerequisite for gallstone formation, it is not sufficient by itself to produce cholesterol precipitation in vivo. Most people with supersaturated bile do not develop stones because the time required for cholesterol crystals to nucleate and grow is longer than the time bile spends in the gallbladder.

A second important mechanism is *nucleation* of cholesterol monohydrate crystals, which is greatly accelerated in human lithogenic bile; it is this feature rather than the degree of cholesterol supersaturation that distinguishes lithogenic from normal gallbladder bile. Accelerated nucleation of cholesterol monohydrate in bile may be due to either an *excess of pronucleating factors* or a *deficiency of antinucleating factors*. Mucin and

certain non-mucin glycoproteins appear to be pronucleating factors, while apolipoproteins AI and AII and other glycoproteins appear to be antinucleating factors. Cholesterol monohydrate crystal nucleation and crystal growth probably occur within the mucin gel layer. Vesicle fusion leads to liquid crystals, which, in turn, nucleate into solid cholesterol monohydrate crystals. Continued growth of the crystals occurs by direct nucleation of cholesterol molecules from supersaturated unilamellar or multilamellar biliary vesicles.

A third important mechanism in cholesterol gallstone formation is *gallbladder hypomotility*. If the gallbladder emptied all supersaturated or crystal-containing bile completely, stones would not be able to grow. A high percentage of patients with gallstones exhibits abnormalities of gallbladder emptying. Ultrasonographic studies show that gallstone patients have an increased gallbladder volume during fasting and also after a test meal (residual volume) and that fractional emptying after gallbladder stimulation is decreased. Gallbladder emptying is a major determinant of gallstone recurrence in patients who underwent biliary lithotripsy. Within 3 years, only 13% of patients with good but 53% of patients with poor gallbladder emptying form recurrent stones.

Biliary sludge is a thick mucous material that upon microscopic examination reveals lecithin-cholesterol crystals, cholesterol monohydrate crystals, calcium bilirubinate, and mucin thread or mucous gels. Biliary sludge typically forms a crescent-like layer in the most dependent portion of the gallbladder and is recognized by characteristic echoes on ultrasonography (see below). The presence of biliary sludge implies two abnormalities: (1) the normal balance between gallbladder mucin secretion and elimination has become deranged and (2) nucleation of biliary solutes has occurred. That biliary sludge may be a precursor form of gallstone disease is evident from several observations. In one study, 96 patients with gallbladder sludge were followed prospectively by serial ultrasound studies. In 18%, biliary sludge disappeared and did not recur for at least 2 years. In 60%, biliary sludge disappeared and reappeared; in 14%, gallstones (8% asymptomatic, 6% symptomatic) developed, and in 6%, severe biliary pain with or without acute pancreatitis occurred. In 12 patients, cholecystectomies were performed, 6 for gallstone-associated biliary pain and 3 in symptomatic patients with sludge but without gallstones who had prior attacks of pancreatitis; the latter did not recur after cholecystectomy. It should be emphasized that biliary sludge can develop with disorders that cause gallbladder hypomotility, i.e., surgery, burns, total parenteral nutrition, pregnancy, and oral contraceptives -- all of which are associated with gallstone formation.

Two other conditions are associated with cholesterol stone or biliary sludge formation: pregnancy and very low calorie diet. There appear to be two key changes during pregnancy that contribute to a "cholelithogenic state." First, the composition of the bile acid pool and the cholesterol-carrying capacity of bile change, with a resultant marked increase in cholesterol saturation during the third trimester. Second, ultrasonographic studies have demonstrated that gallbladder contraction in response to a standard meal is sluggish, resulting in impaired gallbladder emptying. That these changes are related to pregnancy per se is supported by several studies that show reversal of these abnormalities after delivery. During pregnancy, gallbladder sludge develops in 20 to 30% of women and gallstones in 5 to 12%. While biliary sludge is a common finding

during pregnancy, it is usually asymptomatic and often resolves spontaneously after delivery. Gallstones, which are less common than sludge and frequently associated with biliary colic, may also disappear after delivery because of spontaneous dissolution related to bile becoming unsaturated with cholesterol post partum.

From 10 to 20% of people having rapid weight reduction through very low calorie dieting develop gallstones. In a study involving 600 patients who completed a 16-week, 520-kcal/d diet,UDCA in a dosage of 600 mg/d proved highly effective in preventing gallstone formation; gallstones developed in only 3% of UDCA recipients compared to 28% of placebo-treated patients.

To summarize, cholesterol gallstone disease occurs because of several defects, which include (1) bile supersaturation with cholesterol, (2) nucleation of cholesterol monohydrate with subsequent crystal retention and stone growth, and (3) abnormal gallbladder motor function with delayed emptying and stasis. Other important factors known to predispose to cholesterol stone formation are summarized inTable 302-1.

Pigment Stones Gallstones composed largely of calcium bilirubinate are much more common in the Far East than in western countries. The presence of increased amounts of unconjugated, insoluble bilirubin in bile results in the precipitation of bilirubin, which may aggregate to form pigment stones or may form the nidus for growth of mixed cholesterol gallstones. In western countries, chronic hemolytic states (with increased conjugated bilirubin in bile) or alcoholic liver disease are associated with an increased incidence of pigment stones. Deconjugation of an excess of soluble bilirubin mono- and diglucuronide may be mediated by endogenous b-glucuronidase but may also occur by spontaneous alkaline hydrolysis. Sometimes, the enzyme is also produced when bile is chronically infected by bacteria. Pigment stone formation is especially prominent in Asians and is often associated with infections in the biliary tree (Table 302-1).

Diagnosis Procedures of potential use in the diagnosis of cholelithiasis and other diseases of the gallbladder are detailed inTable 302-2. The plain abdominal film may detect gallstones containing sufficient calcium to be radiopaque (10 to 15% of cholesterol and mixed stones and approximately 50% of pigment stones). Plain radiography may also be of use in the diagnosis of emphysematous cholecystitis, porcelain gallbladder, limey bile, and gallstone ileus.

Ultrasonography of the gallbladder is very accurate in the identification of cholelithiasis and has several advantages over oral cholecystography (Fig. 302-2*A*). The gallbladder is easily visualized with the technique, and in fact, failure to image the gallbladder successfully in a fasting patient correlates well with the presence of underlying gallbladder disease. Stones as small as 2 mm in diameter may be confidently identified provided that firm criteria are used [e.g., acoustic "shadowing" of opacities that are within the gallbladder lumen and that change with the patient's position (by gravity)]. In major medical centers, the false-negative and false-positive rates for ultrasound in gallstone patients are about 2 to 4%. Biliary sludge is material of low echogenic activity that typically forms a layer in the most dependent position of the gallbladder. This layer shifts with postural changes but fails to produce acoustic shadowing; these two characteristics distinguish sludges from gallstones. Ultrasound can also be used to assess the emptying function of the gallbladder.

Oral cholecystography (OCG) is a useful procedure for the diagnosis of gallstones but has been largely replaced by ultrasound. However, OCG is still useful for the selection of patients for nonsurgical therapy of gallstone disease such as lithotripsy or bile acid dissolution therapy. In both these settings, OCG is used to assess the patency of the cystic duct and gallbladder emptying function. Further, OCG can also delineate the size and number of gallstones and determine whether they are calcified. Factors that may produce nonvisualization of the OCG are summarized in Table 302-2.

Radiopharmaceuticals such as ^{99m}Tc-labeled *N*-substituted iminodiacetic acids (HIDA, DIDA, DISIDA, etc.) are rapidly extracted from the blood and are excreted into the biliary tree in high concentration even in the presence of mild to moderate serum bilirubin elevations. Failure to image the gallbladder in the presence of biliary ductal visualization may indicate cystic duct obstruction, acute or chronic cholecystitis, or surgical absence of the organ. Such scans have their greatest application in the diagnosis of acute cholecystitis.

Symptoms of Gallstone Disease Gallstones usually produce symptoms by causing inflammation or obstruction following their migration into the cystic duct orCBD. The most specific and characteristic symptom of gallstone disease is biliary colic. Obstruction of the cystic duct or CBD by a stone produces increased intraluminal pressure and distention of the viscus that cannot be relieved by repetitive biliary contractions. The resultant visceral pain is characteristically a severe, steady ache or pressure in the epigastrium or right upper quadrant (RUQ) of the abdomen with frequent radiation to the interscapular area, right scapula, or shoulder.

Biliary colic begins quite suddenly and may persist with severe intensity for 30 min to 5 h, subsiding gradually or rapidly. An episode of biliary pain is sometimes followed by a residual mild ache or soreness in theRUQ, which may persist for 24 h or so. Nausea and vomiting frequently accompany episodes of biliary colic. An elevated level of serum bilirubin and/or alkaline phosphatase suggests a common duct stone. Fever or chills (rigors) with biliary colic usually imply a complication, i.e., cholecystitis, pancreatitis, or cholangitis. Complaints of vague epigastric fullness, dyspepsia, eructation, or flatulence, especially following a fatty meal, should not be confused with biliary colic. Such symptoms are frequently elicited from patients with gallstone disease but are not specific for biliary calculi. Biliary colic may be precipitated by eating a fatty meal, by consumption of a large meal following a period of prolonged fasting, or by eating a normal meal.

Natural History Gallstone disease discovered in an asymptomatic patient or in a patient whose symptoms are not referable to cholelithiasis is a common clinical problem. The natural history of "silent" or asymptomatic gallstones has occasioned much debate. A study of predominantly male silent gallstone patients suggests that the cumulative risk for the development of symptoms or complications requiring surgery is relatively low -- 10% at 5 years, 15% at 10 years, and 18% at 15 years. Patients remaining asymptomatic for 15 years were found to be unlikely to develop symptoms during further follow-up, and most patients who did develop complications from their gallstones experienced *prior* warning symptoms. Similar conclusions apply to diabetic patients with silent gallstones. Decision analysis has suggested that (1) the cumulative risk of death

due to gallstone disease while on expectant management is small, and (2) prophylactic cholecystectomy is not warranted.

Complications requiring cholecystectomy are much more common in gallstone patients who have developed symptoms of biliary colic. Patients found to have gallstones at a young age are more likely to develop symptoms from cholelithiasis than are patients older than 60 years at the time of initial diagnosis. Patients with diabetes mellitus and gallstones may be somewhat more susceptible to septic complications, but the magnitude of risk of septic biliary complications in diabetic patients is incompletely defined. In addition, asymptomatic gallstone patients with nonvisualization of the gallbladder onOCGappear to have an increased tendency to develop symptoms and complications.

TREATMENT

Surgical Therapy In asymptomatic gallstone patients, the risk of developing symptoms or complications requiring surgery is quite small (in the range of 1 to 2% per year). Thus a recommendation for cholecystectomy in a patient with gallstones should probably be based on assessment of three factors: (1) the presence of symptoms that are frequent enough or severe enough to interfere with the patient's general routine; (2) the presence of a prior complication of gallstone disease, i.e., history of acute cholecystitis, pancreatitis, gallstone fistula, etc.; or (3) the presence of an underlying condition predisposing the patient to increased risk of gallstone complications (e.g., calcified or porcelain gallbladder and/or a previous attack of acute cholecystitis regardless of current symptomatic status). Patients with very large gallstones (over 2 cm in diameter) and patients having gallstones in a congenitally anomalous gallbladder might also be considered for prophylactic cholecystectomy. Although age under 50 years is a worrisome factor in asymptomatic gallstone patients, few authorities would now recommend routine cholecystectomy in all young patients with silent stones. Laparoscopic cholecystectomy is a minimal-access approach for the removal of the gallbladder together with its stones. Its advantages include a markedly shortened hospital stay as well as decreased cost, and it is the procedure of choice for most patients referred for elective cholecystectomy.

From several studies involving over 4000 patients undergoing laparoscopic cholecystectomy, the following key points emerge: (1) complications develop in about 4% of patients, (2) conversion to laparotomy occurs in 5%, (3) the death rate is remarkably low (i.e.,<0.1%), and (4) bile duct injuries are unusual (i.e., 0.2 to 0.5%). These data indicate why laparoscopic cholecystectomy has become the "gold standard" for treating symptomatic cholelithiasis.

Medical Therapy -- Gallstone Dissolution UDCAdecreases cholesterol saturation of bile and also appears to produce a lamellar liquid crystalline phase in bile that allows a dispersion of cholesterol from stones by physiochemical means. UDCA may also retard cholesterol crystal nucleation. In carefully selected patients with a functioning gallbladder and with radiolucent stones <10 mm in diameter, complete dissolution can be achieved in about 50% of patients within 6 months to 2 years with UDCA at a dose of 8 to 10 mg/kg per day. The highest success rate (i.e., >70%) occurs in patients with small (<5 mm) floating radiolucent gallstones. Probably no more than 10% of patients

with *symptomatic* cholelithiasis are candidates for such treatment. However, in addition to the vexing problem of recurrent stones (30 to 50% over 3 to 5 years of follow-up), there is also the factor of taking an expensive drug for an indefinite period of time. The advantages and success of laparoscopic cholecystectomy have largely reduced the role of gallstone dissolution to patients who wish to avoid or are not candidates for elective cholecystectomy.

Gallbladder stones may be fragmented by extracorporeal shock waves. While such shock wave lithotripsy combined with medical litholytic therapy is safe and effective in carefully selected patients with gallbladder calculi (radiolucent, solitary stone<2 cm in well-contracting gallbladder), the procedure is employed infrequently because of the emergence of laparoscopic cholystectomy as the procedure of choice for symptomatic cholelithiasis, the recurrence of gallstones in 30% of patients within 5 years after lithotripsy combined with medical litholytic therapy, and the cost of takingUDCA for a variable period after the procedure.

ACUTE AND CHRONIC CHOLECYSTITIS

Acute Cholecystitis Acute inflammation of the gallbladder wall usually follows obstruction of the cystic duct by a stone. Inflammatory response can be evoked by three factors: (1) *mechanical inflammation* produced by increased intraluminal pressure and distention with resulting ischemia of the gallbladder mucosa and wall, (2) *chemical inflammation* caused by the release of lysolecithin (due to the action of phospholipase on lecithin in bile) and other local tissue factors, and (3) *bacterial inflammation*, which may play a role in 50 to 85% of patients with acute cholecystitis. The organisms most frequently isolated by culture of gallbladder bile in these patients include *Escherichia coli*, *Klebsiella* spp., group D *Streptococcus*, *Staphylococcus* spp., and *Clostridium* spp.

Acute cholecystitis often begins as an attack of biliary colic that progressively worsens. Approximately 60 to 70% of patients report having experienced prior attacks that resolved spontaneously. As the episode progresses, however, the pain of acute cholecystitis becomes more generalized in the right upper abdomen. As with biliary colic, the pain of cholecystitis may radiate to the interscapular area, right scapula, or shoulder. Peritoneal signs of inflammation such as increased pain with jarring or on deep respiration may be apparent. The patient is anorectic and often nauseated. Vomiting is relatively common and may produce symptoms and signs of vascular and extracellular volume depletion. Jaundice is unusual early in the course of acute cholecystitis but may occur when edematous inflammatory changes involve the bile ducts and surrounding lymph nodes.

A low-grade fever is characteristically present, but shaking chills or rigors are not uncommon. TheRUQ of the abdomen is almost invariably tender to palpation. An enlarged, tense gallbladder is palpable in one-quarter to one-half of patients. Deep inspiration or cough during subcostal palpation of the RUQ usually produces increased pain and inspiratory arrest (Murphy's sign). A light blow delivered to the right subcostal area may elicit a marked increase in pain. Localized rebound tenderness in the RUQ is common, as are abdominal distention and hypoactive bowel sounds from paralytic ileus, but generalized peritoneal signs and abdominal rigidity are usually lacking, absent perforation.

The diagnosis of acute cholecystitis is usually made on the basis of a characteristic history and physical examination. The triad of sudden onset ofRUQtenderness, fever, and leukocytosis is highly suggestive. Typically, leukocytosis in the range of 10,000 to 15,000 cells per microliter with a left shift on differential count is found. The serum bilirubin is mildly elevated [<85.5 umol/L (5 mg/dL)] in 45% of patients, while 25% have modest elevations in serum aminotransferases (usually less than a fivefold elevation). The radionuclide (e.g., HIDA) biliary scan may be confirmatory if bile duct imaging is seen without visualization of the gallbladder. Ultrasound will demonstrate calculi in 90 to 95% of cases.

Approximately 75% of patients treated medically have remission of acute symptoms within 2 to 7 days following hospitalization. In 25%, however, a complication of acute cholecystitis will occur despite conservative treatment (see below). In this setting, prompt surgical intervention is required. Of the 75% of patients with acute cholecystitis who undergo remission of symptoms, approximately one-quarter will experience a recurrence of cholecystitis within 1 year, and 60% will have at least one recurrent bout within 6 years. In view of the natural history of the disease, acute cholecystitis is best treated by early surgery whenever possible.

Acalculous Cholecystitis In 5 to 10% of patients with acute cholecystitis, calculi obstructing the cystic duct are not found at surgery. In over 50% of such cases, an underlying explanation for acalculous inflammation is not found. An increased risk for the development of acalculous cholecystitis is especially associated with serious trauma or burns, with the postpartum period following prolonged labor, and with orthopedic and other nonbiliary major surgical operations in the postoperative period. Other precipitating factors include vasculitis, obstructing adenocarcinoma of the gallbladder, diabetes mellitus, torsion of the gallbladder, "unusual" bacterial infections of the gallbladder (e.g., *Leptospira*, *Streptococcus*, *Salmonella*, or *Vibrio cholerae*), and parasitic infestation of the gallbladder. Acalculous cholecystitis may also be seen with a variety of other systemic disease processes (sarcoidosis, cardiovascular disease, tuberculosis, syphilis, actinomycosis, etc.) and may possibly complicate periods of prolonged parenteral hyperalimentation.

Although the clinical manifestations of acalculous cholecystitis are indistinguishable from those of calculous cholecystitis, the setting of acute gallbladder inflammation complicating severe underlying illness is characteristic of acalculous disease. Ultrasound, computed tomography (CT) scanning, or radionuclide examinations demonstrating a large, tense, static gallbladder without stones and with evidence of poor emptying over a prolonged period may be diagnostically useful in some cases. The complication rate for acalculous cholecystitis exceeds that for calculous cholecystitis. Successful management of acute acalculous cholecystitis appears to depend primarily on early diagnosis and surgical intervention, with meticulous attention to postoperative care.

Acalculous Cholecystopathy Disordered motility of the gallbladder can produce recurrent biliary pain in patients without gallstones. Infusion of an octapeptide ofCCK can be used to measure the gallbladder ejection fraction during cholescintigraphy. In a representative study, CCK cholescintigraphy using^{99m}Tc-diisopropyl iminodiacetic acid

(DIDA) identified 21 patients with an abnormal gallbladder ejection fraction (<40% at 45 min); 10 of 11 patients who underwent surgery became asymptomatic; all 10 showed abnormalities, i.e., chronic cholecystitis, gallbladder muscle hypertrophy, and/or a markedly narrowed cystic duct. From this and other similar studies, the following criteria can be used to identify patients with acalculous cholecystopathy: (1) recurrent episodes of typicalRUQ pain characteristic of biliary tract pain, (2) abnormal CCK cholescintigraphy demonstrating a gallbladder ejection fraction of less than 40%, and (3) infusion of CCK reproduces the patient's pain. An additional clue would be the identification of a large gallbladder on ultrasound examination. Finally, it should be noted that sphincter of Oddi dysfunction can also give rise to recurrent RUQ pain and CCK-scintigraphic abnormalities.

Emphysematous Cholecystitis So-called emphysematous cholecystitis is thought to begin with acute cholecystitis (calculous or acalculous) followed by ischemia or gangrene of the gallbladder wall and infection by gas-producing organisms. Bacteria most frequently cultured in this setting include anaerobes, such as *C. welchii* or *C. perfringens*, and aerobes, such as *E. coli.* This condition occurs most frequently in elderly men and in patients with diabetes mellitus. The clinical manifestations are essentially indistinguishable from those of nongaseous cholecystitis. The diagnosis is usually made on plain abdominal film by the finding of gas within the gallbladder lumen, dissecting within the gallbladder wall to form a gaseous ring, or in the pericholecystic tissues. The morbidity and mortality rates with emphysematous cholecystitis are considerable. Prompt surgical intervention coupled with appropriate antibiotics is mandatory.

Chronic Cholecystitis Chronic inflammation of the gallbladder wall is almost always associated with the presence of gallstones and is thought to result from repeated bouts of subacute or acute cholecystitis or from persistent mechanical irritation of the gallbladder wall. The presence of bacteria in the bile occurs in more than one-quarter of patients with chronic cholecystitis. Although the presence of infected bile in a patient with *chronic* cholecystitis undergoing elective cholecystectomy probably adds little to the operative risk, intraoperative Gram's staining and routine culturing of bile have been advocated to identify those patients whose gallbladder is colonized with *Clostridium* spp. Appropriate antibiotics intra- and postoperatively are recommended in such patients because colonization with these organisms may be associated with devastating septic complications following surgery. Chronic cholecystitis may be asymptomatic for years, may progress to symptomatic gallbladder disease or to acute cholecystitis, or may present with complications (see below).

Complications of Cholecystitis

Empyema and Hydrops Empyema of the gallbladder usually results from progression of acute cholecystitis with persistent cystic duct obstruction to superinfection of the stagnant bile with a pus-forming bacterial organism. The clinical picture resembles that of cholangitis with high fever, severeRUQpain, marked leukocytosis, and often, prostration. Empyema of the gallbladder carries a high risk of gram-negative sepsis and/or perforation. Emergency surgical intervention with proper antibiotic coverage is required as soon as the diagnosis is suspected.

Hydrops or mucocele of the gallbladder may also result from prolonged obstruction of the cystic duct, usually by a large solitary calculus. In this instance, the obstructed gallbladder lumen is progressively distended, over a period of time, by mucus (mucocele) or by a clear transudate (hydrops) produced by mucosal epithelial cells. A visible, easily palpable, nontender mass sometimes extending from theRUQ into the right iliac fossa may be found on physical examination. The patient with hydrops of the gallbladder frequently remains asymptomatic, although chronic RUQ pain may also occur. Cholecystectomy is indicated, since empyema, perforation, or gangrene may complicate the condition.

Gangrene and Perforation Gangrene of the gallbladder results from ischemia of the wall and patchy or complete tissue necrosis. Underlying conditions often include marked distention of the gallbladder, vasculitis, diabetes mellitus, empyema, or torsion resulting in arterial occlusion. Gangrene usually predisposes to perforation of the gallbladder, but perforation may also occur in chronic cholecystitis without premonitory warning symptoms. *Localized perforations* are usually contained by the omentum or by adhesions produced by recurrent inflammation of the gallbladder. Bacterial superinfection of the walled-off gallbladder contents results in abscess formation. Most patients are best treated with cholecystectomy, but some seriously ill patients may be managed with cholecystostomy and drainage of the abscess. *Free perforation* is less common but is associated with a mortality rate of approximately 30%. Such patients may experience a sudden transient relief ofRUQ pain as the distended gallbladder decompresses; this is followed by signs of generalized peritonitis.

Fistula Formation and Gallstone Ileus Fistulization into an adjacent organ adherent to the gallbladder wall may result from inflammation and adhesion formation. Fistulas into the duodenum are most common, followed in frequency by those involving the hepatic flexure of the colon, stomach or jejunum, abdominal wall, and renal pelvis. Clinically "silent" biliary-enteric fistulas occurring as a complication of chronic cholecystitis have been found in up to 5% of patients undergoing cholecystectomy. Asymptomatic cholecystoenteric fistulas may sometimes be diagnosed by finding gas in the biliary tree on plain abdominal films. Barium contrast studies or endoscopy of the upper gastrointestinal tract or colon may demonstrate the fistula. Treatment in the symptomatic patient usually consists of cholecystectomy,CBDexploration, and closure of the fistulous tract.

Gallstone ileus refers to mechanical intestinal obstruction resulting from the passage of a large gallstone into the bowel lumen. The stone customarily enters the duodenum through a cholecystoenteric fistula at that level. The site of obstruction by the impacted gallstone is usually at the ileocecal valve, provided that the more proximal small bowel is of normal caliber. The majority of patients do not give a history of either prior biliary tract symptoms or complaints suggestive of acute cholecystitis or fistulization. Large stones over 2.5 cm in diameter are thought to predispose to fistula formation by gradual erosion through the gallbladder fundus. Diagnostic confirmation may occasionally be found on the plain abdominal film (e.g., small-intestinal obstruction with gas in the biliary tree and a calcified, ectopic gallstone) or following an upper gastrointestinal series (cholecystoduodenal fistula with small-bowel obstruction at the ileocecal valve). Laparotomy with stone extraction (or propulsion into the colon) remains the procedure of choice to relieve obstruction. Evacuation of large stones within the gallbladder should

also be performed. In general, the gallbladder and its attachment to the intestines should be left alone.

Limey (Milk of Calcium) Bile and Porcelain Gallbladder Calcium salts may be secreted into the lumen of the gallbladder in sufficient concentration to produce calcium precipitation and diffuse, hazy opacification of bile or a layering effect on plain abdominal roentgenography. This so-called limey bile, or milk of calcium bile, is usually clinically innocuous, but cholecystectomy is recommended because limey bile most often occurs in a hydropic gallbladder. In the entity called *porcelain gallbladder*, calcium salt deposition within the wall of a chronically inflamed gallbladder may be detected on the plain abdominal film. Cholecystectomy is advised in all patients with porcelain gallbladder because in a high percentage of cases this finding appears to be associated with the development of carcinoma of the gallbladder.

TREATMENT

Medical Therapy Although surgical intervention remains the mainstay of therapy for acute cholecystitis and its complications, a period of in-hospital stabilization may be required before cholecystectomy. Oral intake is eliminated, nasogastric suction may be indicated, and extracellular volume depletion and electrolyte abnormalities are repaired. Meperidine or nonsteroidal antiinflammatory drugs (NSAIDs) are usually employed for analgesia because they may produce less spasm of the sphincter of Oddi than drugs such as morphine. Intravenous antibiotic therapy is usually indicated in patients with severe acute cholecystitis even though bacterial superinfection of bile may not have occurred in the early stages of the inflammatory process. Postoperative complications of wound infection, abscess formation, or sepsis are reduced in antibiotic-treated patients. Effective antibiotics include ureidopenicillins, ampicillin, metronidazole, and cephalosporins. Combination with an aminoglycoside or other antibiotics may be considered in diabetic or debilitated patients and in those with signs of gram-negative sepsis (Chap. 134).

Surgical Therapy The optimal timing of surgical intervention in patients with acute cholecystitis depends on stabilization of the patient. The clear trend is toward earlier surgery, and this is due in part to requirements for shorter hospital stays. Urgent (emergency) cholecystectomy or cholecystostomy is probably appropriate in most patients in whom a complication of acute cholecystitis such as empyema, emphysematous cholecystitis, or perforation is suspected or confirmed. In uncomplicated cases of acute cholecystitis, up to 30% of patients fail to resolve their symptoms on appropriate medical therapy, and progression of the attack or a supervening complication leads to the performance of early operation (within 24 to 72 h). The technical complications of surgery are not increased in patients undergoing early as opposed to delayed cholecystectomy. Delayed surgical intervention is probably best reserved for (1) patients in whom the overall medical condition imposes an unacceptable risk for early surgery and (2) patients in whom the diagnosis of acute cholecystitis is in doubt. Early cholecystectomy is the treatment of choice for most patients with acute cholecystitis. Mortality figures for emergency cholecystectomy in most centers approach 3%, while the mortality risk for elective or early cholecystectomy approximates 0.5% in patients under age 60. Of course, the operative risks increase with age-related diseases of other organ systems and with the presence of long- or

short-term complications of gallbladder disease. Seriously ill or debilitated patients with cholecystitis may be managed with cholecystostomy and tube drainage of the gallbladder. Elective cholecystectomy may then be done at a later date.

Postcholecystectomy Complications Early complications following cholecystectomy include atelectasis and other pulmonary disorders, abscess formation (often subphrenic), external or internal hemorrhage, biliary-enteric fistula, and bile leaks. Jaundice may indicate absorption of bile from an intraabdominal collection following a biliary leak or mechanical obstruction of theCBD by retained calculi, intraductal blood clots, or extrinsic compression. Routine performance of intraoperative cholangiography during cholecystectomy has helped to reduce the incidence of these early complications.

Overall, cholecystectomy is a very successful operation that provides total or near-total relief of preoperative symptoms in 75 to 90% of patients. The most common cause of persistent postcholecystectomy symptoms is an overlooked extrabiliary disorder (e.g., reflux esophagitis, peptic ulceration, pancreatitis, or -- most often -- irritable bowel syndrome). In a small percentage of patients, however, a disorder of the extrahepatic bile ducts may result in persistent symptomatology. These so-called postcholecystectomy syndromes may be due to (1) biliary strictures, (2) retained biliary calculi, (3) cystic duct stump syndrome, (4) stenosis or dyskinesia of the sphincter of Oddi, or (5) bile salt-induced diarrhea or gastritis.

Cystic Duct Stump Syndrome In the absence of cholangiographically demonstrable retained stones, symptoms resembling biliary colic or cholecystitis in the postcholecystectomy patient have frequently been attributed to disease in a long (>1 cm) cystic duct remnant (cystic duct stump syndrome). Careful analysis, however, reveals that postcholecystectomy complaints are attributable to other causes in almost all patients in whom the symptom complex was originally thought to result from the existence of a long cystic duct stump. Accordingly, considerable care should be taken to investigate the possible role of other factors in the production of postcholecystectomy symptoms before attributing them to cystic duct stump syndrome.

Papillary dysfunction, papillary stenosis, spasm of the sphincter of Oddi, and biliary dyskinesia Symptoms of biliary colic accompanied by signs of recurrent, intermittent biliary obstruction may be produced by papillary stenosis, papillary dysfunction, spasm of the sphincter of Oddi, and biliary dyskinesia. Papillary stenosis is thought to result from acute or chronic inflammation of the papilla of Vater or from glandular hyperplasia of the papillary segment. Five criteria have been used to define papillary stenosis: (1) upper abdominal pain, usuallyRUQ or epigastric; (2) abnormal liver tests; (3) dilatation of the common bile duct upon endoscopic retrograde cholangiopancreatography (ERCP) examination; (4) delayed (>45 min) drainage of contrast material from the duct; and (5) increased basal pressure of the sphincter of Oddi, a finding that may be of only minor significance. An alternative to ERCP is magnetic resonance cholangiography if ERCP and/or biliary manometry are either unavailable or not feasible. In patients with papillary stenosis, quantitative hepatobiliary scintigraphy has revealed delayed transit from the common bile duct to the bowel, ductal dilatation, and abnormal time-activity dynamics. This technique can also be used before and after sphincterotomy to document improvement in biliary emptying. Treatment consists of endoscopic or

surgical sphincteroplasty to ensure wide patency of the distal portions of both the bile and pancreatic ducts. The greater the number of the preceding criteria present, the greater the likelihood that a patient does have a degree of papillary stenosis sufficient to justify correction. The factors usually considered as indications for sphincterotomy include (1) prolonged duration of symptoms, (2) lack of response to symptomatic treatment, (3) presence of severe disability, and (4) the patient's choice of sphincterotomy over surgery (given a clear understanding on his or her part of the risks involved in both procedures).

Criteria for diagnosing dyskinesia of the sphincter of Oddi are even more controversial than those for papillary stenosis. Proposed mechanisms include spasm of the sphincter, denervation sensitivity resulting in hypertonicity, and abnormalities of the sequencing or frequency rates of sphincteric contraction waves. When thorough evaluation has failed to demonstrate another cause for the pain, and when cholangiographic and manometric criteria suggest a diagnosis of biliary dyskinesia, medical treatment with nitrites or anticholinergics to attempt pharmacologic relaxation of the sphincter has been proposed. Endoscopic biliary sphincterotomy (EBS) or surgical sphincteroplasty may be indicated in patients who fail to respond to a 2- to 3-month trial of medical therapy, especially if basal sphincter of Oddi pressures are elevated. EBS has become a well-established procedure for removing bile duct stones and for other biliary and pancreatic problems. Approximately 150,000 such procedures are performed annually in the United States. Key findings in a recent study of EBS include: (1) Dysfunction of the sphincter of Oddi was the most frequent patient-related risk factor for complications; (2) pancreatitis was more frequent in young patients; (3) difficulty in cannulating the bile duct and the use of "precut" sphincterotomy were important technique-related risk factors for complications; and (4) experience in the volume of procedures proved to be important; endoscopists who perform more than one EBS per week had lower complication rates than endoscopists who performed a smaller number of procedures.

Bile Salt-Induced Diarrhea and Gastritis Postcholecystectomy patients may develop symptoms and signs of gastritis, which has been attributed to duodenogastric reflux of bile. However, firm data linking an increased incidence of bile gastritis with surgical removal of the gallbladder are lacking. Cholecystectomy induces persistent changes in gut transit, and these changes effect a noticeable modification of bowel habits. Cholecystectomy shortens gut transit time by accelerating passage of the fecal bolus through the colon with marked acceleration in the right colon, thus causing an increase in colonic bile acid output and a shift in bile acid composition toward the more diarrheagenic secondary bile acids. Diarrhea that is severe enough, i.e., three or more watery movements per day, can be classified as postcholecystectomy diarrhea, and this occurs in 8 to 12% of patients undergoing elective cholecystectomy. Treatment with a bile acid sequestering agent, such as cholestyramine, is often effective in ameliorating troublesome diarrhea.

THE HYPERPLASTIC CHOLECYSTOSES

The term *hyperplastic cholecystoses* is used to denote a group of disorders of the gallbladder characterized by excessive proliferation of normal tissue components.

Adenomyomatosis is characterized by a benign proliferation of gallbladder surface

epithelium with glandlike formations, extramural sinuses, transverse strictures, and/or fundal nodule ("adenoma" or "adenomyoma") formation. Outpouchings of mucosa termed *Rokitansky-Aschoff sinuses* may be seen on oral cholecystography in conjunction with hyperconcentration of contrast medium. Characteristic dimpled filling defects also may be seen.

Cholesterolosis is characterized by abnormal deposition of lipid, especially cholesterol esters, in the lamina propria of the gallbladder wall. In its diffuse form ("strawberry gallbladder"), the gallbladder mucosa is brick red and speckled with bright yellow flecks of lipid. The localized form shows solitary or multiple "cholesterol polyps" studding the gallbladder wall. Cholesterol stones of the gallbladder are found in nearly half the cases. Cholecystectomy is indicated in both adenomyomatosis and cholesterolosis when symptomatic or when cholelithiasis is present.

DISEASES OF THE BILE DUCTS

CONGENITAL ANOMALIES

Biliary Atresia and Hypoplasia Atretic and hypoplastic lesions of the extrahepatic and major intrahepatic bile ducts are the most common biliary anomalies of clinical relevance encountered in infancy. The clinical picture is one of severe obstructive jaundice during the first month of life, with pale stools. The diagnosis is confirmed by surgical exploration with operative cholangiography. Approximately 10% of cases of biliary atresia are treatable with roux-en-Y choledochojejunostomy, with the Kasai procedure (hepatic portoenterostomy) being attempted in the remainder in an effort to restore some bile flow. Most patients, even those having successful biliary-enteric anastomoses, eventually develop chronic cholangitis, extensive hepatic fibrosis, and portal hypertension.

Choledochal Cysts Cystic dilatation may involve the free portion of theCBD, i.e., choledochal cyst, or may present as diverticulum formation in the intraduodenal segment. In the latter situation, chronic reflux of pancreatic juice into the biliary tree can produce inflammation and stenosis of the extrahepatic bile ducts leading to cholangitis or biliary obstruction. Because the process may be gradual, approximately 50% of patients present with onset of symptoms after age 10. The diagnosis may be made by ultrasound, abdominalCT, or cholangiography. Only one-third of patients show the classic triad of abdominal pain, jaundice, and an abdominal mass. Ultrasonographic detection of a cyst separate from the gallbladder should suggest the diagnosis of choledochal cyst, which can be confirmed by demonstrating the entrance of extrahepatic bile ducts into the cyst. Surgical treatment involves excision of the "cyst" and biliary-enteric anastomosis. Patients with choledochal cysts are at increased risk for the subsequent development of cholangiocarcinoma.

Congenital Biliary Ectasia Cystic dilatation of the intrahepatic bile ducts may involve either the major intrahepatic radicles (Caroli's disease), the inter- and intralobular ducts (congenital hepatic fibrosis), or both. In Caroli's disease, clinical manifestations include recurrent cholangitis, abscess formation in and around the affected ducts, and, sometimes, gallstone formation within portions of ectatic intrahepatic biliary radicles. TheCT scan and cholangiographic patterns are usually diagnostic, and treatment with

ongoing antibiotic therapy is usually undertaken in an effort to limit the frequency and severity of recurrent bouts of cholangitis. Progression to secondary biliary cirrhosis with portal hypertension, amyloidosis, extrahepatic biliary obstruction, cholangiocarcinoma, or recurrent episodes of sepsis with hepatic abscess formation is common.

CHOLEDOCHOLITHIASIS

Pathophysiology and Clinical Manifestations Passage of gallstones into theCBDoccurs in approximately 10 to 15% of patients with cholelithiasis. The incidence of common duct stones increases with increasing age of the patient, so that up to 25% of elderly patients may have calculi in the common duct at the time of cholecystectomy. Undetected duct stones are left behind in approximately 1 to 5% of cholecystectomy patients. The overwhelming majority of bile duct stones are cholesterol or mixed stones formed in the gallbladder, which then migrate into the extrahepatic biliary tree through the cystic duct. Primary calculi arising de novo in the ducts are usually pigment stones developing in patients with (1) chronic hemolytic diseases; (2) hepatobiliary parasitism or chronic, recurrent cholangitis; (3) congenital anomalies of the bile ducts (especially Caroli's disease); or (4) dilated, sclerosed, or strictured ducts. Common duct stones may remain asymptomatic for years, may pass spontaneously into the duodenum, or (most often) may present with biliary colic or a complication.

Complications

Cholangitis Cholangitis may be acute or chronic, and symptoms result from inflammation, which usually requires at least partial obstruction to the flow of bile. Bacteria are present on bile culture in approximately 75% of patients with acute cholangitis early in the symptomatic course. The characteristic presentation of acute cholangitis involves biliary colic, jaundice, and spiking fevers with chills (Charcot's triad). Blood cultures are frequently positive, and leukocytosis is typical. *Nonsuppurative* acute cholangitis is most common and may respond relatively rapidly to supportive measures and to treatment with antibiotics. In *suppurative* acute cholangitis, however, the presence of pus under pressure in a completely obstructed ductal system leads to symptoms of severe toxicity -- mental confusion, bacteremia, and septic shock. Response to antibiotics alone in this setting is relatively poor, multiple hepatic abscesses are often present, and the mortality rate approaches 100% unless prompt endoscopic or surgical relief of the obstruction and drainage of infected bile are carried out. Endoscopic management of bacterial cholangitis is as effective as surgical intervention.ERCPwith endoscopic sphincterotomy is safe and the preferred initial procedure for both establishing a definitive diagnosis and providing effective therapy.

Obstructive Jaundice Gradual obstruction of theCBD over a period of weeks or months usually leads to initial manifestations of jaundice or pruritus without associated symptoms of biliary colic or cholangitis. Painless jaundice may occur in patients with choledocholithiasis, but this manifestation is much more characteristic of biliary obstruction secondary to malignancy of the head of the pancreas, bile ducts, or ampulla of Vater.

In patients whose obstruction is secondary to choledocholithiasis, associated chronic calculous cholecystitis is very common, and the gallbladder in this setting may be

relatively indistensible. The absence of a palpable gallbladder in most patients with biliary obstruction from duct stones is the basis for *Courvoisier's law*, i.e., that the presence of a palpably enlarged gallbladder suggests that the biliary obstruction is secondary to an underlying malignancy rather than to calculous disease. Biliary obstruction causes progressive dilatation of the intrahepatic bile ducts as intrabiliary pressures rise. Hepatic bile flow is suppressed, and regurgitation of conjugated bilirubin into the bloodstream leads to jaundice accompanied by dark urine (bilirubinuria) and light-colored (acholic) stools.

CBDstones should be suspected in any patient with cholecystitis whose serum bilirubin level exceeds 85.5 umol/L (5 mg/dL). The maximum bilirubin level is seldom over 256.5 umol/L (15.0 mg/dL) in patients with choledocholithiasis unless concomitant hepatic disease or another factor leading to marked hyperbilirubinemia exists. Serum bilirubin levels of 342.0 umol/L (20 mg/dL) or more should suggest the possibility of neoplastic obstruction. The serum alkaline phosphatase level is almost always elevated in biliary obstruction. A rise in alkaline phosphatase often precedes clinical jaundice and may be the only abnormality in routine liver function tests. There may be a two- to tenfold elevation of serum aminotransferases, especially in association with acute obstruction. Following relief of the obstructing process, serum aminotransferase elevations usually return rapidly to normal, while the serum bilirubin level may take 1 to 2 weeks to return to normal. The alkaline phosphatase level usually falls slowly, lagging behind the decrease in serum bilirubin.

Pancreatitis The most common associated entity discovered in patients with nonalcoholic acute pancreatitis is biliary tract disease. Biochemical evidence of pancreatic inflammation complicates acute cholecystitis in 15% of cases and choledocholithiasis in over 30%, and the common factor appears to be the passage of gallstones through the common duct. Coexisting pancreatitis should be suspected in patients with symptoms of cholecystitis who develop (1) back pain or pain to the left of the abdominal midline, (2) prolonged vomiting with paralytic ileus, or (3) a pleural effusion, especially on the left side. Surgical treatment of gallstone disease is usually associated with resolution of the pancreatitis.

Secondary Biliary Cirrhosis Secondary biliary cirrhosis may complicate prolonged or intermittent duct obstruction with or without recurrent cholangitis. Although this complication may be seen in patients with choledocholithiasis, it is more common in cases of prolonged obstruction from stricture or neoplasm. Once established, secondary biliary cirrhosis may be progressive even after correction of the obstructing process, and increasingly severe hepatic cirrhosis may lead to portal hypertension or to hepatic failure and death. Prolonged biliary obstruction may also be associated with clinically relevant deficiencies of the fat-soluble vitamins A, D, and K.

Diagnosis and Treatment The diagnosis of choledocholithiasis is usually made by cholangiography (Table 302-3), either preoperatively byERCP or intraoperatively at the time of cholecystectomy. As many as 15% of patients undergoing cholecystectomy will prove to haveCBDstones. With the advent of laparoscopic cholecystectomy, the management of CBD stones in the presence of gallstones is gradually being clarified. Preoperative ERCP with endoscopic papillotomy and stone extraction is the preferred approach. It not only provides stone clearance but also defines the anatomy of the

biliary tree in relationship to the cystic duct. ERCP is indicated in gallstone patients who have any of the following risk factors: (1) a history of jaundice or pancreatitis, (2) abnormal tests of liver function, and (3) ultrasonographic evidence of a dilated CBD or stones in the duct. Alternatively, if intraoperative cholangiography reveals retained stones, postoperative ERCP can be carried out. The need for preoperative ERCP is expected to decrease further as laparoscopic techniques improve.

The widespread use of laparoscopic cholecystectomy andERCP has decreased the incidence of complicated biliary tract disease and the need for choledocholithotomy and T-tube drainage of the bile ducts.EBSfollowed by spontaneous passage or stone extraction is the treatment of choice in the management of patients with common duct stones, especially in elderly or poor-risk patients.

TRAUMA, STRICTURES, AND HEMOBILIA

Benign strictures of the extrahepatic bile ducts result from surgical trauma in approximately 95% of cases and occur in about 1 in 500 cholecystectomies. Strictures may present with bile leak or abscess formation in the immediate postoperative period or with biliary obstruction or cholangitis as long as 2 years or more following the inciting trauma. The diagnosis is established by percutaneous or endoscopic cholangiography. Endoscopic brushing of biliary strictures is an effective way to establish the nature of the lesion and is more accurate than bile cytology alone. When positive exfoliative cytology is obtained, the diagnosis of a neoplastic stricture is established. This procedure is especially important in patients with primary sclerosing cholangitis who are predisposed to the development of cholangiocarcinomas. Successful operative correction by a skillful surgeon with duct-to-bowel anastomosis is usually possible, although mortality rates from surgical complications, recurrent cholangitis, or secondary biliary cirrhosis are high.

Hemobilia may follow traumatic or operative injury to the liver or bile ducts, intraductal rupture of a hepatic abscess or aneurysm of the hepatic artery, biliary or hepatic tumor hemorrhage, or mechanical complications of choledocholithiasis or hepatobiliary parasitism. Diagnostic procedures such as liver biopsy, percutaneous transhepatic cholangiography (PTHC), and transhepatic biliary drainage catheter placement may also be complicated by hemobilia. Patients often present with a classic triad of biliary colic, obstructive jaundice, and melena or occult blood in the stools. The diagnosis is sometimes made by cholangiographic evidence of blood clot in the biliary tree, but selective angiographic verification may be required. Although minor episodes of hemobilia may resolve without operative intervention, surgical ligation of the bleeding vessel is frequently required.

EXTRINSIC COMPRESSION OF THE BILE DUCTS

Partial or complete biliary obstruction may sometimes be produced by extrinsic compression of the ducts. The most common cause of this form of obstructive jaundice is carcinoma of the head of the pancreas. Biliary obstruction may also occur as a complication of either acute or chronic pancreatitis or involvement of lymph nodes in the porta hepatis by lymphoma or metastatic carcinoma. The latter should be distinguished from cholestasis resulting from massive replacement of the liver by tumor.

HEPATOBILIARY PARASITISM

Infestation of the biliary tract by adult helminths or their ova may produce a chronic, recurrent pyogenic cholangitis with or without multiple hepatic abscesses, ductal stones, or biliary obstruction. This condition is relatively rare but does occur in inhabitants of southern China and elsewhere in Southeast Asia. The organisms most commonly involved are trematodes or flukes, including *Clonorchis sinensis*, *Opisthorchis viverrini* or *O. felineus*, and *Fasciola hepatica*. The biliary tract also may be involved by intraductal migration of adult *Ascaris lumbricoides* from the duodenum or by intrabiliary rupture of hydatid cysts of the liver produced by *Echinococcus* spp. The diagnosis is made by cholangiography and the presence of characteristic ova on stool examination. When obstruction is present, the treatment of choice is laparotomy under antibiotic coverage, with common duct exploration and a biliary drainage procedure. It should be emphasized that in the Far East, one also sees cholangiohepatitis associated with pigment lithiasis, which may, in fact, be more common than cholangitis due to parasites.

SCLEROSING CHOLANGITIS

Primary or idiopathic sclerosing cholangitis is characterized by a progressive, inflammatory, sclerosing, and obliterative process affecting the extrahepatic and/or the intrahepatic bile ducts. The disorder occurs in about 70% in association with inflammatory bowel disease, especially ulcerative colitis. It may also be associated (albeit rarely) with multifocal fibrosclerosis syndromes such as retroperitoneal, mediastinal, and/or periureteral fibrosis; Riedel's struma; or pseudotumor of the orbit. In patients with AIDS, cholangiopancreatography may demonstrate a broad range of biliary tract changes as well as pancreatic duct obstruction and occasionally pancreatitis (Chap. 309). Further, biliary tract lesions in AIDS include infection and cholangiopancreatographic changes similar to primary sclerosing cholangitis. Changes noted include: (1) diffuse involvement of intrahepatic bile ducts alone, (2) involvement of both intra- and extrahepatic bile ducts, (3) ampullary stenosis, (4) stricture of the intrapancreatic portion of the common bile duct, and (5) pancreatic duct involvement. Associated infectious organisms include *Cryptosporidium*, *Mycobacterium avium-intracellulare*, cytomegalovirus, *Microsporidia*, and *Isospora*. In addition, acalculous cholecystitis occurs in up to 10% of patients.ERCPsphincterotomy, while not without risk, provides significant pain reduction in patients with AIDS-associated papillary stenosis. Secondary sclerosing cholangitis may occur as a long-term complication of choledocholithiasis, cholangiocarcinoma, operative or traumatic biliary injury, or contiguous inflammatory processes.

Patients with primary sclerosing cholangitis often present with signs and symptoms of chronic or intermittent biliary obstruction: jaundice, pruritus,RUQabdominal pain, or acute cholangitis. Late in the course, complete biliary obstruction, secondary biliary cirrhosis, hepatic failure, or portal hypertension with bleeding varices may occur. The diagnosis is usually established by finding multifocal, diffusely distributed strictures with intervening segments of normal or dilated ducts, producing a beaded appearance on cholangiography (Fig. 302-2*D*). The cholangiographic technique of choice in suspected cases isERCP, since intrahepatic ductal involvement may makePTHCdifficult. When a diagnosis of sclerosing cholangitis has been established, a search for associated diseases, especially for chronic inflammatory bowel disease, should be carried out.

A recent study describes the natural history and outcome for 305 patients of Swedish descent with primary sclerosing cholangitis; 134 (44%) of the patients were asymptomatic at the time of diagnosis and, not surprisingly, had a significantly higher survival rate with a median follow-up time of 63 months. The independent predictors of a bad prognosis were age, serum bilirubin concentration, and liver histologic changes. Cholangiocarcinoma was found in 24 patients (8%). Inflammatory bowel disease was closely associated with primary sclerosing cholangitis and had a prevalence of 81% in this study population.

TREATMENT

Therapy with cholestyramine may help control symptoms of pruritus, and antibiotics are useful when cholangitis complicates the clinical picture. Vitamin D and calcium supplementation may help prevent the loss of bone mass frequently seen in patients with chronic cholestasis. Glucocorticoids, methotrexate, and cyclosporine have not been shown to be efficacious.UDCAimproves serum liver tests, but an effect on survival has not been documented. In cases where complete or high-grade biliary obstruction (dominant strictures) has occurred, balloon dilatation, stenting, or (rarely) surgical intervention may be appropriate. Efforts at biliary-enteric anastomosis or stent placement may, however, be complicated by recurrent cholangitis and further progression of the stenosing process. The role of colectomy in patients with sclerosing cholangitis complicating chronic ulcerative colitis is uncertain. The prognosis is unfavorable, with a median survival of 9 to 12 years following the diagnosis, regardless of therapy. Four variables (age, serum bilirubin level, histologic stage, and splenomegaly) predict survival in patients with primary sclerosing cholangitis and serve as the basis for a risk score. Primary sclerosing cholangitis is one of the most common indications for liver transplantation.

In two large studies involving 627 and 3147 patients, the prevalence of gallbladder polyps was 6.7 and 6.9%, respectively, with a marked male predominance. Few significant changes occurred over a 5-year period in asymptomatic patients in whom gallbladder polyps<10 mm in diameter were found. If polyps>10 mm are present and show rapid growth, cholecystectomy should be considered.

ACKNOWLEDGEMENT

SECTION 3 -DISORDERS OF THE PANCREAS

303. APPROACH TO THE PATIENT WITH PANCREATIC DISEASE - *Phillip P. Toskes, Norton J. Greenberger*

GENERAL CONSIDERATIONS

Inflammatory disease of the pancreas may be acute or chronic. Although good data exist concerning the frequency of acute pancreatitis (about 5000 new cases per year in the United States, with a mortality rate of about 10%), the number of patients who suffer with recurrent acute pancreatitis or chronic pancreatitis is largely undefined. Only one prospective study on the incidence of chronic pancreatitis is available; it showed an incidence of 8.2 new cases per 100,000 per year and a prevalence of 26.4 cases per 100,000. These numbers probably underestimate considerably the true incidence and prevalence, because non-alcohol-induced pancreatitis was largely ignored. At autopsy, the prevalence of chronic pancreatitis ranges from 0.04 to 5%. The relative inaccessibility of the pancreas to direct examination and the nonspecificity of the abdominal pain associated with pancreatitis make the diagnosis of pancreatitis difficult and usually dependent on elevation of blood amylase levels. Many patients with chronic pancreatitis do not have elevated blood amylase levels. Some patients with chronic pancreatitis develop signs and symptoms of pancreatic exocrine insufficiency, and thus objective evidence for pancreatic disease can be demonstrated. However, there is a very large reservoir of pancreatic exocrine function. More than 90% of the pancreas must be damaged before maldigestion of fat and protein is manifested. Even the secretin stimulation test, which is the most sensitive method of assessing pancreatic exocrine function, is probably abnormal only when more than 60% of exocrine function has been lost. Noninvasive, indirect tests of pancreatic exocrine function (bentiromide, serum trypsinogen) are much more likely to give abnormal results in patients with obvious pancreatic disease, i.e., pancreatic calcification, steatorrhea, or diabetes mellitus, than in patients with occult disease. Thus, the number of patients who have subclinical exocrine dysfunction (less than 90% loss of function) is unknown.

The clinical manifestations of acute and chronic pancreatitis and pancreatic insufficiency are protean. Thus, patients may present with hypertriglyceridemia, vitamin B_{12}malabsorption, hypercalcemia, hypocalcemia, hyperglycemia, ascites, pleural effusions, and chronic abdominal pain with normal blood amylase levels. Indeed, if the clinician considers pancreatitis as a possible diagnosis only when presented with a patient having classic symptoms (i.e., severe, constant epigastric pain that radiates through to the back, along with an elevated blood amylase level), only a minority of patients with pancreatitis will be diagnosed correctly.

As emphasized inChap. 304, the etiologies as well as the clinical manifestations of pancreatitis are quite varied. Although it is well appreciated that pancreatitis is frequently secondary to alcohol abuse and biliary tract disease, it can also be caused by drugs, trauma, and viral infections and is associated with metabolic and connective tissue disorders. In approximately 30% of patients with acute pancreatitis and 25 to 40% of patients with chronic pancreatitis, the etiology is obscure.

TESTS USEFUL IN THE DIAGNOSIS OF PANCREATIC DISEASE

Several tests have proved of value in the evaluation of pancreatic exocrine function. Examples of specific tests and their usefulness in the diagnosis of acute and chronic pancreatitis are summarized inTable 303-1. At most institutions, pancreatic function tests are performed if the diagnosis of pancreatic disease remains a possibility after noninvasive tests [ultrasound, computed tomography (CT)] and invasive tests [endoscopic retrograde cholangiopancreatography (ERCP)] have given normal or inconclusive results. In this regard, tests employing *direct* stimulation of the pancreas are the most sensitive.

PANCREATIC ENZYMES IN BODY FLUIDS

The serum amylase level is widely used as a screening test for acute pancreatitis in the patient with acute abdominal pain or back pain. A value greater than 65 U/L should raise the question of acute pancreatitis. Levels greater than 130 U/L make the diagnosis more likely, and values greater than three times normal virtually clinch the diagnosis if gut perforation or infarction is excluded. In acute pancreatitis, the serum amylase is usually elevated within 24 h of onset and remains so for 1 to 3 days. Levels return to normal within 3 to 5 days unless there is extensive pancreatic necrosis, incomplete ductal obstruction, or pseudocyst formation. Approximately 85% of patients with acute pancreatitis have an elevated serum amylase level. This index may be normal, however, if (1) there is a delay (of 2 to 5 days) before blood samples are obtained, (2) the underlying disorder is chronic pancreatitis rather than acute pancreatitis, or (3) hypertriglyceridemia is present. Patients with hypertriglyceridemia and proven pancreatitis have been found to have spuriously low levels of amylase and lipase activity.

The serum amylase is often elevated in other conditions (Table 303-2), in part because the enzyme is found in many organs in addition to the pancreas (salivary glands, liver, small intestine, kidney, fallopian tube) and can be produced by various tumors (carcinomas of the lung, esophagus, breast, and ovary). Isoenzymes of amylase fall into two general categories: those arising from the pancreas (P isoamylases) and those arising from nonpancreatic sources (S isoamylases). The measurement of serum isoamylases is of clinical importance. In normal serum, about 35 to 45% of the amylase is of pancreatic origin. For example, in patients with acute pancreatitis, the total serum amylase level returns to normal more rapidly than the level of pancreatic isoamylase. Thus, in patients seen after the first day, the pancreatic isoamylase level is a more sensitive indicator of pancreatitis than the total serum amylase level. In the past, elevations in serum amylase seen in certain conditions, such as the postoperative state, acute alcohol intoxication, and diabetic ketoacidosis, were assumed to indicate acute pancreatitis. However, the elevation of serum amylase in such conditions has been shown to be due to an elevation of the S isoamylase. Simple tests to distinguish pancreatic from nonpancreatic amylase are no longer readily available, and such tests are often not reliable when the total amylase is minimally to moderately elevated. An assay of serum trypsinogen (performed by several commercial laboratories) is quite helpful in this regard. Since this enzyme is secreted specifically by the pancreas, a normal serum trypsinogen level in a patient with minimal elevation of serum amylase essentially rules out acute pancreatitis. Urinary amylase measurements, including the amylase/creatinine clearance ratio, are no more sensitive or specific than blood amylase

levels.

Elevation of ascitic fluid amylase occurs in acute pancreatitis as well as in (1) pancreatogenous ascites due to disruption of the main pancreatic duct or a leaking pseudocyst and (2) other abdominal disorders that simulate pancreatitis (e.g., intestinal obstruction, intestinal infarction, and perforated peptic ulcer). Elevation of pleural fluid amylase occurs in acute pancreatitis, chronic pancreatitis, carcinoma of the lung, and esophageal perforation.

Lipase may now be the single best enzyme to measure for the diagnosis of acute pancreatitis. Improvements in substrates and technology offer clinicians improved options, especially when a turbidimetric assay is used. The newer lipase assays have colipase as a cofactor and are fully automated.

An assay for trypsinogen (or for trypsin-like immunoreactivity) has a theoretical advantage over amylase and lipase determinations in that the pancreas is the only organ that contains this enzyme. The test appears to be useful in the diagnosis of both acute and chronic pancreatitis. Sensitivity and specificity are comparable to those of amylase and lipase determinations. Since trypsinogen is also excreted by the kidney, elevated serum values are found in renal failure, as is the case with serum amylase and lipase levels. *No single blood test is reliable for the diagnosis of acute pancreatitis in patients with renal failure.* Determining whether a patient with renal failure and abdominal pain has pancreatitis remains a difficult clinical problem. A recent study found that serum amylase levels were elevated in patients with renal dysfunction only when creatinine clearance was less than 50 mL/min. In such patients, the serum amylase level was invariably less than 500 IU/L in the absence of objective evidence of acute pancreatitis. In that study, serum lipase and trypsin levels paralleled serum amylase values.

A recent study evaluated the sensitivity and specificity of five assays used to diagnose acute pancreatitis: two for amylase, one for lipase, one for trypsin-like immunoreactivity (TLI), and one for pancreatic isoamylase. The data obtained (1) show that, if the best cutoff level is used, all these assays have similar specificities and (2) suggest that total serum amylase is as good an indicator of acute pancreatitis as any of the alternatives. However, inherent in many such studies is the problem that the recognition and diagnosis of acute pancreatitis hinge on the finding of an elevated serum amylase level. The question arises as to whether any diagnostic test result can be proved superior to the total serum amylase level if hyperamylasemia is required for the diagnosis. In other studies, when "objective" confirmation of the clinical diagnosis of pancreatitis was required (ultrasonography,CT, laparotomy), the sensitivity of the serum amylase has been found to be as low as 68%. With these limitations in mind, the recommended screening tests for acute pancreatitis are *total serum amylase* and *serum lipase activities*. Serum amylase values greater than three times normal are highly specific.

STUDIES PERTAINING TO PANCREATIC STRUCTURE

Radiologic Tests Plain films of the abdomen provide useful information in 30 to 50% of patients with acute pancreatitis. The most frequent abnormalities include (1) a localized ileus, usually involving the jejunum ("sentinel loop"); (2) a generalized ileus with air-fluid

levels; (3) the "colon cutoff sign," which results from isolated distention of the transverse colon; (4) duodenal distention with air-fluid levels; and (5) a mass, which is frequently a pseudocyst. In chronic pancreatitis, an important radiographic finding is pancreatic calcification, which characteristically is localized adjacent to and superimposed on the second lumbar vertebra (see Fig. 304-3*A*).

Upper gastrointestinal x-rays may reveal displacement of the stomach by the retroperitoneal mass (see Fig. 304-2*A*) or widening and effacement of the duodenal C loop, which also suggest the presence of a pancreatic mass, which could be inflammatory, cystic, or neoplastic. However, the use of x-ray films has been largely superseded by ultrasound.

Ultrasonography can provide important information in patients with acute pancreatitis, chronic pancreatitis, pancreatic calcification, pseudocyst, and pancreatic carcinoma. Echographic appearances can indicate the presence of edema, inflammation, and calcification (not obvious on plain films of the abdomen), as well as pseudocysts, mass lesions, and gallstones (see Figs. 304-2*B* and 304-3*B*). In acute pancreatitis, the pancreas is characteristically enlarged. In pancreatic pseudocyst, the usual appearance is that of an echo-free, smooth, round fluid collection. Pancreatic carcinoma distorts the usual landmarks, and mass lesions greater than 3.0 cm are usually detected as localized, echo-free solid lesions. Ultrasound is often the initial investigation for most patients with suspected pancreatic disease. However, obesity, excess small- and large-bowel gas, and recently performed barium contrast examinations can interfere with ultrasound studies.

CTis the best imaging study for initial evaluation of a suspected chronic pancreatic disorder and for the complications of acute and chronic pancreatitis. It is especially useful in the detection of pancreatic tumors, fluid-containing lesions such as pseudocysts and abscesses, and calcium deposits (seeFigs. 304-3*C* and 304-4*A*). Most lesions are characterized by (1) enlargement of the pancreatic outline, (2) distortion of the pancreatic contour, and/or (3) a fluid filling that has a different attenuation coefficient than normal pancreas. However, it is occasionally difficult to distinguish between inflammatory and neoplastic lesions. Oral water-soluble contrast agents may be used to opacify the stomach and duodenum during CT scans; this strategy permits more precise delineation of various organs as well as mass lesions. Dynamic CT (using rapid intravenous administration of contrast) is useful in estimating the degree of pancreatic necrosis and in predicting morbidity and mortality. Spiral (helical) CT provides clear images much more rapidly and essentially negates artifact caused by patient movement (see Fig. 304-2*D*).

Endoscopic ultrasonography (*EUS*) produces high-resolution images of the pancreatic parenchyma and pancreatic duct with a transducer fixed to an endoscope that can be directed onto the surface of the pancreas through the stomach or duodenum. Although criteria for abnormalities on EUS in severe pancreatic disease have been developed, the true sensitivity and specificity of this procedure has yet to be determined. In particular, it is not clear whether EUS can detect early pancreatic disease before abnormalities appear on more conventional radiograph tests such as ultrasonography orCT. The exact role of EUS versusERCP and CT has yet to be defined.

Magnetic resonance cholangiopancreatography (*MRCP*) is now being used to view both the bile duct and the pancreatic duct. Nonbreath-hold and 3D turbo spin-echo techniques are being utilized to produce superb MRCP images. The main pancreatic duct and common bile duct can be seen well, but there is still a question as to whether changes can be detected consistently in the secondary ducts. MRCP may be particularly useful to evaluate the pancreatic duct in high-risk patients such as the elderly because this is a noninvasive procedure.

BothEUS andMRCP may replaceERCP in some patients. As these techniques become more refined, they may well be the diagnostic tests of choice to evaluate the pancreatic duct. ERCP is still needed to perform therapy of bile duct and pancreatic duct lesions.

Selective catheterization of the celiac and superior mesenteric arteries combined with superselective catheterization of others arteries, such as the hepatic, splenic, and gastroduodenal arteries permits visualization of the pancreas and detection of pancreatic neoplasms and pseudocysts. Pancreatic neoplasms can be identified by the sheathing of blood vessels by a mass lesion (seeFig. 304-1*D*). Hormone-producing pancreatic tumors are especially likely to exhibit increased vascularity and tumor staining. Angiographic abnormalities are noted in many patients with pancreatic carcinoma but are uncommon in patients without pancreatic disease. Angiography complements ultrasonography andERCP in the study of patients with a suspected pancreatic lesion and may be carried out if ERCP is either unsuccessful or nondiagnostic.

ERCPmay provide useful information on the status of the pancreatic ductal system and thus aid in the differential diagnosis of pancreatic disease (seeFigs. 304-1*C*, 304-3*D*, and 304-4*B*). Pancreatic carcinoma is characterized by stenosis or obstruction of either the pancreatic duct or the common bile duct; both ductal systems are often abnormal. In chronic pancreatitis, ERCP abnormalities include (1) luminal narrowing, (2) irregularities in the ductal system with stenosis, dilation, sacculation, and ectasia, and (3) blockage of the pancreatic duct by calcium deposits. The presence of ductal stenosis and irregularity can make it difficult to distinguish chronic pancreatitis from carcinoma. It is important to be aware that ERCP changes interpreted as indicating chronic pancreatitis actually may be due to the effects of aging on the pancreatic duct or to the fact that the procedure was performed within several weeks of an attack of acute pancreatitis. Although aging may cause impressive ductal alterations, it does not affect the results of pancreatic function tests (i.e., the secretin test). Elevated serum and/or urine amylase levels after ERCP have been reported in 25 to 75% of patients, but clinical pancreatitis is uncommon. In a series of 300 patients, pancreatitis occurred in only 5 patients after ERCP. If no lesion is found in the biliary and/or pancreatic ducts in a patient with repeated attacks of acute pancreatitis, manometric studies of the sphincter of Oddi may be indicated. Such studies, however, do increase the risk of post-ERCP/manometry acute pancreatitis. Such pancreatitis appears to be more common in patients with a nondilated pancreatic duct.

Pancreatic Biopsy with Radiologic Guidance Percutaneous aspiration biopsy of a pancreatic mass often distinguishes a pancreatic inflammatory mass from a pancreatic neoplasm.

TESTS OF EXOCRINE PANCREATIC FUNCTION

Pancreatic function tests (Table 303-1) can be divided into the following:

1. *Direct stimulation of the pancreas* by intravenous infusion of secretin or secretin plus cholecystokinin (CCK) followed by collection and measurement of duodenal contents

2. *Indirect stimulation of the pancreas* using nutrients or amino acids, fatty acids, and synthetic peptides followed by assays of proteolytic, lipolytic, and amylolytic enzymes

3. Study of *intraluminal digestion products*, such as undigested meat fibers, stool fat, and fecal nitrogen

4. *Measurement of fecal pancreatic enzymes* such as elastase

The secretin test, used to detect diffuse pancreatic disease, is based on the physiologic principle that the pancreatic secretory response is directly related to the functional mass of pancreatic tissue. In the standard assay, secretin is given intravenously in a dose of 1 clinical unit (CU) per kilogram, as either a bolus or a continuous infusion. The results will vary with the secretin preparation used, the dose, the mode of administration, and the completeness with which the duodenal contents are collected. Normal values for the standard secretin test are (1) volume output >2.0 mL/kg per hour, (2) bicarbonate (HCO_3^-) concentration >80 meql/L, and (3) HCO_3^-output >10 meq/L in 1 h. The most reproducible measurement, giving the highest level of discrimination between normal subjects and patients with chronic pancreatitis, appears to be the maximal bicarbonate concentration.

The *combined secretin-CCK test* permits measurement of pancreatic amylase, lipase, trypsin, and chymotrypsin. Although there is overlap in the distributions of enzyme output in normal subjects and patients with pancreatitis in response to this test, markedly low enzyme outputs suggest advanced damage and destruction of acinar cells. With frank exocrine pancreatic insufficiency, there is usually an overall reduction in both HCO_3^-concentration and output of several enzymes. However, with lesser degrees of pancreatic damage there may be a dissociation between HCO_3^-concentration and enzyme output. There also may be a dissociation between the results of the secretin test and those of tests of absorptive function. For example, patients with chronic pancreatitis often have abnormally low outputs of HCO_3^-after secretin but have normal fecal fat excretion. Thus the secretin test measures the secretory capacity of ductular epithelium, while fecal fat excretion indirectly reflects intraluminal lipolytic activity. Steatorrhea does not occur until intraluminal levels of lipase are markedly reduced, underscoring the fact that only small amounts of enzymes are necessary for intraluminal digestive activities. An abnormal secretin test result suggests only that chronic pancreatic damage is present; it will not consistently distinguish between chronic pancreatitis and pancreatic carcinoma.

Another test of exocrine pancreatic function is the *bentiromide test*. This test is an indirect measure of pancreatic function and reflects intraluminal chymotrypsin activity. The test has excellent specificity but is not very sensitive. It no longer is available for clinical use in the United States.

The *serum trypsinogen level*, which is determined by radioimmunoassay, also has excellent specificity but is not very sensitive. It is a simple blood test that can detect severe damage to the exocrine pancreas. The normal values are 28 to 58 ng/mL, and any value below 20 ng/mL reflects pancreatic steatorrhea.

Measurement of *intraluminal digestion products*, i.e., undigested muscle fibers, stool fat, and fecal nitrogen, is discussed in Chap. 286. The amount of elastase in stool reflects the pancreatic output of this proteolytic enzyme. Decreased elastase activity in stool has been reported in patients with chronic pancreatitis and cystic fibrosis.**Tests useful in the diagnosis of exocrine pancreatic insufficiency and the differential diagnosis of malabsorption are also discussed in Chaps. 286 and 304.*

304. ACUTE AND CHRONIC PANCREATITIS - *Norton J. Greenberger*, *Phillip P. Toskes*

BIOCHEMISTRY AND PHYSIOLOGY OF PANCREATIC EXOCRINE SECRETION

GENERAL CONSIDERATIONS

The pancreas secretes 1500 to 3000 mL of isosmotic alkaline (pH >8.0) fluid per day containing about 20 enzymes and zymogens. The pancreatic secretions provide the enzymes needed to effect the major digestive activity of the gastrointestinal tract and provide an optimal pH for the function of these enzymes.

REGULATION OF PANCREATIC SECRETION

The exocrine pancreas is influenced by intimately interacting hormonal and neural systems. *Gastric acid* is the stimulus for the release of secretin, a peptide with 27 amino acids. Sensitive radioimmunoassay studies for secretin suggest that the pH threshold for its release from the duodenum and jejunum is 4.5. Secretin stimulates the secretion of pancreatic juice rich in *water and electrolytes*. Release of cholecystokinin (CCK) from the duodenum and jejunum is largely triggered by long-chain fatty acids, certain essential amino acids (tryptophan, phenylalanine, valine, methionine), and gastric acid itself. CCK evokes an *enzyme-rich secretion from the pancreas*. Gastrin, although it has the same terminal tetrapeptide as CCK, is a weak stimulus for pancreatic enzyme output. The *parasympathetic nervous system* (via the vagus nerve) exerts significant control over pancreatic secretion. Secretion evoked by secretin and CCK depends on permissive roles of vagal afferent and efferent pathways. This is particularly true for enzyme secretion, whereas water and bicarbonate secretion is heavily dependent on the hormonal effects of secretin and CCK. Also, vagal stimulation effects the release of vasoactive intestinal peptide (VIP), a secretin agonist. Bile salts also stimulate pancreatic secretion, thereby integrating the functions of the biliary tract, pancreas, and small intestine.

Somatostatin acts on multiple sites to induce inhibition of pancreatic secretion. The appropriate roles of other peptides, such as peptide YY, pancreastatin, gastrin-releasing peptide, pituitary adenylate cyclase-activating polypeptide, calcitonin gene-related peptide, and galanin are still being defined. Nitric oxide is an important neurotransmitter in the regulation of pancreatic exocrine secretion, although its mechanism of action has not been fully elucidated.

WATER AND ELECTROLYTE SECRETION

Although sodium, potassium, chloride, calcium, zinc, phosphate, and sulfate are found in pancreatic secretions, *bicarbonate is the ion of primary physiologic importance*. In the acini and in the ducts, secretin causes the cells to add water and bicarbonate to the fluid. In the ducts, an exchange occurs between bicarbonate and chloride. There is a good correlation between the maximal bicarbonate output after stimulation with secretin and the pancreatic mass. The bicarbonate output of 120 to 300 mmol/d helps neutralize gastric acid and creates the appropriate pH for the activity of the pancreatic enzymes.

ENZYME SECRETION

The pancreas secretes amylolytic, lipolytic, and proteolytic enzymes. *Amylolytic enzymes*, such as amylase, hydrolyze starch to oligosaccharides and to the disaccharide maltose. The *lipolytic enzymes* include lipase, phospholipase A, and cholesterol esterase. Bile salts *inhibit* lipase in isolation; but colipase, another constituent of pancreatic secretion, binds to lipase and prevents this inhibition. Bile salts *activate* phospholipase A and cholesterol esterase. *Proteolytic enzymes* include *endopeptidases* (trypsin, chymotrypsin), which act on internal peptide bonds of proteins and polypeptides; *exopeptidases* (carboxypeptidases, aminopeptidases), which act on the free carboxyl- and amino-terminal ends of peptides, respectively; and elastase. The proteolytic enzymes are secreted as inactive precursors (zymogens). Ribonucleases (deoxyribonucleases, ribonuclease) are also secreted. Although pancreatic enzymes usually are secreted in parallel, nonparallel secretion can occur as a result of exocytosis from heterogeneous sources in the pancreas. *Enterokinase*, an enzyme found in the duodenal mucosa, cleaves the lysine-isoleucine bond of trypsinogen to form trypsin. Trypsin then activates the other proteolytic zymogens in a cascade phenomenon. All pancreatic enzymes have pH optima in the alkaline range.

AUTOPROTECTION OF THE PANCREAS

Autodigestion of the pancreas is prevented by the packaging of proteases in precursor form and by the synthesis of protease inhibitors. These protease inhibitors are found in the acinar cell, the pancreatic secretions, and the alpha$_1$- and alpha$_2$-globulin fractions of plasma.

EXOCRINE-ENDOCRINE RELATIONSHIPS

Insulin appears to be needed locally for secretin andCCK to promote exocrine secretion; thus, it acts in a permissive role for these two hormones.

ENTEROPANCREATIC AXIS AND FEEDBACK INHIBITION

Pancreatic enzyme secretion is controlled, at least in part, by a negative feedback mechanism induced by the presence of active serine proteases in the duodenum. To illustrate, perfusion of the duodenal lumen with phenylalanine causes a prompt increase in plasmaCCKlevels as well as increased secretion of chymotrypsin. However, simultaneous perfusion with trypsin blunts both responses. Conversely, perfusion of the duodenal lumen with protease inhibitors actually leads to enzyme hypersecretion. The available evidence supports the concept that the duodenum contains a peptide called CCK releasing factor (CCK-RF) that is involved in stimulating CCK release. Two peptides, luminal CCK-RF and diazepam-binding inhibitor, have been found that may be the CCK-RF. Serine proteases inhibit pancreatic secretion by acting on CCK-RF. It appears that serine proteases inhibit pancreatic secretion by acting on a CCK-releasing peptide in the lumen of the small intestine.

ACUTE PANCREATITIS

GENERAL CONSIDERATIONS

Pancreatic inflammatory disease may be classified as (1) acute pancreatitis and (2) chronic pancreatitis. The pathologic spectrum of acute pancreatitis varies from *edematous pancreatitis*, which is usually a mild and self-limited disorder, to *necrotizing pancreatitis*, in which the degree of pancreatic necrosis correlates with the severity of the attack and its systemic manifestations. The term *hemorrhagic pancreatitis* is less meaningful in a clinical sense because variable amounts of interstitial hemorrhage can be found in pancreatitis as well as in other disorders such as pancreatic trauma, pancreatic carcinoma, and severe congestive heart failure.

The incidence of pancreatitis varies in different countries and depends on cause, e.g., alcohol, gallstones, metabolic factors, and drugs (Table 304-1). In the United States, for example, acute pancreatitis is related to alcohol ingestion more commonly than to gallstones; in England, the opposite obtains. There are 185,000 new cases of acute pancreatitis per year in the United States.

ETIOLOGY AND PATHOGENESIS

There are many causes of acute pancreatitis (Table 304-1), but the mechanisms by which these conditions trigger pancreatic inflammation have not been identified. Alcoholic patients with pancreatitis may represent a special subset, since most alcoholics do not develop pancreatitis. The list of identifiable causes is growing, and it is likely that pancreatitis related to viral infections, drugs, and as yet undefined factors is more common than heretofore recognized.

Approximately 2 to 5% of cases of acute pancreatitis are drug-related (Table 304-1). Drugs cause pancreatitis either by a hypersensitivity reaction or by the generation of a toxic metabolite, although in some cases it is not clear which of these mechanisms is operative.

Autodigestion is one pathogenetic theory, according to which pancreatitis results when proteolytic enzymes (e.g., trypsinogen, chymotrypsinogen, proelastase, and phospholipase A) are activated in the pancreas rather than in the intestinal lumen. A number of factors (e.g., endotoxins, exotoxins, viral infections, ischemia, anoxia, and direct trauma) are believed to activate these proenzymes. Activated proteolytic enzymes, especially trypsin, not only digest pancreatic and peripancreatic tissues but also can activate other enzymes, such as elastase and phospholipase. The active enzymes then digest cellular membranes and cause proteolysis, edema, interstitial hemorrhage, vascular damage, coagulation necrosis, fat necrosis, and parenchymal cell necrosis. Cellular injury and death result in the liberation of activated enzymes. In addition, activation and release of bradykinin peptides and vasoactive substances (e.g., histamine) are believed to produce vasodilation, increased vascular permeability, and edema. Thus, a cascade of events culminates in the development of acute necrotizing pancreatitis.

The autodigestion theory has largely eclipsed two older theories. First, according to the "common channel" theory, the existence of a common anatomic channel for pancreatic secretions and bile permits reflux of bile into the pancreatic duct, which results in activation of pancreatic enzymes. (Actually, a common channel with free communication

between the common bile duct and the main pancreatic duct is infrequently encountered.) The second theory is that obstruction and hypersecretion are pivotal in the development of pancreatitis. Obstruction of the main pancreatic duct, however, produces pancreatic edema but generally not pancreatitis.

A recent hypothesis to explain the intrapancreatic activation of zymogens is that they become activated by *lysosomal hydrolases* in the pancreatic acinar cell itself. In two different types of experimental pancreatitis, it has been demonstrated that digestive enzymes and lysosomal hydrolases become admixed; as a result, the latter can activate the former in the acinar cell. In vitro, lysosomal enzymes such as cathepsin B can activate trypsinogen, and trypsin can activate the other protease precursors. It is still not clear, however, whether the human acinar cell can provide the pH (about 3.0) necessary for activation of trypsinogen by lysosomal hydrolases. It is now believed that ischemia/hypoperfusion can alone result in activation of trypsinogen and pancreatic injury.

CLINICAL FEATURES

Abdominal pain is the major symptom of acute pancreatitis. Pain may vary from a mild and tolerable discomfort to severe, constant, and incapacitating distress. Characteristically, the pain, which is steady and boring in character, is located in the epigastrium and periumbilical region and often radiates to the back as well as to the chest, flanks, and lower abdomen. The pain is frequently more intense when the patient is supine, and patients often obtain relief by sitting with the trunk flexed and knees drawn up. Nausea, vomiting, and abdominal distention due to gastric and intestinal hypomotility and chemical peritonitis are also frequent complaints.

Physical examination frequently reveals a distressed and anxious patient. Low-grade fever, tachycardia, and hypotension are fairly common. Shock is not unusual and may result from (1) hypovolemia secondary to exudation of blood and plasma proteins into the retroperitoneal space (a "retroperitoneal burn"); (2) increased formation and release of kinin peptides, which cause vasodilation and increased vascular permeability; and (3) systemic effects of proteolytic and lipolytic enzymes released into the circulation. Jaundice occurs infrequently; when present, it usually is due to edema of the head of the pancreas with compression of the intrapancreatic portion of the common bile duct. Erythematous skin nodules due to subcutaneous fat necrosis may occur. In 10 to 20% of patients, there are pulmonary findings, including basilar rales, atelectasis, and pleural effusion, the latter most frequently left-sided. Abdominal tenderness and muscle rigidity are present to a variable degree, but, compared with the intense pain, these signs may be unimpressive. Bowel sounds are usually diminished or absent. A pancreatic pseudocyst may be palpable in the upper abdomen. A faint blue discoloration around the umbilicus (Cullen's sign) may occur as the result of hemoperitoneum, and a blue-red-purple or green-brown discoloration of the flanks (Turner's sign) reflects tissue catabolism of hemoglobin. The latter two findings, which are uncommon, indicate the presence of a severe necrotizing pancreatitis.

LABORATORY DATA

The diagnosis of acute pancreatitis is usually established by the detection of an

increased level of serum amylase. Values threefold or more above normal virtually clinch the diagnosis if overt salivary gland disease and gut perforation or infarction are excluded. However, there appears to be no definite correlation between the severity of pancreatitis and the degree of serum amylase elevation. After 48 to 72 h, even with continuing evidence of pancreatitis, total serum amylase values tend to return to normal. However, pancreatic isoamylase and lipase levels may remain elevated for 7 to 14 days. It will be recalled that amylase elevations in serum and urine occur in many conditions other than pancreatitis (seeTable 303-2). Importantly, patients with *acidemia* (arterial pH £7.32) may have spurious elevations in serum amylase. In one study, 12 of 33 patients with acidemia had elevated serum amylase, but only 1 had an elevated lipase value; in 9, salivary-type amylase was the predominant serum isoamylase. This finding explains why patients with diabetic ketoacidosis may have marked elevations in serum amylase without any other evidence of acute pancreatitis. Serum lipase activity increases in parallel with amylase activity, and measurement of both enzymes increases the diagnostic yield. An elevated serum lipase or trypsin value is usually diagnostic of acute pancreatitis; these tests are especially helpful in patients with nonpancreatic causes of hyperamylasemia (seeTable 303-2). Markedly increased levels of peritoneal or pleural fluid amylase [>1500 nmol/L (> 5000 U/dL)] are also helpful, if present, in establishing the diagnosis.

Leukocytosis (15,000 to 20,000 leukocytes per microliter) occurs frequently. Patients with more severe disease may show hemoconcentration with hematocrit values exceeding 50% because of loss of plasma into the retroperitoneal space and peritoneal cavity. *Hyperglycemia* is common and is due to multiple factors, including decreased insulin release, increased glucagon release, and an increased output of adrenal glucocorticoids and catecholamines. *Hypocalcemia* occurs in approximately 25% of patients, and its pathogenesis is incompletely understood. Although earlier studies suggested that the response of the parathyroid gland to a decrease in serum calcium is impaired, subsequent observations have failed to confirm this idea. Intraperitoneal saponification of calcium by fatty acids in areas of fat necrosis occurs occasionally, with large amounts (up to 6.0 g) dissolved or suspended in ascitic fluid. Such "soap formation" also may be significant in patients with pancreatitis, mild hypocalcemia, and little or no obvious ascites. *Hyperbilirubinemia* [serum bilirubin>68 umol/L (> 4.0 mg/dL)] occurs in approximately 10% of patients. However, jaundice is transient, and serum bilirubin levels return to normal in 4 to 7 days. Serum alkaline phosphatase and aspartate aminotransferase (AST) levels are also transiently elevated and parallel serum bilirubin values. Markedly elevated serum lactic dehydrogenase (LDH) levels [>8.5 umol/L (> 500 U/dL)] suggest a poor prognosis. Serum albumin is decreased to £30 g/L (£3.0 g/dL) in about 10% of patients; this sign is associated with more severe pancreatitis and a higher mortality rate (Table 304-2). *Hypertriglyceridemia* occurs in 15 to 20% of patients, and serum amylase levels in these individuals are often spuriously normal (Chap. 303). Most patients with hypertriglyceridemia and pancreatitis, when subsequently examined, show evidence of an underlying derangement in lipid metabolism which probably antedated the pancreatitis (see below). Approximately 25% of patients have *hypoxemia* (arterial P_{O2}£ 60 mmHg), which may herald the onset of adult respiratory distress syndrome. Finally, the electrocardiogram is occasionally abnormal in acute pancreatitis with ST-segment and T-wave abnormalities simulating myocardial ischemia.

Although one or more radiologic abnormalities are found in over 50% of patients, the findings are inconstant and nonspecific. The chief value of conventional x-rays [chest films; kidney, ureter, and bladder (KUB) studies] in acute pancreatitis is to help exclude other diagnoses, especially a perforated viscus. Upper gastrointestinal tract x-rays have been superseded by ultrasonography and computed tomography (CT). A CT scan may confirm the clinical impression of acute pancreatitis even in the face of normal serum amylase levels. Importantly, CT is quite helpful in indicating the severity of acute pancreatitis and the risk of morbidity and mortality (see below). Sonography and radionuclide scanning [*N-p*-isopropylacetanilide-iminodiacetic acid (PIPIDA) scan; hepatic 2,6-dimethyliminodiacetic acid (HIDA) scan] are useful in acute pancreatitis to evaluate the gallbladder and biliary tree.**Radiologic studies useful in the diagnosis of acute pancreatitis are discussed in Chap. 303 and listed in Table 303-1.*

DIAGNOSIS

Any severe acute pain in the abdomen or back should suggest acute pancreatitis. The diagnosis is usually entertained when a patient with a possible predisposition to pancreatitis presents with severe and constant abdominal pain, nausea, emesis, fever, tachycardia, and abnormal findings on abdominal examination. Laboratory studies frequently reveal leukocytosis, an abnormal appearance on x-rays of the abdomen and chest, hypocalcemia, and hyperglycemia. The diagnosis is usually confirmed by the finding of an elevated level of serum amylase and/or lipase. Not all the above features have to be present for the diagnosis to be established.

The *differential diagnosis* should include the following disorders: (1) perforated viscus, especially peptic ulcer; (2) acute cholecystitis and biliary colic; (3) acute intestinal obstruction; (4) mesenteric vascular occlusion; (5) renal colic; (6) myocardial infarction; (7) dissecting aortic aneurysm; (8) connective tissue disorders with vasculitis; (9) pneumonia; and (10) diabetic ketoacidosis. A penetrating duodenal ulcer usually can be identified by upper gastrointestinal x-rays and/or endoscopy. A perforated duodenal ulcer is readily diagnosed by the presence of free intraperitoneal air. It may be difficult to differentiate acute cholecystitis from acute pancreatitis, since an elevated serum amylase may be found in both disorders. Pain of biliary tract origin is more right-sided and gradual in onset, and ileus is usually absent; sonography and radionuclide scanning are helpful in establishing the diagnosis of cholelithiasis and cholecystitis. Intestinal obstruction due to mechanical factors can be differentiated from pancreatitis by the history of colicky pain, findings on abdominal examination, and x-rays of the abdomen showing changes characteristic of mechanical obstruction. Acute mesenteric vascular occlusion is usually evident in elderly debilitated patients with brisk leukocytosis, abdominal distention, and bloody diarrhea, in whom paracentesis shows sanguineous fluid and arteriography shows vascular occlusion. Serum as well as peritoneal fluid amylase levels are increased, however, in patients with intestinal infarction. Systemic lupus erythematosus and polyarteritis nodosa may be confused with pancreatitis, especially since pancreatitis may develop as a complication of these diseases. Diabetic ketoacidosis is often accompanied by abdominal pain and elevated total serum amylase levels, thus closely mimicking acute pancreatitis. However, the serum lipase and pancreatic isoamylase levels are not elevated in diabetic ketoacidosis.

COURSE OF THE DISEASE AND COMPLICATIONS

It is important to identify patients with acute pancreatitis who have an increased risk of dying. Ranson and Imrie have used multiple prognostic criteria and have demonstrated that there is an increased mortality rate when three or more risk factors are identifiable either at the time of admission to the hospital or during the initial 48 h of hospitalization (Table 304-2). Recent studies indicate that obesity is a major risk factor for severe pancreatitis, presumably because the increased deposits of peripancreatic fat in such patients may predispose them to more extensive pancreatic and peripancreatic necrosis. The acute physiology and chronic health evaluation scoring system (APACHE II) uses the worst values of 12 physiologic measurements plus age and previous health status and provides a good description of illness severity for a wide range of common diseases; this score also correlates with outcome. Prospective studies have compared APACHE II with multiple prognostic criteria, i.e., Ranson and Imrie scores, in predicting the severity of acute pancreatitis. On admission, APACHE II identified approximately two-thirds of severe attacks, and after 48 h, the prognostic accuracy of APACHE II is comparable with that of Ranson and Imrie's scoring system. The drawbacks of APACHE II are (1) its complexity, (2) the requirement of a computer for scoring, and (3) standardization regarding peak values and cutoff scores. McMahon and colleagues have shown that the presence of a "toxic broth" or dark (hemorrhagic) fluid in abdominal pancreatitis is also an important prognostic indicator in acute pancreatitis. These multiple-factor scoring systems are difficult to use and have not been embraced consistently by clinicians. There is a great need for a reliable, simple biochemical test that consistently predicts outcome in patients with acute pancreatitis. Three candidate markers that show great promise are C-reactive protein, serum granulocyte elastase, and urinary trypsinogen activation peptide (TAP). The key indicators of a severe attack of acute pancreatitis are also listed inTable 304-2. Importantly, the presence of any one of these factors is associated with an increased risk of complications, and the presence of any two, with a 20 to 30% mortality rate. The high mortality rate of such severely ill patients is due in large part to infection and warrants intensive radiologic intervention and monitoring and/or a combination of radiologic and surgical means, as discussed in detail below.

The local and systemic complications of acute pancreatitis are listed in Table 304-3. In the first 2 to 3 weeks after pancreatitis patients frequently develop an inflammatory mass, which may be due to pancreatic necrosis (with or without infection) or may represent an abscess or pseudocyst (see below). Systemic complications include pulmonary, cardiovascular, hematologic, renal, metabolic, and central nervous system abnormalities. Pancreatitis and hypertriglyceridemia constitute an association in which cause and effect remain incompletely understood. However, several reasonable conclusions can be drawn. First, hypertriglyceridemia can precede and apparently cause pancreatitis. Second, the vast majority (>80%) of patients with acute pancreatitis do not have hypertriglyceridemia. Third, almost all patients with pancreatitis and hypertriglyceridemia have preexisting abnormalities in lipoprotein metabolism. Fourth, many of the patients with this association have persistent hypertriglyceridemia after recovery from pancreatitis and are prone to recurrent episodes of pancreatitis. Fifth, any factor (e.g., drugs or alcohol) that causes an abrupt increase in serum triglycerides to levels greater than 11 mmol/L (1000 mg/dL) can precipitate a bout of pancreatitis that can be associated with significant complications and even become fulminant. To avert the risk of triggering pancreatitis, a fasting serum triglyceride measurement should be

obtained before estrogen replacement therapy is begun in postmenopausal women. Fasting levels less than 300 mg/dL pose no risk, whereas levels greater than 750 mg/dL are associated with a high probability of developing pancreatitis. Finally, patients with a deficiency of apolipoprotein CII have an increased incidence of pancreatitis; apolipoprotein CII activates lipoprotein lipase, which is important in clearing chylomicrons from the bloodstream.

Purtscher's retinopathy, a relatively unusual complication, is manifested by a sudden and severe loss of vision in a patient with acute pancreatitis. It is characterized by a peculiar funduscopic appearance with cotton-wool spots and hemorrhages confined to an area limited by the optic disk and macula; it is believed to be due to occlusion of the posterior retinal artery with aggregated granulocytes.

The two most common causes of acute pancreatitis are alcoholism and biliary tract disease; other causes are listed in Table 304-1. The risk of acute pancreatitis in patients with at least one gallstone smaller than 5 mm in diameter is fourfold greater than that in patients with larger stones. However, after a conventional workup, a specific cause is not identified in about 30% of patients. It is important to note that ultrasound examinations fail to detect gallstones, especially microlithiasis and/or sludge, in 4 to 7% of patients. In one series of 31 patients diagnosed initially as having idiopathic acute pancreatitis, 23 were found to have occult gallstone disease. Thus, approximately two-thirds of patients with recurrent acute pancreatitis without an obvious cause actually have occult gallstone disease due to microlithiasis. Examination of duodenal aspirates in such cases often reveals cholesterol crystals, which confirm the diagnosis. Other diseases of the biliary tree and pancreatic ducts that can cause acute pancreatitis include choledochocele, ampullary tumors, pancreas divisum, and pancreatic duct stones, stricture, and tumor. Approximately 2% of patients with pancreatic carcinoma present with acute pancreatitis.

Pancreatitis in Patients with AIDS The incidence of acute pancreatitis is increased in patients with AIDS for two reasons: (1) the high incidence of infections involving the pancreas, such as infections with cytomegalovirus, *Cryptosporidium*, and the *Mycobacterium avium* complex; and (2) the frequent use by patients with AIDS of medications such as didanosine, pentamidine, and trimethoprim-sulfamethoxazole (Chap. 309).

TREATMENT

In most patients (approximately 85 to 90%) with acute pancreatitis, the disease is self-limited and subsides spontaneously, usually within 3 to 7 days after treatment is instituted. Conventional measures include (1) analgesics for pain, (2) intravenous fluids and colloids to maintain normal intravascular volume, (3) no oral alimentation, and (4) nasogastric suction to decrease gastrin release from the stomach and prevent gastric contents from entering the duodenum. Recent controlled trials, however, have shown that nasogastric suction offers no clear-cut advantages in the treatment of mild to moderately severe acute pancreatitis. Its use, therefore, must be considered elective rather than mandatory.

It has been demonstrated that CCK-stimulated pancreatic secretion is almost abolished

in four different experimental models of acute pancreatitis. This finding probably explains why drugs to block pancreatic secretion in acute pancreatitis have failed to have any therapeutic benefit. For this and other reasons, anticholinergic drugs are not indicated in acute pancreatitis. In addition to nasogastric suction and anticholinergic drugs, other therapies designed to "rest the pancreas" by inhibiting pancreatic secretion have not changed the course of the disease. Although antibiotics have been used in the treatment of acute pancreatitis, randomized, prospective trials have shown no benefit from their use in acute pancreatitis of mild to moderate severity.

However, current experimental evidence favors the use of prophylactic antibiotics in severe acute pancreatitis. Results of four contemporary randomized clinical trials restricted to patients with prognostically severe acute pancreatitis have demonstrated an improved outcome, i.e., reduced rate of infection and/or mortality, associated with the antibiotic treatment. The carbapenem group of antibiotics, including imipenem, has a very broad spectrum including activity against *Pseudomonas*, *Staphylococcus*, and *Enterococcus*; and these agents penetrate well into pancreatic tissue. Furthermore, because secondary infection of necrotic pancreatic tissue (abscess, pseudocyst or obstructed biliary passages, ascending cholangitis complicating choledocholithiasis) contributes to many of the late deaths from pancreatitis, appropriate antibiotic therapy of established infections is quite important.

Several other drugs have been evaluated by prospective controlled trials and found ineffective in the treatment of acute pancreatitis. The list, by no means complete, includes glucagon, H_2blockers, protease inhibitors such as aprotinin, glucocorticoids, calcitonin, nonsteroidal anti-inflammataory drugs (NSAIDs) and lexiplafant, a platelet-activating factor inhibitor. A recent meta-analysis of somatostatin, ocreotide, and the antiprotease gabexate methylate in therapy of acute pancreatitis suggested (1) a reduced mortality rate but no change in complications with octreotide, and (2) no effect on the mortality rate but reduced pancreatic damage with gabexate.

Intraabdominal *Candida* infection during acute necrotizing pancreatitis is increasing in frequency and is associated with an increased mortality rate. In one representatitve trial, intraabdominal *Candida* infection was found in 13 of 37 cases and was associated with a mortality rate fourfold greater than that associated with intraabdominal bacterial infection alone. Given the impact of *Candida* infection on the mortality rate in acute necrotizing pancreatitis and the apparent benefit of prophylactic chemotherapy, these data suggest earlier use of fungicides.

ACT scan, especially a contrast-enhanced dynamic CT (CECT) scan, provides valuable information on the severity and prognosis of acute pancreatitis (Fig. 304-1 andTable 304-4). In particular, a CECT scan allows estimation of the presence and extent of pancreatic necrosis. Recent studies suggest that the likelihood of prolonged pancreatitis or a serious complication is negligible when the CT severity index is 1 or 2 and low with scores of 3 to 6. However, patients with scores of 7 to 10 had a 92% morbidity rate and a 17% mortality rate. Necrosis is present in 20 to 30% of patients. Those with necrosis have a morbidity rate>20%, whereas those without necrosis have a morbidity rate <10% and a negligible mortality rate. A CECT scan is indicated in patients with three or more of Ranson's signs, in all seriously ill patients, and in patients who show evidence of clinical deterioration. The patient with mild to moderate pancreatitis usually requires

treatment with intravenous fluids, fasting, and possibly nasogastric suction for 2 to 4 days. A clear liquid diet is frequently started on the third to sixth day, and a regular diet by the fifth to seventh day. The patient with unremitting *fulminant pancreatitis* usually requires inordinate amounts of fluid and close attention to complications such as cardiovascular collapse, respiratory insufficiency, and pancreatic infection. The latter should be managed by a combination of radiologic and surgical means (see below). While earlier uncontrolled studies suggested that *peritoneal lavage* through a percutaneous dialysis catheter was helpful in severe pancreatitis, subsequent studies indicate that this treatment does not influence the outcome of such attacks. Aggressive surgical pancreatic debridement (necrosectomy) should be undertaken soon after confirmation of the presence of infected necrosis, and multiple operations may be required. Since the mortality rate from sterile acute necrotizing pancreatitis is approximately 10%, laparotomy with adequate drainage and removal of necrotic tissue should be considered if conventional therapy does not halt the patient's deterioration. The use of parenteral nutrition makes it possible to give nutritional support to patients with severe, acute, or protracted pancreatitis who are unable to eat normally. Patients with severe gallstone-induced pancreatitis may improve dramatically if papillotomy is carried out within the first 36 to 72 h of the attack. Studies indicate that only those patients with gallstone pancreatitis who are in the very severe group should be considered for urgent endoscopic retrograde cholangiopancreatography (ERCP). Finally, the treatment for patients with hypertriglyceridemia-associated pancreatitis includes (1) weight loss to ideal weight, (2) a lipid-restricted diet, (3) exercise, (4) avoidance of alcohol and of drugs that can elevate serum triglycerides (i.e., estrogens, vitamin A, thiazides, and beta-blockers), and (5) control of diabetes.

INFECTED PANCREATIC NECROSIS, ABSCESS, AND PSEUDOCYST

Infected pancreatic necrosis should be differentiated from pancreatic abscess. The former is a diffuse infection of an acutely inflamed, necrotic pancreas occurring in the first 1 to 2 weeks after the onset of pancreatitis. In contrast, a pancreatic abscess is an ill-defined, liquid collection of pus that evolves over a longer period, often 4 to 6 weeks. It tends to be less life-threatening and is associated with a lower rate of surgical mortality. Infected pancreatic necrosis should be treated by surgical debridement because the solid component of the infected pancreas is not amenable to effective radiologically guided percutaneous evacuation. Pancreatic abscess can be treated surgically or, in selected cases, by percutaneous drainage. The necrotic pancreas becomes secondarily infected in 40 to 60% of patients, most frequently with gram-negative bacteria of alimentary origin. Whether infection occurs depends on several factors, including the extent of pancreatic and peripancreatic necrosis, the degree of pancreatic ischemia and hypoperfusion, and the presence of organ or multiorgan failure.

The early diagnosis of pancreatic infection can be accomplished byCT-guided needle aspiration. In one study, 60 patients, representing 5% of all admissions for acute pancreatitis, were suspected of harboring a pancreatic infection on the basis of fever, leukocytosis, and an abnormal CT scan (pseudocyst or extrapancreatic fluid collection). Importantly, 60% of these patients had a pancreatic infection, and 55% of these infections developed in the first 2 weeks. These findings suggest that only guided aspiration can reliably distinguish sterile from infected pancreatic necrosis. The following

are guidelines for patients meeting the above selection criteria: (1) Pseudocysts should be aspirated promptly, because more than half may be infected; (2) extrapancreatic fluid collections need not be aspirated promptly, because most are sterile; (3) if a necrotic pancreas is found initially to be sterile but fever and leukocytosis persist, several days of observation should be allowed to pass before reaspiration is considered, as clinical improvement frequently occurs; and (4) if fever and leukocytosis recur after an interval of well-being, reaspiration should be considered.

Severe pancreatitis with the presence of three or more risk factors, postoperative pancreatitis, early oral feeding, early laparotomy, and perhaps injudicious use of antibiotics predispose to the development of pancreatic abscess, which occurs in 3 to 4% of patients with acute pancreatitis. Pancreatic abscess also may develop because of a communication between a pseudocyst and the colon, inadequate surgical drainage of a pseudocyst, or needling of a pseudocyst. The characteristic signs of abscess are fever, leukocytosis, ileus, and rapid deterioration in a patient previously recovering from pancreatitis. Sometimes, however, the only manifestations are persistent fever and signs of continuing pancreatic inflammation. Drainage of pancreatic abscesses by percutaneous catheter techniques, usingCTguidance, has been only moderately successful (resolution in 50 to 60% of patients). Accordingly, laparotomy with radical sump drainage and possibly resection of necrotic tissue is usually required, because the mortality rate for undrained pancreatic abscess approaches 100%. Multiple abscesses are common, and reoperation is frequently necessary.

Pseudocysts of the pancreas are collections of tissue, fluid, debris, pancreatic enzymes, and blood which develop over a period of 1 to 4 weeks after the onset of acute pancreatitis; they form in approximately 15% of patients with acute pancreatitis. In contrast to true cysts, pseudocysts do not have an epithelial lining; their walls consist of necrotic tissue, granulation tissue, and fibrous tissue. Disruption of the pancreatic ductal system is common. However, the subsequent course of this disruption varies widely, ranging from spontaneous healing to continuous leakage of pancreatic juice, which results in tense ascites. Pseudocysts are preceded by pancreatitis in 90% of cases and by trauma in 10%. Approximately 85% are located in the body or tail of the pancreas and 15% in the head. Some patients have two or more pseudocysts. Abdominal pain, with or without radiation to the back, is the usual presenting complaint. A palpable, tender mass may be found in the middle or left upper abdomen. The serum amylase level is elevated in 75% of patients at some point during their illness and may fluctuate markedly.

On x-ray examination, 75% of pseudocysts can be seen to displace some portion of the gastrointestinal tract (Fig. 304-2). Sonography, however, is reliable in detecting pseudocysts. Sonography also permits differentiation between an edematous, inflamed pancreas, which can give rise to a palpable mass, and an actual pseudocyst. Furthermore, serial ultrasound studies will indicate whether a pseudocyst has resolved.CTcomplements ultrasonography in the diagnosis of pancreatic pseudocyst (Fig. 304-2), especially when the pseudocyst is infected.

In studies with sonography, pseudocysts were seen to resolve in 25 to 40% of patients. Pseudocysts that are greater than 5 cm in diameter and that persist for longer than 6 weeks should be considered for drainage. Recent natural history studies have

suggested that noninterventional, expectant management is the best course in selected patients with minimal symptoms and no evidence of active alcohol use in whom the pseudocyst appears mature by radiography and does not resemble a cystic neoplasm. A significant number of these pseudocysts resolve spontaneously more than 6 weeks after their formation. Also, these studies demonstrate that large pseudocyst size is not an absolute indication for interventional therapy and that many peripancreatic fluid collections detected onCT in cases of acute pancreatitis resolve spontaneously. A pseudocyst that does not resolve spontaneously may lead to serious complications, such as (1) pain caused by expansion of the lesion and pressure on other viscera, (2) rupture, (3) hemorrhage, and (4) abscess. Rupture of a pancreatic pseudocyst is a particularly serious complication. Shock almost always supervenes, and mortality rates range from 14% if the rupture is not associated with hemorrhage to over 60% if hemorrhage has occurred. Rupture and hemorrhage are the prime causes of death from pancreatic pseudocyst. A triad of findings -- an increase in the size of the mass, a localized bruit over the mass, and a sudden decrease in hemoglobin level and hematocrit without obvious external blood loss -- should alert one to the possibility of hemorrhage from a pseudocyst. Thus, in patients who are stable and free of complications and in whom serial ultrasound studies show that the pseudocyst is shrinking, conservative therapy is indicated. Conversely, if the pseudocyst is expanding and is complicated by rupture, hemorrhage, or abscess, the patient should be operated on. With ultrasound or CT guidance, sterile chronic pseudocysts can be treated safely with single or repeated needle aspiration or more prolonged catheter drainage with a success rate of 45 to 75%. The success rate of these techniques for infected pseudocysts is considerably less (40 to 50%). Patients who do not respond to drainage require surgical therapy for internal or external drainage of the cyst.

Pseudoaneurysms develop in up to 10% of patients with acute pancreatitis at sites reflecting the distribution of pseudocysts and fluid collections (Fig. 304-2*D*). The splenic artery is most frequently involved, followed by the inferior and superior pancreatic duodenal arteries. This diagnosis should be suspected in patients with pancreatitis who develop upper gastrointestinal bleeding without an obvious cause or in whom thin-cutCTscanning reveals a contrast-enhanced lesion within or adjacent to a suspected pseudocyst. Arteriography is necessary to confirm the diagnosis.

PANCREATIC ASCITES AND PANCREATIC PLEURAL EFFUSIONS

Pancreatic ascites is usually due to disruption of the main pancreatic duct, often by an internal fistula between the duct and the peritoneal cavity or a leaking pseudocyst (Chap. 43). This diagnosis is suggested in a patient with an elevated serum amylase level in whom the ascites fluid has both increased levels of albumin [>30 g/L (>3.0 g/dL)] and a markedly elevated level of amylase. The fluid in true pancreatic ascites usually has an amylase concentration of >20,000 U/L as a result of the ruptured duct or leaking pseudocyst. Lower amylase elevations may be found in the peritoneal fluid of patients with acute pancreatitis. In addition,ERCPoften demonstrates passage of contrast material from a major pancreatic duct or a pseudocyst into the peritoneal cavity. As many as 15% of patients with pseudocysts have concurrent pancreatic ascites. The differential diagnosis should include intraperitoneal carcinomatosis, tuberculous peritonitis, constrictive pericarditis, and Budd-Chiari syndrome.

If the pancreatic duct disruption is posterior, an internal fistula may develop between the pancreatic duct and the pleural space, producing a pleural effusion, which is usually left-sided and often massive. This complication often requires thoracentesis or chest tube drainage.

Treatment usually requires the use of nasogastric suction and parenteral alimentation to decrease pancreatic secretion. In addition, paracentesis is performed to keep the peritoneal cavity free of fluid and, it is hoped, to effect sealing of the leak. The long-acting somatostatin analogue octreotide, which inhibits pancreatic secretion, is useful in cases of pancreatic ascites and pleural effusion. If ascites continues to recur after 2 to 3 weeks of medical management, the patient should be operated on after pancreatography to define the anatomy of the abnormal duct. A disrupted main pancreatic duct can also be treated effectively by stenting. Patients in whomERCPidentifies two or more sites of extravasation are unlikely to respond to conservative management and/or stenting.

CHRONIC PANCREATITIS AND PANCREATIC EXOCRINE INSUFFICIENCY

GENERAL AND ETIOLOGIC CONSIDERATIONS

Chronic inflammatory disease of the pancreas may present as episodes of acute inflammation in a previously injured pancreas or as chronic damage with persistent pain or malabsorption. The causes of relapsing chronic pancreatitis are similar to those of acute pancreatitis (Table 304-1), except that there is an appreciable incidence of cases of undetermined origin. In addition, the pancreatitis associated with gallstones is predominantly acute or relapsing-acute in nature. A cholecystectomy is almost always performed in patients after the first or second attack of gallstone-associated pancreatitis. Patients with chronic pancreatitis may present with persistent abdominal pain, with or without steatorrhea; some (~15%) present with steatorrhea and no pain.

Patients with chronic pancreatitis in whom there is extensive destruction of the pancreas (less than 10% of exocrine function remaining) have steatorrhea and azotorrhea. Among American adults, alcoholism is the most common cause of clinically apparent pancreatic exocrine insufficiency, while cystic fibrosis is the most frequent cause in children. In up to 25% of American adults with chronic pancreatitis, the cause is not known; that is, they have idiopathic chronic pancreatitis. Mutations of the cystic fibrosis transmembrane conductance regulator (CFTR) gene have been documented in patients with idiopathic chronic pancreatitis. It has been estimated that in patients with idiopathic pancreatitis the frequency of a single CFTR mutation is 11 times the expected frequency and the frequency of two mutant alleles is 80 times the expected frequency. The results of sweat chloride testing are not diagnostic of cystic fibrosis in these patients. However, these patients have functional evidence of a defect in CFTR-mediated ion transport in nasal epithelium. It is suggested that up to 25% of patients with idiopathic chronic pancreatitis may have abnormalities of the CFTR gene. The therapeutic and prognostic implication of these findings remain to be determined. In other parts of the world, severe protein-calorie malnutrition is a common cause.Table 304-5 lists other causes of pancreatic exocrine insufficiency, but they are relatively uncommon.

PATHOPHYSIOLOGY

The events that initiate an inflammatory process in the pancreas are still not well understood, and the many hypotheses will not be reviewed here. In the case of alcohol-induced pancreatitis, it has been suggested that the primary defect may be the precipitation of protein (inspissated enzymes) in the ducts. The resulting ductal obstruction could lead to duct dilation, diffuse atrophy of the acinar cells, fibrosis, and eventual calcification of some of the protein plugs. However, the fact that some alcoholic patients with recurrent acute pancreatitis show no evidence of chronic pancreatitis does not support this hypothesis. In fact, experimental and clinical observations have shown that alcohol has direct toxic effects on the pancreas. While patients with alcohol-induced pancreatitis generally consume large amounts of alcohol, some consume very little (50 g/d or less). Thus prolonged consumption of "socially acceptable" amounts of alcohol is compatible with the development of pancreatitis. In addition, the finding of extensive pancreatic fibrosis in patients who died during their first attack of clinical acute alcohol-induced pancreatitis supports the concept that such patients already have chronic pancreatitis.

CLINICAL FEATURES

Patients with relapsing chronic pancreatitis may present with symptoms identical to those of acute pancreatitis, but pain may be continuous, intermittent, or absent. The pathogenesis of this pain is poorly understood. Although the classic description is of epigastric pain radiating through the back, the pain pattern is often atypical; the pain may be worst in the right or left upper quadrant of the back or may be diffuse throughout the upper abdomen; it may even be referred to the anterior chest or flank. Characteristically it is persistent, deep-seated, and unresponsive to antacids. It often is worsened by ingestion of alcohol or a heavy meal (especially one rich in fat). Often the pain is severe enough to necessitate the frequent use of narcotics.

Weight loss, abnormal stools, and other signs or symptoms suggestive of malabsorption (seeTable 286-5) are common in chronic pancreatitis. However, clinically apparent deficiencies of fat-soluble vitamins are surprisingly rare. The physical findings in these patients are usually not impressive, so that there is a disparity between the severity of the abdominal pain and the physical signs (other than some abdominal tenderness and mild temperature elevation).

DIAGNOSTIC EVALUATION (See also Chap. 303)

In contrast to relapsing acute pancreatitis, the serum amylase and lipase levels are usually not elevated in chronic pancreatitis. Elevations of serum bilirubin and alkaline phosphatase levels may indicate cholestasis secondary to chronic inflammation around the common bile duct (Fig. 304-3). Many patients demonstrate impaired glucose tolerance, and some have an elevated fasting blood glucose level.

The classic triad of pancreatic calcification, steatorrhea, and diabetes mellitus usually establishes the diagnosis of chronic pancreatitis and exocrine pancreatic insufficiency but is found in less than one-third of chronic pancreatitis patients. Accordingly, it is often necessary to perform an intubation test such as the *secretin stimulation test*, which

usually gives abnormal results when 60% or more of pancreatic exocrine function has been lost. Approximately 40% of patients with chronic pancreatitis have *cobalamin* (*vitamin B_{12}*) malabsorption, which can be corrected by the administration of oral pancreatic enzymes. There is usually a marked excretion of fecal fat (Chap. 286), which can be reduced by the administration of oral pancreatic enzymes. The serum trypsinogen (Chap. 303) and the D-xylose urinary excretion test are useful in patients with "pancreatic steatorrhea," since the trypsinogen level will be abnormal, and D-xylose excretion usually is normal. A decreased serum trypsinogen level strongly suggests severe pancreatic exocrine insufficiency.

The radiographic hallmark of chronic pancreatitis is the presence of scattered calcification throughout the pancreas (Fig. 304-3). Diffuse pancreatic calcification indicates that significant damage has occurred and obviates the need for a secretin test. While alcohol is by far the most common cause, pancreatic calcification also may be seen in cases of severe protein-calorie malnutrition, hereditary pancreatitis, posttraumatic pancreatitis, hyperparathyroidism, islet cell tumors, and idiopathic chronic pancreatitis. A large prospective study has shown convincingly that pancreatic calcification decreases or even disappears spontaneously in one-third of patients with severe chronic pancreatitis; this outcome may also follow ductal decompression. Pancreatic calcification is a dynamic process that is incompletely understood.

Sonography,CT, andERCPgreatly aid the diagnosis of pancreatic disease. In addition to excluding pseudocysts and pancreatic cancer, sonography and CT may show calcification or dilated ducts associated with chronic pancreatitis (Fig. 304-4). ERCP is the only major technique that provides a direct view of the pancreatic duct. In patients with alcohol-induced pancreatitis, ERCP may reveal a pseudocyst missed by sonography or CT.

COMPLICATIONS OF CHRONIC PANCREATITIS

The complications of chronic pancreatitis are protean. *Cobalamin* (*vitamin B_{12}*) malabsorption occurs in 40% of patients with alcohol-induced chronic pancreatitis and in virtually all with cystic fibrosis. It is consistently corrected by the administration of pancreatic enzymes (containing proteases). It may be due to excessive binding of cobalamin by cobalamin-binding proteins other than intrinsic factor, which ordinarily are destroyed by pancreatic proteases and therefore do not compete with intrinsic factor for cobalamin binding. Although most patients show *impaired glucose tolerance*, diabetic ketoacidosis and coma are uncommon. Similarly, end-organ damage (retinopathy, neuropathy, nephropathy) is also uncommon, and the appearance of these complications should raise the question of concomitant genetic diabetes mellitus. A nondiabetic retinopathy, peripheral in location and secondary to vitamin A and/or zinc deficiency, is common in these patients. *Effusions* containing high concentrations of amylase may occur into the pleural, pericardial, or peritoneal space. *Gastrointestinal bleeding* may occur from peptic ulceration, gastritis, a pseudocyst eroding into the duodenum, or ruptured varices secondary to splenic vein thrombosis due to inflammation of the tail of the pancreas. *Icterus* may occur, caused either by edema of the head of the pancreas, which compresses the common bile duct, or by chronic cholestasis secondary to a chronic inflammatory reaction around the intrapancreatic portion of the common bile duct (Fig. 304-3). The chronic obstruction may lead to

cholangitis and ultimately to biliary cirrhosis. *Subcutaneous fat necrosis* may appear as tender red nodules on the lower extremities. *Bone pain* may be secondary to intramedullary fat necrosis. Inflammation of the large and small joints of the upper and lower extremities may occur. The incidence of pancreatic carcinoma is increased in patients with chronic pancreatitis who have been followed for 2 or more years. Twenty years after the diagnosis of chronic pancreatitis, the cumulative risk of pancreatic carcinoma is 4%. Perhaps the most common and troublesome complication is addiction to narcotics.

TREATMENT

Therapy for patients with chronic pancreatitis is directed toward two major problems -- pain and malabsorption. Patients with intermittent attacks of pain are treated essentially like those with acute pancreatitis (see above). Patients with severe and persistent pain should avoid alcohol completely and avoid large meals rich in fat. Since the pain is often severe enough to require frequent use of narcotics (and hence addiction), a number of surgical procedures have been developed for pain relief.ERCPallows the surgeon to plan the operative approach. If there is a stricture of the pancreatic duct, a *local resection* may ameliorate the pain. Unfortunately, isolated localized strictures are not common. In most patients with alcohol-induced disease, the pancreas is diffusely involved, and surgically correctible localized ductal disease is rare. When there is primary ductal obstruction and dilation, ductal decompression may provide effective pain palliation. Short-term pain relief may be achieved in up to 80% of patients, while long-term pain relief occurs in approximately 50%. In some of these patients, however, pain relief can be achieved only by resecting 50 to 95% of the gland. Although pain relief is achieved in three-quarters of these patients, they tend to develop pancreatic endocrine and exocrine insufficiency and must be treated with pancreatic enzyme replacement therapy. It is important to screen patients carefully, for such radical surgery is contraindicated in those who are severely depressed or suicidal or who continue to drink. Procedures such as splanchnicectomy, celiac ganglionectomy, and nerve blocks usually bring only temporary relief and are not recommended. Endoscopic treatment of chronic pancreatitis may involve sphincterotomy of the minor or major pancreatic sphincter, dilatation of strictures, removal of calculi, or stenting of the ventral or dorsal pancreatic duct. Although many of these techniques are technically impressive, none has been subjected to a randomized trial in patients with chronic pancreatitis. In addition, significant complications -- acute pancreatitis, pancreatic abscess, damage to the pancreatic duct, and death -- have occurred in up to 36% of patients after stent placement.

Three double-blind trials have demonstrated that administration of pancreatic enzymes decreases abdominal pain in selected patients with chronic pancreatitis. In these trials, approximately 75% of the patients evaluated experienced pain relief. The patients most likely to respond are those with mild to moderate exocrine pancreatic dysfunction, as evidenced by an abnormal secretin test, normal fat absorption, and minimal abnormalities onERCPexamination. These clinical observations seem to fit with data from human beings and experimental animals demonstrating a negative feedback regulation for pancreatic exocrine secretion controlled by the amount of proteases within the lumen of the proximal small intestine. It seems reasonable to use the following approach for patients with severe, persistent, or continuous abdominal pain thought to

be caused by chronic pancreatitis. After other causes of abdominal pain (peptic ulcer, gallstones, etc.) have been excluded, a pancreatic *sonogram* should be done. If no mass is found, a *secretin test* may be performed, because its results usually are abnormal in cases of chronic pancreatitis with pain. If the results are abnormal (i.e., decreased bicarbonate concentration or volume output), a 3- to 4-week *trial of pancreatic enzyme administration* is appropriate. Eight conventional tablets or capsules are taken at meals and at bedtime. There are a number of studies suggesting that patients may have small-duct chronic pancreatitis and chronic abdominal pain with a normal appearance on radiographic evaluations (ultrasound,CT, ERCP) but abnormal results on hormone stimulation tests (secretin test) and/or abnormal pancreatic histology. Such minimal-change chronic pancreatitis may respond well to pancreatic enzyme therapy (non-enteric-coated) for relief of abdominal pain. If no relief is obtained, and especially if the volume secreted during the secretin test is very low, ERCP should be performed. If a pseudocyst or a localized ductal obstruction is found, surgery should be considered. A patient who has dilated ducts may be a candidate for a surgical ductal decompression procedure. This procedure provides short-term relief in up to 80% of patients, although long-term results are closer to 50%. Some studies have shown octreotide to be effective in decreasing abdominal pain in patients with severe large-duct disease. If no surgically remediable lesion is found and severe pain continues despite abstinence from alcohol, subtotal pancreatic resection may be necessary.

The treatment of malabsorption rests on the use of pancreatic enzyme replacement therapy. Diarrhea and steatorrhea are usually improved by this treatment, although the steatorrhea may not be completely corrected. The major problem is delivering enough active enzyme into the duodenum. Steatorrhea could be abolished if 10% of the normal amount of lipase could be delivered to the duodenum at the proper time. This concentration of lipase cannot be achieved with the current preparations of pancreatic enzymes, even if the latter are given in large doses. The reason for these poor results may be that lipase is inactivated by gastric acid, that food empties from the stomach faster than do the pancreatic enzymes, and that batches of commercially available pancreatic extracts vary in enzyme activity.

For the usual patient, two or three enteric-coated capsules or eight conventional (non-enteric-coated) tablets of a potent enzyme preparation should be administered with meals. Some patients using conventional tablets require adjuvant therapy to improve enzyme replacement treatment. H_2receptor antagonists, sodium bicarbonate, and proton pump inhibitors are effective adjuvants. Antacids containing calcium carbonate or magnesium hydroxide are not effective and may actually result in increased steatorrhea. Several publications have reported colonic strictures in patients with cystic fibrosis receiving extraordinarily high doses of high-potency pancreatic enzyme preparations. Such lesions have not been reported in adults with chronic pancreatitis.

Supportive measures include diet restriction and pain medications. The diet should be moderate in fat (30%), high in protein (24%), and low in carbohydrate (40%). Restriction of long-chain triglyceride intake can help patients who do not respond satisfactorily to pancreatic enzyme therapy. Use of foods containing mainly medium-chain fatty acids, which do not require lipase for digestion, may be beneficial. Nonnarcotic analgesics should be emphasized. Patients taking narcotic drugs for pain relief often become addicted and continue to have pain.

Patients with severe exocrine pancreatic insufficiency secondary to alcohol who continue to drink have a high mortality rate (in one series, 50% of patients who were followed for 5 to 12 years died during this period) and significant morbidity (weight loss, lassitude, vitamin deficiency, and narcotic addiction). Chronic pancreatitis carries significant medical and social costs. A recent study found that pancreatitis led to retirement in 11% of patients with the disease, accounting for 45% of all retirements. In 87% of patients with chronic pancreatitis unable to maintain gainful employment, alcoholism was a contributing factor. Patients with chronic pancreatitis also use substantial medical resources. In 1987 in the United States, this diagnosis accounted for 122,000 recorded outpatient visits and 56,000 hospital admissions. Pain may abate if progressive severe exocrine insufficiency continues. Patients who abstain from alcohol and use vigorous replacement therapy for maldigestion-malabsorption do reasonably well.

HEREDITARY PANCREATITIS

Hereditary pancreatitis is a rare disease that is similar to chronic pancreatitis except for an early age of onset and evidence of hereditary factors (involving an autosomal dominant gene with incomplete penetrance). A genome-wide search using genetic linkage analysis identified the hereditary pancreatitis gene on chromosome 7. An R117H mutation in the cationic trypsinogen gene occurs in most of the families with hereditary pancreatitis that have been studied. Molecular modeling predicts the formation of hydrolysis-resistant trypsin that could lead to pancreatic autodigestion. These patients have recurring attacks of severe abdominal pain which may last from a few days to a few weeks. The serum amylase and lipase levels may be elevated during acute attacks but usually are normal. Patients frequently develop pancreatic calcification, diabetes mellitus, and steatorrhea, and, in addition, they have an increased incidence of pancreatic carcinoma. Such patients often require ductal decompression for pain relief. Abdominal complaints in relatives of patients with hereditary pancreatitis should raise the question of pancreatic disease.

PANCREATIC ENDOCRINE TUMORS

**Pancreatic endocrine tumors are summarized in Table 304-6 and are discussed in Chap. 93.*

OTHER CONDITIONS

ANNULAR PANCREAS

When the ventral pancreatic anlage fails to migrate correctly to make contact with the dorsal anlage, the result may be a ring of pancreatic tissue encircling the duodenum. Such an annular pancreas may cause intestinal obstruction in the neonate or the adult. Symptoms of postprandial fullness, epigastric pain, nausea, and vomiting may be present for years before the diagnosis is entertained. The radiographic findings are symmetric dilation of the proximal duodenum with bulging of the recesses on either side of the annular band, effacement but not destruction of the duodenal mucosa, accentuation of the findings in the right anterior oblique position, and lack of change on

repeated examinations. The differential diagnosis should include duodenal webs, tumors of the pancreas or duodenum, postbulbar peptic ulcer, regional enteritis, and adhesions. Patients with annular pancreas have an increased incidence of pancreatitis and peptic ulcer. Because of these and other potential complications, the treatment is surgical even if the condition has been present for years. Retrocolic duodenojejunostomy is the procedure of choice, although some surgeons advocate Billroth II gastrectomy, gastroenterostomy, and vagotomy.

PANCREAS DIVISUM

Pancreas divisum occurs when the embryologic ventral and dorsal pancreatic anlagen fail to fuse, so that pancreatic drainage is accomplished mainly through the accessory papilla. Pancreas divisum is the most common congenital anatomic variant of the human pancreas. Current evidence indicates that this anomaly does not predispose to the development of pancreatitis in the great majority of patients who harbor it. However, the combination of pancreas divisum and a small accessory orifice could result in dorsal duct obstruction. The challenge is to identify this subset of patients with dorsal duct pathology. Cannulation of the dorsal duct byERCP is not as easily done as is cannulation of the ventral duct. Patients with pancreatitis and pancreas divisum demonstrated by ERCP should be treated with conservative measures. In many of these patients, pancreatitis is idiopathic and unrelated to the pancreas divisum. Endoscopic or surgical intervention is indicated only when the above methods fail. If marked dilation of the dorsal duct can be demonstrated, surgical ductal decompression should be performed. The appropriate therapy for patients without dilation of the dorsal duct is not yet defined. It should be stressed that the ERCP appearance of pancreas divisum -- i.e., a small-caliber ventral duct with an arborizing pattern -- may be mistaken as representing an obstructed main pancreatic duct secondary to a mass lesion.

MACROAMYLASEMIA

In macroamylasemia, amylase circulates in the blood in a polymer form too large to be easily excreted by the kidney. Patients with this condition demonstrate an elevated serum amylase value, a low urinary amylase value, and a C_{am}/C_{cr} ratio of less than 1%. The presence of macroamylase can be documented by chromatography of the serum. The prevalence of macroamylasemia is 1.5% of the nonalcoholic general adult hospital population. Usually macroamylasemia is an incidental finding and is not related to disease of the pancreas or other organs.

Macrolipasemia has now been documented in a few patients with cirrhosis or non-Hodgkin's lymphoma. In these patients, the pancreas appeared normal on ultrasound andCTexamination. Lipase was shown to be complexed with immunoglobulin A. Thus, the possibility of *both* macroamylasemia and macrolipasemia should be considered in patients with elevated blood levels of these enzymes.

ACKNOWLEDGEMENT

This chapter represents a revised version of a chapter by Dr. Norton J. Greenberger, Dr. Phillip P. Toskes, and Dr. Kurt J. Isselbacher that was in the previous editions of this textbook.

PART TWELVE -DISORDERS OF THE IMMUNE SYSTEM, CONNECTIVE TISSUE, AND JOINTS

SECTION 1 - DISORDERS OF THE IMMUNE SYSTEM

305. INTRODUCTION TO THE IMMUNE SYSTEM - *Barton F. Haynes*, *Anthony S. Fauci*

DEFINITIONS

·*Adaptive immune system* -- recently evolved system of immune responses mediated by T and B lymphocytes. Immune responses by these cells are based on specific antigen recognition by clonotypic receptors that are products of genes that rearrange during development and throughout the life of the organism. Additional cells of the adaptive immune system include various types of antigen-presenting cells.

· *Antibody* -- B cell-produced molecules encoded by genes that rearrange during B cell development consisting of immunoglobulin heavy and light chains that together form the central component of the B cell receptor for antigen. Antibody can exist as B cell surface antigen-recognition molecules or as secreted molecules in plasma and other body fluids.

· *Antigens* -- foreign or self molecules that are recognized by the adaptive and innate immune systems resulting in innate immune cell triggering, T cell activation, and/or B cell antibody production.

· *Antimicrobial peptides* -- small peptides<100 amine acids in length that are produced by cells of the innate immune system and have anti-infectious agent activity.

· *B lymphocytes* -- bone marrow-derived or bursal-equivalent lymphocytes that express surface immunoglobulin (the B cell receptor for antigen) and secrete specific antibody after interaction with antigen.

· *B cell receptor for antigen* -- complex of surface molecules that rearrange during postnatal B cell development, made up of surface immunoglobulin (Ig) and associated Ig ab chain molecules that recognize nominal antigen via Ig heavy and light chain variable regions, and signal the B cell to terminally differentiate to make antigen-specific antibody.

· *Complement* -- cascading series of plasma enzymes and effector proteins whose function is to lyse pathogens and/or target them to be phagocytized by neutrophils and monocyte/macrophage lineage cells of the reticuloendothelial system.

· *Co-stimulatory molecules* -- molecules of antigen-presenting cells (such as B7-1 and B7-2 or CD40) that lead to T cell activation when ligated by ligands on activated T cells (such as CD28 or CD40 ligand).

· *Cytokines* -- soluble proteins that interact with specific cellular receptors that are involved in the regulation of the growth and activation of immune cells and mediate

normal and pathologic inflammatory and immune responses.

· *Dendritic cells* -- myeloid and/or lymphoid lineage antigen-presenting cells of the adaptive immune system. Immature dendritic cells, or dendritic cell precursors, are key components of the innate immune system by responding to infections with production of high levels of cytokines. Dendritic cells are key initiators both of innate immune responses via cytokine production and of adaptive immune responses via presentation of antigen to T lymphocytes.

· *Innate immune system* -- ancient immune recognition system of host cells bearing germline encoded pattern recognition receptors (PRRs) that recognize pathogens and trigger a variety of mechanisms of pathogen elimination. Cells of the innate immune system include natural killer (NK) cell lymphocytes, monocytes/macrophages, immature or dendritic cell precursors, neutrophils, basophils, eosinophils, tissue mast cells, and epithelial cells.

· *Large granular lymphocytes* -- lymphocytes of the innate immune system with azurophilic cytotoxic granules that haveNK cell activity capable of killing foreign and host cells with little or no self major histocompatibility complex (MHC) class I molecules.

· *Natural killer cells* -- large granular lymphocytes that kill target cells that express little or no HLA class I molecules, such as malignantly transformed cells and virally infected cells. NK cells express receptors that inhibit killer cell function when self MHC class I is present.

· *Pathogen-associated molecular patterns* -- Invariant molecular structures expressed by large groups of microorganisms that are recognized by host cellularPRRs in the mediation of innate immunity.

· *Pattern recognition receptors* -- germline-encoded receptors expressed by cells of the innate immune system that recognize pathogen-associated molecular patterns (PAMPs).

· *T cells* -- thymus-derived lymphocytes that mediate adaptive cellular immune responses including T helper and cytotoxic T lymphocyte effector cell functions.

· *T cell receptor for antigen* -- complex of surface molecules that rearrange during postnatal T cell development made up of clonotypic T cell receptor (TCR) a andb chains that are associated with the CD3 complex composed of invariant g, d,e, z, andh chains. The clonotypic TCRa and b chains recognize peptide fragments of protein antigen physically bound in antigen-presenting cell MHC class I or II molecules, leading to signaling via the CD3 complex to mediate effector functions.

· *Tolerance* -- recognition of foreign or self antigens by B and T lymphocytes in the absence of expression of antigen-presenting cell co-stimulatory molecules that leads to B and T cell nonresponsiveness to antigens. Active T lymphocyte tolerance can be achieved through blockade of the B7/CD28 co-stimulatory pathway.

INTRODUCTION

The human immune system has evolved over millions of years from both invertebrate and vertebrate organisms to develop sophisticated defense mechanisms highly specific for invading pathogens. Immune systems evolved to protect the host from microbes and their virulence factors. From invertebrates, humans have inherited the innate immune system, an ancient defense system that uses germ line-encoded proteins to recognize pathogens. Cells of the innate immune system, such as macrophages andNKlymphocytes, recognize pathogen molecular motifs that are highly conserved among many microbes (PAMPs) and use a diverse set of receptor molecules (PRRs). Important components of the recognition of microbes by the innate immune system are: (1) recognition by germ line-encoded host molecules, (2) recognition of key microbe virulence factors but not recognition of self molecules, and (3) nonrecognition of benign foreign molecules or microbes. It is particularly important for the innate immune system to not recognize foreign nonpathogenic molecules that are common in the environment, since reaction against them would cause continuous inflammatory disease. Upon contact with pathogens, macrophages and NK cells may kill pathogens directly or may activate a series of events that both slows the infection and recruits the more recently evolved arm of the human immune system, the adaptive immune system.

Adaptive immunity is found only in vertebrates and is based on the generation of antigen receptor T and B lymphocytes by germ-line gene rearrangements that occur during the development of each person. By a complex series of molecular mechanisms of gene rearrangement, individual T or B cells express unique antigen receptors on their surface, such that taken together the pools of adult human T and B lymphocytes contain cells capable of specifically recognizing the diverse antigens of the myriad of infectious agents in the environment. Coupled with finely tuned specific recognition mechanisms that maintain tolerance to self antigen, T and B lymphocytes of the adaptive immune system with their postnatally rearranged clonotypic antigen receptors bring both *specificity* and *immune memory* to vertebrate host defenses.

This chapter describes the cellular components, molecules, and mechanisms that make up the innate and adaptive immune systems and describes how adaptive immunity is recruited to the defense of the host by innate immune responses. An appreciation of the cellular and molecular bases of innate and adaptive immune responses is critical to understanding the pathogenesis of inflammatory, autoimmune, infectious, and immunodeficiency diseases.

THE CD CLASSIFICATION OF HUMAN LYMPHOCYTE DIFFERENTIATION ANTIGENS

The development of monoclonal antibody technology led to the discovery of a large number of new leukocyte surface molecules. In 1982, the First International Workshop on Leukocyte Differentiation Antigens was held to establish a nomenclature for cell-surface molecules of human leukocytes. From this and subsequent leukocyte differentiation workshops has come the cluster of differentiation (CD) classification of leukocyte antigens (Table 305-1). The data presented inTable 305-1 establish a context to facilitate discussion and study of the complex series of events that transpire during normal and aberrant innate and adaptive human immune responses.

THE INNATE IMMUNE SYSTEM

All multicellular organisms, including humans, have developed the use of a limited number of germ line-encoded molecules that recognize large groups of pathogens. Because of the myriad human pathogens, host molecules of the human innate immune system must recognizePAMPs, the common molecular structures shared by many pathogens. PAMPs must be conserved structures vital to pathogen virulence and survival, such as bacterial endotoxin, so that pathogens cannot mutate molecules of PAMPs to evade human innate immune responses. In addition, one major end product of innate immunity is the destruction of the invading pathogen, thus necessitating that PAMPs recognized by innate immune responses be completely distinct from self molecules.PPRs are host proteins of the innate immune system that recognize PAMPs and are human molecules whose ancestors are evolutionarily ancient (Tables 305-2,305-3). Thus, recognition of pathogen molecules by hematopoietic and nonhematopoietic cell types leads to activation/production of the complement cascade, cytokines, and antimicrobial peptides as effector molecules.

PATTERN RECOGNITION

MajorPRRfamilies of proteins include C-type lectins, leucine-rich proteins, macrophage scavenger receptor proteins, plasma pentraxins, lipid transferase, and integrins (Table 305-3). A major group of PRR collagenous glycoproteins with C-type lectin domains are termed *collectins* and include the serum protein, mannose-binding lectin. Mannose-binding lectin and other collectins, as well as two other protein families -- the pentraxins (such as C-reactive protein and serum amyloid P) and macrophage scavenger receptors -- all have the property of opsonizing (coating) bacteria for phagocytosis by macrophages and can also activate the complement cascade to lyse bacteria. Integrins are cell-surface adhesion molecules that signal cells after cells bind bacterial lipopolysacchride (LPS) and activate phagocytic cells to ingest pathogens.

A remarkable series of recent discoveries has revealed the mechanisms of connection between the innate and adaptive immune systems; these include (1) the plasma protein,LPS-binding protein, which binds and transfers LPS to the macrophage LPS receptor, CD14; and (2) a human family of proteins called *Toll proteins*, which are associated with CD14, bind LPS, and signal the macrophage to produce cytokines and upregulate cell-surface molecules that signal the initiation of adaptive immune responses (Fig. 305-1,Table 305-3, andTable 305-4). Proteins in the Toll family are expressed on macrophages (Toll 2 and Toll 4) and on dendritic cells and B cells (RP105). Upon ligation these receptors activate a series of intracellular events that lead to the killing of bacteria as well as to the recruitment and ultimate activation of antigen-specific T and B lymphocytes (Fig. 305-1). Importantly, signaling by massive amounts of LPS through Toll receptors leads to the release of large amounts of cytokines that mediate LPS-induced shock. Mutations in Toll proteins in mice protect from LPS shock, and mutations in Toll proteins in humans similarly protect from LPS-induced inflammatory diseases such as LPS-induced asthma.

Cells of invertebrates and vertebrates produce antimicrobial small peptides containing fewer than 100 amino acids that can act as endogenous antibodies (Table 305-2). Some of these peptides are produced by epithelia that line various organs, while others

are found in macrophages or neutrophils that ingest pathogens. Antimicrobial peptides have been identified that kill bacteria such as *Pseudomonas* spp., *Escherichia coli*, and *Mycobacterium tuberculosis*.

EFFECTOR CELLS OF INNATE IMMUNITY

Cells of the innate immune system and their roles in the first line of host defense are described in Table 305-4. Equally important as their roles in the mediation of innate immune responses are the roles that each cell type plays in recruiting T and B lymphocytes of the adaptive immune system to engage in specific antipathogen responses.

Monocytes-Macrophages Monocytes arise from precursor cells within bone marrow (Fig. 305-2) and circulate with a half-life ranging from 1 to 3 days. Monocytes leave the peripheral circulation by marginating in capillaries and migrating into a vast extravascular pool. Tissue macrophages arise from monocytes that have migrated out of the circulation and by in situ proliferation of macrophage precursors in tissue. Common locations where tissue macrophages (and certain of their specialized forms) are found are lymph node, spleen, bone marrow, perivascular connective tissue, serous cavities such as the peritoneum, pleura, skin connective tissue, lung (alveolar macrophage), liver (Kupffer cell), bone (osteoclast), central nervous system (microglia), and synovium (type A lining cell).

In general, monocytes-macrophages are on the first line of defense associated with innate immunity; however, they also play a major role in recruitment of adaptive immune responses by mediation of functions such as bindingLPS, the presentation of antigen to T lymphocytes, and the secretion of factors such as interleukin (IL) 1, tumor necrosis factor (TNF), IL-12, and IL-6, which are central to antigen-specific activation of T and B lymphocytes (Fig. 305-1). Although monocytes-macrophages were originally thought to be the major antigen-presenting cells (APCs) of the immune system, it is now clear that dendritic/Langerhans cells are the most potent and effective APCs in the body (see below). Monocytes-macrophages mediate innate immune effector functions such as destruction of antibody-coated bacteria, tumor cells, or even normal hematopoietic cells in certain types of autoimmune cytopenias. Activated macrophages can also mediate antigen-nonspecific lytic activity and eliminate cell types such as tumor cells in the absence of antibody. This activity is largely mediated by cytokines (i.e., TNF-a and IL-1). Monocytes-macrophages express lineage-specific molecules (e.g., the cell-surface LPS receptor, CD14) as well as surface receptors for a number of molecules, including the Fc region of IgG (CD16, CD32, CD64), activated complement components (CD35) (Table 305-1), and various cytokines (Table 305-5). Finally, macrophage secretory products are more diverse than those of any other cell of the immune system. Among monocyte-macrophage-secreted products are hydrolytic enzymes, products of oxidative metabolism, TNF-a, IL-1, -6, -10, -12, -15, -18, and a number of chemoattractant cytokines (chemokines) involved in the orchestration of an immune response in tissues (Table 305-5).

Dendritic/Langerhans Cells Dendritic/Langerhans cells are bone marrow-derivedAPCsthat are distinct from monocytes-macrophages and are derived from both lymphoid and myeloid lineages. They generally lack the standard T, B,NK,

and monocyte cell markers but do express CD83 and other molecules that aid in their identification. They can be expanded in culture, and their function is enhanced by the cytokines granulocyte-macrophage colony stimulating factor (GM-CSF),IL-1, IL-4, andTNF-a. They are distinguished by an exceptional ability to present antigen, by expression of high levels ofMHCclass II and co-stimulatory molecules, and by dendritic morphology with multiple thin membrane projections (veils).

Dendritic cells are referred to as Langerhans cells when they are present in the skin and beneath the mucosal surface. They comprise the dendritic cells of the blood and the spleen and the veil cells of afferent lymphatics, and they form part of the interdigitating cell network of lymphoid organs. In responses involving the innate immune system, bacterialLPSbinds to dendritic cell RP105 Toll-like protein, upregulating dendritic cell molecules, such asMHCclass II, B7-1 (CD80), and B7-2 (CD86), which enhance specific antigen presentation and induce dendritic cell cytokine production.

A critical cell type of the innate immune system is the dendritic cell precursor that, in response to viral infections, produces high levels of interferon (IFN)a. IFN-a in turn activatesNK cells to kill virally infected cells and activates monocytes-macrophages and otherAPCs to recruit antigen-specific T and B cells to respond to viral infections. thus, immature dendritic cells are important components of innate immunity, while mature dendritic cells, as APCs, are important components of adaptive immunity.

Follicular Dendritic Cells Follicular dendritic cells (FDCs) areAPCs for B cells and their lineage is distinct from that of dendritic/Langerhans cells, the major APCs for T cells. FDCs are located in the germinal centers of follicles of secondary lymphoid organs. Their main function is to trap and retain antigens in the germinal centers of lymphoid organs and to present these antigens to B cells. Antigen is retained on their membranes in the form of antigen-antibody complexes that bind to the cell via the cellular receptor for C3. FDCs have extensive, thin, finger-like projections that surround the B cells in the germinal centers, allowing for maximal exposure of trapped antigen. The retention of antigen on the surface of FDC membranes is critical for the selection and growth of high-affinity clones of B cells and for the maintenance of B cell memory. Of note, HIV is trapped in large quantities on the processes of FDCs in lymphoid organs, allowing the lymphoid tissue to serve as a reservoir of virus and a source of infection for CD4+ T cells migrating into the area to provide help to B cells in the initiation and propagation of an HIV-specific humoral response (Chap. 309).

Large Granular Lymphocytes/Natural Killer Cells Large granular lymphocytes (LGLs) account for approximately 5 to 10% of peripheral blood lymphocytes. LGLs are nonadherent, nonphagocytic cells with large azurophilic cytoplasmic granules. LGLs express surface receptors for the Fc portion of IgG (CD16) and for NCAM-I (CD56), and many LGLs express some T lineage markers, particularly CD8, and proliferate in response toIL-2. LGLs arise in both bone marrow and thymic microenvironments (Fig. 305-2).

Functionally,LGLsshare features with both monocytes-macrophages and neutrophils in that LGLs mediate both antibody-dependent cellular cytotoxicity (ADCC) andNKactivity. ADCC is the binding of an opsonized (antibody-coated) target cell to an Fc receptor-bearing effector cell via the Fc region of antibody, resulting in lysis of the target

by the effector cell. NK cell activity is the nonimmune (i.e., effector cell never having had previous contact with the target),MHC-unrestricted, non-antibody-mediated killing of target cells, which are usually malignant cell types, transplanted foreign cells, or virus-infected cells. Thus, LGLs that mediate NK cell activity may play an important role in immune surveillance and destruction of cells that spontaneously undergo malignant transformation in vivo. Subsets of NK cells may play a role in hematopoietic cell engraftment; some subsets stimulate bone marrow stem cells, and others stimulate engraftment. Lymphokine-activated killer (LAK) cells are NK lymphocytes that proliferate in vitro to high concentrations ofIL-2 and develop the ability to kill tumor cells more efficiently than unstimulated NK cells. Rare patients with complete absence of NK cells have been described who lack both NK cell activity and CD56+, CD16+ lymphocytes but have normal T and B cell function. NK cell hyporesponsiveness is also observed in patients with the *Chediak-Higashi syndrome*, an autosomal recessive disease associated with fusion of cytoplasmic granules and defective degranulation of neutrophil lysosomes.

The ability ofNK cells to kill target cells is inversely related to target cell expression ofMHCclass I molecules. Thus, NK cells kill target cells with low or no levels of MHC class I expression and are prevented from killing target cells with high levels of class I expression. Recent studies have demonstrated the presence of NK receptors (NK-Rs) or killer cell inhibitory receptors (KIRs) that bind to either classic MHC class I molecules in a polymorphic way or the MHC-class Ib molecule HLA-E (Fig. 305-3). In every person, NK cells express at least one NK-R that recognizes a self-MHC class I allele. NK-Rs of the Ig superfamily bind specific MHC class I molecules; for example, the NK-R p140 binds HLA-A3, and another NK-R, p70, binds HLA-B27 (Fig. 305-3). A second NK-R of the C-type lectin family of proteins is termed *CD94/NKG2A* and binds the MHC-related protein HLA-E (Fig. 305-3). HLA-E has an MHC class I structure but exclusively binds the leader sequence peptides of classic MHC class I molecules in the HLA-E MHC-like "notch" (see "Molecular Basis of T Cell Recognition of Antigen," below). In this manner, CD94/NKG2A NK cell molecules survey and monitor the total level of classic MHC class I molecules on the surface of host cells. When cell-surface levels of host MHC class I molecules decrease, such as occurs during malignant transformation or viral infection of host cells, the altered host cell with diminished MHC class I expression is recognized by NK-Rs, and the NK cell is activated to kill the host tumor or virally infected cells. The ability of NK-Rs to bind to self-MHC and inhibit NK killing of normal host cells is a key protective mechanism for prevention of NK cell-mediated autoimmune disease.

SomeNK cells express CD3 and are termed *NK/T cells*. NK/T cells can also express oligoclonal forms of theTCR for antigen that can recognize lipid molecules of intracellular bacteria when presented in the context of CD1 molecules onAPCs. This mode of recognition of intracellular bacteria such as *Listeria monocytogenese* and *M. tuberculosis* by NK/T cells is thought to be an important defense mechanism against these organisms that, via usage of a clonal form of TCRs for antigen, incorporates components of both the innate and adaptive immune systems.

Neutrophils, Eosinophils, and Basophils Granulocytes are present in nearly all forms of inflammation and are amplifiers and effectors of innate immune responses. Unchecked accumulation and activation of granulocytes can lead to host tissue

damage, as seen in neutrophil- and eosinophil-mediated *systemic necrotizing vasculitis*. Granulocytes are derived from stem cells in bone marrow (Fig. 305-2). Each type of granulocyte (neutrophil, eosinophil, or basophil) is derived from a different subclass of progenitor cell, which is stimulated to proliferate by colony stimulating factors (Table 305-5). During terminal maturation of granulocytes, class-specific nuclear morphology and cytoplasmic granules appear that allow for histologic identification of granulocyte type.

Neutrophils express Fc receptors for IgG (CD16) and receptors for activated complement components (C3b or CD35) (Table 305-1). Upon interaction of neutrophils with opsonized bacteria or immune complexes, azurophilic granules (containing myeloperoxidase, lysozyme, elastase, and other enzymes) and specific granules (containing lactoferrin, lysozyme, collagenase, and other enzymes) are released, and microbicidal superoxide radicals (O_2^-) are generated at the neutrophil surface. The generation of superoxide leads to inflammation by direct injury to tissue and by alteration of macromolecules such as collagen and DNA.

Eosinophils express Fc receptors for IgG (CD32) and are potent cytotoxic effector cells for various parasitic organisms. Intracytoplasmic contents of eosinophils, such as major basic protein, eosinophil cationic protein, and eosinophil-derived neurotoxin, are capable of directly damaging tissues and may be responsible in part for the organ system dysfunction in the *hypereosinophilic syndromes* (Chap. 64). Since the eosinophil granule contains anti-inflammatory types of enzymes (histaminase, arylsulfatase, phospholipase D), eosinophils may homeostatically downregulate or terminate ongoing inflammatory responses.

The normal functions of basophils and tissue mast cells are not completely understood; they are potent reservoirs of cytokines such asIL-4. The capacity of basophil cytokines and mediators to increase local delivery of antibodies and complement by increasing vascular permeability is hypothetical. Thus, the basophil is identified principally with allergic reactions and some delayed cutaneous hypersensitivity states. Certainly, the promotion of increased vascular permeability by basophils is important in the genesis of inflammatory lesions in some vasculitis syndromes (Chap. 317). Basophils express high-affinity surface receptors for IgE (FcRI) and, upon cross-linking of basophil-bound IgE by antigen, release histamine, eosinophil chemotactic factor of anaphylaxis, and neutral protease -- all mediators of immediate (anaphylaxis) hypersensitivity responses (Table 305-6). In addition, basophils express surface receptors for activated complement components (C3a, C5a), through which mediator release can be directly effected.**For further discussion of tissue mast cells, see Chap. 310.*

THE COMPLEMENT SYSTEM

The complement system, an important soluble component of the innate immune system, is a series of plasma enzymes, regulatory proteins, and proteins that are activated in a cascading fashion, resulting in cell lysis. There are two arms of the complement system (Fig. 305-4). Activation of the classic complement pathway via C1, C4, and C2 and activation of the alternative complement pathway via factor D, C3, and factor B both lead to cleavage and activation of C3. C3 is a protein whose activation fragments, when bound to target surfaces such as bacteria and other foreign antigens, are critical for

opsonization (coating by antibody and complement) in preparation for phagocytosis.

The protein fragment C3b, split from C3, is necessary for activation of the terminal complement components C5 through C9. These form the membrane attack complex, which, when inserted into cell membranes, brings about osmotic lysis of the cell.

C3b also joins with a cleavage product of factor B (called Bb) to form C3bBb, also known as the *alternative pathway C3 convertase*. Activation of the classic complement pathway results in cleavage of C4 and C2 with a resulting complex of fragments, C4b2a, also called the *classic pathway C3 convertase*. Both the classic pathway C3 convertase (C4b2a) and the alternative pathway C3 convertase (C3bBb) function to cleave C3 to form active C3b, thus driving activation of the C5-9 membrane attack complex. The fact that C3b can combine with Bb to form the alternative pathway C3 convertase gives rise to a potent positive-feedback loop for production of C3b and thus continued activation of terminal complement components.

The classic complement pathway is activated by interaction of antigen and antibody to form immune complexes that bind C1q, a subunit of C1. Immunoglobulin isotypes that bind C1q and activate the classic pathway are IgM, IgG1, IgG2, and IgG3. In contrast, IgA1, IgA2, and IgD activate complement via the alternative pathway. Activation of the complement cascade via the classic pathway by IgG- or IgM-containing immune complexes is a rapid and efficient pathway to activation of terminal complement components. In contrast, activation of the alternative complement pathway via IgA-containing immune complexes or by bacterial endotoxin is a slower and less efficient pathway to terminal component activation. Thus the immunoglobulin isotype composition of immune complexes is a critical factor in determining complement activation and the efficiency of clearance of immune complexes by C3 receptor-bearing cells.

In addition to the role of complement in opsonization of bacteria and cell lysis, several complement fragments are potent mediators of immune cell activation. C3a and C5a bind to receptors on mast cells and basophils, resulting in release of histamine and other mediators of anaphylaxis. C5a is also a potent chemoattractant for neutrophils and monocytes-macrophages (Table 305-7).

CYTOKINES

Cytokines are soluble proteins produced by a wide variety of hematopoietic and nonhematopoietic cell types (Table 305-5). They are critical for both normal innate and adaptive immune responses, and their expression may be perturbed in most immune, inflammatory, and infectious disease states.

Cytokines are involved in the regulation of the growth, development, and activation of immune system cells and in the mediation of the inflammatory response. In general, cytokines are characterized by considerable redundancy in that different cytokines have similar functions. In addition, many cytokines are pleiotropic in that they are capable of acting on many different cell types. This pleiotropism results from the expression on multiple cell types of receptors for the same cytokine (see below), leading to the formation of "cytokine networks." The action of cytokines may be: (1) autocrine when

the target cell is the same cell that secretes the cytokine, (2) paracrine when the target cell is nearby, and (3) endocrine when the cytokine is secreted into the circulation and acts distal to the source. A number of classifications have been proposed for the grouping of cytokines according to functions; however, these are all imperfect because of the fact that a number of cytokines overlap these groupings. One empirical classification divides the cytokines into the following three groups:

1. Immunoregulatory cytokines involved in the activation, growth, and differentiation of lymphocytes and monocytes, e.g.,IL-2, IL-4, IL-10,IFN-g, and transforming growth factor (TGF) b

2. Proinflammatory cytokines produced predominantly by mononuclear phagocytes in response to infectious agents (e.g.,IL-1,TNF-a, and IL-6) and the chemokine family of inflammatory cytokines, within which are included IL-8, monocyte chemotactic protein (MCP)-1, MCP-2, MCP-3, macrophage inflammatory protein (MIP)-1a, MIP-1b, and regulation-upon-activation, normal T expressed and secreted (RANTES) (Chap. 64)

3. Cytokines that regulate immature leukocyte growth and differentiation, e.g.,IL-3, IL-7, andGM-CSF.

In general, cytokines exert their effects by influencing gene activation that results in cellular activation, growth, differentiation, functional cell-surface molecule expression, and cellular effector function. In this regard, cytokines can have dramatic effects on the regulation of immune responses and the pathogenesis of a variety of diseases. Indeed, T cells have been categorized on the basis of the pattern of cytokines that they secrete that results in either humoral immune response (T_H2) or a cell-mediated immune response (T_H1).

Cytokine receptors can be grouped into five general families based on similarities in their extracellular amino acid sequences and conserved structural domains (Fig. 305-5). The *immunoglobulin (Ig) superfamily* represents a large number of cell-surface and secreted proteins. All members of the Ig superfamily must have at least one common domain in their protein structure. TheIL-1 receptors (type 1, type 2) are examples of cytokine receptors with extracellular Ig domains.

The hallmark of the *hematopoietic growth factor (type 1) receptor* family is that the extracellular regions of each receptor contain two conserved motifs. One motif located at the N terminus is rich in cysteine residues. The other motif is located at the C terminus proximal to the transmembrane region and comprises five amino acid residues, tryptophan-serine-X-tryptophan-serine (WSXWS). Cytokine receptors expressing the WSXWS motif are also referred to as "type I family of cytokine receptors." This family can be further grouped on the basis of the number of receptor subunits they have and on the utilization of shared subunits. The shared common receptors often have a critical role in signal transduction. A number of cytokine receptors, i.e.,IL-6, IL-11, IL-12, and leukemia inhibitory factor, are paired with gp130. There is also a common 150-kDa subunit shared by IL-3, IL-5, andGM-CSFreceptors. The gamma chain (g_c) of the IL-2 receptor is common to the IL-2, IL-4, IL-7, IL-9, and IL-15 receptors. Thus, the specific cytokine receptor is responsible for ligand-specific binding, while the subunits such as gp130, the 150-kDa subunit, andg_c are important in

signal transduction. The γ_c gene is on the X chromosome, and mutations in the γ_c protein result in the X-linked form of severe combined immune deficiency syndrome (X-SCID) (Chap. 308).

The members of the *interferon (type II) receptor* family include the receptors for IFN-g, and -b, which share a similar 210-amino-acid binding domain with conserved cysteine pairs at both the amino and carboxy termini. The receptors for the interferons consist of at least two distinct subunits.

The members of the *TNF (type III) receptor family* share a common binding domain composed of repeated cysteine-rich regions. Members of this family include the p55 and p75 receptors for TNF (TNFR1 and TNFR2, respectively); CD40 antigen, which is an important B cell-surface marker involved in immunoglobulin isotype switching; fas/Apo-1, whose triggering induces apoptosis (programmed cell death); CD27 and CD30, which are found on activated T cells and B cells; and nerve growth factor receptor.

The common motif for the *seven transmembrane helix family* was originally found in receptors linked to GTP-binding proteins. This family includes receptors for chemokines, b-adrenergic receptors, and retinal rhodopsin. It is important to note that two members of the chemokine receptor family, CXC chemokine receptor type 4 (CXCR4) and b chemokine receptor type 5 (CCR5), have recently been found to serve as the two major coreceptors for binding and entry of HIV into CD4-expressing host cells (Chap. 309). Both cytokines and their receptors share similar structures and functions. For example, ligands for the TNF receptor family of receptors regulate and determine activation for programmed cell death (*apoptosis*) and all ligate molecules of the same structural family. Similarly IL-3, IL-5, and GM-CSF are all produced by T helper (T_H) 2 cells, and the receptors of these cytokines share common g chains. Thus, cytokines and their receptors may have diversified together during evolution.

Significant advances have been made in defining the signaling pathways through which cytokines exert their effects intracellularly. This is particularly true with regard to the diverse family of hematopoietin receptors. The Janus family of protein tyrosine kinases (JAK) is a critical element involved in signaling via the hematopoietin receptors. There are four known JAK kinases, JAK1, JAK2, JAK3, and Tyk2, which preferentially bind different receptor subunits. Cytokine binding to its receptor brings the cytokine receptor subunits into apposition and allows a pair of JAKs to transphosphorylate and activate one another. The JAKs then phosphorylate the receptor on the tyrosine residues and allow signaling molecules to bind to the receptor, where these molecules in turn can become phosphorylated. These signaling molecules can bind the receptor because they have domains (SH2, or src homology 2 domains) that can bind phosphorylated tyrosine residues. There are a number of these important signaling molecules that bind the receptor, such as the adapter molecule SHC, which can couple the receptor to the activation of the mitogen-activated protein kinase pathway. In addition, a very important class of substrate of the JAKs is the signal transducers and activators of transcription (STAT) family of transcription factors. STATs have SH2 domains that enable them to bind to phosphorylated receptors, where they are then phosphorylated by the JAKs. It appears that different STATs have specificity for different receptor subunits. The STATs then dissociate from the receptor and translocate to the nucleus, bind to DNA motifs that

they recognize, and regulate gene expression. The STATs preferentially bind DNA motifs that are slightly different from one another and thereby presumably control transcription of specific genes. The importance of this pathway is particularly relevant to lymphoid development. Mutations of JAK3 itself also result in a disorder identical toX-SCID; however, since JAK3 is found on chromosome 19 and not on the X chromosome, JAK3 deficiency occurs in boys and girls (Chap. 308). In this chapter the cytokines that affect various cell types are discussed in the context of each of the cell types.

THE ADAPTIVE IMMUNE SYSTEM

Adaptive immunity is characterized by antigen-specific responses to a foreign antigen or pathogen and, compared to innate immunity which occurs immediately (1 to 2 days), generally takes several days or longer to materialize. A key feature of adaptive immunity is memory for the antigen such that subsequent antigen exposures lead to more rapid and often more vigorous immune responses. The adaptive immune system consists of dual limbs of cellular and humoral immunity. The principal effectors of cellular immunity are T lymphocytes, while the principal effectors of humoral immunity are B lymphocytes (Table 305-8). Both B and T lymphocytes derive from a common stem cell (Fig. 305-2).

The proportion and distribution of immunocompetent cells in various tissues reflect cell traffic, homing patterns, and functional capabilities. Bone marrow is the major site of maturation of B cells, monocytes-macrophages, and granulocytes and contains pluripotent stem cells which, under the influence of various colony stimulating factors, are capable of giving rise to all hematopoietic cell types (Fig. 305-2). T cell precursors also arise from hematopoietic stem cells and home to the thymus for maturation. Mature T lymphocytes, B lymphocytes, monocytes, and dendritic/Langerhans cells enter the circulation and home to peripheral lymphoid organs (lymph nodes, spleen) and the gut-associated lymphoid tissue (tonsil, Peyer's patches, and appendix) as well as the skin and mucous membranes and await activation by foreign antigen.

T CELLS

The pool of effector T cells is established in the thymus early in life and is maintained throughout life both by new T cell production in the thymus and by antigen-driven expansion of virgin peripheral T cells into "memory" T cells that reside in peripheral lymphoid organs. The thymus exports approximately 2% of the total number of thymocytes per day throughout life, with the total number of daily thymic emigrants decreasing by approximately 3% per year during the first four decades of life. Thymic emigrants can be identified by the expression of certain combinations of T cell surface markers and by the presence in nuclei of excised (deleted) pieces of rearrangedTCR DNA, called *T cell receptor excision circles*.

Mature T lymphocytes constitute 70 to 80% of normal peripheral blood lymphocytes (only 2% of the total-body lymphocytes are contained in peripheral blood), 90% of thoracic duct lymphocytes, 30 to 40% of lymph node cells, and 20 to 30% of spleen lymphoid cells. In lymph nodes, T cells occupy deep paracortical areas around B cell germinal centers, and in the spleen, they are located in periarteriolar areas of white pulp (Chap. 63). T cells are the primary effectors of cell-mediated immunity, with subsets of T

cells maturing into CD8+ cytotoxic T cells capable of lysis of virus-infected or foreign cells. In general, CD4+ T cells are also the primary regulatory cells of T and B lymphocyte and monocyte function by the production of cytokines and by direct cell contact. In addition, T cells regulate erythroid cell maturation in bone marrow, and through cell contact (CD40 ligand) have an important role in activation of B cells and induction of Ig isotype switching.

Human T cells express cell-surface proteins that mark stages of intrathymic T cell maturation or identify specific functional subpopulations of mature T cells. Many of these molecules mediate or participate in important T cell functions (Table 305-1;Fig. 305-6).

A number of cytokines regulate the process of T cell proliferation and differentiation (Table 305-5). The earliest identifiable T cell precursors in bone marrow are CD34+ pro-T cells (i.e., cells in whichTCRgenes are neither rearranged nor expressed). In the thymus, CD34+ T cell precursors begin cytoplasmic (c) synthesis of components of the CD3 complex of TCR-associated molecules (Fig. 305-6.) Within T cell precursors, TCR for antigen gene rearrangement begins under the influence ofIL-7 and yields two T cell lineages, expressing either TCRabchains or TCRgd chains. T cells expressing the TCRab chains comprise the majority of peripheral T cells in blood, lymph node, and spleen and terminally differentiate into either CD4+ or CD8+ cells. Cells expressing TCRgd chains circulate as a minor population in blood; their functions, although not fully understood, have been postulated to be those of immune surveillance at epithelial surfaces and cellular defenses against mycobacterial organisms and other intracellular bacteria (see below). Immature cortical thymocytes express, in addition to CD1, both CD4 and CD8 (i.e., they are double positive); however, upon reaching functional maturity, T cell expression of CD1 ceases, and CD4 and CD8 are reciprocally expressed. (i.e., T cells become single positive for either CD4 or CD8).

In the thymus, the recognition of self-peptides on thymic epithelial cells, thymic macrophages, and dendritic cells plays an important role in shaping the T cell repertoire to recognize foreign antigen (*positive selection*) and in eliminating highly autoreactive T cells (*negative selection*). As immature cortical thymocytes begin to express surfaceTCR for antigen, autoreactive thymocytes are destroyed (negative selection), thymocytes with TCRs capable of interacting with foreign antigen peptides in the context of self\en\MHCantigens are activated and develop to maturity (positive selection), and thymocytes with TCR that are incapable of binding to self-MHC antigens die of attrition (*no selection*). Mature thymocytes that are positively selected are either CD4+ helper T cells or MHC class II-restricted cytotoxic (killer) T cells, or they are CD8+ T cells destined to become MHC class I-restricted cytotoxic T cells. For T cells to be *MHC class I-* or *class II-restricted* means that T cells recognize antigen peptide fragments only when they are presented in the antigen-recognition site of a class I or class II MHC molecule, respectively (see below).

After thymocyte maturation and selection, mature CD4 and CD8 thymocytes leave the thymus and migrate to all sites of the peripheral immune system. It is important to note that the adult thymus continues to function, albeit with decreasing output, well into adult life, with detectable function though age 50. Thus, the thymus continues to be a contributor to the peripheral immune system, both normally and when the peripheral T cell pool is damaged, such as occurs in AIDS and cancer chemotherapy.

MOLECULAR BASIS OF T CELL RECOGNITION OF ANTIGEN

TheTCR for antigen is a complex of molecules consisting of an antigen-binding heterodimer of either ab or gd chains noncovalently linked with five CD3 subunits (g,d, e,z, and h) (Fig. 305-7). The CD3 z chains are either disulfide-linked homodimers (CD3-z_2) or disulfide-linked heterodimers composed of one zchain and one h chain. TCRabor TCRgd molecules must be associated with CD3 molecules to be inserted into the T cell surface membrane, TCRa being paired with TCRband TCRg being paired with TCRd. Molecules of the CD3 complex mediate transduction of T cell activation signals via TCRs, while TCRa and b org and d molecules combine to form the TCR antigen-binding site.

Thea, b,g, and dTCR for antigen molecules have amino acid sequence homology and structural similarities to immunoglobulin heavy and light chains and are thus members, along with other important molecules of immune cells of the *immunoglobulin gene superfamily* of molecules (e.g., MHC class I or II, CD3, CD4, CD8). The genes encoding the TCR molecules are encoded as clusters of gene segments that rearrange during the course of T cell maturation. This creates an efficient and compact mechanism for housing the diversity requirements of antigen receptor molecules. The TCRa chain is on chromosome 14 and consists of a series of V (variable), J (joining), and C (constant) regions. The TCRb chain is on chromosome 7 and consists of multiple V, D (diversity), J, and C TCRb loci. The TCRg chain is on chromosome 7, and the TCRd chain is in the middle of the TCRa locus on chromosome 14. Thus, molecules of the TCR for antigen have constant (framework) and variable regions, and the gene segments encoding the a, b,g, and d chains of these molecules are recombined and selected in the thymus, culminating in synthesis of the completed molecule. In both T and B cell precursors (see below), DNA rearrangements of antigen receptor genes involves the same enzymes, recombinase activating gene (RAG)1 and RAG2, both DNA-dependent protein kinases.

TCRdiversity is created by the different V, (D), and J segments that are possible for each receptor chain by the many permutations of V, D, and J segment combinations, by "N-region diversification" due to the addition of nucleotides at the junction of rearranged gene segments, and the pairing of individual chains to form a TCR dimer. As T cells mature in the thymus, the repertoire of antigen-reactive T cells is modified by selection processes that eliminate many autoreactive T cells, enhance the proliferation of cells that function appropriately with self-MHCmolecules and antigen, and allow T cells with nonproductive TCR rearrangements to die. Like B cell antigen receptors (Ig molecules), TCRs may also undergo affinity maturation by somatic mutation of the receptor, once they leave the thymus.

T cells do not recognize native protein or carbohydrate antigens. Instead, T cells recognize only short (approximately 9 to 13 amino acids) peptide fragments derived from protein antigens taken up or produced inAPCs. Foreign antigens may be taken up by endocytosis into acidified intracellar vesicles and degraded into small peptides that associate withMHCclass II molecules (exogenous antigen-presentation pathway). Other foreign antigens arise endogenously in the cytosol (such as from replicating viruses) and are broken down into small peptides that associate with MHC class I molecules (endogenous antigen-presenting pathway). Thus, APCs proteolytically degrade foreign

proteins and display peptide fragments embedded in the MHC class I or II antigen-recognition site on the MHC molecule surface, where foreign peptide fragments are available to bind toTCRab or TCRgd chains of reactive T cells (Fig. 305-8). CD4 molecules act as an adhesive and, by direct binding to MHC class II (DR, DQ, or DP) molecules, stabilize the interaction of TCR with peptide antigen (Fig. 305-7). Similarly, CD8 molecules also act as adhesives to stabilize the TCR-antigen interaction by direct CD8 molecule binding to MHC class I (A, B, or C) molecules.

Antigens that arise in the cytosol and are processed via the endogenous antigen-presentation pathway are cleaved into small peptides by a 28-subunit complex of proteases called the *proteasome*. From the proteasome, antigen peptide fragments are transported from the cytosol into the lumen of the endoplasmic reticulum by a heterodimeric complex termed *transporters associated with antigen processing*, or TAP proteins. There,MHCclass I molecules in the endoplasmic reticulum membrane physically associate with processed cytosolic peptides. Following peptide association with class I molecules, peptide-class I complexes are exported to the Golgi apparatus, and then to the cell surface, for recognition by CD8+ T cells.

Antigens taken up from the extracellular space via endocytosis into intracellular acidified vesicles are degraded by vesicle proteases into peptide fragments. Intracellular vesicles containingMHCclass II molecules fuse with peptide-containing vesicles, thus allowing peptide fragments to physically bind to MHC class II molecules. Peptide-MHC class II complexes are then transported to the cell surface for recognition by CD4+ T cells.

Whereas it is generally agreed that theTCRabreceptor recognizes peptide antigens in the context ofMHCclass I or class II molecules, recent data suggest that lipids in the cell wall of intracellular bacteria such as *M. tuberculosis* can also be presented to a wide variety of T cells, including subsets of CD4-, CD8-TCRab T cells, TCRgd T cells, and a subset of CD8+ TCRab T cells. Importantly, bacterial lipid antigens are not presented in the context of MHC class I or II molecules, but rather are presented in the context of MHC-related CD1 molecules. Some gd T cells that recognize lipid antigens via CD1 molecules have very restricted TCR usage, do not need antigen priming to respond to bacterial lipids, and may actually be a form of innate rather than acquired immunity to intracellular bacteria.

Just as foreign antigens are degraded and their peptide fragments presented in the context ofMHCclass I or class II molecules onAPCs, endogenous self-proteins are also degraded and self-peptide fragments are presented to T cells in the context of MHC class I or class II molecules on APCs. In peripheral lymphoid organs, T cells are present that are capable of recognizing self-protein fragments but normally are *anergic* or *tolerant*, i.e., nonresponsive to self-antigenic stimulation, due to lack of self-antigen upregulating APC *co-stimulatory molecules* such as B7-1 and B7-2 (see below).

Once engagement of mature T cellTCR by foreign peptide occurs in the context of self-MHCclass I or class II molecules, binding of non-antigen-specific adhesion ligand pairs such as CD54-CD11/CD18 and CD58-CD2 stabilizes MHC peptide-TCR binding and the expression of these adhesion molecules is upregulated (Fig. 305-7). Once antigen ligation of the TCR occurs, the T cell membrane is partitioned into *lipid membrane microdomains*, or *lipid rafts*, that coalesce the key signaling molecules

TCR/CD3 complex, CD28, CD2, LAT (linker for activation of T cells), intracellular activated (dephosphorylated) src family protein tyrosine kinases (PTKs), and the key CD3z-associated protein-70 (ZAP-70) PTK (Fig. 305-7). Importantly, during T cell activation, the dephosphorylating molecule, CD45, with protein tyrosine phosphatase activity is partitioned away from the TCR complex to allow activating phosphorylation events to occur. The coalescence of signaling molecules of activated T lymphocytes in *microdomains* has suggested that T cell-APCinteractions can be considered *immunologic synapses*, analogous in function to neuronal synapses.

AfterTCR-MHCbinding is stabilized, activation signals are transmitted through the cell to the nucleus that lead to the expression of gene products important in mediating the wide diversity of T cell functions such as the secretion ofIL-2. The TCR does not have intrinsic signaling activity but is linked to a variety of signaling pathways via immunoreceptor tyrosine-based activation motifs (ITAMs) expressed on the various CD3 chains that bind to proteins that mediate signal transduction. Each of the pathways results in the activation of particular transcription factors that control the expression of cytokine and cytokine receptor genes. Thus, antigen-MHC binding to the TCR induces the activation of the src family ofPTKs, fyn and lck (lck is associated with CD4 or CD8 co-stimulatory molecules); phosphorylation of CD3z chain; activation of the related tyrosine kinases ZAP-70 and syk; and downstream activation of the calcium-dependent calcineurin pathway, the ras pathway, and the protein kinase C pathway. Each of these pathways leads to activation of specific families of transcription factors (including NF-AT, fos and jun, and rel/NF-kB) that form heteromultimers capable of inducing expression of IL-2, IL-2 receptor, IL-4,TNF-a, and other T cell mediators. The src family kinases require dephosphorylation of an inactivation site by CD45 phosphatase before they can be phosphorylated on an activation site. Furthermore, the activity through the receptor is downregulated by the csk-PEP enzyme, a phosphatase that inactivates the src family kinases.

In addition to the signals delivered to the T cell from theTCR and CD4 and CD8 molecules, co-stimulatory receptors [such as CD28 activated by CD80 (B7-1) and/or CD86 (B7-2)] also deliver important signals that upregulate the function of the T cell. The CD28 signal transduction pathway appears particularly important. CD28 signals through phosphoinositide-3-phosphate kinase; its downstream effects are not completely clear. However, if signal transduction through CD28 does not occur in concert with TCR ligation, or if CD28 is blocked, the T cell becomes inactivated or anergic (nonresponsive or tolerant) rather than activated.

CTLA-4 (CD52) is an Ig superfamily molecule on T cells that, like CD28, is a ligand for B7-1 and B7-2 but has a higher affinity for B7-1 and B7-2 than does CD28. T cell CTLA-4 ligation sends a negative signal to the T cell to become tolerant or nonresponsive to antigen stimulation afterTCR-MHCligation. Blocking of CD28-mediated co-stimulation occurs when a second ligand for B7-1 and B7-2 ligates anAPCwhile the TCR is bound to MHC. Thus, a convergence of molecular and biochemical events involving co-stimulatory molecules is required for normal T cell recognition of antigen and consequent T cell activation. In order to exploit this biology for therapeutic purposes, one clinical strategy currently being tested is administration of soluble recombinant CTLA-4 protein to patients at the time of organ transplantation in order to induce a cohort of organ transplant-specific tolerant T cells and thereby reduce

the rejection of organ allografts. Alternatively, blocking CTLA-4/B7 interactions with soluble CD28 or CTLA-4 monoclonal antibodies might possibly be therapeutically useful to enhance immune responses to human cancers (see "Immunotherapy," below).

T CELL SUPERANTIGENS

Conventional antigens bind toMHCclass I or II molecules in the groove of the abheterodimer and bind to T cells via the V regions of theTCRa and -b chains (Fig. 305-7). In contrast, superantigens bind directly to the lateral portion of the TCRb chain and MHC class II b chain and stimulate T cells based solely on the Vb gene segment utilized independent of the D, J, and Va sequences present. *Superantigens* are protein molecules capable of activating up to 20% of the peripheral T cell pool, whereas conventional antigens activate fewer than 1 in 10,000 T cells. T cell superantigens include staphylococcal enterotoxins, other bacterial products, and certain nonhuman retroviral proteins. Superantigen stimulation of human peripheral T cells occurs in the clinical setting of the *staphylococcal toxic shock syndrome*, leading to massive overproduction of T cell cytokines (Chap. 139).

B CELLS

Mature B cells comprise 10 to 15% of human peripheral blood lymphocytes, 50% of splenic lymphocytes, and approximately 10% of bone marrow lymphocytes. B cells express on their surface intramembrane immunoglobulin (Ig) molecules that function as B cell receptors (BCR) for antigen in a complex of Ig-associated a andb signaling molecules with properties similar to those described in T cells (Fig. 305-9). Unlike T cells, which recognize only processed peptide fragments of conventional antigens embedded in the notches ofMHCclass I and class II antigens ofAPCs, B cells are capable of recognizing and proliferating to whole unprocessed native antigens via antigen binding to B cell surface Ig (sIg) receptors. B cells also express surface receptors for the Fc region of IgG molecules (CD32) as well as receptors for activated complement components (C3d or CD21, C3b or CD35). The primary function of B cells is to produce antibodies. B cells also serve as APCs and are highly efficient at antigen processing. Their antigen-presenting function is enhanced by a variety of cytokines. Mature B cells are derived from bone marrow precursor cells that arise continuously throughout life (Figs. 305-2,305-10).

B lymphocyte development can be separated into antigen-independent and antigen-dependent phases. Antigen-independent B cell development occurs in primary lymphoid organs, including fetal liver and bone marrow, and includes all stages of B cell maturation up to the sIg+ mature B cell. Antigen-dependent B cell maturation is driven by the interaction of antigen with the mature B cell sIg, leading to memory B cell induction, Ig class switching, and plasma cell formation. Antigen-dependent stages of B cell maturation occur in secondary lymphoid organs, including lymph node, spleen, and gut Peyer's patches. In contrast to the T cell repertoire that is for the most part generated intrathymically before contact with foreign antigen, the repertoire of B cells expressing diverse antigen-reactive sites is modified by further alteration of Ig genes after stimulation by antigen -- a process called *somatic mutation* -- which occurs in lymph node germinal centers.

During B cell development, diversity of the antigen-binding variable region of Ig is generated by an ordered set of Ig gene rearrangements that are similar to the rearrangements undergone byTCRa, b,g, and d genes. Heavy chain rearrangements precede those for light chains. For the heavy chain, there is first a rearrangement of D segments to J segments, followed by a second rearrangement between a V gene segment and the newly formed D-J sequence; the C segment is aligned to the V-D-J complex to yield a functional Ig heavy chain gene (V-D-J-C). During later stages, a functional k orl light chain gene is generated by rearrangement of a V segment to a J segment, ultimately yielding an intact Ig molecule composed of heavy and light chains.

The process of Ig gene rearrangement is regulated to result in a single antibody specificity produced by each B cell, with each Ig molecule comprising one type of heavy chain and one type of light chain. Although each B cell contains two copies of Ig light and heavy chain genes, only one gene of each type is productively rearranged and expressed in each B cell, a process termed *allelic exclusion*.

There are approximately 300 V_k genes and 5 J_k genes, resulting in the pairing of $V_k$and J_k genes to create over 1500 different light chain combinations. The number of distinctk light chains that can be generated is increased by somatic mutations within the V_k and J_k genes, thus creating large numbers of possible specificities from a limited amount of germ-line genetic information. As noted above, in heavy chain Ig gene rearrangement, the VH domain is created by the joining of three types of germ-line genes called V_H, D_H, and J_H, thus allowing for even greater diversity in the variable region of heavy chains than of light chains.

The most immature B cell precursors (early pro-B cells) lack cytoplasmic Ig (cIg) and sIg (Fig. 305-10). The large pre-B cell is marked by the acquisition of the surface pre-BCRcomposed of u heavy (H) chains and a pre-B light chain, termedyLC (Fig. 305-9). yLC is a surrogate light chain receptor encoded by the nonrearranged V pre-B and thel5 light chain locus (the pre-BCR). Pro- and pre-B cells are driven to proliferate and mature by signals from bone marrow stroma, in particular,IL-7. Light chain rearrangement occurs in the small pre-B cell stage such that the full BCR is expressed at the immature B cell stage. Immature B cells have rearranged Ig light chain genes and express sIgM. As immature B cells develop into mature B cells, sIgD is expressed as well as sIgM. At this point, B lineage development in bone marrow is complete, and B cells exit into the peripheral circulation and migrate to secondary lymphoid organs to encounter specific antigens.

Random rearrangements of Ig genes occasionally generates self-reactive antibodies, and mechanisms must be in place to correct these mistakes. One such mechanism isBCRediting, whereby autoreactive BCRs are mutated to not react with self-antigens. If receptor editing is unsuccessful in eliminating autoreactive B cells, then autoreactive B cells undergo negative selection in the bone marrow through induction of apoptosis after BCR engagement of self-antigen.

After leaving the bone marrow, B cells populate peripheral B cell sites, such as lymph node and spleen, and await contact with foreign antigens that react with each B cell's clonotypic receptor. As antigen-driven B cell activation occurs through theBCR, a process known as *somatic hypermutation* takes place whereby point mutations in

rearranged H- and L-genes give rise to mutant sIg molecules, some of which bind antigen better than the original sIg molecules. Somatic hypermutation, therefore, is a process whereby memory B cells in peripheral lymph organs have the best binding, or the highest affinity antibodies. This overall process of generating the best antibodies is called *affinity maturation of antibody*.

Lymphocytes that synthesize IgG, IgA, and IgE are derived from sIgM+, sIgD+ mature B cells. Ig class switching occurs in lymph node and other peripheral lymphoid tissue germinal centers. Pairs of CD40+ B cells and CD40 ligand+ T cells bind and drive B cell Ig switching via T cell-produced cytokines such asIL-4 andTGF-b. IL-1, -2, -4, -5, and -6 synergize to drive mature B cells to proliferate and differentiate into Ig-secreting cells.

Humoral Mediators of Adaptive Immunity: Immunoglobulins Immunoglobulins are the products of differentiated B cells and mediate the humoral arm of the immune response. The primary functions of antibodies are to bind specifically to antigen and bring about the inactivation or removal of the offending toxin, microbe, parasite, or other foreign substance from the body. The structural basis of Ig molecule function and Ig gene organization has provided insight into the role of antibodies in normal protective immunity, pathologic immune-mediated damage by immune complexes, and autoantibody formation against host determinants.

All immunoglobulins have the basic structure of two heavy and two light chains (Figs. 305-9 and305-11). Immunoglobulin isotype (i.e., G, M, A, D, E) is determined by the type of Ig heavy chain present. IgG and IgA isotypes can be divided further into subclasses (G1, G2, G3, G4, and A1, A2) based on specific antigenic determinants on Ig heavy chains. The characteristics of human immunoglobulins are outlined inTable 305-9. The four chains are covalently linked by disulfide bonds. Each chain is made up of a V region and C regions (also called *domains*), themselves made up of units of approximately 110 amino acids. Light chains have one variable (V_L) and one constant (C_L) unit; heavy chains have one variable unit (V_H) and three or four constant (C_H) units, depending on isotype. As the name suggests, the constant, or C, regions of Ig molecules are made up of homologous sequences and share the same primary structure as all other Ig chains of the same isotype and subclass. Constant regions are involved in biologic functions of Ig molecules. The C_{H2}domain of IgG and the C_{H4}units of IgM are involved with the binding of the C1q portion of C1. The $C_H$region at the carboxy-terminal end of the IgG molecule, the Fc region (Fig. 305-11), binds to surface Fc receptors (CD16, CD32, CD64) of macrophages,LGLs, B cells, neutrophils, and eosinophils.

Variable regions (V_L and V_H) constitute the antibody-binding (Fab) region of the molecule. Within the V_L and $V_H$regions are hypervariable regions (extreme sequence variability) that constitute the antigen-binding site unique to each Ig molecule. The idiotype is defined as the specific region of the Fab portion of the Ig molecule to which antigen binds. Antibodies against the idiotype portion of an antibody molecule are called *anti-idiotype antibodies*. The formation of such antibodies in vivo during a normal B cell antibody response may generate a negative (or "off") signal to B cells to terminate antibody production.

IgG comprises approximately 75 to 85% of total serum immunoglobulin. The four IgG

subclasses are numbered in order of their level in serum, IgG1 being found in greatest amounts and IgG4 the least. IgG subclasses have clinical relevance in their varying ability to bind macrophage and neutrophil Fc receptors and to activate complement (Table 305-9). Moreover, selective deficiencies of certain IgG subclasses give rise to clinical syndromes in which the patient is inordinately susceptible to bacterial infections. IgG antibodies are frequently the predominant antibody made after rechallenge of the host with antigen (secondary antibody response).

IgM antibodies normally circulate as a 950-kDa pentamer with 160-kDa bivalent monomers joined by a molecule called the *J chain*, a 15-kDa nonimmunoglobulin molecule that also effects polymerization of IgA molecules. IgM is the first immunoglobulin to appear in the immune response (primary antibody response) and is the initial type of antibody made by neonates. Membrane IgM in the monomeric form also functions as a major antigen receptor on the surface of mature B cells (Fig. 305-9). IgM is an important component of immune complexes in autoimmune diseases. For example, IgM antibodies against IgG molecules (rheumatoid factors) are present in high titers in *rheumatoid arthritis*, other collagen diseases, and some infectious diseases (*subacute bacterial endocarditis*). IgM antibody binds the C1 component of complement via the CH4 domain and thus is a potent activator of the complement cascade.

IgA comprises only 7 to 15% of total serum immunoglobulin but is the predominant class of immunoglobulin in secretions. IgA in secretions (tears, saliva, nasal secretions, gastrointestinal tract fluid, and human milk) is in the form of secretory IgA (sIgA), a polymer consisting of two IgA monomers, a joining molecule, again called the J chain, and a glycoprotein called the *secretory protein*. Of the two IgA subclasses, IgA1 is primarily found in serum, whereas IgA2 is more prevalent in secretions. IgA fixes complement via the alternative complement pathway and has potent antiviral activity in humans by prevention of virus binding to respiratory and gastrointestinal epithelial cells.

IgD is found in minute quantities in serum and, together with IgM, is a major receptor for antigen on the B cell surface (Table 305-9). IgE, which is present in serum in very low concentrations, is the major class of immunoglobulin involved in arming mast cells and basophils by binding to these cells via the Fc region. Antigen cross-linking of IgE molecules on basophil and mast cell surfaces results in release of mediators of the immediate hypersensitivity response (Table 305-6).

CELLULAR INTERACTIONS IN REGULATION OF NORMAL IMMUNE RESPONSES

The net result of activation of the humoral (B cell) and cellular (T cell) arms of the adaptive immune system by foreign antigen is the elimination of antigen directly by specific effector T cells or in concert with specific antibody. In addition, regulatory T cells are activated that modulate effector T cell activation and B cell antibody production. Figure 305-12 is a simplified schematic diagram of the T and B cell responses indicating some of these cellular interactions.

The expression of adaptive immune cell function is the result of a complex series of immunoregulatory events that occur in phases. Both T and B lymphocytes mediate immune functions, and each of these cell types, when given appropriate signals, passes through stages, from activation and induction through proliferation, differentiation, and

ultimately effector functions. The effector function expressed may be at the end point of a response, such as secretion of antibody by a differentiated plasma cell, or it might serve a regulatory function that modulates other functions, such as is seen with CD4+ inducer or CD8+ regulatory T lymphocytes, which modulate both differentiation of B cells and activation of CD8+ or CD4+ cytotoxic T cells.

CD4 helper T cells can be subdivided on the basis of cytokines produced (Fig. 305-13). Activated T_H1-type helper T cells secreteIL-2,IFN-g, IL-3,TNF-a,GM-CSF, and TNF-b, while activated T_H2-type helper T cells secrete IL-3, -4, -5, -6, -10, and -13. T_H1 CD4+ T cells, through elaboration of IFN-g, have a central role in mediating intracellular killing by a variety of pathogens. T_H1 CD4+ T cells also provide T cell help for generation of cytotoxic T cells and some types of opsonizing antibody, and generally respond to antigens that lead to delayed hypersensitivity types of immune responses for many intracellular viruses and bacteria (such as HIV or *M. tuberculosis*). In contrast, T_H2 cells have a primary role in regulatory humoral immunity and isotype switching. In addition, T_H2 cells, through production of IL-4 and IL-10, have a regulatory role in limiting proinflammatory responses mediated by T_H1 cells (Table 305-5). In addition, T_H2 CD4+ T cells provide help to B cells for specific Ig production and respond to antigens that require high antibody levels for foreign antigen elimination (extracellular encapsulated bacteria such as *Streptococcus pneumoniae* and certain parasite infections). Different cytokines can drive the immune response preferentially towards a T_H1 or a T_H2 response. For example,APC-derived IL-12 induces CD4+ T cell differentiation towards a T_H1 type cell, whereas IL-4 drives differentiation towards a T_H2 type cell (Fig. 305-13).

As shown in Fig. 305-12, upon activation byAPCssuch as dendritic cells, regulatory T cell subsets that produceIL-2, IL-3,IFN-g, and/or IL-4, -5, -6, -10, and -13 are generated that exert positive and negative influences on effector T and B cells. For B cells, trophic effects are mediated by a variety of cytokines, particularly T cell-derived IL-3, -4, -5, and -6, which act at sequential stages of B cell maturation, resulting in B cell proliferation, differentiation, and ultimately antibody secretion (Table 305-5). For cytotoxic T cells, trophic factors include inducer T cell secretion of IL-2, IFN-g, and IL-12 (Table 305-5). In addition, B cells themselves are capable of serving as APCs, processing and presenting antigens to T cells, and secretingTNF-aand IL-6.

Although B cells recognize native antigen via B cell surface Ig receptors, B cells require T cell help to produce high-affinity antibody of multiple isotypes that are the most effective in eliminating foreign antigen. This T cell dependence likely functions in the regulation of B cell responses and in protection against excessive autoantibody production. T cell-B cell interactions that lead to high-affinity antibody production require: (1) processing of native antigen by B cells and expression of peptide fragments on the B cell surface for presentation to $T_H$cells, (2) the ligation of B cells both by the T cell receptor complex and the CD40 ligand, (3) induction of the process termed *antibody isotype switching* in antigen-specific B cell clones, and (4) induction of the process of *affinity maturation* of antibody in the germinal centers of B cell follicles of lymph node and spleen.

Naive B cells express cell-surface IgD and IgM, and initial contact of naive B cells with antigen is via binding of native antigen to B cell-surface IgM. T cell cytokines, released following T_H2 cell contact with B cells or by a "bystander" effect, induce changes in Ig

gene conformation that promote recombination of Ig genes. These events then result in the "switching" of expression of heavy chain exons in a triggered B cell, leading to the secretion of IgG, IgA, or, in some cases, IgE antibody with the same V region antigen specificity as the original IgM antibody, for response to a wide variety of extracellular bacteria, protozoa, and helminths. CD40 ligand expression by activated T cells is critical for induction of B cell antibody isotype switching and for B cell responsiveness to cytokines. Patients with mutations in T cell CD40 ligand have B cells that are unable to undergo isotype switching, resulting in lack of memory B cell generation and the immunodeficiency syndrome of *X-linked hyper-IgM syndrome* (Chap. 308).

MECHANISMS OF IMMUNE-MEDIATED DAMAGE TO MICROBES OR HOST TISSUES

Several responses by the host innate and adaptive immune systems to foreign microbes culminate in rapid and efficient elimination of microbes. In these scenarios, the classic weapons of the adaptive immune system (T cells, B cells) interface with cells (macrophages, dendritic cells,NKcells, neutrophils, eosinophils, basophils) and soluble products (microbial peptides, pentraxins, complement and coagulation systems) of the innate immune system (Chaps. 64 and310).

There are five general phases of host defenses: (1) migration of leukocytes to sites of antigen localization; (2) antigen nonspecific recognition of pathogens by macrophages and other cells and systems of the innate immune system; (3) specific recognition of foreign antigens mediated by T and B lymphocytes; (4) amplification of the inflammatory response with recruitment of specific and nonspecific effector cells by complement components, cytokines, kinins, arachidonic acid metabolites, and mast cell-basophil products; and (5) macrophage, neutrophil, and lymphocyte participation in destruction of antigen with ultimate removal of antigen particles by phagocytosis (by macrophages or neutrophils) or by direct cytotoxic mechanisms (involving macrophages, neutrophils, and lymphocytes). Under normal circumstances, orderly progression of host defenses through these phases results in a well-controlled immune and inflammatory response that protects the host from the offending antigen. However, dysfunction of any of the host defense systems can damage host tissue and produce clinical disease. Furthermore, for certain pathogens or antigens, the normal immune response itself might contribute substantially to the tissue damage. For example, the immune and inflammatory response in the brain to certain pathogens such as *M. tuberculosis* may be responsible for much of the morbidity of this disease in that organ system (Chap. 169). In addition, the morbidity associated with certain pneumonias such as that caused by *Pneumocystis carinii* may be associated more with inflammatory infiltrates than with the tissue destructive effects of the microorganism itself (Chap. 209). Thus, it is important to appreciate how normally protective proinflammatory responses that mediate intracellular killing are regulated. What follows are brief discussions of mechanisms of leukocyte migration to sites of inflammation, immune complex formation, immediate-type hypersensitivity responses, cytotoxic reactions of antibody, delayed cellular types of hypersensitivity responses, and programmed cell death of immune competent cells.

The Molecular Basis of Lymphocyte-Endothelial Cell Interactions The control of lymphocyte circulatory patterns between the bloodstream and peripheral lymphoid organs operates at the level of lymphocyte-endothelial cell interactions to control the

specificity of lymphocyte subset entry into organs. Similarly, lymphocyte-endothelial cell interactions regulate the entry of lymphocytes into inflamed tissue. Adhesion molecule expression on lymphocytes and endothelial cells regulates the retention and subsequent egress of lymphocytes within tissue sites of antigenic stimulation, delaying cell exit from tissue and preventing reentry into the circulating lymphocyte pool. All types of lymphocyte migration begin with lymphocyte attachment to specialized regions of vessels, termed *high endothelial venules* (HEVs). An important concept for many of the adhesion molecules listed in Table 305-10 is that the molecules do not generally bind their ligand until a conformational change (ligand activation) occurs in the adhesion molecule that allows ligand binding. Induction of a conformation-dependent determinant on an adhesion molecule can be accomplished by cytokines or via ligation of other adhesion molecules on the cell.

The first stage of lymphocyte-endothelial cell interactions, *attachment and rolling*, occurs when lymphocytes leave the stream of flowing blood cells in a postcapillary venule and roll along venule endothelial cells (Fig. 305-14). Lymphocyte rolling is mediated by the L-selectin molecule (LECAM-1, LAM-1) and slows cell transit time through venules, allowing time for activation of adherent cells.

The second stage of lymphocyte-endothelial cell interactions, *adhesion triggering*, requires stimulation of lymphocytes by chemoattractants or by endothelial cell-derived cytokines. Cytokines thought to participate in adherent cell triggering include members of theIL-8 family, platelet-activation factor, leukotriene B_4, and C5a. Following activation by chemoattractants, lymphocytes shed L-selectin from the cell surface and upregulate cell CD11b/18 (MAC-1) or CD11a/18 (LFA-1) molecules, resulting in firm attachment of lymphocytes toHEVs.

Lymphocyte homing to peripheral lymph nodes involves adhesion of L-selectin to carbohydrate of peripheral nodeHEVs, whereas homing of lymphocytes to intestine Peyer's patches primarily involves adhesion of the a4,b7 integrin to MAdCAM-1 oligosaccharides on the Peyer's patch HEVs. However, for migration to mucosal Peyer's patch lymphoid aggregates, naive lymphocytes primarily use L-selectin, whereas memory lymphocytes usea4,b7 integrin.a4,b1 integrin (CD49d/CD29, VLA-4)-VCAM-1 interactions are important in the initial interaction of memory lymphocytes with HEVs of multiple organs in sites of inflammation.

The third stage of leukocyte emigration inHEVs, *sticking and arrest*, is sticking of the lymphocyte and arrest at the site of sticking, mediated predominantly by ligation ofaL,b2 integrin LFA-1 to the integrin ligands ICAM-1 and ICAM-2 on HEVs. While the first three stages of lymphocyte attachment to HEVs takes only a few seconds, the fourth stage of lymphocyte emigration, *transendothelial migration*, takes approximately 10 min. Although the molecular mechanisms that control lymphocyte transendothelial migration are not fully characterized, the HEV CD44 molecule and molecules of the HEV glycocalyx (extracellular matrix) are thought to play important regulatory roles in this process (Fig. 305-14). Finally, expression of matrix metalloproteases capable of digesting the subendothelial basement membrane, rich in nonfibrillar collagen, appears to be required for the penetration of lymphoid cells into the extravascular sites.

Abnormal induction ofHEVformation and use of the molecules discussed above have

been implicated in the induction and maintenance of inflammation in a number of chronic inflammatory diseases. In animal models of insulin-dependent diabetes mellitus (IDDM), MAdCAM-1 and GlyCAM-1 have been shown to be highly expressed on HEVs in inflamed pancreatic islets, and treatment of these animals with inhibitors of L-selectin and a4 integrin function blocked the development of IDDM (Chap. 333). A similar role for abnormal induction of the adhesion molecules of lymphocyte emigration has been suggested in rheumatoid arthritis (Chap. 312), Hashimoto's thyroiditis (Chap. 330), Graves' disease (Chap. 330), multiple sclerosis (Chap. 371), Crohn's disease (Chap. 287), and ulcerative colitis (Chap. 287).

Immune-Complex Formation Clearance of antigen by immune-complex formation between antigen and antibody is a highly effective mechanism of host defense. However, depending on the level of immune complexes formed and their physicochemical properties, immune complexes may or may not result in host and foreign cell damage. After antigen exposure, certain types of soluble antigen-antibody complexes freely circulate and, if not cleared by the reticuloendothelial system, can be deposited in blood vessel walls and in other tissues such as renal glomeruli (Chap. 317).

Immediate-Type Hypersensitivity Helper T cells that drive antiallergen IgE responses are usually T_H2-type inducer T cells that secreteIL-4, IL-5, IL-6, and IL-10. Mast cells and basophils have high-affinity receptors for the Fc portion of IgE (FcRI), and cell-bound antiallergen IgE effectively "arms" basophils and mast cells. Mediator release is triggered by antigen (allergen) interaction with Fc receptor-bound IgE; the mediators released are responsible for the pathophysiologic changes of allergic diseases (Table 305-6). Mediators released from mast cells and basophils can be divided into three broad functional types: (1) those that increase vascular permeability and contract smooth muscle (histamine, platelet-activating factor, SRS-A, BK-A), (2) those that are chemotactic for or activate other inflammatory cells (ECF-A, NCF, leukotriene B_4), and (3) those that modulate the release of other mediators (BK-A, platelet-activating factor) (Chap. 310).

Cytotoxic Reactions of Antibody In this type of immunologic injury, complement-fixing (C1-binding) antibodies against normal or foreign cells or tissues (IgM, IgG1, IgG2, IgG3) bind complement via the classic pathway and initiate a sequence of events similar to that initiated by immune-complex deposition, resulting in cell lysis or tissue injury. Examples of antibody-mediated cytotoxic reactions include red cell lysis in *transfusion reactions*, *Goodpasture's syndrome* with anti-glomerular basement membrane antibody formation, and *pemphigus vulgaris* with antiepidermal antibodies inducing blistering skin disease.

Classic Delayed-Type Hypersensitivity Reactions Inflammatory reactions initiated by mononuclear leukocytes and not by antibody alone have been termed *delayed-type hypersensitivity reactions*. The term *delayed* has been used to contrast a secondary cellular response that appears 48 to 72 h after antigen exposure with an *immediate* hypersensitivity response generally seen within 12 h of antigen challenge and initiated by basophil mediator release or preformed antibody. For example, in an individual previously infected with *M. tuberculosis* organisms, intradermal placement of tuberculin purified-protein derivative as a skin test challenge results in an indurated area of skin at 48 to 72 h, indicating previous exposure to tuberculosis.

The cellular events that result in classic delayed-type hypersensitivity responses are centered around T cells (predominantly, though not exclusively,IFN-g,IL-2, andTNF-a-secreting T_H1-type helper T cells) and macrophages. First, local immune and inflammatory responses at the site of foreign antigen upregulate endothelial cell adhesion molecule expression, promoting the accumulation of lymphocytes at the tissue site. In the general scheme outlined in Fig. 305-12, antigen is processed by dendritic/Langerhans cells or monocytes-macrophages and presented to small numbers of CD4+ T cells expressing aTCRspecific for the antigen. IL-12 produced byAPCsinduces T cells to produce IFN-g(T_H-1 response). IL-1 and IL-6 secreted by APCs amplify the clonal expansion of antigen-specific T cells, and other cytokines (primarily IL-2, IFN-g, and TNF-b) are secreted that promote recruitment of diverse populations of T cells and macrophages to the site of the cellular inflammatory response. In particular, CD8+ cytotoxic T cells are induced by IL-2 to become active killer cells. Once recruited, macrophages frequently undergo epithelioid cell transformation and fuse to form multinucleated giant cells. This type of mononuclear cell infiltrate is termed *granulomatous inflammation*. Examples of diseases in which delayed-type hypersensitivity plays a major role are fungal infections (*histoplasmosis*) (Chap. 201), mycobacterial infections (*tuberculosis*, *leprosy*) (Chaps. 169 and170), chlamydial infections (*lymphogranuloma venereum*) (Chap. 179), helminth infections (*schistosomiasis*) (Chap. 224), reactions to toxins (*berylliosis*) (Chap. 254), and hypersensitivity reactions to organic dusts (*hypersensitivity pneumonitis*) (Chap. 253). In addition, delayed-type hypersensitivity responses play important roles in tissue damage in autoimmune diseases such as *rheumatoid arthritis*, *temporal arteritis*, and *Wegener's granulomatosis* (Chaps. 312 and317).

The Cellular and Molecular Control of Programmed Cell Death (Apoptosis) The process of apoptosis plays a crucial role in regulating normal immune responses to antigen. In general, a wide variety of stimuli trigger cell surface receptors (e.g.,TNFreceptor family members or related proteins) or cytoplasmic receptors (e.g., ceramide, glucocorticoids) that activate groups of proteases such as FADD-likeIL-1b-converting enzyme (FLICE) or Caspase 8 (Fig. 305-15). These proteases either cleave molecules that lead to cell death themselves or activate other enzymes to cleave molecules that eventuate in cell death (Fig. 305-15). The end stages of this sequence of events lead to cell death characterized by degradation of cytoplasmic (actin) and nuclear cytoskeletal proteins as well as cleavage of DNA at regular intervals (nucleosomes), leading to nuclear disintegration seen on electron microscopy and "laddering" of DNA when analysed by agarose gel electrophoresis. The level of expression of certain cytosolic proteins, such as Bcl-2 and Bcl-XL, negatively regulates the process of apoptosis by inhibiting activation of cytosolic proteases that induce cell death. For example, T cells that are negatively selected in the thymus are induced to undergo apoptosis and have low levels of proteins such as Bcl-2, whereas medullary thymocytes that have been triggered to proliferate and survive thymocyte selection (positive selection) have high levels of Bcl-2.

Thus, in the immune system, apoptosis is a mechanism induced to remove autoreactive T cells from the thymus during negative selection, to remove autoreactive B and T cells from peripheral lymphoid organs upon contact with antigen or antigen-reactive helper T cells in spleen and lymph node, and to remove virus-infected or malignant cells after

contact with antigen-specific CD8+ cytotoxic T lymphocytes. Induction of apoptosis is one of two principal mechanisms of target cell lysis by cytotoxic T lymphocytes, the other consisting of the release of cytotoxic perforin molecules.

CLINICAL EVALUATION OF IMMUNE FUNCTION

Clinical assessment of immunity requires investigation of the four major components of the immune system that participate in host defense and in the pathogenesis of autoimmune diseases: (1) humoral immunity (B cells); (2) cell-mediated immunity (T cells, monocytes); (3) phagocytic cells of the reticuloendothelial system (macrophages), as well as polymorphonuclear leukocytes; and (4) complement. Clinical problems that require an evaluation of immunity include chronic infections, recurrent infection, unusual infecting agents, and certain autoimmune syndromes. The type of clinical syndrome under evaluation can provide information regarding possible immune defects (Chap. 308). Defects in cellular immunity generally result in viral, mycobacterial, and fungal infections. An extreme example of deficiency in cellular immunity is AIDS (Chap. 309). Antibody deficiencies result in recurrent bacterial infections, frequently with organisms such as *S. pneumoniae* and *Haemophilus influenzae* (Chap. 308). Disorders of phagocyte function frequently are manifested by recurrent skin infections, often due to *Staphylococcus aureus* (Chap. 64). Finally, deficiencies of early and late complement components are associated with autoimmune phenomena and recurrent *Neisseria* infections (Table 305-10).**For further discussion of useful initial screening tests of immune function, see Chap. 308.*

IMMUNOTHERAPY

Most current therapies for autoimmune and inflammatory diseases involve the use of nonspecific immune-modulating or immunosuppressive agents such as glucocorticoids or cytotoxic drugs. The goal of development of new treatments for immune-mediated diseases is to design ways to specifically interrupt pathologic immune responses, leaving nonpathologic immune responses intact. Novel ways to interrupt pathologic immune responses that are under investigation include: the use of anti-inflammatory cytokines or specific cytokine inhibitors as anti-inflammatory agents; the use of monoclonal antibodies against T or B lymphocytes as therapeutic agents; the induction of anergy by administration of soluble CTLA-4 protein, the use of intravenous Ig for certain infections and immune complex-mediated diseases, and the use of specific cytokines to reconstitute components of the immune system (Table 305-11) (Chaps. 64,308, and309).

Cytokines and Cytokine Inhibitors Recently a humanized mouse anti-TNF-amonoclonal antibody (MAB) has been tested in both rheumatoid arthritis and ulcerative colitis. Use of anti-TNF-a antibody therapy has resulted in clinical improvement in patients with these diseases and has opened the way for targeting TNF-a to treat other severe forms of autoimmune and/or inflammatory disease. Anti-TNF-a MAB has been approved for treatment of patients with rheumatoid arthritis.

Other cytokine inhibitors under investigation are recombinant solubleTNF-areceptor (R) fused to human Ig and solubleIL-1 receptor (termed *IL-1 receptor antagonist*, or IL-1 ra). Soluble TNF-aR and IL-1 ra act to inhibit the activity of pathogenic cytokines in

rheumatoid arthritis, i.e., TNF-a and IL-1 respectively. Similarly, anti-IL-6,IFN-b, and IL-11 act to inhibit pathogenic proinflammatory cytokines. Anti-IL-6 inhibits IL-6 activity, while IFN-b and IL-11 decrease IL-1 and TNF-aproduction.

Recent studies have identified mutations in theIL-12 gene in patients susceptible to severe myobacterial infections. IL-12 is a critical cytokine for induction ofIFN-gand cytotoxic T lymphocytes (CTLs) against intracellular organisms; it is under study for treatment of severe infections such as that caused by *M. tuberculosis* and for treatment of various cancers. In this latter setting, IL-12 is being studied for its ability to enhance antitumor cellular immunity by enhancing the induction of antitumor CTL.

Of particular note has been the successful use ofIFN-gin the treatment of the phagocytic cell defect in *chronic granulomatous disease* (Chap. 64). Intermittent infusions ofIL-2 in HIV-infected individuals in the early or intermediate stages of disease have resulted in substantial and sustained increases in CD4+ T cells.

Monoclonal Antibodies to T and B Cells The OKT3MABagainst human T cells has been used for several years as a T cell-specific immunosuppressive agent that can substitute for horse anti-thymocyte globulin (ATG) in the treatment of solid organ transplant rejection. OKT3 produces fewer allergic reactions than ATG but does induce human anti-mouse Ig antibody -- thus limiting its use. Anti-CD4 MAB therapy has been used in trials to treat patients with rheumatoid arthritis. While inducing profound immunosuppression, anti-CD4 MAB treatment also induces considerable susceptibility to severe infections. Treatment of patients with a MAB against the T cell molecule CD40 ligand (CD154) is under investigation to induce tolerance to organ transplants, with promising results reported in animal studies.

Tolerance Induction Specific immunotherapy has moved into a new era with the introduction of soluble CTLA-4 protein into clinical trials. Use of this molecule to block T cell activation viaTCR/CD28 ligation during organ or bone marrow transplantation has showed promising results in animals and in early human clinical trials. Specifically, treatment of bone marrow with CTLA-4 protein reduces rejection of the graft in HLA-mismatched bone marrow transplantation. In addition, promising results with soluble CTLA-4 have been reported in the downmodulation of autoimmune T cell responses in the treatment of psoriasis.

Intravenous Immunoglobulin (IVIg) IVIg has been successfully used to block reticuloendothelial cell function and immune complex clearance in various immune cytopenias such as immune thrombocytopenia (Chap. 116). In addition, IVIg is useful for prevention of tissue damage in certain inflammatory syndromes such as Kawasaki's disease (Chap. 317) and as Ig replacement therapy for certain types of immunoglobulin deficiencies (Chap. 308). In addition, controlled clinical trials support the use of IVIg in selected patients with graft-versus-host disease, multiple sclerosis, myasthenia gravis, Guillain-Barre syndrome, and chronic demyelinating polyneuropathy (Table 305-11).

Thus, a number of recent insights into immune system function have spawned a new field of interventional immunotherapy and have enhanced the prospect for development of specific and nontoxic therapies for immune and inflammatory diseases.

306. THE MAJOR HISTOCOMPATIBILITY GENE COMPLEX - *Gerald T. Nepom*, *Joel D. Taurog*

THE HLA COMPLEX AND ITS PRODUCTS

The human major histocompatibility complex (MHC), commonly called the human leukocyte antigen (HLA) complex, is a 4-megabase (Mb) region on chromosome 6 (6p21.3) that is densely packed with expressed genes. The best known of these genes are the HLA class I and class II genes, whose products are critical for immunologic specificity and transplantation histocompatibility; they play a major role in susceptibility to a number of autoimmune diseases. Many other genes in the HLA region are also essential to the innate and antigen-specific functioning of the immune system. The HLA region shows extensive conservation with the MHC of other mammals in terms of genomic organization, gene sequence, and protein structure and function. Much of our understanding of the MHC has come from investigation of the MHC in mice, where it is termed the *H-2 complex*, and to a lesser degree from other species as well. Nonetheless, in this chapter the discussion will be confined to information applicable to the MHC in humans.

The *HLA class I genes* are located in a 2-Mb stretch of DNA at the telomeric end of the HLA region (Fig. 306-1). The classic (MHCclass Ia) HLA-A, -B, and -C loci, the products of which are integral participants in the immune response to intracellular infections, tumors, and allografts, are expressed in all nucleated cells and are highly polymorphic in the population. *Polymorphism* refers to a high degree of allelic variation within a genetic locus that leads to extensive variation between different individuals expressing different alleles. Over 100 alleles at HLA-A, 200 at HLA-B, and 50 at HLA-C have been identified in different human populations. Each of the alleles at these loci encodes a *heavy chain* (also called an*a chain*) that associates noncovalently with the nonpolymorphic light chain*b_2-microglobulin*, encoded on chromosome 15.

The *nomenclature* of HLA genes and their products reflects the grafting of newer DNA sequence information on an older system based on serology. Among class I genes, alleles of the HLA-A, -B, and -C loci were originally identified in the 1950s, 1960s, and 1970s by alloantisera, derived primarily from multiparous women, who in the course of normal pregnancy produce antibodies against paternal antigens expressed on fetal cells. The serologic allotypes were designated by consecutive numbers, e.g., HLA-A1, HLA-B8. The HLA-C locus alleles were designated HLA-Cw, rather than HLA-C, partly to distinguish them from the HLA-encoded complement loci C2 and C4. With the application of DNA sequence analysis and other molecular techniques in the 1980s, and particularly polymerase chain reaction-based techniques since the late 1980s, most serologically defined specificities were found to include a number of closely related alleles differing by only a few amino acids. These are commonly termed *subtypes* of the parent specificity. Currently, under World Health Organization nomenclature, class I alleles are given a single designation that indicates locus, serologic specificity, and sequence-based subtype. For example, HLA-A*0201 indicates subtype 1 of the serologically defined allele HLA-A2. As new alleles are discovered, they are named and numbered based on sequence homology to known alleles or, in the absence of strong homology, designated as consecutively numbered separate alleles, irrespective of serologic reactivity. Subtypes that differ from each other at the nucleotide but not the

amino acid sequence level are designated by an extra numeral; e.g., HLA-B*07021 and HLA-B*07022 are two variants of the HLA-B7 subtype of HLA-B*0702. The nomenclature of class II genes, discussed below, is made more complicated by the fact that both chains of a class II molecule are encoded by closely linked HLA-encoded loci, both of which may be polymorphic, and by the presence of differing numbers of isotypic DRB loci in different individuals. It has become clear that accurate HLA genotyping requires DNA sequence analysis, and the identification of alleles at the DNA sequence level has contributed greatly to the understanding of the role of HLA molecules as peptide-binding ligands, to the analysis of associations of HLA alleles with certain diseases, to the study of the population genetics of HLA, and to a clearer understanding of the contribution of HLA differences in allograft rejection and graft-vs.-host disease. Current databases of HLA class I and class II sequences can be accessed by internet (e.g., from the American Society for Histocompatibility and Immunogenetics,http://www.swmed.edu/home_pages/ASHI/sequences/seq3.htm), and frequent updates of HLA gene lists are published in several journals.

As shown inFig. 306-2 and discussed below in detail, a characteristic structural feature of class I and class II HLA molecules is the *peptide-binding groove* that enables these molecules to form highly stable complexes with a wide array of peptide sequences that can be recognized as antigens by T cells. In the case of class I molecules, peptide binding provides a display on the cell surface of peptides derived from intracellular proteins, and this serves as a readout to CD8+ T cells of the proteins being produced within somatic cells. The polymorphism at the loci encoding these molecules predominantly affects the amino acid residues that make up the peptide-binding groove, further amplifying the array of peptides that can be bound by different HLA molecules and generating important functional immune differences and transplantation incompatibility among different individuals.

The nonclassic, or class Ib,MHCmolecules, HLA-E, -F, and -G, are much less polymorphic than MHC Ia and, except for HLA-E, have a more limited tissue distribution. The HLA-E molecule, which has a peptide repertoire restricted to signal peptides cleaved from classic MHC class I molecules, is the major self-recognition target for the natural killer (NK) cell inhibitory receptors NKG2A or NKG2C paired with CD94 (see below andChap. 305). HLA-G is expressed selectively in extravillous trophoblasts, the fetal cell population directly in contact with maternal tissues. It binds a wide array of peptides, is expressed in six different alternatively spliced forms, and provides inhibitory signals to both NK cells and T cells, presumably in the service of maintaining maternofetal tolerance. The function of HLA-F remains largely unknown. Although HLA-C is considered a classic class I molecule, its degree of polymorphism and level of surface expression are significantly lower than those of HLA-A and HLA-B. Moreover, unlike HLA-A and -B molecules, which function primarily by presenting antigen to CD8+ T cells expressing ab T cell receptors (TCRs), the primary function of HLA-C molecules appears to be to serve as targets of NK cell recognition (see below).

Additional class I-like genes have been identified, some HLA-linked and some encoded on other chromosomes, that show only distant homology to the class Ia and Ib molecules but that share the three-dimensional class I structure. Those on chromosome 6p21 include MIC-A and MIC-B, which are encoded centromeric to HLA-B; and HLA-HFE, located 3 to 4 cM (centi-Morgan) telomeric of HLA-F. MIC-A and MIC-B do

not bind peptide but are expressed on gut and other epithelium in a stress-inducible manner and serve as activation signals for certain gd T cells andNKcells, whereas HLA-HFE encodes the gene defective in hereditary hemochromatosis (Chap. 345). Among the non-HLA, class I-like genes, CD1 refers to a family of molecules that present glycolipids or other nonpeptide ligands to certain T cells, including T cells with NK activity; FcRn binds IgG within lysosomes and protects it from catabolism (Chap. 305); and Zn-a_2-glycoprotein 1 binds a nonpeptide ligand and promotes catabolism of triglycerides in adipose tissue. Like the HLA-A, -B, -C, -E, -F, and -G heavy chains, each of which forms a heterodimer withb_2-microglobulin (Fig. 306-2), the class I-like molecules HLA-HFE, FcRn, and CD1 also bind tob_2-microglobulin, but MIC-A, MIC-B, and Zn-a_2-glycoprotein 1 do not.

The *HLA class II region* is also illustrated in Fig. 306-1. Multiple class II genes are arrayed within the centromeric 1 Mb of the HLA region, forming distinct haplotypes. A *haplotype* refers to an array of alleles at polymorphic loci along a chromosomal segment. In the context of HLA, haplotype can refer either to a large segment of the HLA region encompassing many of the polymorphic HLA loci (also called an *extended haplotype* or to a more restricted segment such as the tightly linked DR and DQ loci. Multiple class II genes are present on a single haplotype, clustered into three major subregions: HLA-DR, -DQ, and -DP. Each of these subregions contains at least one functional alpha (A) locus and one functional beta (B) locus. Together these encode proteins that form thea and b polypeptide chains of a mature class II HLA molecule. Thus, the DRA and DRB genes encode an HLA-DR molecule; products of the DQA1 and DQB1 genes form an HLA-DQ molecule; and the DPA1 and DPB1 genes encode an HLA-DP molecule. There are several DRB genes (DRB1, DRB2, and DRB3, etc.), so that two expressed DR molecules are encoded on most haplotypes by combining the a-chain product of the DRA gene with separate bchains.

The class II region was originally termed the *D-region*. The allelic gene products were first detected by their ability to stimulate lymphocyte proliferation by *mixed lymphocyte reaction*, and were named Dw1, Dw2, etc. Subsequently, serology was used to identify gene products on peripheral blood B cells, and the antigens were termed *DR* (D-related). After additional class II loci were identified, these came to be known as DQ and DP.

The HLA class II DRB and DPB loci are extremely polymorphic, with over 200 DR alleles and over 75 DP alleles, respectively. In the DQ region, both DQA1 and DQB1 are polymorphic, with 20 DQA1 alleles and over 40 DQB1 alleles. The current nomenclature is largely analogous to that discussed above for class I, using the convention "locus*allele." Thus, for example, subtypes of the serologically defined specificity DR4, encoded by the DRB1 locus, are termed DRB1*0401, -0402, etc. In addition to allelic polymorphism, products of different DQA1 alleles can, with some limitations, pair with products of different DQB1 alleles through both *cis* and *trans* pairing to create combinatorial complexity and expand the number of expressed class II molecules. Because of the enormous allelic diversity in the general population, most individuals are heterozygous at all of the class I and class II loci. Thus, most individuals express six classic class I molecules (two each of HLA-A, -B, and -C) and approximately eight class II molecules -- two DP, two DR (more in the case of haplotypes with additional functional DRB genes), and up to four DQ (two *cis* and two *trans*).

The localization of polymorphic residues in class II molecules is similar to that for class I, i.e., it is predominantly in sites that affect peptide binding (see below). In the case of class II molecules, the peptides displayed on the cell surface are primarily derived from proteins acquired from the extracellular environment, processed through the endosomal-lysosomal pathway, and presented to CD4+ T cells.

OTHER GENES IN THE MHC

Immunologically Relevant Genes In addition to the class I and class II genes themselves, there are numerous genes interspersed among the HLA loci that have interesting and important immunologic functions. The current concept of the function ofMHCgenes now encompasses many of these additional genes. As discussed in more detail below, TAP and LMP genes encode molecules that participate in intermediate steps in the HLA class I biosynthetic pathway, and deficiencies of the TAP or LMP genes can markedly alter class I-mediated immune recognition. Another set of HLA genes, DMA and DMB, performs an analogous function for the class II pathway. These genes encode an intracellular molecule that facilitates the proper complexing of HLA class II molecules with antigen (see below). The HLA class III region is a name given to a cluster of genes between the class I and class II complexes, which includes genes for the two closely related cytokines tumor necrosis factor (TNF) a and lymphotoxin (TNF-b); the complement components C2, C4, and Bf; heat shock protein (HSP)70; and the enzyme 21-hydroxylase.

The class I genes HLA-A, -B, and -C are expressed in all nucleated cells, although generally to a higher degree on leukocytes than on other cells. In contrast, the class II genes show a more restricted distribution: HLA-DR and HLA-DP genes are constitutively expressed on most cells of the myeloid cell lineage, whereas all three class II gene families (HLA-DR, -DQ, and -DP) are inducible by certain stimuli provided by inflammatory cytokines such as interferon g. Within the lymphoid lineage, expression of these class II genes is constitutive on B cells and inducible on human T cells. Most endothelial and epithelial cells in the body, including the vascular endothelium and the intestinal epithelium, are also inducible for class II gene expression. Thus, while these somatic tissues normally express only class I and not class II genes, during times of local inflammation they are recruited by cytokine stimuli to express class II genes as well, thereby becoming active participants in ongoing immune responses. Other HLA genes involved in the immune response, such as TAP and LMP, are also susceptible to upregulation by signals such as interferong.

Other Genes and Genetic Elements Large-scale genomic sequencing projects have recently yielded sequence data for the entire HLA region, which can be accessed on the internet (e.g.,http://www.sanger.ac.uk/HGP/Chr6/). As a result, many new genes have been discovered, the functions of which remain to be determined, as well as numerous microsatellite regions and other genetic elements. The gene density of the class II region is high, with approximately one protein encoded every 30 kb; that of the class I and class III regions is even higher, with approximately one protein encoded every 15 kb. It is also of interest that these regions also differ with respect to the GC (guanidine + cytosine) content. Vertebrate genomes have a long-range mosaic structure with regard to relative GC content that is related to chromosome banding. Regions of homogeneous

GC content are termed *isochores.* The HLA class I and class III regions belong to the H3 (highest GC) isochore, with 53% GC, whereas the class II region belongs to the L or H1 isochores (low GC), with 40 to 45% GC. An abrupt demarcation between these two isochores occurs near the boundary separating the class II and class III regions.

LINKAGE DISEQUILIBRIUM

In addition to extensive polymorphism at the class I and class II loci, another characteristic feature of the HLA complex is *linkage disequilibrium*. This is formally defined as a deviation from Hardy-Weinberg equilibrium for alleles at linked loci. This is reflected in the very low recombination rates between certain loci within the HLA. For example, recombination between DR and DQ loci is almost never observed in family studies, and characteristic haplotypes with particular arrays of DR and DQ alleles are found in every population. Similarly, the complement components C2, C4, and Bf are almost invariably inherited together, and the alleles at these loci are found in characteristic haplotypes. In contrast, there is a recombinational hotspot between DQ and DP, which are separated by 1 to 2 cM of genetic distance, despite their close physical proximity. Certain extended haplotypes encompassing the interval from DQ into the class I region are commonly found, the most notable being the haplotype DR3-B8-A1, which is found, in whole or in part, in 10 to 30% of northern European Caucasians. The genetic mechanisms that account for linkage disequilibrium in HLA have not been determined. It has been hypothesized that selective pressures may maintain certain haplotypes, but this remains to be demonstrated. As discussed below under HLA and immunologic disease, one consequence of the phenomenon of linkage disequilibrium has been the difficulty it produces in assigning HLA disease associations to a single allele at a single locus.

MHC STRUCTURE AND FUNCTION

Class I and class II molecules display a distinctive structural architecture that contains specialized functional domains responsible for the unique genetic and immunologic properties of the HLA complex. The principal known function of both class I and class II HLA molecules is to bind antigenic peptides in order to present antigen to an appropriate T cell. The ability of a particular peptide to bind to an individual HLA molecule satisfactorily is a direct function of the molecular fit between the amino acid residues on the peptide with respect to the amino acid residues of the HLA molecule. The bound peptide forms a tertiary structure called the *MHC-peptide complex*, which communicates with T lymphocytes through binding to theTCRmolecule. The first site of TCR-MHC-peptide interaction in the life of a T cell occurs in the thymus, where self-peptides are presented to developing thymocytes by MHC molecules expressed on thymic epithelium and hematopoietically derived antigen-presenting cells, which are primarily responsible for positive and negative selection, respectively (seeChap. 305 for details of thymic selection of the T cell repertoire). Mature T cells encounter MHC molecules in the periphery both in the maintenance of tolerance (Chap. 305) and in the initiation of immune responses. Because most antibody responses and all T cell responses are T cell dependent (Chap. 305), the MHC-peptide-TCR interaction is the central event in the initiation of most antigen-specific immune responses, since it is the event that actually confers the specificity. Thus, the population of MHC-T cell complexes expressed in the thymus shapes the TCR repertoire. For potentially immunogenic

peptides, the ability of a given peptide to be generated and bound by an HLA molecule is a primary determinant of whether or not an immune response to that peptide can be generated; the repertoire of peptides that a particular individual's HLA molecules can bind exerts a major influence over the specificity of that individual's immune response.

When aTCRmolecule binds to an HLA-peptide complex, it forms intermolecular contacts with both the antigenic peptide and with the HLA molecule itself. The outcome of this recognition event depends on the density and duration of the binding interaction, accounting for a dual specificity requirement for activation of the T cell. That is, the TCR must be specific both for the antigenic peptide and for the HLA molecule. The polymorphic nature of the presenting molecules, and the influence that this exerts on the peptide repertoire of each molecule, results in the phenomenon of *MHC restriction* of the T cell specificity for a given peptide. The binding of CD8 or CD4 molecules, respectively, to the class I or class II molecule also contributes to the interaction between T cell and the HLA-peptide complex, by providing for the selective activation of the appropriate T cell.

CLASS I STRUCTURE (Fig. 306-2*A*)

As noted above,MHCclass I molecules provide a cell-surface display of peptides derived from intracellular proteins; they also provide the signal for self-recognition byNKcells. Surface-expressed class I molecules consist of an MHC-encoded 44-kDa glycoprotein heavy chain, a non-MHC-encoded 12-kDa light chainβ_2-microglobulin; and an antigenic peptide, typically 8 to 11 amino acids in length and derived from intracellularly produced protein. The heavy chain contains three domains, termedα_1,α_2, andα_3. Theα_1 and$\alpha_2$domains form an "intrachain dimer," which together form a peptide-binding groove. In HLA-A and -B molecules, the groove is approximately 3 nm in length by 1-2 nm in maximum width (30 A ´ 12 A), whereas it is apparently somewhat wider in HLA-C. In cell surface-expressed class molecules, each domain contributes four of the eight strands of antiparallelβ sheet, the membrane-distal side of which forms the floor of the groove, and one of the pair of α helices, the two coils of which form the walls of the groove (Fig. 306-2*A*). The membrane-anchored$\alpha_3$domain and noncovalently associatedβ_2-microglobulin chain reside on the membrane-proximal side of the βsheet, each folded in the conformation of an immunoglobulin domain. The peptide is noncovalently bound in an extended conformation within the peptide-binding groove, with both N- and C-terminal ends anchored in pockets within the groove (A and F pockets, respectively) and, in many cases, with a prominent kink, or arch, approximately one-third of the way from the N-terminus that elevates the peptide main chain off the floor of the groove.

A remarkable property of peptide binding byMHCmolecules is the ability to form highly stable complexes with a wide array of peptide sequences. This is accomplished by a combination of peptide sequence-independent and -dependent bonding. The former consists of hydrogen bond and van der Waals interactions between conserved residues in the peptide-binding groove and charged or polar atoms along the peptide backbone. The latter are dependent upon the six side pockets that are formed by the irregular surface produced by protrusion of amino acid side chains from within the binding groove. The side chains lining the pockets interact with some of the peptide side chains. The sequence polymorphism among different class I alleles and isotypes predominantly

affects the residues that line these pockets, and the interactions of these residues with peptide residues constitute the sequence-dependent bonding that confers a particular sequence "motif" on the range of peptides that can bind any given MHC molecule.

CLASS I BIOSYNTHESIS (Fig. 306-3*A*)

The biosynthesis of the classicalMHCclass I molecules reflects their role in presenting endogenous peptides. The heavy chain is cotranslationally inserted into the membrane of the endoplasmic reticulum (ER), where it becomes glycosylated and associates sequentially with the chaperone proteins calnexin and ERp57. It then forms a complex withβ_2-microglobulin, and this complex associates with the chaperone calreticulin and the MHC-encoded molecule tapasin. Meanwhile, peptides generated within the cytosol from intracellular proteins by the multisubunit, multicatalytic proteasome complex are actively transported into the ER by MHC-encoded TAP (transporter associated with antigen processing) heterodimer. Following association with chaperones and trimming by peptidases within the ER, peptides bind to nascent class I molecules for which they have requisite affinity, to form complete, folded heavy chain-β_2-microglobulin-peptide trimer complexes. These are transported rapidly from the ER, through the *cis*- and *trans*-Golgi, where the N-linked oligosaccharide is further processed, and thence to the cell surface. Other proteins have been implicated in MHC class I assembly, e.g., the chaperones BiP and HSP70, but their roles in the pathway are not clear. The pathways for surface MHC class I degradation are poorly understood. A small proportion of heavy chains within properly assembled MHC class I molecules apparently become unfolded and subsequently degraded in the lysosomal pathway.

Most of the peptides transported by TAP are produced in the cytosol by proteolytic cleavage of intracellular proteins by the multisubunit, multicatalytic proteasome. Inhibitors of the proteasome dramatically reduce expression of class I-presented antigenic peptides, but other proteolytic systems may also generate peptides bound to class I. TheMHC-encoded proteasome subunits LMP2 and LMP7 may influence the spectrum of peptides produced, but they are not essential for proteasome function. Under certain circumstances, peptides derived from extracellular proteins in particulate form can become associated with class I molecules, but not necessarily by entering the class I pathway. Peptides are apparently bound to chaperones in the cytosol, including HSP90 and HSP70.

CLASS I FUNCTION

Peptide Antigen Presentation It is estimated that on any given cell, a given class I allele binds several hundred to several thousand distinct peptide species. The vast majority of these peptides are self peptides to which the host immune system is tolerant by one or more of the mechanisms that maintain tolerance, e.g., clonal deletion in the thymus or clonal anergy or clonal ignorance in the periphery (Chaps. 305 and307). However, class I molecules bearing foreign peptides expressed in a permissive immunologic context activate CD8 T cells, which, if naive, will then differentiate into cytolytic T lymphocytes (CTL). These T cells and their progeny, through their ab T cell receptors, are then capable of Fas/CD95- and/or perforin-mediated cytotoxicity and/or cytokine secretion (Chap. 305) upon further encounter with the class I-peptide combination that originally activated it, and also with other combinations of class I

molecules plus peptide that present a similar immunochemical stimulus to theTCR. As alluded to above, this phenomenon by which T cells recognize foreign antigens in the context of specificMHCalleles is termed *MHC restriction*, and the specific MHC molecule is termed the *restriction element*. The most common source of foreign peptides presented by class I molecules is viral infection, in the course of which peptides from viral proteins enter the class I pathway. The generation of a strong CTL response that destroys virally infected cells represents an important antigen-specific defense against many viral infections (Chap. 305). In the case of some viral infections -- hepatitis B, for example -- CTL-induced target cell apoptosis is thought to be a more important mechanism of tissue damage than any direct cytopathic effect of the virus itself. The importance of the class I pathway in the defense against viral infection is underscored by the identification of a number of viral products that interfere with the normal class I biosynthetic pathway and thus block the immunogenetic expression of viral antigens.

Other examples of intracellularly generated peptides that can be presented by class I molecules in an immunogenic manner include peptides derived from nonviral intracellular infectious agents (e.g., *Listeria*, *Plasmodium*), tumor antigens, minor histocompatibility antigens, and presumably certain autoantigens. There are also situations in which cell surface-expressed class I molecules are thought to acquire and present exogenously derived peptides.

The role of class I HLA molecules in transplantation and in infectious and autoimmune diseases is discussed below.

NK Cell Recognition (See alsoChap. 305) NKcells, which play an important role in innate immune responses, are activated to cytotoxicity and cytokine secretion by contact with cells that lackMHCclass I expression, and NK cell activation is inhibited by cells that express MHC class I. In humans, the recognition of class I molecules by NK cells is carried out by two classes of receptor families, the killer cell-inhibitory cell receptor (KIR) family and the CD94/NKG2 family. The KIR family, encoded on chromosome 19q13.4, comprises glycoproteins of the immunoglobulin (Ig) superfamily that bind HLA class I molecules and inhibit NK cell-mediated cytotoxicity. An estimated 40 genes are divided into two subfamilies, KIR2D and KIR3D, which contain either two or three Ig domains, respectively. The KIR2D molecules primarily recognize alleles of HLA-C. The latter all possess either asparagine at position 77 and lysine at position 80, or serine at 77 and asparagine at 80 in the$\alpha_1$domain of the heavy chain. Different members of the KIR2D family recognize the alternative forms of this polymorphism as well as other residues of the HLA-C heavy chain. The KIR3D molecules predominantly recognize HLA-B alleles. The latter carry a supertypic polymorphism defined serologically by two allotypes, HLA-Bw4 and -Bw6, that are determined by residues 77 to 83 in the$\alpha_1$domain of the heavy chain. It is primarily alleles of the Bw4 supertype that bind KIR3D molecules. Although there is KIR recognition of some HLA-A and -Bw6 alleles, many of these alleles appear not to have a corresponding KIR ligand.

The second family of inhibitoryNKreceptors for HLA is encoded in the NK complex on chromosome 12p12.3-13.1 and consists of CD94 and four NKG2 genes: A, C, E, and D/F. These molecules are C-type (calcium-binding) lectins and are thought to exist as disulfide-bonded heterodimers between CD94 and the various NKG2 glycoproteins. CD94/NKG2A apparently binds to HLA-E and -G and several alleles of HLA-A, -B, and

-C. CD94/NKG2C binds primarily to HLA-E. The specificities of the other NKG2 molecules are not yet established.*The function of NK cells in immune responses is discussed in Chap. 305.

CLASS II STRUCTURE

A specialized functional architecture similar to that of the class I molecules can be seen in the example of a class II molecule depicted in Fig. 306-2*B*, with an antigen-binding cleft arrayed above a supporting scaffold that extends the cleft toward the external cellular environment. However, in contrast to the HLA class I molecular structure, b_2-microglobulin is not associated with class II molecules. Rather, the class II molecule is a heterodimer, composed of a 29-kDa b chain and a 34-kDa a chain. The amino-terminal domains of each chain form the antigen-binding elements, which, like the class I molecule, cradle a bound peptide in a groove bounded by extended a-helical loops, one encoded by the A (a chain) gene and one by the B (b chain) gene. Like the class I groove, the class II antigen-binding groove is punctuated by pockets that contact the side chains of amino acid residues of the bound peptide; unlike the class I groove, it is open at both ends. Therefore, peptides bound by class II molecules vary greatly in length, since both the N- and C-terminal ends of the peptides can extend through the open ends of this groove. Approximately 11 amino acids within the bound peptide form intimate contacts with the class II molecule itself, with backbone hydrogen bonds and specific side chain interactions combining to provide stability and specificity, respectively, to the binding (Fig. 306-4).

The genetic polymorphisms that distinguish different class II genes correspond to changes in the amino acid composition of the class II molecule, and these variable sites are clustered predominantly around the pocket structures within the antigen-binding groove. As with class I, this is a critically important feature of the class II molecule, which explains how genetically different individuals have functionally different HLA molecules.

As noted above, the class I-peptide complex is preferentially recognized by CD8 T cells, and the class II-peptide complex is preferentially recognized by CD4 T cells. These interactions provide an important signal for activation of specific T cell lineages during antigen-recognition events. The CD8 recognition site is located on the a_3 domain of the MHC class I molecule, and the CD4 recognition site is located on the b_2 domain of the class II molecule, in both cases remote from the peptide-binding site.

BIOSYNTHESIS AND FUNCTION OF CLASS II MOLECULES

The intracellular assembly of class II molecules occurs within a specialized compartmentalized pathway that differs dramatically from the class I pathway described above. As illustrated in Fig. 306-3*B*, the class II molecule assembles in the ER in association with a chaperone molecule, known as the *invariant chain*. The invariant chain performs at least two roles. First, it binds to the class II molecule and blocks the peptide-binding groove, thus preventing antigenic peptides from binding. This role of the invariant chain appears to account for one of the important differences between class I and class II MHC pathways, since it can explain why class I molecules present endogenous peptides from proteins newly synthesized in the ER, but class II molecules

generally do not. Second, the invariant chain contains molecular localization signals that direct the class II molecule to traffic into post-Golgi compartments known as *endosomes*, which develop into specialized acidic compartments where proteases cleave the invariant chain, and antigenic peptides can now occupy the class II groove. It is at this stage in the intracellular pathway that the MHC-encoded DM molecule catalytically facilitates the exchange of peptides within the class II groove to help optimize the specificity and stability of the MHC-peptide complex.

Once thisMHC-peptide complex is deposited in the outer cell membrane, it becomes the target for T cell recognition via a specificTCRexpressed on lymphocytes. Because the endosome environment contains internalized proteins retrieved from the extracellular environment, the class II-peptide complex often contains bound antigens that were originally derived from extracellular proteins. In this way, the class II peptide loading pathway provides a mechanism for immune surveillance of the extracellular space. This appears to be an important feature that permits the class II molecule to bind foreign peptides, distinct from the endogenous pathway of class I-mediated presentation.

ROLE OF HLA IN TRANSPLANTATION

The development of modern clinical transplantation in the decades since the 1950s provided a major impetus for elucidation of the HLA system, as allograft survival is highest when donor and recipient are HLA-identical. Although many molecular events participate in transplantation rejection, allogeneic differences at class I and class II loci play a major role. Class I molecules can promote T cell responses in several different ways. In the cases of allografts in which the host and donor are mismatched at one or more class I loci, host T cells can be activated by classical *direct alloreactivity*, in which the antigen receptors on the host T cells react with the foreign class I molecule expressed on the allograft. In this situation, the response of any givenTCR may be dominated by the allogeneicMHCmolecule, the peptide bound to it, or some combination of the two. Another type of host antigraft T cell response involves the uptake and processing of donor MHC antigens by host antigen-presenting cells and the subsequent presentation of the resulting peptides by host MHC molecules. This mechanism is termed *indirect alloreactivity*, or *cross-priming*. It appears to play a quantitatively significant role in allograft rejection, although the molecular and cellular basis for the antigen processing remain to be completely elucidated. In the case of class I molecules on allografts that are shared by the host and the donor, a host T cell response may still be triggered because of peptides that are presented by the class I molecules of the graft but not of the host. The most common basis for the existence of these endogenous antigenic peptides, called *minor histocompatibility antigens*, is a genetic difference between donor and host at a non-MHC locus encoding the structural gene for the protein from which the peptide is derived. These loci are termed *minor histocompatibility loci*, and nonidentical individuals typically differ at many such loci, although only a few provide peptides for any given HLA allele. In recent years, the peptides and parent proteins for a number of human and experimental rodent minor histocompatibility antigens have been identified. In many of these cases of allograft rejection, T cell help for the generation of class I-restricted CD8 cells is provided by CD4 T cells reacting to analogous II differences. Moreover, class II differences alone are sufficient to drive allograft rejection.

ASSOCIATION WITH INFECTIOUS DISEASE

It has long been postulated that infectious agents provide the driving force for the allelic diversification seen in the HLA system. This has been difficult to confirm definitively, but one corollary of this hypothesis, namely, that it would be unusual to find HLA alleles strongly associated with susceptibility to any particular infectious disease, has generally been observed. Some modest associations of susceptibility to tuberculosis and leprosy have been found for several subtypes of HLA-DR2 (DRB1*15), and progression of HIV has been associated with several HLA haplotype including HLA-B35, HLA-CW*04, and HLA-A1-B8-DR3 in some studies (Chap. 309). With regard to resistance to infectious disease, the best documented example has been shown for malaria, in which B*5301, DRB1*1302, and DRB1*0101 have been shown to exert varying degrees of protection against severe disease. Slow progression of HIV has been associated with several HLA haplotypes (Chap. 309), and reduced persistence of hepatitis B and C viruses has been associated, respectively, with DRB1*1302 and with DR5.

A polymorphism in the promoter of theTNF-agene in the HLA class III region, which is associated with quantitative variation in the production of TNF, has recently been shown to have an association with the manifestations of a number of infectious diseases, including cerebral malaria, mucocutaneous leishmaniasis, lepromatous leprosy, scarring trachoma, persistent hepatitis B infection, and fatal meningicoccal meningitis.

ASSOCIATION OF HLA ALLELES WITH SUSCEPTIBILITY TO IMMUNOLOGICALLY MEDIATED DISEASES

Because of the immense polymorphism of HLA loci and strong linkage disequilibrium within the HLA region, it became possible, once a sufficient number of alleles had been defined by the early 1970s, to find associations of particular HLA alleles with certain disease states by comparing allele frequencies in patients with any particular disease and in control populations. A large number of such associations were identified during the 1970s. Most subsequent work in this field has been devoted to refining these associations to molecularly defined alleles and attempting to elucidate the contribution of HLA to disease pathogenesis.Table 306-1 lists the major diseases associated with HLA class I and class II genes. The strength of genetic association is reflected in the term *relative risk*, which is a statistical odds ratio representing the risk of disease in an individual carrying a particular genetic marker compared with the risk in individuals in that population without that marker. The nomenclature shown in Table 306-1 reflects both the HLA serotype (e.g., DR3, DR4) and the HLA genotype (e.g., DRB1*0301, DRB1*0401). Both because of the strong linkage disequilibrium within HLA and because the serologically identified loci represent only a small fraction of the total genes within the region, for many years it could not be established whether the associated alleles themselves participated in disease pathogenesis or were merely markers that were in linkage disequilibrium with the true disease allele. In recent years, it has become clear that it is very likely that the class I and class II alleles themselves are the true disease alleles for most of these associations. However, as discussed below, because of the extremely strong linkage disequilibrium between the DR and DQ loci, in some cases it has been difficult to determine the specific locus or combination of class II loci involved. At a minimum, different populations with different DR-DQ haplotypes need to be compared.

As might be predicted from the known function of the class I and class II gene products, almost all of the diseases associated with specific HLA alleles have an immunologic component to their pathogenesis. In some cases, as discussed below, specific protein and even peptide antigens have been implicated, but in no case is the molecular and cellular pathogenesis well understood. From a genetic point of view, strong HLA associations with disease (those associations with a relative risk of 10 or greater) are unusual because the implicated HLA alleles are normal, rather than defective, alleles. However, even in diseases with very strong HLA associations such as ankylosing spondylitis (AS) and type I diabetes mellitus, the non-HLA contribution exceeds 50% of the genetic predisposition, and the concordance of disease in monozygotic twins is considerably higher than in HLA-identical dizygotic twins or other sibling pairs. Genome-wide linkage analyses in these two diseases have found that the non-HLA genetic contribution comes from several other regions, although the linkage to HLA is by far the strongest.

Another group of diseases is genetically linked to HLA, not because of the immunologic function of HLA alleles, but rather because they are caused by autosomal dominant or recessive abnormal alleles at loci that happen to reside in or near the HLA region. Examples of these are 21-hydroxylase deficiency, hemochromatosis, and spinocerebellar ataxia (Chaps. 338,345, and364, respectively).

CLASS I DISEASE ASSOCIATIONS

Although the associations of human disease with particular HLA alleles or haplotypes predominantly involve the class II region, there are also several prominent disease associations with class I alleles. These include the association of Behcet's disease (Chap. 316) with HLA-B51, psoriasis vulgaris (Chap. 56) with HLA-Cw6, and, most prominently, the spondyloarthropathies (Chap. 315) with HLA-B27. The latter is among the strongest of all HLA associations with disease.

HLA-B27 was originally defined as a serologic determinant. It currently includes a family of 15 HLA-B locus alleles, designated HLA-B*2701-2715, as determined by nucleotide sequencing. HLA-B*2705 is the predominant subtype in Caucasians and most other non-Asian populations, and this subtype has been subjected to the most extensive investigation. All of the subtypes share a common B pocket in the peptide-binding groove, containing characteristic residues His9, Thr24, Glu45, and Cys67, and almost all share adjacent residues Ala69, Lys70, and Ala71. This deep, negatively charged pocket shows a strong preference for binding the arginine side chain, explaining the preference of the B27 binding group for peptides with Arg at P2 (peptide residue 2), as suggested by the crystal structure and confirmed by peptide isolation and sequencing. In addition, B27 is among the most negatively charged of HLA class I heavy chains, and the overall preference is for positively charged peptides. B27 is distinguished among class I alleles as a dominant restricting element forCTLrecognition of antigens from a wide variety of viruses, including HIV, and it is associated with prolonged survival in HIV infection (Chap. 309).

HLA-B27 and Disease HLA-B27 is very highly associated withAS(Chap. 315), both in its idiopathic form and in association with chronic inflammatory bowel disease or

psoriasis vulgaris. It is also associated with reactive arthritis (ReA;Chap. 315), with other idiopathic forms of peripheral arthritis (undifferentiated spondyloarthropathy), and with recurrent acute anterior uveitis. B27 is found in 50 to 90% of individuals with these conditions, compared with a prevalence of ~7% in North American Caucasians. The prevalence of B27 in patients with idiopathic AS is 90%, and in AS complicated by iritis or aortic insufficiency is close to 100%. The absolute risk of spondyloarthropathy in unselected B27+ individuals has been variously estimated at 2 to 13% and >20% if a B27+ first-degree relative is affected. The concordance rate of AS in identical twins is very high, approximately 75%. It can be concluded that the B27 molecule itself is involved in disease pathogenesis, based on strong evidence from clinical epidemiology and on the occurrence of a spondyloarthropathy-like disease in HLA-B27 transgenic rats. A well-established association with both AS and ReA exists for subtypes B*2702, -04, and -05, and anecdotal association has been reported for subtypes B*2701, -03, -07, -08, -10, and -11. The propensity of the B27 molecule to induce disease thus presumably derives from one or more unique features of its structure that are shared by several B27 subtypes. It remains a central unanswered question whether the pathogenesis of B27-associated disease derives from the specificity of a particular peptide or family of peptides bound to B27 or whether another mechanism is involved that is independent of the peptide specificity of B27. The first alternative can be further subdivided into mechanisms that involve T cell recognition of B27-peptide complexes, and those that do not. A variety of other roles for B27 in disease pathogenesis have been postulated, including molecular or antigenic mimicry between B27 and certain bacteria and reduced killing of intracellular bacteria in cells expressing B27. However, the most straightforward possibility is the presentation of peptides to CD8 T cells in a way that somehow promotes joint inflammation, i.e., the "arthritogenic peptide" hypothesis. This concept has been supported in ReA by the finding of CD8-restricted antigen-specific T cells, particularly in *Yersinia*-induced ReA. It is of particular interest that the HSP60 molecule from *Y. enterocolitica* has been shown to give rise to dominant antigens recognized by both synovial B27-restricted CD8 and class II-restricted CD4 T cells. This suggests a T cell pathogenesis involving intramolecular help and/or epitope spreading in which a B27-restricted response could well be primary.

In contrast toReA, there is little direct evidence regarding the molecular role of HLA-B27 in ankylosing spondylitis. However, correlations between disease susceptibility and the peptide-binding specificity of the B27 subtypes have been found that support the "arthritogenic peptide" hypothesis inAS. Specifically, a lack of disease susceptibility has been documented for the subtypes B*2706, found mainly amongst Southeast Asians, and B*2709, found mainly amongst Sardinians. B*2709 differs from B*2705 only at residue 116, carrying His instead of Asp. B*2706 differs from B*2704 at 114 and 116, carrying Asp and Tyr instead of His and Asp. These residues, which lie in the floor of the peptide-binding groove, interact with the C-terminal end of the bound peptide. Unlike the disease-associated subtypes, B*2706 and B*2709 have been found not to carry peptides with C-terminal Tyr. This has led to the hypothesis of a disease-prone B27-bound peptide with C-terminal Tyr.

CLASS II DISEASE ASSOCIATIONS

The majority of associations between HLA and disease are with class II alleles (Table 306-1). Several diseases have complex HLA genetic associations.

Celiac Disease In the case of celiac disease (Chap. 286), it is probable that the HLA-DQ genes are the primary basis for the disease association. HLA-DQ genes present on both the celiac-associated DR3 and DR7 haplotypes include the DQB1*0201 gene, and further detailed studies have documented a specific class IIab dimer encoded by the DQA1*0501 and DQB1*0201 genes, which appears to account for the HLA genetic contribution to celiac disease susceptibility. This specific HLA association with celiac disease may have a straightforward explanation: peptides derived from the wheat gluten component gliaden are bound to the molecule encoded by DQA1*0501 and DQB1*0201 and presented to T cells. A gliaden-derived peptide that has been implicated in this immune activation binds the DQ class II dimer best when the peptide contains a glutamine to glutamic acid substitution. It has been proposed that tissue transglutaminase, an enzyme present at increased levels in the intestinal cells of celiac patients, converts glutamine to glutamic acid in gliadin, creating peptides that are capable of being bound by the DQ2 molecule and presented to T cells.

Pemphigus Vulgaris In the case of pemphigus vulgaris (Chap. 58), there are two HLA haplotypes associated with disease: DRB1*0402-DQB1*0302 and DRB1*1401-DQB1*0503. Peptides derived from epidermal autoantigens have been implicated that preferentially bind to the DRB1*0402-encoded molecule, suggesting that specific peptide binding by this disease-associated class II molecule is important in disease. However, there are no class II genes in common between the disease-associated DR4 and DR14 haplotypes, and there is no evidence for any interaction of the latter haplotype interacting with the epidermal peptides that bind the DRB1*0402-encoded molecule. Thus, the most likely interpretation is that each of these class II associations with pemphigus represents a different pathway to a comparable clinical outcome.

Juvenile Arthritis Pauciarticular juvenile arthritis (Chap. 312) is an autoimmune disease associated with genes at the DRB1 locus and also with genes at the DPB1 locus. Patients with both DPB1*0201 and a DRB1 susceptibility allele (usually DRB1*08 or -*05) have a higher relative risk than expected from the additive effect of those genes alone. In juvenile patients with rheumatoid factor-positive polyarticular disease, heterozygotes carrying both DRB1*0401 and -*0404 have a relative risk>100, reflecting an apparent synergy in individuals inheriting both of these susceptibility genes.

Type 1 Diabetes Mellitus There are several aspects of the genetics of type 1 diabetes (Chap. 333) that illustrate the complex nature of HLA associations with autoimmune diseases. First, type 1 (autoimmune) diabetes mellitus is associated with both DR3 and DR4 serotypes and their corresponding genes. The presence of both the DR3 and DR4 haplotypes in one individual confers the highest known genetic risk for type diabetes, and individuals carrying either of these haplotypes also carry some increased risk. Specific class II genes on each haplotype have been thoroughly studied, and the strongest association is with DQB1*0302, a specific gene on the diabetes-associated DR4 haplotypes. Thus, all DR4 haplotypes that carry a DQB1*0302 gene are associated with type 1 diabetes, whereas related DR4 haplotypes that carry a different DQB1 gene are not. The primary class II determinant of susceptibility, therefore, is HLA-DQB1*0302. However, the relative risk associated with inheritance of this gene can be modified, depending on other HLA genes present either on the same or a second haplotype. For

example, just as the presence of a second haplotype containing DR3 is associated with an increased risk of diabetes, the presence of a DR2-positive haplotype containing a DQB1*0602 gene is associated with decreased risk. This gene, DQB1*0602, is considered "protective" for type 1 diabetes. Even some DRB1 genes that can occur on the same haplotype as DQB1*0302 may modulate risk, so that individuals with the DR4 haplotype that contains DRB1*0403 are less susceptible to type 1 diabetes than individuals with other DR4-DQB1*0302 haplotypes.

Although the presence of a DR3 haplotype in combination with the DR4-DQB1*0302 haplotype is a very high risk combination for diabetes susceptibility, the specific gene on the DR3 haplotype that is responsible for this synergy has not yet been identified. This is because the predominant HLA-DR3 haplotype in Caucasians has very tight linkage with other genes within theMHC, including HLA-A1, -B8, -Cw7, and -C4A, as discussed above. Thus, any of a large variety of genes within the HLA region on this DR3 haplotype may be the primary gene(s) responsible for contributing to diabetes susceptibility. An example that more directly implicates other genes linked to DR3 is the association between HLA genes and systemic lupus erythematosus (SLE;Chap. 311). The C4A null alleles that are present on the HLA-DR3 haplotypes in SLE are also often present in patients without DR3, notably those with HLA-DR2. This implies the presence of a C4A silent allele, which is a defective structural gene for the C4 complement component, rather than the expression of any particular class II gene, as a potential susceptibility gene within HLA associated with SLE.

HLA and Rheumatoid Arthritis The HLA genes most highly associated with rheumatoid arthritis (RA) are DRB1*0401 and DRB1*0404 (Chap. 312). These genes encode a distinctive sequence of amino acids from codons 67 to 74 of the DRb molecule: RA-associated class II molecules carry the sequence LeuLeuGluGlnArgArgAlaAla or LeuLeuGluGlnLysArgAlaAla in this region, while non-RA-associated genes carry one or more differences in this region. These residues form a portion of the molecule that lies in the middle of the a-helical portion of the DRB1-encoded class II molecule, termed the *shared epitope*.

These DR4+RA-associated alleles are most frequent among patients with more severe, erosive disease. The frequency of these DR4+ alleles is lower among patients with RA who are rheumatoid factor-negative and those with nonerosive forms of the disease. Although the frequency of these DRB1 susceptibility alleles in RA patients is high, the same genes are also prevalent in the unaffected population, and thus the absolute risk associated with these susceptibility alleles is low. The highest risk for susceptibility to RA comes in individuals who carry both a DRB1*0401 and DRB1*0404 gene. Some forms of RA are associated with other HLA genes, such as DRB1*01, -*1001, and -*1402, which also carry the shared epitope sequence, strongly suggesting that this part of the class II molecule contributes directly to disease pathogenesis.

MOLECULAR MECHANISMS FOR HLA DISEASE ASSOCIATIONS

As noted above, HLA molecules play a key role in the selection and establishment of the antigen-specific T cell repertoire and a major role in the subsequent activation of those T cells during the initiation of an immune response. Precise genetic polymorphisms characteristic of individual alleles dictate the specificity of these

interactions and thereby instruct and guide antigen-specific immune events. These same genetically determined pathways are therefore implicated in disease pathogenesis when specific HLA genes are responsible for autoimmune disease susceptibility.

The fate of developing T cells within the thymus is determined by the affinity of interaction betweenTCR and HLA molecules bearing self peptides; thus, the particular HLA types of each individual control the precise specificity of the T cell repertoire (Chap. 305). The primary basis for HLA-associated disease susceptibility may well lie within this thymic maturation pathway. The positive selection of potentially autoreactive T cells, based on the presence of specific HLA susceptibility genes, may establish the threshold for disease risk in a particular individual.

At the time of onset of a subsequent immune response, the primary role of the HLA molecule is to bind peptide and present it to antigen-specific T cells. The HLA complex can therefore be viewed as encoding genetic determinants of precise immunologic activation events. Antigenic peptides that bind particular HLA molecules are capable of stimulating T cell immune responses; peptides that do not bind are not presented to T cells and are not immunogenic. This genetic control of the immune response is mediated by the polymorphic sites within the HLA antigen-binding groove that interact with the bound peptides. In autoimmune and immune-mediated diseases, it is likely that specific tissue antigens that are targets for pathogenic lymphocytes are complexed with the HLA molecules encoded by specific susceptibility alleles. In autoimmune diseases with an infectious etiology, it is likely that immune responses to peptides derived from the initiating pathogen are bound and presented by particular HLA molecules to activate T lymphocytes that play a triggering or contributory role in disease pathogenesis. The concept that early events in disease initiation are triggered by specific HLA-peptide complexes offers some prospects for therapeutic intervention, since it may be possible to design compounds that interfere with the formation or function of specific HLA-peptide-TCRinteractions.

When considering mechanisms of HLA associations with the immune response and with disease it is well to remember that just as HLA genetics are complex, so are the mechanisms likely to be heterogeneous. Immune-mediated disease is a multistep process in which one of the HLA-associated functions is to establish a repertoire of potentially reactive T cells, while another HLA-associated function is to provide the essential peptide-binding specificity for T cell recognition. For diseases with multiple HLA genetic associations, it is possible that both of these interactions occur and synergize to advance an accelerated pathway of disease.

307. AUTOIMMUNITY AND AUTOIMMUNE DISEASES - *Peter E. Lipsky*, *Betty Diamond*

One of the classically accepted features of the immune system is the capacity to distinguish self from non-self. Although they are able to recognize and generate reactions to a vast array of foreign materials, most animals do not mount immune responses to self-antigens under ordinary circumstances and thus are tolerant to self. Although recognition of self plays an important role in generating both the T cell and B cell repertoires of immune receptors and plays an essential role in the recognition of nominal antigen by T cells, the development of potentially harmful immune responses to self-antigens is, in general, precluded. Autoimmunity, therefore, represents the end result of the breakdown of one or more of the basic mechanisms regulating immune tolerance.

The presence or absence of pathologic consequences resulting from self-reactivity determines whether autoimmunity leads to the development of an autoimmune disease. The essential feature of an autoimmune disease is that tissue injury is caused by the immunologic reaction of the organism with its own tissues. Autoimmunity, on the other hand, refers merely to the presence of antibodies or T lymphocytes that react with self-antigens and does not necessarily imply that the development of self-reactivity has pathogenic consequences.

Autoimmunity may occur as an isolated event or in the setting of specific clinical syndromes. Autoimmunity may be seen in normal individuals and in higher frequency in normal older people. In addition, autoreactivity may develop during various infectious conditions. The expression of autoimmunity may be self-limited, as occurs with many infectious processes, or persistent. In both circumstances there is a tendency to develop autoreactivity directed against a variety of different tissues or organs. As mentioned above, autoimmunity does not necessarily lead to tissue damage, and even in the presence of organ pathology, it may be difficult to determine whether the damage is mediated by autoreactivity. Thus, the presence of self-reactivity may be either the cause or a consequence of an ongoing pathologic process. Furthermore, when autoreactivity is induced by an inciting event, such as infection or tissue damage from trauma or infarction, there may or may not be ensuing pathology.

MECHANISMS OF AUTOIMMUNITY

Since Ehrlich first postulated the existence of mechanisms to prevent the generation of self-reactivity in 1900, ideas concerning the nature of this inhibition have developed in parallel with the progressive increase in understanding of the immune system. Burnet's clonal selection theory included the idea that interaction of lymphoid cells with their specific antigens during fetal or early postnatal life would lead to elimination of such "forbidden clones." This idea became untenable, however, when it was shown by a number of investigators that autoimmune diseases could be induced by simple immunization procedures, that autoantigen-binding cells could be demonstrated easily in the circulation of normal individuals, and that self-limited autoimmune phenomena frequently developed during infections. These observations indicated that clones of cells capable of responding to autoantigens were present in the repertoire of antigen-reactive cells in normal adults and suggested that mechanisms in addition to clonal deletion

were responsible for preventing their activation.

Currently, three general processes are thought to be involved in the maintenance of selective unresponsiveness to autoantigens (Table 307-1): (1) sequestration of self-antigens, rendering them inaccessible to the immune system; (2) specific unresponsiveness (tolerance or anergy) of relevant T or B cells; and (3) limitation of potential reactivity by regulatory mechanisms. These mechanisms permit the host to respond to the vast universe of foreign antigens but preclude responses to autoantigens that might have pathogenic consequences.

Derangements of these normal processes may predispose to the development of autoimmunity (Table 307-2). In general, these abnormal responses relate to stimulation by exogenous agents, usually bacterial or viral, or endogenous abnormalities in the cells of the immune system. Thus, autoreactivity can result from exogenous stimulation of the immune system in a manner that overcomes the regulated unresponsiveness to self-antigens. Microbial superantigens, such as staphylococcal protein A and staphylococcal enterotoxins, are substances that can stimulate a broad range of T and B cells based upon specific interactions with selected families of immune receptors irrespective of their antigen specificity. If autoantigen reactive T and/or B cells express these receptors, autoimmunity might develop. Alternatively, molecular mimicry or cross-reactivity between a microbial product and a self-antigen might lead to activation of autoreactive lymphocytes. One of the best examples of autoreactivity and autoimmune disease resulting from molecular mimicry is rheumatic fever, in which antibodies to the M protein of streptococci cross-react with myosin, laminin, and other matrix proteins. Deposition of these autoantibodies in the heart initiates an inflammatory response. Molecular mimicry between microbial proteins and host tissues has been reported in insulin-dependent diabetes mellitus (IDDM), rheumatoid arthritis, and multiple sclerosis. The capacity of nonspecific stimulation of the immune system to predispose to the development of autoimmunity has been explored in a number of models; one is provided by the effect of adjuvants on the production of autoimmunity. Autoantigens become much more immunogenic when administered with adjuvant. It is presumed that infectious agents may be able to overcome self-tolerance because they possess molecules, such as bacterial endotoxin, that have adjuvant-like effects on the immune system.

Endogenous derangements of the immune system may also contribute to the loss of immunologic tolerance, or anergy, to self-antigens and the development of autoimmunity (Table 307-2). Many autoantigens reside in immunologically privileged sites, such as the brain or the anterior chamber of the eye. These sites are characterized by the inability of engrafted tissue to elicit immune responses. Immunologic privilege results from a number of events, including the limited entry of proteins from those sites into lymphatics, the local production of immunosuppressive cytokines such as transforming growth factor (TGF) b, and the local expression of molecules such as Fas ligand that can induce apoptosis of activated T cells. Lymphoid cells remain in a state of immunologic ignorance (neither activated nor anergized) to proteins expressed uniquely in immunologically privileged sites. If the privileged site is damaged by trauma or inflammation, or if T cells are activated elsewhere, proteins expressed at this site can become the targets of immunologic assault. Such an event may occur in multiple sclerosis and sympathetic ophthalmia, in which antigens uniquely

expressed in the brain and eye, respectively, become the target of activated T cells.

Alterations in antigen presentation may also contribute to autoimmunity. This may occur by epitope spreading, in which protein determinants (*epitopes*) not routinely seen by lymphocytes (*cryptic epitopes*) are recognized as a result of immunologic reactivity to associated molecules. For example, animals immunized with one protein component of the spliceosome may be induced to produce antibodies to multiple other spliceosome proteins. Finally, inflammation, drug exposure, or normal senescence may cause a primary chemical alteration in proteins, resulting in the generation of immune responses that cross-react with normal self-proteins. Alterations in the availability and presentation of autoantigens may be important components of immunoreactivity in certain models of organ-specific autoimmune diseases. In addition, these factors may be relevant in understanding the pathogenesis of various drug-induced autoimmune conditions. However, the diversity of autoreactivity manifest in non-organ-specific systemic autoimmune diseases suggests that these conditions might result from a more general activation of the immune system rather than from an alteration in individual self-antigens.

A number of experimental models have suggested that intense stimulation of T lymphocytes can produce nonspecific signals that bypass the need for antigen-specific helper T cells and lead to polyclonal B cell activation with the formation of multiple autoantibodies. For example, antinuclear, antierythrocyte, and antilymphocyte antibodies are produced during the chronic graft-versus-host reaction. In addition, true autoimmune diseases, including autoimmune hemolytic anemia and immune complex-mediated glomerulonephritis, can also be induced in this manner. While it is clear that such diffuse activation of helper T cell activity can cause autoimmunity, nonspecific stimulation of B lymphocytes can also lead to the production of autoantibodies. Thus, the administration of polyclonal B cell activators, such as bacterial endotoxin, to normal mice leads to the production of a number of autoantibodies, including those directed to DNA and IgG (rheumatoid factor).

Primary alterations in the activity of T and/or B cells, cytokine imbalances, or defective immunoregulatory circuits may also contribute to the emergence of autoimmunity. Although the biochemical bases of many of these abnormalities have not been documented, they may contribute to the emergence of autoimmunity either alone or in concert. For example, decreased apoptosis, as can be seen in animals with defects in Fas (CD95) or Fas ligand or in patients with related abnormalities, can be associated with the development of autoimmunity. Similarly, diminished production of tumor necrosis factor (TNF) a and interleukin (IL)10 has been reported to be associated with the development of autoimmunity.

An alternative explanation for the development of autoimmunity is that self-reactivity results not from overstimulation of the immune system but rather from an abnormality of immunoregulatory mechanisms. Observations made in both human autoimmune disease and animal models suggest that defects in the generation and expression of regulatory T cell activity may allow for the production of autoantibodies. The importance of defects in immunoregulatory cells is confirmed by the finding that administration of normal suppressor T cells or factors derived from them can prevent the development of autoimmune disease in rodent models of autoimmunity.

One of the mechanisms that regulates normal humoral immune responses is the production of anti-idiotype antibodies. These are immunoglobulin molecules directed against antigen-binding determinants of the specific antibodies originally elicited by the immunogen. Production of anti-idiotype antibodies may be dependent on helper T cell activity even when the initial immunogen is T cell independent. Therefore, it is possible that abnormalities in the generation of appropriate anti-idiotype antibodies, either at the B or T cell level, are responsible for the development of autoimmunity in certain circumstances.

It should be apparent that no single mechanism can explain all the varied manifestations of autoimmunity. Indeed, it appears likely, especially in systemic autoimmune diseases, that a number of abnormalities may converge to induce the complete syndrome. Moreover, one abnormality may cause a second, which, in concert with the first, facilitates the expression of autoimmunity. This possibility is consistent with recent findings in murine models ofIDDM; systemic lupus erythematosus (SLE), rheumatoid arthritis, and multiple sclerosis in which multiple genetic regions, many of which are involved in controlling immune reactivity, appear to contribute to the development of autoimmune disease.

Despite the plethora of immunologic derangements identified in systemic autoimmune diseases such asSLE, the primary abnormality causing the disease remains unclear. In fact, detailed examination of a number of murine strains that spontaneously develop a lupus-like syndrome has failed to demonstrate a common immunologic abnormality. Additional factors that appear to be important determinants in the induction of autoimmunity include age, sex, genetic background, exposure to infectious agents, and environmental contacts. How all of these disparate factors affect the capacity to develop self-reactivity is currently being intensively investigated.

GENETIC CONSIDERATIONS

Evidence in humans that there are susceptibility genes for autoimmunity comes from family studies and especially from studies of twins. Studies inIDDM, rheumatoid arthritis, multiple sclerosis, andSLE have shown that approximately 15 to 30% of pairs of monozygotic twins show disease concordance, compared with <5% of dizygotic twins. The occurrence of different autoimmune diseases within the same family has suggested that certain susceptibility genes may predispose to a variety of autoimmune diseases. In addition to this evidence from humans, certain inbred mouse strains reproducibly develop specific spontaneous or experimentally induced autoimmune diseases, whereas others do not. These findings have led to an extensive search for genes that determine susceptibility to autoimmune disease.

The most consistent association for susceptibility to autoimmune disease has been with the major histocompatibility complex (MHC). Many human autoimmune diseases are associated with particular HLA alleles (Chap. 306). It has been suggested that the association of MHC genotype with autoimmune disease relates to differences in the ability of different allelic variations of MHC molecules to present autoantigenic peptides to autoreactive T cells. An alternative hypothesis involves the role of MHC alleles in shaping the T cell receptor repertoire during T cell ontongeny in the thymus.

Additionally, specific MHC gene products themselves may be the source of peptides that can be recognized by T cells. Cross-reactivity between such MHC peptides and peptides derived from proteins produced by common microbes may trigger autoimmunity by molecular mimicry. However, MHC genotype alone does not determine the development of autoimmunity. Identical twins are far more likely to develop the same autoimmune disease than MHC-identical nontwin siblings, suggesting that genetic factors other than the MHC also affect disease susceptibility. Recent studies of the genetics ofIDDM,SLE, and multiple sclerosis in humans and mice have shown that there are several independently segregating disease susceptibility loci in addition to the MHC.

There is evidence that several other genes are important in increasing susceptibility to autoimmune disease. In humans, inherited homozygous deficiency of the early proteins of the classic pathway of complement (C1, C4, or C2) is very strongly associated with the development ofSLE. In mice and humans, abnormalities in the genes encoding proteins involved in the regulation of apoptosis, including Fas (CD95) and Fas ligand (CD95 ligand), are strongly associated with the development of autoimmunity. There is also evidence that inherited variation in the level of expression of certain cytokines, such asTNF-aorIL-10, may also increase susceptibility to autoimmune disease.

A further important factor in disease susceptibility is the hormonal status of the patient. Many autoimmune diseases show a strong sex bias, which appears in most cases to relate to the hormonal status of women.

IMMUNOPATHOGENIC MECHANISMS IN AUTOIMMUNE DISEASES

The mechanisms of tissue injury in autoimmune diseases can be divided into antibody-mediated and cell-mediated processes. Representative examples are listed inTable 307-3.

The pathogenicity of autoantibodies can be mediated through several mechanisms, including opsonization of soluble factors or cells, activation of an inflammatory cascade via the complement system, and interference with the physiologic function of soluble molecules or cells.

In autoimmune thrombocytopenic purpura, opsonization of platelets targets them for elimination by phagocytes. Likewise, in autoimmune hemolytic anemia, binding of immunoglobulin to red cell membranes leads to phagocytosis and lysis of the opsonized cell. Goodpastures' syndrome, a disease characterized by lung hemorrhage and severe glomerulonephritis, represents an example of antibody binding leading to local activation of complement and neutrophil accumulation and activation. The autoantibody in this disease binds to theα_3 chain of type IV collagen in the basement membrane. InSLE, activation of the complement cascade at sites of immunoglobulin deposition in renal glomeruli is considered to be a major mechanism of renal damage.

Autoantibodies can also interfere with normal physiologic functions of cells or soluble factors. Autoantibodies against hormone receptors can lead to stimulation of cells or to inhibition of cell function through interference with receptor signaling. For example, long-acting thyroid stimulators (LATS), which are autoantibodies that bind to the receptor for thyroid-stimulating hormone (TSH), are present in Graves' disease and

function as agonists, causing the thyroid to respond as if there were an excess of TSH. Alternatively, antibodies to the insulin receptor can cause insulin-resistant diabetes mellitus through receptor blockade. In myasthenia gravis, autoantibodies to the acetylcholine receptor can be detected in 85 to 90% of patients and are responsible for muscle weakness. The exact location of the antigenic epitope, the valence and affinity of the antibody, and perhaps other characteristics determine whether activation or blockade results from antibody binding.

Antiphospholipid antibodies are associated with thromboembolic events in primary and secondary antiphospholipid syndrome and have also been associated with fetal wastage. The major antibody is directed to the phospholipid-b_2-glycoprotein I complex and appears to exert a procoagulant effect. In pemphigus vulgaris, autoantibodies bind to a component of the epidermal cell desmosome, desmoglein 3, and play a role in the induction of the disease. They exert their pathologic effect by disrupting cell-cell junctions through stimulation of the production of epithelial proteases, leading to blister formation. Cytoplasmic antineutrophil cytoplasmic antibody (c-ANCA), found in Wegener's granulomatosis, is an antibody to an intracellular antigen, the 29-kDa serine protease (proteinase-3). In vitro experiments have shown that IgG c-ANCA causes cellular activation and degranulation of primed neutrophils.

It is important to note that autoantibodies of a given specificity may cause disease only in genetically susceptible hosts, as has been shown in experimental models of myasthenia gravis. Finally, some autoantibodies seem to be markers for disease but have as yet no known pathogenic potential.

AUTOIMMUNE DISEASE

Manifestations of autoimmunity are found in a large number of pathologic conditions. However, their presence does not necessarily imply that the pathologic process is an autoimmune disease. A number of attempts to establish formal criteria for the diagnosis of autoimmune diseases have been made, but none is universally accepted. One set of criteria is shown in Table 307-4; however, this should be viewed merely as a guide in consideration of the problem.

To classify a disease as autoimmune, it is necessary to demonstrate that the immune response to a self-antigen causes the observed pathology. Initially, the demonstration that antibodies against the affected tissue could be detected in the serum of patients suffering from various diseases was taken as evidence that these diseases had an autoimmune basis. However, such autoantibodies are also found when tissue damage is caused by trauma or infection, and the autoantibody is secondary to tissue damage. Thus, it is necessary to show that autoimmunity is pathogenic before classifying a disease as autoimmune.

If the autoantibodies are pathogenic, it may be possible to transfer disease to experimental animals by the administration of autoantibodies, with the subsequent development of pathology in the recipient similar to that seen in the patient from whom the antibodies were obtained. This has been shown, for example, in Graves' disease. Some autoimmune diseases can be transferred from mother to fetus and are observed in the newborn babies of diseased mothers. The symptoms of the disease in the

newborn usually disappear as the levels of the maternal antibody decrease. An exception is congenital heart block, in which damage to the developing conducting system of the heart as a result of transfer of anti-Ro antibody from the mother results in permanent heart block.

In most situations, the critical factors that determine when the development of autoimmunity results in autoimmune disease have not been delineated. The relationship of autoimmunity to the development of autoimmune disease may relate to the fine specificity of the antibodies or T cells or their specific effector capabilities. In many circumstances a mechanistic understanding of the pathogenic potential of autoantibodies has not been established. In some autoimmune diseases, biased production of cytokines by helper T (T_H) cells may play a role in pathogenesis. In this regard, T cells can differentiate into specialized effector cells that predominantly produce interferong(T_H1) orIL-4 (T_H2) (Chap. 305). The former facilitate macrophage activation and classic cell-mediated immunity, whereas the latter are thought to have regulatory functions and are involved in the resolution of normal immune responses and also the development of responses to a variety of parasites. In a number of autoimmune diseases, such as rheumatoid arthritis, multiple sclerosis,IDDM, and Crohn's disease, there appears to be biased differentiation of T_H1 cells, with resultant organ damage.

ORGAN-SPECIFIC VERSUS SYSTEMIC AUTOIMMUNE DISEASES

Autoimmune diseases form a spectrum, from those specifically affecting a single organ to systemic disorders with involvement of many organs (Table 307-5). Hashimoto's autoimmune thyroiditis is probably the best studied example of an organ-specific autoimmune disease (Chap. 330). In this disorder, there is a specific lesion in the thyroid associated with infiltration of mononuclear cells and damage to follicular cells. Antibody to thyroid constituents can be demonstrated in nearly all cases. Other organ- or tissue-specific autoimmune disorders include pemphigus vulgaris, autoimmune hemolytic anemia, idiopathic thrombocytopenic purpura, Goodpasture's syndrome, myasthenia gravis, and sympathetic ophthalmia. One important feature of some organ-specific autoimmune diseases is the tendency for overlap, such that an individual with one specific syndrome is more likely to develop a second syndrome. For example, there is a high incidence of pernicious anemia in individuals with autoimmune thyroiditis. More striking is the tendency for individuals with an organ-specific autoimmune disease to develop multiple other manifestations of autoimmunity without the development of associated organ pathology. Thus, as many as 50% of individuals with pernicious anemia have non-cross-reacting antibodies to thyroid constituents, whereas patients with myasthenia gravis may develop antinuclear antibodies, antithyroid antibodies, rheumatoid factor, antilymphocyte antibodies, and polyclonal hypergammaglobulinemia. Part of the explanation for this may relate to the genetic elements shared by individuals with these different diseases.

SYSTEMIC AUTOIMMUNE DISEASE

Systemic autoimmune diseases differ from organ-specific diseases in that pathologic lesions are found in multiple, diverse organs and tissues. The hallmark of these conditions is the demonstration of associated relevant autoimmune manifestations that are likely to be etiologic in the organ pathology.SLE is the best example of such a

disorder. Although a number of other diseases such as Sjogren's syndrome possess certain of the features of a systemic autoimmune disease, SLE represents the prototype of these disorders because of its abundance of autoimmune manifestations.

SLEis a disease of protean manifestations that characteristically involves the kidneys, joints, skin, serosal surfaces, blood vessels, and central nervous system (Chap. 311). The disease is associated with a vast array of autoantibodies whose production appears to be a part of a generalized hyperreactivity of the humoral immune system. Other features of SLE include generalized B cell hyperresponsiveness, polyclonal hypergammaglobulinemia, and increased titers of antibodies to commonly encountered viral antigens.

A number of the autoantibodies found in SLEhave clearly been implicated in certain of the pathologic features of the disease. Classically, SLE has been considered a disorder in which immune complexes are the major pathogenic entity. While immune-complex deposition or in situ formation of complexes appears to be a major pathogenic mechanism in lupus renal disease, additional autoimmune processes may be implicated in the pathogenesis of other features of the disease (Table 307-6).

The etiology ofSLEremains unknown, and the interplay of a number of factors appears to be involved in its pathogenesis. Race and gender play an important role as evidenced by the increased incidence in young black females. The role of environmental factors is suggested by the high incidence of autoantibodies, especially antilymphocyte antibodies, in nonconsanguineous household contacts of individuals with SLE. The importance of genetic influences is suggested by family studies indicating that first-degree relatives of SLE patients have an increased likelihood of developing autoimmunity and autoimmune disease. The very high concordance rate for SLE and even higher rate for autoimmunity in monozygotic twins supports this concept. Finally, the association of SLE withMHCgenes confirms the importance of immunogenetic factors in its pathogenesis. Current hypotheses concerning the immunopathogenesis of SLE suggest that autoantibody formation may result from a combination of exaggerated B cell activation owing either to excessive exogenous stimulation or endogenous hyperactivity and inadequate regulatory T cell or anti-idiotype regulation. Genetic elements may contribute to each of these abnormalities.

308. PRIMARY IMMUNE DEFICIENCY DISEASES - *Max D. Cooper*, *Harry W. Schroeder, Jr.*

Immunologic functions are mediated by developmentally independent, but functionally interacting, families of lymphocytes. The activities of B and T lymphocytes and their products in host defense are closely integrated with the functions of other cells of the reticuloendothelial system. Dendritic cells, Langerhans' cells in the skin, and macrophages play an important role in the trapping and presentation of antigens to T and B cells to initiate the immune response. Macrophages also become effector cells, especially when activated by cytokine products of lymphocytes. The scavenger activity of macrophages and polymorphonuclear leukocytes is directed and made specific by antibodies in concert with cytokines and the complement system. Natural killer (NK) cells, a population of granular lymphocytes with receptors specific for MHC class I molecules, may spontaneously kill tumor and virus-infected cells, activities that are enhanced by the cytokine products of immune and inflammatory cells. Killing by NK cells can also be targeted by IgG antibodies for which NK cells have cell-surface receptors. The interaction of basophils and tissue mast cells with IgE antibodies in causation of immediate-type hypersensitivity is discussed in Chap. 310. Consideration of these interrelationships is an important part of the analysis of patients with suspected immune deficiency.

DIFFERENTIATION OF T AND B CELLS

The functional deficits that occur in both congenital and acquired immunodeficiencies are usefully viewed as being caused by defects at various points along the differentiation pathways of immunocompetent cells. A subpopulation of hematopoietic stem cells become restricted to lymphoid differentiation prior to migration to the thymus, where T cells are generated, and in the fetal liver and adult bone marrow, where B cell development begins (Fig. 308-1). Immature T and B cells then migrate through the circulation to the spleen, lymph nodes, intestine and other peripheral lymphoid organs. In these sites, they may encounter antigens presented by dendritic cells or macrophages and respond with proliferation, differentiation and mediation of immune responses.Chap. 305 provides a general account of their roles in cellular and humoral immunity.

Differentiation of T or B cells may be arrested at either the primary or secondary stages. Reflecting the complex cellular interactions involved in immune responses and the pivotal role played by T lymphocytes, immune deficiencies primarily involving T cells are usually also associated with abnormal B cell function. Conversely, immunodeficiencies manifested primarily by inability to produce antibodies may be caused by T cell defects not associated with abnormal cell-mediated immunity.

CLINICAL DISEASE FEATURES COMMON TO IMMUNE DEFICIENCY

Immunodeficiency syndromes, whether congenital, spontaneously acquired, or iatrogenic, are characterized by unusual susceptibility to infection and not infrequently to autoimmune disease and lymphoreticular malignancies. The types of infection often provide the first clue to the nature of the immunologic defect.

Patients with *defects in humoral immunity* have recurrent or chronic sinopulmonary infection, meningitis, and bacteremia, most commonly caused by pyogenic bacteria such as *Haemophilus influenzae*, *Streptococcus pneumoniae*, and staphylococci. These and other pyogenic organisms also cause frequent infections in individuals who have either neutropenia or a deficiency of the pivotal third component of complement (C3). The tripartite collaboration of antibody, complement, and phagocytes in host defense against pyogenic organisms makes it important to assess all three systems in individuals with unusual susceptibility to bacterial infections.

Antibody-deficient patients in whom cell-mediated immunity is intact have an interesting response to viral infections. The clinical course of primary infection with viruses such as varicella zoster or rubeola, unless complicated by bacterial infection, does not differ significantly from that of the normal host. However, long-lasting immunity may not develop, and as a result, multiple bouts of chickenpox and measles may occur. Such observations suggest that intact T cells may be sufficient for control of established viral infections, while antibodies play an important role in limiting the initial dissemination of virus and in providing long-lasting protection. Exceptions to this generalization are becoming more widely recognized. Agammaglobulinemic patients fail to clear hepatitis B virus from their circulation and have a progressive, and often fatal, course. Poliomyelitis has occurred following live-virus vaccination in some patients. Chronic encephalitis, which may progress over a period of months to years, is a particular threat in congenitally agammaglobulinemic boys. Echoviruses and adenoviruses have been isolated from brain, spinal fluid, or other sites in such patients.

The occurrence of an unusually serious infection, for example, *H. influenzae* meningitis in an older child or adult, warrants consideration of humoral immune deficiency. Recurrent bacterial pneumonias also suggest this possibility. Chronic otitis media occurs frequently in patients with hypogammaglobulinemia and is significant because of its relative rarity in normal adults. Pansinusitis, although almost invariably present in immunoglobulin deficiency, is a less helpful finding because it is not rare in apparently normal people. Bacterial infections of the skin or urinary tract are less frequent problems in hypogammaglobulinemic patients.

Infestation with the intestinal parasite *Giardia lamblia* is a frequent cause of diarrhea in antibody-deficient patients.

Abnormalities of cell-mediated immunity predispose to disseminated virus infections, particularly with latent viruses such as herpes simplex (Chap. 182), varicella zoster (Chap. 183), and cytomegalovirus (Chap. 185). In addition, patients so affected almost invariably develop mucocutaneous candidiasis and frequently acquire systemic fungal infections. Pneumonia caused by *Pneumocystis carinii* is also common (Chap. 209). Severe enteritis caused by *Cryptosporidium* infection may extend to the biliary tract to result in sclerosing cholangitis.

T cell deficiency is always accompanied by some abnormality of antibody responses (Fig. 308-1), although this may not be reflected by hypogammaglobulinemia. This explains in part why patients with primary T cell defects are also subject to overwhelming bacterial infection.

The most severe form of immune deficiency occurs in individuals, often infants, who lack both cell-mediated and humoral immune functions. Individuals with severe combined immunodeficiency (SCID) are susceptible to the whole range of infectious agents including organisms not ordinarily considered pathogenic. Multiple infections with viruses, bacteria, and fungi occur, often simultaneously. Because donor lymphocytes cannot be rejected by these recipients, blood transfusions can produce fatal graft-versus-host disease.

EVALUATION OF IMMUNODEFICIENT PATIENTS

A careful history and physical examination will usually indicate whether the major problem involves the antibody-complement-phagocyte system or cell-mediated immunity. A history of contact dermatitis due to poison ivy suggests intact cellular immunity. Persistent mucocutaneous candidiasis suggests deficient cell-mediated immunity. Lymphopenia and the absence of palpable lymph nodes may be important findings. However, patients with profound immunodeficiency may have diffuse lymphoid hyperplasia. Most immunodeficiencies may be diagnosed by thoughtful use of tests available in local or regional clinical laboratories. More precise evaluation of immunologic functions and treatment may require referral to specialized centers.Table 308-1 presents a resume of widely available laboratory investigations.

Humoral Immunity With rare exceptions, deficiency of humoral immunity is accompanied by diminished serum concentration of one or more classes of immunoglobulin. Normal values vary with age, and adult concentrations of IgM (1.0 ± 0.4 g/L) are reached at about 1 year, of IgG (10.0 ± 3.0 g/L) at 5 to 6 years, and of IgA (2.5 ± 1.0 g/L) by puberty (Chap. 305). The wide range of values among normal adults creates difficulty in defining the lower limits of normal. Reasonable estimates for low values are below 0.4 g/L for IgM, 5 g/L for IgG, and 0.5 g/L for IgA. In the presence of borderline hypogammaglobulinemia, assessing the patient's capacity to produce specific antibodies becomes particularly important. Isohemagglutinins, anti-streptolysin O, and "febrile agglutinins" are valuable standard assays, and measurements of pre- and postimmunization titers to tetanus toxoid, diphtheria toxoid, *H. influenzae* capsular polysaccharide, and *S. pneumoniae* serotypes provide a comprehensive assessment of humoral responsiveness.

Estimation of numbers of circulating B and T lymphocytes is of value in determining the pathogenesis of certain types of immune deficiency. B lymphocytes are identified by the presence of membrane-bound immunoglobulins, their associated a- and b-chain units, and other lineage-specific molecules on the B cell surface (Table 308-1), which can be identified and enumerated by specific monoclonal antibodies.

Since antibody deficiency may be mimicked clinically by deficiency of complement components, measurement of total hemolytic complement (CH_{50}) should be a part of the evaluation of host defense. Measurement of C3 alone is inadequate for screening, since deficiencies of both early and late complement components may predispose to bacterial infection (Chap. 305).

Cellular Immunity T lymphocytes may be enumerated by their expression of the TCR/CD3 complex of surface molecules. The CD4 molecule serves as a marker for

helper T cells, although macrophages also express this molecule in relatively low levels. Conversely, CD8ab heterodimers are expressed by cytotoxic T cells. CD8 is also expressed by some gd T cells and byNKcells, although usually as CD8aa homodimeric molecules.

Normal levels of serum immunoglobulins and antibody responsiveness are reliable indices of intact helper T cell function. T lymphocyte function can be measured directly by delayed hypersensitivity skin testing using a variety of antigens to which the majority of older children and adults have been sensitized. A generally useful skin test antigen is a 1:5 dilution of tetanus toxoid injected intradermally, since almost all individuals will have been sensitized. Purified protein derivative (PPD), histoplasmin, mumps antigen, and extracts of *Candida* or *Trichophyton* also may be used.

T lymphocyte function may be estimated in vitro by the capacity of cells to proliferate in response to antigens to which the patient has been sensitized, to lymphocytes from an unrelated donor, to antibodies that cross-link the CD3/TCR complex, or to the T cell mitogens, such as phytohemagglutinin and concanavalin A. The response is usually quantified by measurement of incorporation of radioactive thymidine into newly synthesized DNA. The production of cytokines (or interleukins) by activated T cells, can be measured as can the ability of T cells activated in mixed lymphocyte culture to lyse target cells. Finally, assays exist for detection of defects in T cell surface receptors and specific elements of their signal transduction pathways.

CLASSIFICATION

Primary immunodeficiencies may be either congenital or manifested later in life and are currently classified according to mode of inheritance and whether the genetic defect affects T cells, B cells, or both (Table 308-2). The following discussion emphasizes three related concepts: (1) that immunodeficiencies are logically viewed as defects of cellular differentiation; (2) that these defects may involve either primary development of T or B cells or the antigen-dependent phase of their differentiation; and (3) that defects of B cell differentiation may in some instances reflect faulty T-B collaboration.

Secondary immunodeficiencies are those not caused by intrinsic abnormalities in development or function of T and B cells. The best known of these is AIDS, which may follow infection with the human immunodeficiency virus (Chap. 309). Other examples are immune deficiency associated with malnutrition, protein-losing enteropathy, and intestinal lymphangiectasia. Also considered secondary are immunodeficiencies resulting from hypercatabolic states such as occur in myotonic dystrophy, immunodeficiency associated with lymphoreticular malignancy, and immunodeficiency resulting from treatment with x-rays, antilymphocyte antibodies, or immunosuppressive drugs.

Incidence As a group, the primary immunodeficiencies are relatively common. The most frequent, isolated IgA deficiency, occurs in approximately 1 in 600 individuals in North America. Common variable immunodeficiency, a related disorder characterized by pan-hypogammaglobulinemia, is the next most common disorder. Both of these immunodeficiency states often become clinically evident in young adults.

The more severe forms of primary immunodeficiency are relatively rare, have their onset early in life, and all too frequently result in death during childhood. However, patients with congenital hypogammaglobulinemia may survive to middle age and beyond with replacement antibody therapy. In a referral center for patients with immunodeficiency diseases, approximately two-thirds of the immunodeficient patients will be adults.

Severe Combined Immunodeficiency TheSCIDsyndrome is characterized by gross functional impairment of both humoral and cell-mediated immunity and by susceptibility to devastating fungal, bacterial, and viral infections. It is usually congenital, may be inherited either as an X-linked or autosomal recessive defect, or may occur sporadically. Affected infants rarely survive beyond 1 year without treatment.

The syndrome has been associated with a diversity of defects in development of immunocompetent cells, which are caused by mutations in genes whose products are necessary for the normal differentiation of T, B, and, sometimes,NKcells.

In one autosomal recessive form ofSCID characterized by severe lymphopenia, the failure in T and B cell development is due to *mutations in the* RAG-*1* or RAG-*2 genes*, the combined activities of which are needed for V(D)J recombination. A function-loss *mutation in the DNA-dependent tyrosine kinase gene* in SCID mice may prove to be a cause for SCID in humans as well, since this is another essential enzyme in the V(D)J gene rearrangement process. About half of patients with autosomal recessive SCID are deficient in an enzyme involved in purine metabolism, adenosine deaminase (ADA), due to *mutations in the* ADA *gene*. The abortive lymphoid differentiation associated with ADA deficiency is due to intracellular accumulation of adenosine and deoxyadenosine nucleotides that interferes with critical metabolic functions, including DNA synthesis.

SCIDalso may occur with an X-linked inheritance pattern. Aborted thymocyte differentiation and an absence of peripheral T cells andNK cells is seen in *X-linked* SCID. B lymphocytes are present in normal numbers but are functionally defective. The defective gene encodes a commong chain of the receptors for IL-2, -4, -7, -9, and -15, thus disrupting the action of this important set of lymphokines.

The same T^-NK-B^+SCIDphenotype seen in X-linked SCID can be inherited as an autosomal recessive disease due to mutations in the gene for *JAK3 protein kinase deficiency*. This enzyme associates with the common g chain of the receptors for IL-2, -4, -7, -9, and -15 to serve as a key element in their signal transduction pathways.

TREATMENT

The cellular defects inSCIDpatients logically rest with the pluripotent hematopoietic stem cells or their lymphoid progenitor progeny. Accordingly, the immunological deficits in all of the different types of SCID patients have been repaired by transplantation of histocompatible bone marrow as a source of stem cells, thereby implying that the stromal microenvironments of these individuals are intact and capable of supporting T and B cell development. However, antibody deficiency requiring immunoglobulin replacement therapy may persist for years in thegc deficient and JAK3 deficient patients, unless the defective B cells are eliminated prior to bone marrow transplantation to allow their replacement with normal B cells of donor origin. InADA-deficient patients

without histocompatible bone marrow donors, the administration of exogenous ADA (conjugated to polyethylene glycol to prolong its half-life) may improve immunological function and clinical status. ADA gene therapy has also been used with limited success in these patients. Treatment of SCID patients should be performed in centers with a strong research interest in this problem. It is crucial that these patients be recognized early and not be given live viral vaccines or blood transfusions, which may cause fatal graft-versus-host disease.

Primary T Cell Immunodeficiency Reflecting the diversity of T cell functions, abnormalities of T cell development may be responsible for a wide spectrum of immune deficiencies, including combined immunodeficiency, selective defects in cell-mediated immunity, and syndromes presenting as antibody deficiency. These defects may be acquired (Chap. 309) as well as congenital.

DiGeorge's syndrome This classic example of isolated T cell deficiency results from maldevelopment of thymic epithelial elements derived from the third and fourth pharyngeal pouches. The gene defect has been mapped to chromosome 22q11 in most patients with DiGeorge's syndrome, and to chromosome 10p in others. Defective development of organs dependent on cells of embryonic neural crest origin includes: congenital cardiac defects, particularly those involving the great vessels; hypocalcemic tetany, due to failure of parathyroid development; and absence of a normal thymus. Facial abnormalities may include abnormal ears, shortened philtrum, micrognathia, and hypertelorism. Serum immunoglobulin concentrations are frequently normal, but antibody responses, particularly of IgG and IgA isotypes, are usually impaired. T cell levels are reduced, whereas B cell levels are normal. Affected individuals usually have a small, histologically normal thymus located near the base of the tongue or in the neck, allowing most patients to develop functional T cells in numbers that may or may not be adequate for host defense.

The Nude Syndrome The human disease counterpart to the *nude* mouse is also caused by mutations of the *whn (winged-helix-nude)* gene that result in impairment of hair follicle and epithelial thymic development. The human *nude* phenotype is characterized by congenital baldness, nail dystrophy and severe T cell immunodeficiency.

T Cell Receptor Deficiency Since the expression and function of antigen-specific T cell receptors (TCR) is dependent on their companion CD3g,d, e, andz-h chains, defective genes for any of these receptor components can impair T cell development and function. Immunodeficiencies due to inherited CD3g and CD3e mutations have been identified. CD3g mutations result in a selective deficit in CD8 T cells, whereas CD3e mutations lead to a preferential reduction in CD4 T cells, thus implying differences in the signal transduction roles for each CD3 component.

Major histocompatibility complex (MHC) class II deficiency Because T cells are required for B cell responses to most antigens, any gene defect (or acquired disorder) that interferes with T cell development and cell-mediated immunity will also compromise antibody production and humoral immunity. MHC class II deficiency results in one such immunodeficiency in that theTCRabmust see protein antigens as peptide fragments held within thea helical grooves of class II and class I molecules encoded by the MHC. Antigen-presenting cells in individuals with this relatively rare disorder fail to express the

class II molecules DP, DQ, and DR on their surface. Limited numbers of helper CD4 T cells are therefore generated in the thymus, and they fail to see antigen in the periphery. Affected individuals experience recurrent bronchopulmonary infections, chronic diarrhea, and severe viral infections that usually prove fatal before 4 years of age. The defect is caused by mutations in genes that encode essential transcriptional factors that bind to promoter elements for the MHC class II genes. The class II transactivator gene is mutated in one subgroup of MHC class II deficient patients, whereas mutations in RFX genes encoding additional transcriptional factors for MHC class II genes are responsible for the defective development and function of CD4 T cells in other families: RFXANK in subgroup B, RFX5 in subgroup C, and RFXAP in subgroup D.

ZAP70 Tyrosine Kinase Deficiency Recurrent and opportunistic infections begin within the first year of life in individuals with a deficiency in ZAP70 tyrosine kinase, a pivotal component in theTCR/CD3 signal transduction cascade. The rare inheritance of mutations in both alleles of the ZAP70 gene results in a selective deficiency of CD8 T cells and dysfunction of CD4 T cells, which are present in normal numbers. Severe immunodeficiency is the inevitable consequence.

Purine Nucleoside Phosphorylation Deficiency Function-loss mutations of the purine nucleoside phosphorylase (PNP) gene are associated with an often severe and selective deficiency of T lymphocyte function. This enzyme functions in the same purine salvage pathway asADA; toxic effects of the PNP deficiency may result from the intracellular accumulation of deoxyguanosine triphosphate.

Ataxia-Telangiectasia Ataxia-telangiectasia (AT) is an autosomal recessive genetic disorder characterized by cerebellar ataxia, oculocutaneous telangiectasia, and immunodeficiency. The mutant ATM gene has sequence similarity to the phosphatidyl-inositol-3 kinases that are involved in signal transduction. The ATM gene belongs to a conserved family of genes that monitor DNA repair and coordinate DNA synthesis with cell division. The deleterious effects of the ATM gene are widespread. Truncal ataxia may become evident when walking begins and is progressive. Telangiectasia, primarily represented by dilated blood vessels in the ocular sclera, a butterfly area of the face and on the ears, is an early diagnostic feature. Immunodeficiency may be clinically manifest by recurrent and chronic sinopulmonary infection leading to bronchiectasis, although not all patients have overt immunodeficiency. Ovarian agenesis is a frequent occurrence. Persistence of very high serum levels of oncofetal proteins, includinga fetoprotein and carcinoembryonic antigen, may be of diagnostic value. Frequent causes of death are chronic pulmonary disease and malignancy. Lymphomas are most common, although carcinomas also have occurred.

The immunologic abnormalities seem to be related to maldevelopment of the thymus. The markedly hypoplastic thymus is similar in appearance to an embryonic thymus. The peripheral T cell pool is reduced in size, especially in lymphoid tissue compartments. Cutaneous anergy and delayed rejection of skin grafts are common. Although B lymphocyte development is normal, most patients are deficient in serum IgE and IgA, and a smaller number have reduced serum levels of IgG, particularly of the IgG2, IgG4 subclasses.

The defect in DNA repair mechanisms in these patients renders their cells highly susceptible to radiation-induced chromosomal damage and resultant tumor development.AT is a rare disorder, one in 10,000 to 100,000 incidence, but 1% of the population is heterozygous for an AT mutation. This is important because the heterozygous state also predisposes to enhanced cellular radiosensitivity and cancer, especially breast cancer in females (Chap. 364).

TREATMENT

Therapeutic options other than symptomatic treatment are limited for this group of patients. Live vaccines and blood transfusions containing viable T cells should be assiduously avoided. Exposure to X-irradiation should also be avoided in patients withAT. Therapeutic intervention in the form of an epithelial thymic transplant should repair the T cell deficiency in patients with the *nude* syndrome and in the most severe cases of DiGeorge's syndrome where T cells are absent. Preventive therapy for *P. carinii* in the form of trimethoprim-sulfamethoxazole should be considered. Immunoglobulin infusions are also recommended for those T cell deficient individuals with severe antibody deficiency reflected by low serum levels of IgG.

Immunoglobulin Deficiency Syndromes

X-LINKED AGAMMAGLOBULINEMIA Males with this syndrome often begin to have recurrent bacterial infections late in the first year of life, when maternally derived immunoglobulins have disappeared. Although B cell progenitors are found in the bone marrow, affected individuals have very few immunoglobulin-bearing B lymphocytes in their circulation and lack primary and secondary lymphoid follicles. The developmental block is evident at the pre-B cell level (Fig. 308-1). Mutations of Bruton's tyrosine kinase (Btk) gene are responsible for X-linked agammaglobulinemia. B cells in heterozygous female carriers exclusively utilize the X chromosome with the normal Btk gene, while T cells and myeloid cells express either X chromosome. *X-linked agammaglobulinemia with growth hormone deficiency* is a rare variant disorder caused by another gene defect that maps to the same region of the X chromosome.

Agammaglobulinemia is a misnomer, since most of these patients synthesize some immunoglobulins. Within the same family, some affected males may have substantial levels of IgM, IgG, and IgA, while others are nearly agammaglobulinemic.Btk-deficient patients typically are very deficient in circulating B lymphocytes. The few B lymphocytes that escape the block in pre-B cell differentiation are impaired in their responsiveness to antigenic stimulation, making antibody replacement therapy essential in these patients.

Sinopulmonary bacterial infections constitute the most frequent clinical problem. Mycoplasma infections also cause arthritis in some of these patients. Chronic encephalitis of viral etiology, sometimes associated wtih dermatomyositis, can be a fatal complication. These complications are reduced by treatment with intravenous immunoglobulin.

Autosomal Recessive Agammaglobulinemia This syndrome can result from mutations in a variety of genes whose products are required for B lineage differentiation. For example, signals induced via pre-B receptors are essential for pre-B cell development.

Consequently, mutations in any of the genes coding pre-B receptor components -- u heavy chains, surrogate light chains (VpreB and l5/14.1), Iga and Igb -- can block B lineage differentiation. Congenital absence of B cells, agammaglobulinemia and recurrent bacterial infections have been seen in children with function-loss mutations in both alleles of the u heavy chain gene or the l5/14.1 surrogate light chain gene. Disruption of B cell development may also occur as a consequence of mutations in genes coding transcription factors for pre-B receptor genes or for key elements in the pre-B receptor signaling pathway.

Transient Hypogammaglobulinemia of Infancy This diagnosis is reserved for those rare instances in which normal physiologic hypogammaglobulinemia of infancy is unusually prolonged and severe. IgG levels normally drop to 3.0 to 4.0 g/L between 3 and 6 months of age as maternally derived IgG is catabolized. The IgG levels subsequently rise, reflecting the infants' increased synthetic capacity. Periodic immunologic assessment is needed to differentiate transient hypogammaglobulinemia from other forms of antibody deficiency. Antibody replacement therapy is recommended only in the face of severe or recurrent infections.

IgA Deficiency An inability to produce antibodies of the IgA1 and IgA2 subclasses occurs in approximately 1 in 600 individuals of European origin, a much higher incidence than is seen for other primary immunodeficiencies. IgA deficiency is much less common in people of Asian and African origin. In Japan, for example, the incidence is approximately 1 in 18,500. While the precise genetic basis for this difference in incidence is unknown, IgA deficiency is frequently associated with certainMHChaplotypes that are more common in Caucasians.

Individuals with isolated IgA deficiency may appear healthy or present with an increased number of respiratory infections of varying severity, and a few have progressive pulmonary disease leading to bronchiectasis. Chronic diarrheal diseases also occur. Reductions in the IgG2 and IgG4 subclasses are associated with the increased infections in some IgA-deficient individuals. The incidence of asthma and other atopic diseases among IgA-deficient patients is high. Conversely, the incidence of IgA deficiency among atopic children has been found to be more than 20 times that in the normal population. IgA deficiency is also significantly associated with arthritis (Chap. 312) and systemic lupus erythematosus (Chap. 311). IgA-deficient patients frequently produce autoantibodies. Some of them develop significant levels of antibodies to IgA, which may render them vulnerable to severe anaphylactic reactions when transfused with normal blood or blood products.

An accurate picture of the clinical consequences of IgA deficiency requires lifelong study of affected individuals. Among 204 healthy young adults whose IgA deficiency was identified when they served as blood donors, 80% were found to experience episodes of infections, drug allergy, autoimmune disorders, or atopic disease during the next 20 years of their life. They had an increased susceptibility to pneumonia, recurrent episodes of respiratory infections, and a higher incidence of autoimmune diseases, including vitiligo, autoimmune thyroiditis, and possibly rheumatoid arthritis.

IgA deficiency is often familial. It can also occur in association with congenital intrauterine infections, such as toxoplasmosis, rubella, and cytomegalovirus infection, or

following treatment with phenytoin, penicillamine, or other medications in genetically susceptible individuals. The pathogenesis of IgA deficiency, whether genetic or triggered by environmental insult, involves a block in B cell differentiation that may reflect defective interaction between T and B cells.

Treatment of IgA deficiency is essentially symptomatic. IgA cannot be effectively replaced by exogenous immunoglobulin or plasma, and use of either can increase the risk of development of antibodies to IgA. IgA-deficient patients in need of transfusion should be screened for the presence of antibodies to IgA and ideally should be given blood only from IgA-deficient donors. Immunoglobulin infusions may benefit the exceptional IgA deficient person in whom IgG2 and IgG4 subclass deficiencies are associated with severe infections, but the risk of anaphylactic reactions to contaminating IgA must always be considered in treating these patients.

IgG Subclass Deficiencies Selective deficiencies in one or more of the four IgG subclasses are seen in some patients with repeated infections. The IgG subclass deficiency may easily go undetected when the total serum IgG level is measured, because IgG2, IgG3, and IgG4 together account for only 30 to 40% of the IgG antibodies. Even a deficiency in IgG1 may be masked by increases in the remaining IgG isotypes. However, the availability of subclass-specific monoclonal antibodies allows precise measurement of IgG subclass levels.

Homozygous deletions of genes encoding the constant region of the different g chains is the basis for the IgG subclass deficiency in some individuals. For example, deletion of the C_{a1}, C_{g2}, C_{g4}, and C_{e} genes in the heavy chain locus on both chromosomes 14 was responsible for one individual's inability to make IgA1, IgG2, IgG4, and IgE. Because other components of their immune system are intact, individuals with this and other patterns of C_{H}-gene deletions may not have unusual infections.

Most of the IgG subclass-deficient individuals with repeated infections appear to have regulatory defects that prevent normal B cell differentiation. The defect may extend to other isotypes. IgA deficiency may accompany IgG2 and IgG4 subclass deficiencies (see "IgA Deficiency" above); an inability to produce IgM antibodies to polysaccharide antigens often reflects a broader defect in antibody responsiveness. While patients with IgG subclass deficiency may benefit from administration of immunoglobulin, a thorough assessment of humoral immunity is needed to identify the relatively few who need this therapy.

Common Variable Immunodeficiency This diagnostic category includes a heterogeneous group of males and females, mostly adults, who have in common the clinical manifestations of deficient production of all the different classes of antibodies. The majority of these hypogammaglobulinemic patients have normal numbers of B lymphocytes that are clonally diverse but phenotypically immature. B lymphocytes in these patients are able to recognize antigens and can proliferate in response, but they largely fail to become mature plasma cells. This abortive differentiation pattern leads to the frequent occurrence of nodular B lymphocyte hyperplasia, resulting in splenomegaly and intestinal lymphoid hyperplasia, sometimes of massive proportion.

It is important to note that common variable immunodeficiency and IgA deficiency

represent polar ends of a clinical spectrum due to the same underlying gene defect in a large subset of these patients. The two disorders feature similar B cell differentiation arrests, differing only in the numbers of immunoglobulin classes involved. Over a period of years, IgA deficient patients may progress to the pan-hypogammaglobulinemia phenotype characteristic of common variable immunodeficiency, and vice versa. Both disorders occur frequently within the same family, and the sameMHChaplotypes are associated with both immunodeficiency patterns. Family studies suggest an underlying susceptibility gene in the MHC class III region for both disorders.

It is important to consider the diagnosis of common variable immunodeficiency in adults with chronic pulmonary infections, some of whom will present with bronchiectasis. Intestinal diseases -- including chronic giardiasis, intestinal malabsorption, and atrophic gastritis with pernicious anemia -- are common in this group of patients. Patients with common variable immunodeficiency also may present with signs and symptoms highly suggestive of lymphoid malignancy, including fever, weight loss, anemia, thrombocytopenia, splenomegaly, generalized lymphadenopathy, and lymphocytosis. Histologic examination of lymphoid tissues usually reveals germinal center hyperplasia which may be difficult to distinguish from nodular lymphoma (Chap. 112). Demonstration of a normal distribution of immunoglobulin isotypes and light chain classes for circulating and tissue B lymphocytes can serve to distinguish these patients from those having a monoclonal B cell malignancy with secondary hypogammaglobulinemia. The administration of intravenous immunoglobulin in adequate doses (see below) is an essential part of the prevention and treatment of all these complications.

X-Linked Immunodeficiency with Hyper IgM In this syndrome, typically the IgG and IgA levels are very low, while IgM levels may be very high, normal, or even low. The development of B lymphocytes bearing IgM and IgD and the absence of IgG and IgA B lymphocytes indicate a defect in isotype switching. The defective gene in these patients encodes a transiently expressed molecule on activated T cells that is the ligand for the CD40 molecule on dendritic cells (DC) and B cells. Gene mutations that preclude normal CD40 ligand expression prevent normal T and B cell cooperation, germinal center formation, V-region diversification by somatic hypermutation, and isotype switching. T cell responses are also compromised in these CD40 ligand deficient patients because their T cells are deprived of an important feedback stimulus as a consequence of the defective T, DC, B cell interactions (Chap. 305). Consequently, these patients experience more severe infections than those occurring with other hypogammaglobulinemic states. In addition to recurrent bacterial infections, pneumonia may be caused by *P. carinii*, cytomegalovirus, *Aspergillus*, *Cryptosporidium*, and other unusual organisms. Enteritis due to cryptosporidial infection may extend into the biliary tract to result in a sclerosing cholangitis and hepatic cirrhosis. Neutropenia is frequent in affected males and increases their vulnerability to infections.

Immunodeficiency with hyper IgM is also seen in patients of both sexes who lack mutations in their CD40 ligand gene. While the phenotype in the non-X-linked form of immunodeficiency with hyper IgM is similar, the clinical course is usually milder than in CD40 ligand deficient patients. Candidate disease genes in this syndrome include the CD40 gene and genes coding signaling elements in the CD40 signaling pathway.

TREATMENT

Replacement therapy with human immunoglobulin is the therapeutic cornerstone for antibody-deficient patients who have recurrent infections and who are deficient in IgG. Maintenance of serum IgG levels above 5.0 g/L will prevent most systemic infections in the patients. These serum levels usually can be achieved by intravenous administration of immunoglobulin, 400 to 500 mg/kg, at 3- to 4-week intervals. In patients with mild to moderate IgG deficiency (3.0 to 5.0 g/L) or isolated IgG subclass deficiencies, the decision to treat should be based on evaluation of clinical symptoms and antibody responses to antigenic challenge. Since immunoglobulin preparations are comprised almost entirely of IgG antibodies, they are of no value for repairing deficiencies of immunoglobulins other than IgG. Infusions of immunoglobulin are also not benign. While HIV transmission has not been reported, previous epidemics of hepatitis C virus infections in hypogammaglobulinemic patients receiving contaminated immunoglobulin preparations have led to improved safety measures for current commercial preparations. Some antibody-deficient patients develop symptoms of diaphoresis, tachycardia, flank pain, and hypotension during immunoglobulin infusion. This reaction may be mediated by aggregates of IgG or other biologically active substances and often is resolved by slowing the rate of immunoglobulin infusion. More serious anaphylactic reactions may occur as a consequence of antibodies produced by the patient against donor immunoglobulins, particularly IgA (Chap. 114). The potential for severe adverse reactions merits administration of the initial immunoglobulin infusion under medical supervision in a hospital or clinic setting.

A heightened index of suspicion of infection is essential for antibody-deficient patients. Identification of infectious agents in order to select appropriate antibiotic, antiparasitic, or antiviral therapy is also very important. Immunoglobulin infusions usually do not suffice to eliminate chronic sinopulmonary infections with *H. influenzae* and other microorganisms, and a prolonged course of antibiotic therapy may be required to effectively treat these infections and prevent progression to pulmonary fibrosis and bronchiectasis. Maintenance of good pulmonary toilet with regular postural drainage can also be especially important in management of these patients. Infestation with *G. lamblia*, a common cause of chronic diarrhea in antibody deficient patients, usually responds to therapy with metronidazole.

Cryptosporidial infections in CD40 ligand deficient patients may respond to long-term treatment with amphotericin B and flucytosine. The neutropenia frequently associated with infections in these patients may or may not resolve with improvement of infections and antibody replacement therapy. Bone marrow transplantation following myeloablative pretransplantation therapy can be curative for boys with this devastating immunodeficiency. This treatment has a much greater chance of success when performed during childhood.

Miscellaneous Immunodeficiency Syndromes Infection with *Candida albicans* is the almost universal accompaniment of severe deficiencies in cell-mediated immunity. *Chronic mucocutaneous candidiasis* is different because superficial candidiasis is usually the only major manifestation of immunodeficiency in this syndrome. These patients rarely develop systemic infection with *Candida* or other fungal agents and are not unusually susceptible to virus or bacterial disease. No uniformity of immunologic defects has been identified in these patients, although defects of antibody formation

have been detected occasionally. Humoral immunity, including ability to make specific anti-*Candida* antibodies, is usually normal. Many patients are anergic, some to a variety of antigens and some only to *Candida*. The syndrome is often congenital and may be associated with single or multiple endocrinopathies as well as iron deficiency. Treatment of associated conditions may lead to improvement or even cure of *Candida* infection. In other patients, intensive treatment with amphotericin B coupled with surgical removal of infected nails has led to sustained improvement. Oral antifungal agents, such as fluconazole and itraconazole, also may be effective.

Interferong Receptor Deficiency This immunodeficiency is characterized by serious infections caused by bacille Calmette-Guerin vaccine and environmental non-tuberculous mycobacteria. Associated salmonella infections occur in a minority of the cases. This syndrome can be caused by mutations in the interferon greceptor signal-transducing chain (IFNGR2). Two additional forms of this syndrome are caused by different types of mutations in the interferong receptor 1 (IFNGR1) gene that encodes the ligand binding chain of the interferon g receptor. Null mutations in both IFNGR1 alleles are responsible for a more severe autosomal recessive form. A less severe form, inherited in an autosomal dominant pattern, is caused by IFNGR1 mutations in a small deletional hotspot that result in a truncated receptor chain lacking the cytoplasmic tail. Accumulation of the truncated receptor on the surface of macrophages compromises their response to interferon g and the killing of ingested mycobacterium.

Interleukin 12 Receptor Deficiency Mutations in the gene coding the$b_1$subunit of the IL-12 receptor can cause this syndrome. Affected patients suffer from disseminated mycobacterial infections attributable to bacille Calmette-Guerin and nontuberculous mycobacteria, and in some cases non-typhi salmonella infections. Although the clinical manifestations are usually less severe than in patients with completeIFNGR1deficiency, IL-12 receptor deficiency may predispose individuals to clinical tuberculosis as well. Deficient interferon gproduction by the otherwise normalNK and T cells is seen in IL-12 receptor deficient patients, and therapeutic use of interferon g may cure their mycobacterial infection.

Immunodeficiency with Thymoma The association of hypogammaglobulinemia with spindle cell thymoma usually occurs relatively late in adult life. Bacterial infections and severe diarrhea often reflect the antibody deficiency, whereas fungal and viral infections are infrequent complications. T cell numbers and cell-mediated immunity are usually intact, but these patients are very deficient in circulating B lymphocytes and pre-B cells in the bone marrow. They also frequently have eosinopenia and may develop erythroid aplasia. Complete bone marrow failure sometimes occurs. The relationship between the thymoma and apparent abnormalities of hematopoietic stem cells remains conjectural, and treatment is limited to immunoglobulin administration and symptomatic therapy.

Wiskott-Aldrich Syndrome This X-linked disease characterized by eczema, thrombocytopenia, and repeated infections, is caused by mutations in the WASP gene. The WASP protein is expressed in cells of all hematopoietic lineages. It may serve a cytoskeletal organizing role for signaling elements that are particularly important in platelets and T cells. The platelets are small and have a shortened half-life. Affected male infants often present with bleeding, and most do not survive childhood, dying of

complications of bleeding, infection, or lymphoreticular malignancy. The immunologic defects include low serum concentrations of IgM, while IgA and IgG are normal and IgE is frequently increased. The number and class distribution of B lymphocytes are usually normal. Functionally, these patients are unable to make antibodies to polysaccharide antigens normally; responses to protein antigens may also be impaired late in the course of the disease. Most patients eventually acquire T cell deficiencies. Affected boys frequently become anergic, and their T cells do not respond normally to antigenic challenge. This results in vulnerability to overwhelming infections with herpes simplex virus and other infectious agents.

Transplantation of histocompatible bone marrow from a sibling donor following myeloablative therapy can correct both the hematologic and immunologic abnormalities. In patients lacking a suitable donor, intravenous immunoglobulin infusions or splenectomy may improve platelet counts and reduce the risk of serious hemorrhage. Because of the increased risk of pneumococcal bacteremia, splenectomized patients should receive prophylactic penicillin.

X-Linked Lymphoproliferative Syndrome This disease involves a selective impairment in immune elimination of Epstein-Barr virus (EBV). A fulminant and fatal outcome is the consequence of EBV infection in approximately half of the affected males. Hypogammaglobulinemia is the outcome in 30%, and B cell malignancies are acquired in approximately 25% of EBV-infected patients. The disease may be manifested from early childhood onward, depending on the time of EBV infection. Carrier females handle EBV infections normally. Generation of cytotoxic T cells appears to be the primary mechanism of control of EBV infection in normal persons. In males with the X-linked lymphoproliferative syndrome, this process is impaired as a consequence of mutations in a gene coding for a T cell signaling element called SH2D1A or SAP. Intravenous immunoglobulins should be administered to affected males who develop hypogammaglobulinemia. Bone marrow transplantation from an HLA-matched donor may be curative, especially in younger children with this syndrome. However, myeloablative chemotherapy is a necessary prerequisite to successful bone marrow transplantation, thereby increasing the risk of this procedure.

Hyper-IgE Syndrome The hyper IgE syndrome (Chap. 64) is characterized by recurrent abscesses involving skin, lungs, and other organs and very high IgE levels. IgE levels may decline with time to reach normal levels in approximately 20% of affected adults. Staphylococcal infection is common to all patients, but most have infections with other pyogenic organisms as well. Abnormal neutrophil chemotaxis is an inconsistent finding, and diminished antibody responses to secondary immunization have been noted. Non-immunologic features include impaired shedding of the primary teeth, recurrent bone fractures, hyperextensible joints and scoliosis. Males and females are affected in an inheritance pattern suggesting an autosomal dominant defect with variable penetrance, but the gene defect has not been identified. Prophylaxis with penicillinase-resistant penicillins or cephalosporins is highly recommended to prevent staphylococcal infections. Pneumatoceles, a frequent complication of pneumonias, may require surgical excision.

Metabolic Abnormalities Associated with Immunodeficiency The relation of deficiencies of the purine salvage enzymes adenosine deaminase and purine

nucleoside phosphorylase to immunodeficiency was discussed earlier. The syndrome of *acrodermatitis enteropathica* includes severe desquamating skin lesions, intractable diarrhea, bizarre neurologic symptoms, variable combined immunodeficiency, and an often fatal outcome. This disease is apparently caused by an inborn error of metabolism resulting in malabsorption of dietary zinc and can be treated effectively by parenteral or large oral doses of zinc. Zinc deficiency might in part account for the immunodeficiency that accompanies severe malnutrition. Inherited *deficiency of transcobalamin II*, the serum carrier molecule responsible for transport of vitamin B_{12} to tissues, is associated with failure of immunoglobulin production as well as megaloblastic anemia, leukopenia, thrombocytopenia, and severe malabsorption. All abnormalities of this rare disorder are reversed by administration of vitamin B_{12}.

CONCLUSION

Defective genes have been identified for most of the primary immunodeficiency diseases that are currently recognized (Table 308-3). It can be anticipated that many different gene mutations will be identified in other individuals with increased susceptibility to infection. Identification of the mutant genes is the first step toward a better understanding of the pathogenesis of immunodeficiency disease and improved therapeutic strategies. Successful gene repair is the ultimate goal for these individuals.

ACKNOWLEDGEMENT

This chapter represents a revised version of a chapter by Dr. Max D. Cooper and Dr. Alexander R. Lawton III that has appeared in previous editions of this textbook.

309. HUMAN IMMUNODEFICIENCY VIRUS (HIV) DISEASE: AIDS AND RELATED DISORDERS - *Anthony S. Fauci*, *H. Clifford Lane*

AIDS was first recognized in the United States in the summer of 1981, when the U.S. Centers for Disease Control and Prevention (CDC) reported the unexplained occurrence of *Pneumocystis carinii* pneumonia in five previously healthy homosexual men in Los Angeles and of Kaposi's sarcoma (KS) in 26 previously healthy homosexual men in New York and Los Angeles. Within months, the disease became recognized in male and female injection drug users (IDUs) and soon thereafter in recipients of blood transfusions and in hemophiliacs. As the epidemiologic pattern of the disease unfolded, it became clear that a microbe transmissible by sexual (homosexual and heterosexual) contact and blood or blood products was the most likely etiologic agent of the epidemic.

In 1983, HIV was isolated from a patient with lymphadenopathy, and by 1984 it was demonstrated clearly to be the causative agent of AIDS. In 1985, a sensitive enzyme-linked immunosorbent assay (ELISA) was developed, which led to an appreciation of the scope of HIV infection among cohorts of individuals in the United States who admitted to practicing high-risk behavior (see below) as well as among selected populations that had been screened, such as blood donors, military recruits and active-duty military personnel, Job Corps applicants, and patients in selected sentinel hospitals. In addition, seroprevalance studies revealed the enormity of the global pandemic, particularly in developing countries (see below).

The staggering worldwide growth of the HIV pandemic has been matched by an explosion of information in the areas of HIV virology, the pathogenesis (both immunologic and virologic) and treatment of HIV disease, the treatment and prophylaxis of the opportunistic diseases associated with HIV infection, and vaccine development. The information flow related to HIV disease is enormous, and it has become almost impossible for the health care generalist to stay abreast of the literature. The purpose of this chapter is to present the most current information available on the scope of the epidemic; on its pathogenesis, treatment, and prevention; and on prospects for vaccine development. Above all, the aim is to provide a solid scientific basis and practical guidelines for a state-of-the-art approach to the HIV-infected patient.

DEFINITION

With the identification of HIV in 1983 and its proof as the etiologic agent of AIDS in 1984, and with the availability of sensitive and specific diagnostic tests for HIV infection, the case definition of AIDS has undergone several revisions over the years. The latest revision took place in 1993; this revisedCDCclassification system for HIV-infected adolescents and adults categorizes persons on the basis of clinical conditions associated with HIV infection and CD4+ T lymphocyte counts. The system is based on three ranges of CD4+ T lymphocyte counts and three clinical categories and is represented by a matrix of nine mutually exclusive categories (Tables 309-1 and309-2). Using this system, any HIV-infected individual with a CD4+ T cell count of<200/uL has AIDS by definition, regardless of the presence of symptoms or opportunistic diseases (Table 309-1). The clinical conditions in clinical category C now include pulmonary tuberculosis (TB), recurrent pneumonia, and invasive cervical cancer (Table 309-2). Once individuals have had a clinical condition in category B, their disease cannot again

be classified as category A, even if the condition resolves; the same holds true for category C in relation to category B.

While the definition of AIDS is complex and comprehensive, the clinician should not focus on whether AIDS is present but should view HIV disease as a spectrum ranging from primary infection, with or without the acute syndrome, to the asymptomatic stage, to advanced disease (see below). The definition of AIDS was established not for the practical care of patients but for surveillance purposes.

ETIOLOGIC AGENT

The etiologic agent of AIDS is HIV, which belongs to the family of human retroviruses (Retroviridae) and the subfamily of lentiviruses (Chap. 191). Nononcogenic lentiviruses cause disease in other animal species, including sheep, horses, goats, cattle, cats, and monkeys. The four recognized human retroviruses belong to two distinct groups: the human T lymphotropic viruses (HTLV) I and HTLV-II, which are transforming retroviruses; and the human immunodeficiency viruses, HIV-1 and HIV-2, which are cytopathic viruses (Chap. 191). The most common cause of HIV disease throughout the world, and certainly in the United States, is HIV-1. HIV-1 comprises several subtypes with different geographic distributions (see below). HIV-2 was first identified in 1986 in West African patients and was originally confined to West Africa. However, a number of cases that can be traced to West Africa or to sexual contacts with West Africans have been identified throughout the world. HIV-2 is more closely related phylogenetically to the simian immunodeficiency virus (SIV) found in sooty mangabeys than it is to HIV-1. In 1999, it was demonstrated that HIV-1 infection in humans was zoonotic and had originated from the *Pan troglodytes troglodytes* species of chimpanzees in whom the virus had co-evolved over centuries. The taxonomic relationship among primate lentiviruses is shown in Fig. 309-1.

MORPHOLOGY OF HIV

Electron microscopy shows that the HIV virion is an icosahedral structure (Fig. 309-2*A*) containing numerous external spikes formed by the two major envelope proteins, the external gp120 and the transmembrane gp41. The virion buds from the surface of the infected cell and incorporates a variety of host proteins, including major histocompatibility complex (MHC) class I and II antigens (Chap. 306), into its lipid bilayer. The structure of HIV-1 is schematically diagrammed inFig. 309-2*B* (Chap. 191).

REPLICATION CYCLE OF HIV

HIV is an RNA virus whose hallmark is the reverse transcription of its genomic RNA to DNA by the enzyme *reverse transcriptase*. The replication cycle of HIV begins with the high-affinity binding of the gp120 protein via a portion of its V1 region near the N terminus to its receptor on the host cell surface, the CD4 molecule (Fig. 309-3). The CD4 molecule is a 55-kDa protein found predominantly on a subset of T lymphocytes that are responsible for helper or inducer function in the immune system (Chap. 305). It is also expressed on the surface of monocytes/macrophages and dendritic/Langerhans cells. In order for HIV-1 to fuse to and enter its target cell, it must also bind to one of a group of co-receptors. The two major co-receptors for HIV-1 are CCR5 and CXCR4.

Both receptors belong to the family of seven-transmembrane-domain G protein-coupled cellular receptors, and the use of one or the other or both receptors by the virus for entry into the cell is an important determinant of the cellular tropism of the virus (see below for details). Following binding, the conformation of the viral envelope changes dramatically, and fusion with the host cell membrane occurs in a coiled-spring fashion via the newly exposed gp41 molecule (Fig. 309-4); the HIV genomic RNA is uncoated and internalized into the target cell (Fig. 309-3). The reverse transcriptase enzyme, which is contained in the infecting virion, then catalyzes the reverse transcription of the genomic RNA into double-stranded DNA. The DNA translocates to the nucleus, where it is integrated randomly into the host cell chromosomes through the action of another virally encoded enzyme, *integrase*. This provirus may remain transcriptionally inactive (latent), or it may manifest varying levels of gene expression, up to active production of virus.

Cellular activation plays an important role in the life cycle of HIV and is critical to the pathogenesis of HIV disease (see below). Following initial binding and internalization of virions into the target cell, incompletely reverse-transcribed DNA intermediates are labile in quiescent cells and will not integrate efficiently into the host cell genome unless cellular activation occurs shortly after infection. Furthermore, some degree of activation of the host cell is required for the initiation of transcription of the integrated proviral DNA into either genomic RNA or mRNA. In this regard, activation of HIV expression from the latent state depends on the interaction of a number of cellular and viral factors. Following transcription, HIV mRNA is translated into proteins that undergo modification through glycosylation, myristylation, phosphorylation, and cleavage. The viral particle is formed by the assembly of HIV proteins, enzymes, and genomic RNA at the plasma membrane of the cells. Budding of the progeny virion occurs through the host cell membrane, where the core acquires its external envelope (Chap. 191). The virally encoded protease then catalyzes the cleavage of the gag-pol precursor to yield the mature virion. Each point in the life cycle of HIV is a real or potential target for therapeutic intervention (see below). Thus far, the reverse transcriptase and protease enzymes have proven to be susceptible to pharmacologic disruption (see below).

HIV GENOME

Figure 309-5 illustrates the arrangement of the HIV genome schematically. Like other retroviruses, HIV-1 has genes that encode the structural proteins of the virus: *gag* encodes the proteins that form the core of the virion (including p24 antigen); *pol* encodes the enzymes responsible for reverse transcription and integration; and *env* encodes the envelope glycoproteins. However, HIV-1 is more complex than other retroviruses, particularly those of the nonprimate group, in that it also contains at least six other genes (*tat*, *rev*, *nef*, *vif*, *vpr*, and *vpu*), which code for proteins involved in the regulation of gene expression (Chap. 191). Several of these proteins are felt to play a role in the pathogenesis of HIV disease. For example, Tat, Nef, and Vpu have all been shown to downregulateMHCclass I expression; this may be a strategy that the virus employs to evade immune-mediated elimination by CD8+ cytolytic T cells. Nef also downregulates cell surface expression of CD4 by inducing endocytosis and lysosomal degradation. Supernatants from Nef-expressing macrophages have been shown to induce chemotaxis and activation of resting T lymphocytes leading to productive HIV infection. In addition to its primary function as a transcriptional enhancer in infected

cells, Tat may also be secreted and directly activate potential target cells. In addition, in its secreted form Tat has been shown to be immunosuppressive directly as well as indirectly by inducing secretion of interferon (IFN)a from monocytes/macrophages. Flanking these genes are the long terminal repeats (LTRs), which contain regulatory elements involved in gene expression (see below) such as the polyadenylation signal sequence; the TATA promotor sequence; the NF-kB and Sp1 enhancer binding sites; the transactivating response (TAR) sequences, where the Tat protein binds; and the negative regulatory element (NRE), whose deletion increases the level of gene expression (Fig. 309-5). The major difference between the genomes of HIV-1 and HIV-2 is the fact that HIV-2 lacks the *vpu* gene and has a *vpx* gene not contained in HIV-1.

MOLECULAR HETEROGENEITY OF HIV-1

Molecular analyses of various HIV isolates reveal sequence variations over many parts of the viral genome. For example, in different isolates, the degree of difference in the coding sequences of the viral envelope protein ranges from a few percent (very close) to 50%. These changes tend to cluster in hypervariable regions. One such region, called V3, is a target for neutralizing antibodies and contains recognition sites for T cell responses (see below). Variability in this region is likely due to selective pressure from the host immune system. The extraordinary variability of HIV-1 is in marked contrast to the relative genetic stability ofHTLV-I and -II.

There are two groups of HIV-1: group M (major), which is responsible for most of the infections in the world; group O (outlier), a relatively rare viral form found originally in Cameroon, Gabon, and France; and a third group (group N) first identified in a Cameroonian woman with AIDS. The M group comprises eight subtypes, or *clades*, designated A, B, C, D, F, G, H, and J, as well as four major circulating recombinant forms (CRFs). These four CRFs are the AE virus, prevalent in southeast Asia and often referred to simply as E, despite the fact that the parental E virus has never been found; AG from west and central Africa; AGI from Cyprus and Greece; and AB from Russia. These 8 subtypes and 4 CRFs create the major branches in the phylogenetic tree that represents the lineage of the M group of HIV-1 (Fig. 309-6; also seehttp://hiv-web.lanl.gov/ALIGN_CURRENT/SUBTYPE-REF/Table1.html).

The global patterns of HIV-1 variation likely result from accidents of viral trafficking. Subtype B viruses, which now differ by up to 17% in their *env* coding sequences, are the overwhelmingly predominant viruses seen in the United States, Canada, certain countries in South America, western Europe, and Australia. Other subtypes are also present in these countries to varying degrees. It is thought that, purely by chance, subtype B was seeded into the United States in the late 1970s, thereby establishing an overwhelming founder effect. Subtype C viruses (of the M group) are the most common form worldwide; many countries have cocirculating viral subtypes that are giving rise toCRFs.Figure 309-7 schematically diagrams the worldwide distribution of HIV-1 subtypes by region. The predominant subtype in Europe and the Americas is subtype B. In Africa, >75% of strains recovered to date have been of subtypes A, C, and D, with C being the most common. In Asia, HIV-1 isolates of subtypes E, C, and B predominate. Subtype E accounts for most infections in Southeast Asia, while subtype C is prevalent in India (see "HIV Infections and AIDS Worldwide," below). Sequence analyses of HIV-1 isolates from infected individuals indicate that recombination among viruses of different

clades likely occurs as a result of infection of an individual with viruses of more than one clade, particularly in geographic areas where clades overlap.

TRANSMISSION

HIV is transmitted by both homosexual and heterosexual contact; by blood and blood products; and by infected mothers to infants either intrapartum, perinatally, or via breast milk. After approximately 20 years of scrutiny, there is no evidence that HIV is transmitted by casual contact or that the virus can be spread by insects, such as by a mosquito bite.

SEXUAL TRANSMISSION

HIV infection is predominantly a sexually transmitted disease (STD) worldwide. Although approximately 42% of new HIV infections in the United States are among men who have sex with men, heterosexual transmission is clearly the most common mode of infection worldwide, particularly in developing countries. Furthermore, the yearly incidence of new cases of AIDS attributed to heterosexual transmission of HIV is steadily increasing in the United States, mainly among minorities, particularly women in minority groups (Fig. 309-8).

HIV has been demonstrated in seminal fluid both within infected mononuclear cells and in the cell-free state. The virus appears to concentrate in the seminal fluid, particularly in situations where there are increased numbers of lymphocytes and monocytes in the fluid, as in genital inflammatory states such as urethritis and epididymitis, conditions closely associated with otherSTDs(see below). The virus has also been demonstrated in cervical smears and vaginal fluid. There is a strong association of transmission of HIV with receptive anal intercourse, probably because only a thin, fragile rectal mucosal membrane separates the deposited semen from potentially susceptible cells in and beneath the mucosa and trauma may be associated with anal intercourse. Anal douching and sexual practices such as insertion of hard objects or a clenched fist into the rectum ("fisting") traumatize the rectal mucosa, thereby increasing the likelihood of infection during receptive anal intercourse. It is likely that anal intercourse provides at least two modalities of infection: (1) direct inoculation into blood in cases of traumatic tears in the mucosa; and (2) infection of susceptible target cells, such as Langerhans cells, in the mucosal layer in the absence of trauma (see below). Although the vaginal mucosa is several layers thicker than the rectal mucosa and less likely to be traumatized during intercourse, it is clear that the virus can be transmitted to either partner through vaginal intercourse. In a 10-year prospective study in the United States of heterosexual transmission of HIV, male-to-female transmission was approximately eight times more efficient than female-to-male transmission. This difference may be due in part to the prolonged exposure to infected seminal fluid of the vaginal and cervical mucosa, as well as the endometrium (when semen enters through the cervical os). By comparison, the penis and urethral orifice are exposed relatively briefly to infected vaginal fluid. Among various cofactors examined in this study, a history of STDs (see below) was most strongly associated with HIV transmission. In this regard, there is a close association between genital ulcerations and transmission, from the standpoints of both susceptibility to infection and infectivity. Infections with microorganisms such as *Treponema pallidum* (Chap. 172), *Haemophilus ducreyi* (Chap. 149), and herpes

simplex virus (HSV;Chap. 182) are important causes of genital ulcerations linked to transmission of HIV. In addition, pathogens responsible for nonulcerative inflammatory STDs such as those caused by *Chlamydia trachomatis* (Chap. 179), *Neisseria gonorrhoeae* (Chap. 147), and *Trichomonas vaginalis* (Chap. 218) are also associated with an increased risk of transmission of HIV infection. Bacterial vaginosis, an infection related to sexual behavior, but not strictly an STD, may also be linked to an incresed risk of transmission of HIV infection. Several studies suggest that treating other STDs and genital tract syndromes may help prevent transmission of HIV. In two studies in Africa aimed at decreasing the incidence of HIV infection by empirical treatment of village inhabitants for other STDs, there were divergent results. In Mwanza, Tanzania, empirical treatment for STDs resulted in a decrease in STDs, including HIV infection. In contrast, in the Rakai district of Uganda, empirical treatment of STDs resulted in a decrease in these diseases but not a decrease in HIV infections. The prevalance of HIV infection in Uganda was considerably greater than that in Tanzania at the time of the studies, and, according to a model of the dynamics of sexual spread of HIV, treatment of other STDs would be expected to have less of an effect on decreasing the transmission of HIV in a population with a higher prevalence than in a population with a lower prevalence of HIV infection. Subsequent studies in Uganda indicated that the chief predictor of heterosexual transmission of HIV was the level of plasma viremia. In some studies the use of oral contraceptives was associated with an increase in incidence of HIV infection over and above that which might be expected by not using a condom for birth control. Finally, lack of circumcision has been strongly associated with a higher risk of HIV infection in certain cohorts. This difference may be due to increased susceptibility of uncircumcised men to ulcerative STDs, as well as other factors such as microtrauma. In addition, the moist environment under the foreskin may promote the presence or persistence of microbial flora which, via inflammatory changes, may lead to higher concentrations of target cells for HIV in the foreskin. Some studies suggest that only circumcision performed before age 20 is associated with a reduced risk of HIV infection. Thus, in certain cases, these phenomena can also be considered as cofactors for HIV transmission.

Oral sex is a much less efficient mode of transmission of HIV than is receptive anal intercourse. However, there is a misperception by some persons that oral sex, particularly among homosexual men, can be proposed as a form of "safe sex" and a substitute for receptive anal intercourse. This is a dangerous approach, as there have been several reports of documented HIV transmission resulting solely from receptive fellatio and insertive cunnilingus. For example, one study reported that in 12 subjects where the precise date of seroconversion could be identified, 4 individuals reported oral-genital contact as their sole risk factor. There are probably many more cases that go unreported because of the frequent practice of both oral sex and receptive anal intercourse by the same person. The association of alcohol consumption and illicit drug use with unsafe sexual behavior, both homosexual and heterosexual, leads to an increased risk of sexual transmission of HIV.

TRANSMISSION BY BLOOD AND BLOOD PRODUCTS

HIV can be transmitted to individuals who receive HIV-tainted blood transfusions, blood products, or transplanted tissue, as well as toIDUs who are exposed to HIV while sharing injection paraphernalia such as needles, syringes, the water in which drugs are

mixed, or the cotton through which drugs are filtered. Parenteral transmission of HIV during injection drug use does not require intravenous puncture; subcutaneous ("skin popping") or intramuscular ("muscling") injections can transit HIV as well, even though these behaviors are sometimes erroneously perceived as low-risk. Among IDUs, the risk of HIV infection increases with the duration of injection drug use; the frequency of needle sharing; the number of partners with whom paraphernalia are shared, particularly in the setting of "shooting galleries" where drugs are sold and large numbers of IDUs may share a limited number of "works"; comorbid psychiatric conditions such as antisocial personality disorder; the use of cocaine in injectable form or smoked as "crack"; and the use of injection drugs in a geographic location with a high prevalence of HIV infection, such as certain inner-city areas in the United States.

From the late 1970s until the spring of 1985, when mandatory testing of donated blood for HIV-1 was initiated, it has been estimated that over 10,000 individuals in the United States were infected through transfusions of blood or blood products (Chap. 114). Approximately 8900 individuals in the United States who survived the illness for which they received HIV-contaminated blood transfusions, blood components, or transplanted tissue have developed AIDS. It is estimated that 90 to 100% of individuals who were exposed to such HIV-contaminated products became infected. Transfusions of whole blood, packed red blood cells, platelets, leukocytes, and plasma are all capable of transmitting HIV infection. In contrast, hyperimmune gamma globulin, hepatitis B immune globulin, plasma-derived hepatitis B vaccine, and Rh_o immune globulin have not been associated with transmission of HIV infection. The procedures involved in processing these products either inactivate or remove the virus.

In addition to the above, several thousand individuals in the United States with hemophilia or other clotting disorders were infected with HIV by receipt of HIV-contaminated fresh frozen plasma or concentrates of clotting factors; approximately 5310 of these individuals have developed AIDS. Currently, in the United States and in most developed countries, the following measures have made the risk of transmission of HIV infection by transfused blood or blood products extremely small: (1) the screening of all blood for p24 antigen and for HIV antibody byELISA, with a confirmatory western blot where applicable; (2) the self-deferral of donors on the basis of risk behavior; (3) the screening out of HIV-negative individuals with positive surrogate laboratory parameters of HIV infection, such as hepatitis B and C; and (4) serologic testing for syphilis. It is currently estimated that the risk of infection with HIV in the United States via transfused screened blood is approximately 1 in 676,000 donations. Therefore, among the 12 million donations collected in the United States each year, an estimated 18 infectious donations are available for transfusion. The addition of nucleic acid testing to the blood screening protocol to capture some of these rare HIV antibody-negative units should decrease even further the chances of transmission by transfused blood or blood products. There have been several reports of sporadic breakdowns in routinely available screening procedures in certain countries, where contaminated blood was allowed to be transfused, resulting in small clusters of patients becoming infected. There have been no reported cases of transmission of HIV-2 in the United States via donated blood, and, currently, donated blood is screened for both HIV-1 and HIV-2 antibodies. The chance of infection of a hemophiliac via clotting factor concentrates has essentially been eliminated because of the added layer of safety resulting from heat treatment of the concentrates.

Prior to the screening of donors, a small number of cases of transmission of HIV via semen used in artificial insemination and tissues used in organ transplantation were well documented. At present, donors of such tissues are prescreened for HIV infection.

OCCUPATIONAL TRANSMISSION OF HIV: HEALTH CARE WORKERS AND LABORATORY WORKERS

There is a small, but definite, occupational risk of HIV transmission in health care workers and laboratory personnel and potentially in others who work with HIV-infected specimens, particularly when sharp objects are used. An estimated 600,000 to 800,000 health care workers are stuck with needles or other sharp medical instruments in the United States each year. Large, multi-institutional studies have indicated that the risk of HIV transmission following skin puncture from a needle or a sharp object that was contaminated with blood from a person with documented HIV infection is approximately 0.3% (see "HIV and the Health Care Worker," p. 1909). The risk of hepatitis B infection following a similar type of exposure is 6 to 30% in nonimmune individuals; if a susceptible worker is exposed to HBV, postexposure prophylaxis with hepatitis B immune globulin and initiation of HBV vaccine is more than 90% effective in preventing HBV infection. The risk of HCV infection following percutaneous injury is approximately 1.8% (Chap. 295). An increased risk for HIV infection following percutaneous exposures to HIV-infected blood is associated with exposures involving a relatively large quantity of blood, as in the case of a device visibly contaminated with the patient's blood, a procedure that involves a needle placed directly in a vein or artery, or a deep injury. In addition, the risk increases for exposures to blood from patients with advanced-stage disease, probably owing to the higher titer of HIV in the blood as well as to other factors, such as the presence of more virulent strains of virus (see "HIV and the Health Care Worker," p. 1909).

There have been reports of health care workers who became infected through the exposure of mucous membranes or abraded skin to HIV-infected material; however, the risk associated with mucocutaneous exposure has been difficult to quantify, because transmission by this route is extremely rare. Factors that might be associated with mucocutaneous transmission of HIV include exposure to an unusually large volume of blood, prolonged contact, and a potential portal of entry. A prospective study has indicated that the use of antiretroviral drugs as postexposure prophylaxis decreases the risk of infection compared to historic controls in occupationally exposed health care workers. Transmission of HIV through intact skin has not been documented (see "HIV and the Health Care Worker," p. 1909).

Since the beginning of the HIV epidemic, there have been at least three reported instances in which transmission of infection from a health care worker to patients seemed highly probable. The first involved a dentist in Florida who apparently infected six of his patients, most likely through contaminated instruments. Another case involved an orthopedic surgeon in France who apparently infected a patient during placement of a total hip prosthesis. A third case involved the apparent transmission of HIV from a nurse to a surgical patient in France. An additional situation involved the apparent infection of four patients by an HIV-negative general surgeon in Australia during routine outpatient surgery. The cause of the transmission was felt to be a failure on the part of

the surgeon to sterilize instruments properly between procedures following prior surgery on an infected patient. Despite these few cases, the risk of transmission from an infected health care worker to patients is extremely low; in fact, too low to be measured accurately. Indeed several epidemiologic studies have been performed tracing thousands of patients of HIV-infected dentists, physicians, surgeons, obstetricians, and gynecologists and no other cases of HIV infection that could be linked to the health care providers were identified. The very occurrence of transmission of HIV as well as hepatitis B and C to and from health care workers in the workplace underscores the importance of the use of universal precautions when caring for all patients (see below andChap. 134).

MATERNAL-FETAL/INFANT TRANSMISSION

HIV infection can be transmitted from an infected mother to her fetus during pregnancy or to her infant during delivery. This is an extremely important form of transmission of HIV infection in developing countries, where the proportion of infected women to infected men is approximately 1:1. Virologic analysis of aborted fetuses indicate that HIV can be transmitted to the fetus as early as the first and second trimester of pregnancy. However, maternal transmission to the fetus occurs most commonly in the perinatal period. This conclusion is based on a number of considerations, including the time frame of identification of infection by the sequential appearance of classes of antibodies to HIV (i.e., the appearance of HIV-specific IgA antibody within 3 to 6 months after birth); a positive viral culture; the appearance of p24 antigenemia weeks to months after delivery, but not at the time of delivery; a polymerase chain reaction (PCR) assay of infant blood following delivery that is negative at birth and positive several months later; the demonstration that the firstborn twin of an infected mother is more commonly infected than is the second twin; and the evidence that cesarean section results in decreased transmission to the infant.

In the absence of prophylactic antiretroviral therapy to the mother during pregnancy, labor, and delivery, and to the fetus following birth (see below), the probability of transmission of HIV from mother to infant/fetus ranges from 15 to 25% in industrialized countries and from 25 to 35% in developing countries. These differences may relate to the adequacy of prenatal care as well as to the stage of HIV disease and the general health of the mother during pregnancy. Higher rates of transmission have been associated with many factors, including high maternal levels of plasma viremia, low maternal CD4+ T cell counts and HIV p24 antibody levels, maternal vitamin A deficiency, a prolonged interval between membrane rupture and delivery, presence of chorioamnionitis at delivery,STDsduring pregnancy, cigarette smoking and hard drug use during pregnancy, preterm labor, obstetric procedures such as amniocentesis and amnioscopy, and other factors that may increase the exposure of the infant to the mother's blood. With regard to levels of viremia, several studies indicate that the risk of transmission increases with the maternal plasma HIV RNA level. In one series of 552 singleton pregnancies in the United States, the rate of mother-to-baby transmission was 0% among women with <1000 copies of HIV RNA per milliliter of blood, 16.6% among women with 1000 to 10,000/mL, 21.3% among women with 10,001 to 50,000/mL, 30.9% among women with 50,001 to 100,000/mL, and 40.6% among women with >100,000/mL. However, there may be no lower "threshold" below which transmission never occurs, since other studies have reported transmission by women with viral RNA

levels below the level of detectability of 50 copies per milliliter. Finally, it has been speculated that if the mother experiences acute primary infection during pregnancy, there is a higher rate of transmission to the fetus, owing to the high levels of viremia that occur during primary infection (see below). In the United States and other industrialized countries, zidovudine treatment of HIV-infected pregnant women from the beginning of the second trimester through delivery and of the infant for 6 weeks following birth has dramatically decreased the rate of intrapartum and perinatal transmission of HIV infection from 22.6% in the untreated group to <5%. It is expected that the rate of transmission will decrease even further as more potent combinations of drugs are used in HIV-infected pregnant women (see below).

In developed countries, current recommendations to reduce perinatal transmission of HIV include universal voluntary HIV testing and counseling of pregnant women, zidovudine prophylaxis, obstetric management that attempts to minimize exposure of the infant to maternal blood and genital secretions, and avoidance of breast feeding. It is also recommended that the choice of antiretroviral therapy for pregnant women should be based on the same considerations used for women who are not pregnant, with discussion of the recognized and unknown risks and benefits of such therapy during pregnancy. The cost and logistics of the above protocol are not feasible for developing countries, particularly those in sub-Saharan Africa where the per capita health care delivery allocation is often only a few dollars per year. Studies have demonstrated that truncated regimens of zidovudine alone or in combination with lamivudine given to the mother during the last few weeks of pregnancy or even only during labor and delivery, and to the infant for a week or less, reduced transmission to the infant by 50% compared to placebo. One important study in Uganda demonstrated that a single dose of nevirapine given to the mother at the onset of labor followed by a single dose to the newborn within 72 h of birth decreased transmission to 13% compared to 25% transmission at age 14 to 16 weeks when the mother received multiple doses of zidovudine throughout labor and delivery and the infant received zidovudine daily for a full week following birth. The cost of the nevirapine for the mother and infant was a mere $4.00, which would make this regimen affordable for many developing countries. Approximately 1800 babies are born infected each day throughout the world, and 90% of these are in sub-Saharan Africa; thus, implementation of such a regimen could potentially save 1000 babies per day from becoming infected.

Although most transmission of HIV occurs during pregnancy and at birth, breast feeding may account for 5 to 15% of infants becoming infected after delivery. This is an important modality of transmission of HIV infection in developing countries, particularly where mothers continue to breast feed for prolonged periods. The risk factors for mother-to-child transmission of HIV via breast feeding are not fully understood; factors that increase the likelihood of transmission include detectable levels of HIV in breast milk, the presence of mastitis, low maternal CD4+ T cell counts, and maternal vitamin A deficiency. The risk of HIV infection via breast feeding is highest in the early months of breast feeding. In addition, exclusive breast feeding has been reported to carry a lower risk of HIV transmission than mixed feeding. Certainly, in developed countries breast feeding by an infected mother should be avoided. However, there is disagreement regarding recommendations for breast feeding in certain developing countries, where breast milk is the only source of adequate nutrition as well as immunity against potentially serious infections for the infant. Studies are being conducted to determine

whether intermittent administration of nevirapine, which has a relatively long half-life, to uninfected babies born of infected mothers decreases the incidence of infection via breast feeding.

TRANSMISSION BY OTHER BODY FLUIDS

There is no convincing evidence that saliva can transmit HIV infection, either through kissing or through other exposures, such as occupationally to health care workers. HIV can be isolated from saliva of only a small proportion of infected individuals, typically in titers that are low compared to those in blood and genital secretions. In addition, saliva contains endogenous antiviral factors; among these factors, HIV-specific immunoglobulins of IgA, IgG, and IgM isotypes are detected readily in salivary secretions of infected individuals. It has been suggested that large glycoproteins such as mucins and thrombospondin-1 sequester HIV into aggregates for clearance by the host. In addition, a number of soluble salivary factors inhibit HIV to various degrees in vitro, probably by targeting host cell receptors rather than the virus itself. Perhaps the best-studied of these, secretory leukocyte protease inhibitor (SLPI), blocks HIV infection in several cell culture systems, and it is found in saliva at levels that approximate those required for inhibition of HIV in vitro. It has also been suggested that submandibular saliva reduces HIV infectivity by stripping gp120 from the surface of virions, and that saliva-mediated disruption and lysis of HIV-infected cells occurs because of the hypotonicity of oral secretions. There have been outlier cases of suspected transmission by saliva, but these have probably been blood-to-blood transmissions. One case was reported of a 91-year-old man who was bitten during a robbery attempt by an HIV-infected person. He seroconverted, and there was no question that the source of the infection was the human bite. However, the individual who bit him had bleeding gums, and it was thought that the infection was actually transmitted via blood. In addition, a most unusual form of HIV transmission from infected children to mothers in the former Soviet Union has been identified. In those cases, the children (infected through transfusion) were said to have bleeding sores in the mouth, and the mothers were said to have lacerations and abrasions on and around the nipples of the breast resulting from trauma from the children's teeth. Breast feeding had been continued until the children were older than is usual in other developed countries.

Although virus can be identified, if not isolated, from virtually any body fluid, there is no evidence that HIV transmission can occur as a result of exposure to tears, sweat, and urine. However, there have been isolated cases of transmission of HIV infection by body fluids that may or may not have been contaminated with blood. Most of these situations occurred in the setting of a close relative providing intensive nursing care for an HIV-infected person without observing universal precautions. These cases underscore the importance of observing universal precautions in the handling of body fluids and wastes from HIV-infected individuals (see below).
